***Abstract* — Idiopathic scoliosis is a three-dimensional deformity of the spine that can impair respiratory mechanics due to distortion of the thoracic cage. Respiratory oscillometry has emerged as a noninvasive technique capable of detecting subtle alterations in respiratory system mechanics, which can be further enhanced through electrical modeling approaches. However, no previous studies have applied these methods to the assessment of scoliosis. Therefore, the aim of this study was to analyze respiratory mechanical alterations in patients with idiopathic scoliosis using the Extended Resistance–Inertance–Compliance (eRIC) model applied to respiratory oscillometry. Thirty patients diagnosed with idiopathic scoliosis and thirty healthy volunteers comprising the control group were evaluated. All participants underwent spirometry, body plethysmography, and respiratory oscillometry. Oscillometric parameters were analyzed using the eRIC model, which estimates central (R), peripheral (Rp), and total (Rt=R+Rp) airway resistance, as well as respiratory inertance (I) and dynamic compliance (C). Correlation analyses were also performed between eRIC-derived parameters and pulmonary function indices. The scoliosis group presented a mean Cobb angle of 51.9 ± 20.42°. Compared with controls, patients with scoliosis exhibited significantly increased Rp ($p<0.05$) and Rt ($p<0.01$), whereas I and C were significantly reduced ($p<0.001$). Correlation analysis demonstrated significant negative associations between resistive parameters and spirometric indices, with Rt showing the strongest correlations with $FEF_{25–75}$ ($r=−0.534$; $p < 0.0001$), FEV_1/FVC ($r=−0.489$; $p<0.0001$), and FEV_1 ($r=−0.473$; $p<0.0001$). In contrast, C exhibited the strongest positive correlations with pulmonary function parameters, particularly FEV_1 ($r=0.686$; $p<0.0001$), $FEF_{25–75}$ ($r=0.675$; $p<0.0001$), and FVC ($r=0.642$; $p<0.0001$). Among the plethysmographic variables, only total lung capacity was significantly correlated with C ($r=0.389$; $p<0.05$). These findings indicate increased airway obstruction and reduced respiratory system compliance, reflecting the mechanical constraints imposed by thoracic cage deformity and the consequent impairment of respiratory function. In conclusion, respiratory oscillometry combined with eRIC modeling was able to characterize relevant respiratory mechanical abnormalities associated with idiopathic scoliosis. The significant associations observed between eRIC-derived parameters and conventional pulmonary function indices support the physiological relevance of this model and its potential utility as a complementary tool for the functional assessment of patients with spinal deformities, providing information additional to that obtained via spirometry and oscillometry.**

Keywords— Respiratory oscillometry, idiopathic scoliosis, pulmonary function, mathematical models, spirometry.

I. Introduction

Scoliosis is a condition characterized by a three-dimensional postural deformity of the vertebral column that may lead to alterations in respiratory mechanics, resulting in reduced pulmonary capacity and, in more severe curvatures, contributing to additional systemic dysfunctions [1].

Diagnosis is established through radiographic examination, in which the Cobb angle [2] is measured; scoliosis is defined by a curvature greater than 10 degrees accompanied by vertebral rotation. The condition affects approximately 2–4% of adolescents between 10 and 18 years of age, with a higher prevalence in females [3].

The postural deformity associated with idiopathic scoliosis may lead to respiratory impairment; therefore, pulmonary function tests are routinely employed for the evaluation and longitudinal monitoring of these patients, who often do not present with overt respiratory symptoms [1].

Respiratory oscillometry is a noninvasive and easily applicable technique that enables the assessment of respiratory mechanics through parameters capable of detecting subtle physiological abnormalities that may not be evident in conventional pulmonary function tests. Its principal advantage lies in the superimposition of oscillatory signals during spontaneous tidal breathing, thereby eliminating the need for maximal respiratory maneuvers and reducing patient effort [4].

To improve the interpretation of oscillometric data, modeling approaches based on electrical analogs have been developed to represent the mechanical properties of the respiratory system. Among these approaches, the Extended Resistance-Inertance-Compliance (eRIC) model has been widely used to provide physiologically meaningful estimates of central and peripheral airway resistance, inertance, and respiratory system compliance [5]. Despite its increasing application in respiratory research [6-8], the use of the eRIC model in patients with idiopathic scoliosis has not yet been investigated.

Therefore, the aim of the present study was to evaluate the contribution of the eRIC model to the analysis of respiratory mechanical alterations in patients with idiopathic scoliosis.

II. Materials and Methods

A. Volunteers

Telephone contact was established with 106 patients diagnosed with thoracic idiopathic scoliosis, of whom 30 were ultimately included in the study. A total of 76 individuals were excluded for the following reasons: three were unable to complete the examinations, six declined participation, eight did not attend the scheduled evaluation, and 59 could not be reached by telephone.

The final sample comprised 60 volunteers divided into two groups. The control group (CG) included 30 healthy individuals with no history of smoking, no prior pulmonary and/or cardiac diseases, no COVID-19 sequelae or post-COVID-19 syndrome, no postural abnormalities, and with spirometry and respiratory oscillometry results within normal ranges. The group of patients consisted of 30 individuals aged 11 to 50 years, diagnosed with thoracic idiopathic scoliosis [2], with no history of smoking, no prior pulmonary and/or cardiac diseases, and no COVID-19 sequelae or post-COVID-19 syndrome. After the participants were selected, they were referred to the Biomedical Instrumentation Laboratory at the State University of Rio de Janeiro.

B. Ethics

All participants provided written informed consent through a Free and Informed Consent Form approved by the Research Ethics Committees of Hospital Universitário Pedro Ernesto and the National Institute of Traumatology and Orthopedics under number 62654422.3.0000.5259.

For volunteers under 18 years of age, an Assent Form was signed by the participant, and the Informed Consent Form was signed by the legal guardian.

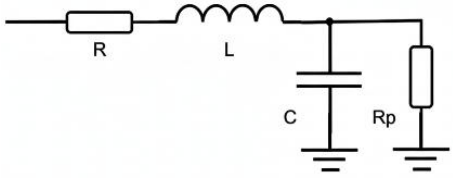
C. Spirometric and plethysmographic tests

Pulmonary function testing was carried out by experienced technicians using calibrated instrumentation. Spirometric data were acquired with a pneumotachograph system (nSpire Health, Inc., Longmont, CO, USA). Prior to testing, participants were carefully instructed to perform the respiratory maneuvers according to standardized procedures, ensuring compliance with national quality control criteria for acceptability and reproducibility. The parameters evaluated included forced vital capacity (FVC), forced expiratory volume in the first second (FEV_1), the FEV_1/FVC ratio, and mid-expiratory flow ($FEF_{25–75}$%). Assessment of lung volumes was performed by body plethysmography, following the methodological recommendations established by the American Thoracic Society (ATS)/ERS guidelines [11]. The variables analyzed comprised total lung capacity (TLC), vital capacity (VC), residual volume (RV), and the RV/TLC ratio, which was used as an indicator of air trapping [9, 10]. Plethysmographic variables were compared with predicted reference values rather than measured values obtained from the control group, which should be considered when interpreting these findings.

D. Respiratory oscillometry test

In these analyses, at least three recordings presenting a coherence function greater than 0.90 were required for the test to be considered acceptable. Following the initial assessment, participants were instructed to perform the maneuver in a seated position, breathing quietly through a mouthpiece while wearing a nasal clip for 16 seconds. Volunteers were also instructed to support the cheeks and chin with their palms to minimize signal loss in the upper airways, which could compromise measurement accuracy. Oscillometric measurements were conducted within a frequency range of 4 to 32 Hz, superimposed on the participants' tidal breathing. Respiratory impedance (Zrs) values were calculated using impedance analyzer system developed in our laboratory [11].

E. Electrical model



The Resistance–Inertance–Compliance (RIC) model represents the respiratory system using three fundamental mechanical components: resistance, inertance, and compliance. In the present study, the Extended Resistance–Inertance–Compliance (eRIC) model was employed (Figure 1). In this model, respiratory resistance is partitioned into central airway resistance (R) and peripheral airway resistance (Rp), whose sum corresponds to the total respiratory system resistance (Rt). This approach enables a more detailed assessment of respiratory mechanics by allowing the independent evaluation of the contributions of central and peripheral airway compartments. This characteristic is particularly relevant because several respiratory diseases initially affect the small airways, introducing a high potential to detect early mechanical abnormalities that may not be evident using conventional pulmonary function tests [12, 13].

Model parameters were estimated using the Levenberg–Marquardt algorithm, which identified the set of model coefficients that minimized the least-squares error between the measured and predicted data. In addition to the estimated parameters, the analysis provided the total error as an overall measure of model goodness of fit. This metric was calculated as the square root of the sum of the errors associated with the real and imaginary components of respiratory impedance.

Furthermore, the parameters derived from the eRIC model provide physiologically meaningful information that complements the findings obtained from spirometry and body plethysmography. While spirometry primarily evaluates airflow and lung volumes, and plethysmography quantifies static lung volumes and airway resistance, the eRIC model allows characterization of the resistive, inertial, and elastic components of the respiratory system. Consequently, it contributes to a more comprehensive understanding of the mechanical alterations associated with respiratory dysfunction [13].

Respiratory inertance (I) describes the inertial properties of the respiratory system, reflecting the mass of air within the airways and the respiratory tissues that must be accelerated during breathing. Respiratory system compliance (C) represents the elastic properties of the lungs and chest wall, incorporating the contributions of both the pulmonary parenchyma and thoracic cage structures [5, 7, 12, 13] .

F. *Statistical analysis*

Statistical analyses and graphical representations were performed using Origin® 8.0 software (Microcal Software Inc., Northampton, MA, USA). Data are presented as mean ± standard deviation (SD) and summarized in tables and box plots. A p-value ≤ 0.05 was considered statistically significant in all analyses.

Data normality was assessed using the Shapiro–Wilk test. Comparisons between groups were performed using the independent-samples Student's t-test for normally distributed variables. When the assumption of normality was not met, the nonparametric Mann–Whitney U test was applied.

Associations between respiratory oscillometry parameters and pulmonary function variables were evaluated through correlation analyses. Pearson's correlation coefficient was used for parametric data, whereas Spearman's rank correlation coefficient was employed for nonparametric data. These analyses were conducted using GraphPad Prism 8 software (GraphPad Software, La Jolla, CA, USA).

The strength of the correlations was interpreted according to the following criteria: coefficients ranging from 0 to 0.25 (or 0 to −0.25) were considered negligible to weak; values between 0.25 and 0.50 (or −0.25 and −0.50) were considered moderate; coefficients between 0.50 and 0.75 (or −0.50 and −0.75) were classified as moderate to strong; and values greater than 0.75 (or less than −0.75) were considered very strong to excellent [14].

III. RESULTS

Table 1 presents the anthropometric and spirometric results. No significant differences were observed in age, body weight, height, or BMI when comparing the control group and the idiopathic scoliosis group.

In the spirometric analysis, the idiopathic scoliosis group demonstrated significantly lower values compared with the control group in FEV_1 (L), FEV_1 (%), FVC (L), FVC (%), FEV_1/FVC (L), FEV_1/FVC (%) e FEF_{25-75} (p<0.0001).

Table 1 - Anthropometric and spirometric measurements of the studied groups.

	Control (n= 30)	Scoliosis (n= 30)	p
Age (years)	22.93 ± 2.75	25.10 ± 9.68	ns
Weight (kg)	58.92 ± 7.90	55.87 ± 11.14	ns
Height (cm)	165.33 ± 7.68	162.63 ± 10.82	ns

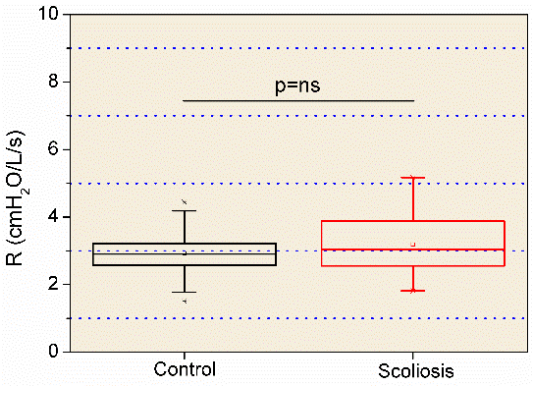
Figures 2A and 2B present the mean respiratory resistance (Rrs) and reactance (Xrs) curves as a function of frequency in healthy individuals and patients with idiopathic scoliosis, respectively. Significant differences (p<0.0001) were observed between all resistance curves (Figure A), while non-significant differences were observed in reactance curves (Figure 2B).

Figure 2: Mean respiratory resistance (A) and reactance (B) curves as a function of frequency of the control and Scoliosis groups.



Legend: Rrs - Respiratory resistance curve; Xrs - Respiratory reactance curve; Hz - Hertz.

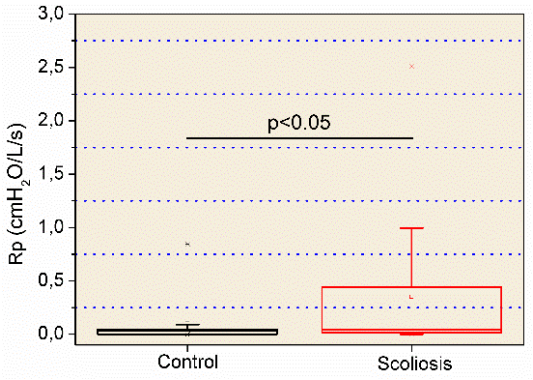


Figure 3 presents the eRIC model analysis. R values, shown in Figure 3A did not demonstrate significant differences compared with the control group (p= ns). In contrast, Rp and Rt, Figures 3B and 3C respectively, were significantly increased in the idiopathic scoliosis group ($p<0.05$).

Respiratory system inertance (Figure 3D), was significantly reduced ($p<0.05$), as was C (Figure 3E, $p<0.001$) when compared with the control group.

Correlation analysis revealed significant associations between the eRIC model parameters and spirometric indices (Table 3). The resistive parameters exhibited negative correlations, indicating that increased respiratory resistance was associated with reduced pulmonary function. Among these parameters, total respiratory resistance (Rt) showed the moderate to strong associations, particularly with $FEF_{25–75}$ ($r=-0.534$, $p<0.0001$), FEV_1/FVC ($r=-0.489$, $p<0.0001$), and FEV_1 ($r=-0.473$, $p<0.0001$).

In contrast, dynamic compliance (C) demonstrated moderate-to-strong positive correlations with several spirometric parameters, with the strongest relationships observed for FEV_1 ($r=0.686$, $p<0.0001$), $FEF_{25–75}$ ($r=0.675$, $p<0.0001$), and FVC ($r=0.642$, $p<0.0001$). Respiratory inertance (I) did not show significant correlations with any of the spirometric variables evaluated.

Regarding body plethysmography (Table 4), C was the only parameter that exhibited a significant moderate correlation, showing a positive association with TLC ($r=0.389$, $p<0.05$).

Table 3 - Correlation coefficient (r) and correlation significance level (p) of the oscillometry parameters in relation to the spirometry. Significant correlations are highlighted in bold.

IV. Discussion

The anthropometric results of the scoliosis group showed no significant differences compared with the control group, indicating that the groups were matched and homogeneous (Table 1). As described in the literature, idiopathic scoliosis is more prevalent in females, which is consistent with the findings of the present study [15].

Regarding spirometry, a significant reduction was observed in all parameters ($p<0.0001$), characterizing the pulmonary restriction found in this population and already well described in the literature. Additionally, signs of airway obstruction were also observed in the studied population [15, 16]. These alterations may be explained by the thoracic cage deformity observed in these individuals, which reduces lung volumes due to abnormal rib angulation and decreased diaphragmatic mobility. Furthermore, depending on the severity of scoliosis, airway obstruction may also be observed, often associated with hypokyphosis. In such cases, the spinal column protrudes into the thoracic cavity, altering the anatomical position of the bronchi and thereby contributing to airway obstruction [17, 18].

The results obtained from the plethysmography examination are presented in Table 2. One volunteer was unable to complete the examination due to his inability to perform the forced maneuvers necessary to obtain the measurements. A significant reduction in VC ($p<0.0001$) in comparison with the predicted values was observed. This finding may be attributed to the reduction in lung volume as a consequence of trunk distortion in these patients [19] A significant increase in RV and RV/TLC ($p<0.001$ and $p<0.0001$, respectively) was also observed, which may be explained by air trapping caused by thoracic distortion [20]. TLC did not show statistically significant changes, which may be partially explained by the fact that reductions in TLC are typically observed in patients with Cobb angles greater than 80 degrees or in the presence of air trapping [20, 21].

The analysis of the Rrs curve (Figure 2A) demonstrated significantly higher values ($p<0.0001$) in patients with idiopathic scoliosis compared with healthy controls across the entire frequency range evaluated (4–32 Hz). The increase in Rrs observed in the scoliosis group suggests greater opposition to airflow, likely resulting from structural alterations of the thoracic cage secondary to spinal deformity [22].

Figure 2B shows the respiratory reactance (Xrs) curves. Although no statistically significant differences were observed, patients with scoliosis exhibited visually more negative Xrs values, particularly within the low-frequency range (4–16 Hz). Similar findings have been reported by Van Noord et al. [22], suggesting a tendency toward reduced

respiratory system compliance and increased mechanical loading of the respiratory system [23].

Taken together, these findings are consistent with the restrictive ventilatory pattern commonly described in idiopathic scoliosis, which is characterized by impaired thoracic expansion and increased ventilation heterogeneity. The observed mechanical abnormalities likely reflect the combined effects of thoracic cage distortion on lung volumes, chest wall mechanics, and regional ventilation distribution, thereby contributing to the respiratory dysfunction observed in this population.

The results using the eRIC model are presented in Figure 3. Although clear visual increases may be observed, no statistically significant differences were observed in R (Figure 3A).

Regarding Rp (Figure 3B), the significant increase in peripheral airway resistance suggests that the thoracic deformity associated with idiopathic scoliosis induces mechanical changes capable of compromising small-airway function. Reduced chest wall mobility, combined with heterogeneous ventilation distribution, may contribute to the functional narrowing of distal airways and increased airflow resistance [24].

These mechanisms may foster the development of ventilatory heterogeneity, a phenomenon consistent with the more negative reactance values observed at lower frequencies (Figure 2B). Taken together, these findings indicate that the respiratory consequences of idiopathic scoliosis extend beyond the reduction in lung volumes typically identified by spirometry and body plethysmography, encompassing complex alterations in peripheral airway function and respiratory system mechanics.

In line with these observations, Rt (Figure 3C), which represents the sum of central and peripheral resistances showed a significant increase. This finding suggests that the alterations observed in idiopathic scoliosis include airway obstruction, predominantly affecting the more peripheral airways. This may be attributed to trunk distortion, leading to deformities of the chest wall and lung parenchyma [25].

Studies applying the eRIC model in patients with chronic obstructive pulmonary disease (COPD) have reported Rt values comparable to those observed in the present study, typically ranging from 3.5 to 4.5 $cmH_2O/l/s$ in individuals with mild to moderate disease. This finding suggests that the airway obstruction associated with spinal deformity in scoliosis may reach a magnitude similar to that observed in obstructive pulmonary disorders [26, 27].

Inertance is related to the movement of the mass of gas within the airways. Theoretically, a reduction in lung volume leads to a decrease in the mass of gas that must be displaced during breathing, reducing I. In line with this proposition, Table 2 shows a reduction in lung volumes, while Figure 3D shows that I reduced in scoliosis. This apparent reduction in I suggested the presence of airway obstruction, particularly in distal regions, which limits the propagation of the oscillatory signal and creates "choke points," thereby reducing the measured inertial component of the respiratory system [28]. In addition, the plethysmographic findings of reduced VC and increased RV/TLC suggest air trapping and impaired lung-emptying, conditions that effectively reduce the ventilated lung volume participating in oscillatory flow. Since inertance is influenced by the mass of air set into motion within the airways, a decrease in effective ventilated volume and airflow distribution may further contribute to the observed reduction in I. This relationship highlights the interplay between structural restriction, airway closure, and altered respiratory mechanics in scoliosis, reinforcing the complementary nature of oscillometry and plethysmography in detecting these changes.

The dynamic compliance of the respiratory system was also reduced (Figure 3E). Alterations in thoracic cage dynamics lead to a reduction in dynamic pulmonary compliance in patients with spinal deformity [29]. The presence of "choke points" is also related to a reduction of dynamic compliance in a phenomena similar to what happens in dynamic inertance [28].

The relationship between oscillometric parameters and disease severity has been examined in three previous studies [24, 30, 31]. In these studies, patients were stratified according to Cobb angle severity to evaluate respiratory mechanics across different stages of idiopathic scoliosis progression.

The negative correlations observed between the resistive parameters (R, Rp, and Rt) and spirometric indices suggest that increased respiratory resistance is associated with deterioration in pulmonary function. From a physiological perspective, this relationship is expected, as elevated airway resistance increases opposition to expiratory airflow, leading to reductions in FEV_1, the FEV_1/FVC ratio, and mid-expiratory flow rates, which are recognized markers of airflow limitation [32].

Among the resistive parameters, Rt demonstrated the strongest associations, indicating that the combined assessment of central and peripheral airway resistance may more accurately reflect the overall mechanical impairment of the respiratory system. This observation is consistent with the structural and functional alterations associated with idiopathic scoliosis, including postural deformities and thoracic cage distortion, which may compromise respiratory mechanics and increase airflow resistance [33].

Given that $FEF_{25–75}$ is commonly considered a surrogate marker of small airway function, these findings suggest that the eRIC model is sensitive to mechanical alterations occurring within the peripheral regions of the respiratory system. This observation reinforces the potential value of respiratory oscillometry as a complementary technique to spirometry, providing additional insights into pulmonary mechanical dysfunction that may not be fully captured by conventional pulmonary function testing [34].

Dynamic compliance exhibited the strongest correlations among all eRIC model parameters, particularly with FVC, FEV_1, and FEF_{25-75}. These findings indicate that reduced respiratory system distensibility is associated with impaired pulmonary function, affecting both lung volumes and airflow. From a physiological perspective, compliance reflects the ability of the respiratory system to expand in response to a given pressure change and is determined by the elastic properties of both the pulmonary parenchyma and the thoracic cage. Therefore, the strong associations observed between C and the spirometric indices suggest that this eRIC parameter may reflect global alterations in respiratory mechanics resulting from the postural deformities characteristic of idiopathic scoliosis [34, 35].

The body plethysmography results further support this interpretation. Among all evaluated parameters, dynamic compliance was the only variable significantly correlated with total lung capacity. Given that TLC represents the maximum volume that can be accommodated by the respiratory system, the positive association observed suggests that individuals with greater compliance exhibit a greater capacity for pulmonary expansion. Conversely, the absence of significant correlations between the resistive parameters and static lung volumes indicates that airway resistance primarily reflects airflow-related abnormalities, whereas lung volumes are predominantly determined by the elastic properties of the respiratory system [32].

Another noteworthy finding was the absence of significant correlations involving respiratory inertance (I). Although inertance reflects the mass of air and tissues that must be accelerated during breathing, its contribution to the functional abnormalities observed in the present sample appears to be limited. Similar findings have been reported in previous respiratory modeling studies, in which resistive and elastic parameters generally demonstrated greater clinical relevance than inertial components. A possible explanation is that patients with idiopathic scoliosis typically exhibit reduced FVC values, resulting in lower displacement of gas volume within the lungs and consequently diminishing the influence of inertial properties on respiratory mechanics. These findings are consistent with those reported by Oliveira et al. [32].

Some limitations of this study should be considered. The cross-sectional design precludes establishing causal relationships between spinal deformity and alterations in respiratory mechanics. Furthermore, the lack of analyses stratified by scoliosis severity limits the assessment of the Cobb angle's influence on the eRIC model parameters. Studies involving larger cohorts, independent validation, and longitudinal follow-up are needed to confirm the diagnostic and prognostic performance of these parameters, as well as to evaluate their ability to monitor disease progression and respiratory changes before and after corrective surgery. Comparisons with more advanced respiratory models will also help define the role of eRIC in functional assessment and clinical follow-up. Finally, the results are limited to idiopathic scoliosis and should not be extrapolated to other etiologies.

V. Conclusion

The present study demonstrated that patients with idiopathic scoliosis exhibit significant alterations in respiratory mechanics, characterized by reduced lung volumes, ventilatory restriction, and signs of air trapping. These abnormalities are likely related to thoracic cage deformity and its effects on lung expansion and respiratory muscle mechanics.

The application of the eRIC model provided a comprehensive characterization of respiratory mechanical abnormalities in idiopathic scoliosis. Patients exhibited increased Rp and Rt, together with reduced I and C. Among the eRIC-derived parameters, C showed the strongest associations with spirometric and plethysmographic indices, while Rt also demonstrated consistent relationships with pulmonary function, supporting the potential of eRIC modeling to complement the assessment of respiratory mechanics in this population.

However, the clinical applicability of these findings remains to be established. External validation, analyses stratified by scoliosis severity, investigation of associations with Cobb angle, assessment of measurement repeatability, appropriate control for multiple comparisons, and longitudinal studies are required to confirm the robustness, diagnostic value, and prognostic utility of eRIC-derived parameters in idiopathic scoliosis.

Acknowledgment

The authors would like to thank CNPq, FAPERJ, and CAPES for their financial support. Special thanks to the partnership with the National Institute of Traumatology and Orthopedics (INTO) and all the volunteers.

Conflict of Interest

The authors report no conflict of interest.

***Abstract*—The longevity of healthy workers in corporate environments is one of the goals of ergonomics programs. The aim of this study was to analyze the posture of office workers using Computer Vision and Artificial Intelligence methods in order to identify postural deviations and ergonomic risks and propose ergonomic recommendations. This was an observational, descriptive, quantitative study conducted with 22 office workers in Goiania, Brazil. The instruments used included a medical history questionnaire, as well as the Rapid Upper Limbs Assessment (RULA) and Rapid Entire Body Assessment (REBA) ergonomic postural evaluation protocols. The material used for data collection was an RGB camera mounted on a tripod at a fixed viewpoint. MediaPipe was used to detect keypoints on the human body. The results showed that 40.9% of the workers reported functional limitations in their office work performance. Regarding work-related complaints or conditions, 13.3% reported pain and tension in the lumbar region, 13.3% in the cervical region, and 13.3% reported knee pain. Segmental analysis of the human body revealed that the cervical region was the primary target for physical therapy and ergonomic interventions among office workers in the evaluated dataset, with an overall median RULA score of 3.65 and REBA score of 4.93. We found that the workers' health conditions compromised the proper performance of their work tasks. The use of Computer Vision and AI proved feasible for estimating postural changes in office work.**

***Index Terms*—Physical Therapy, Ergonomics, Computer Vision, Artificial Intelligence.**

I. Introduction

The longevity of workers in office environments is determined by factors that directly or indirectly influence health and quality of life at work. In this context, Occupational Physical Therapy, with an emphasis on Ergonomics, aims to analyze the relationship between the worker and their work, seeking to adapt work conditions to the worker's biopsychosocial characteristics, thereby minimizing occupational hazards and risks within organizations [1].

Office work requires employees to frequently use computers and cell phones, in addition to spending long periods of time in a seated position. Equipment and furniture are not always suitable or adjusted to individual anthropometric measurements. Consequently, poor ergonomic conditions can lead to the development of Repetitive Strain Injuries (RSIs) and/or Work-Related Disorders (WRDs), resulting in musculoskeletal pain, physical and mental fatigue, exhaustion, and stress among workers, thereby increasing workplace accident statistics [2].

Ergonomics has focused on the role of the human workforce in the face of advances in globalization, the Internet of Things, and Industry 4.0 [1]. However, physical therapy-based workplace assessments and ergonomic evaluations have traditionally relied on standardized observational methods, including the Rapid Upper Limb Assessment (RULA) [3] and the Rapid Entire Body Assessment (REBA) [4]. In these protocols, the physical therapist uses observation, photos, or videos, as well as tools such as goniometers and software, to assess posture, joint angles, and biomechanical variables, which are then converted into risk scores [1]. RULA and REBA are methods with satisfactory reliability in measuring joint angles [5]. However, [6] note that the reliance on observation and human judgment in rapid visual estimation methods can lead to subjective responses that hinder the scalability of assessments.

Disruptive technologies related to the Industry 4.0 paradigm have enabled interesting applications in the field of Occupational Physical Therapy and Ergonomics. More specifically, the impact of automated data collection and analysis is shaping a new set of applications for health assessment and intervention processes [7]. From this perspective, the present study proposes an indirect and automated functional and ergonomic assessment based on Computer Vision (CV) techniques and Large Language Models (LLMs) derived from Generative Artificial Intelligence (GenAI). Human pose estimators, such as MediaPipe, are capable, for instance, of extracting joint coordinates of the upper and lower limbs from images or videos, enabling the automation of ergonomic protocols [8].

Using CV algorithms, it is possible to identify and track

the positions of key points on the human body—particularly at joints and on limbs—which are useful for analyzing the body postures and movements used by office workers, thereby creating a digital skeleton that represents the pose of the person being assessed [9]. There are many pose estimation models, among them MediaPipe, which is considered a lightweight, efficient tool compatible with mobile devices such as cell phones, making it ideal for real-world applications such as offices.

The literature still has gaps regarding the use of Computer Vision in ergonomic assessments of office workers. The authors in [10] proposed a method for recognizing the body postures of construction workers, using 3D Computer Vision techniques based on a single 2D camera installed at strategic points on a construction site. In this model, a technique for recognizing improper postures was developed using computer vision techniques based on a single standard RGB (Red-Green-Blue) camera. Few studies simultaneously address the clinical accuracy required by the RULA and REBA protocols in ergonomic assessments, since data collection via video does not respect the privacy of the worker being assessed. Furthermore, few devices are capable of automatically translating angular measurements into terms that are understandable to end users, such as specialized occupational physical therapists and ergonomists.

Considering this, the goal of this study was to analyze the posture of office workers using Computer Vision, MediaPipe, and Artificial Intelligence, in order to identify postural deviations and ergonomic risks and propose ergonomic recommendations. The study also aimed to survey the musculoskeletal pain and complaints of office workers.

II. Materials and Methods

This is an interprofessional project involving faculty and students from the Physical Therapy, Computer Engineering, and Artificial Intelligence programs at the Federal University of Goiás (UFG). The study employed a field-based, observational, descriptive, and quantitative research design conducted with employees at an Educational Technology office located in the city of Goiânia, Brazil.

Participants were selected using the criteria-based sampling method [11]. Eligible workers were those who had been employed at the office for more than one year and who reported some work-related pain or musculoskeletal disorder. In the end, the sample consisted of 22 workers, including 15 women and seven men with a mean age of ± 32 years (range: 18–57 years).

The data collection instrument followed the measurement techniques recommended by [12] and [13], utilizing self-report and observational methods. A medical history questionnaire was used, containing personal information about the workers, work-related complaints or conditions, and an assessment of postural problems. The Rapid Upper Limb Assessment (RULA) and Rapid Entire Body Assessment (REBA) ergonomic postural assessment protocols were also used to evaluate the risk of RSI/WMSDs among the workers.

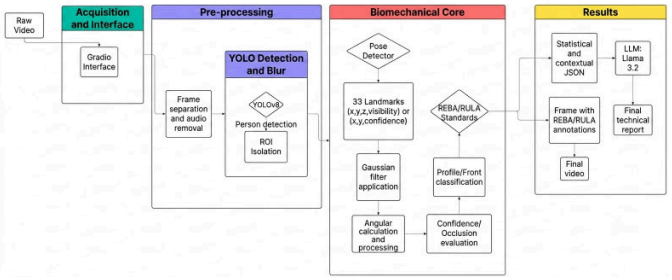

Fig. 1. Proposed framework from raw video to report generation via LLM.

The equipment used included an RGB camera with HD resolution (1024×768 pixels) and a cell phone tripod. Workers underwent video recording to estimate their postures during work, viewed from the right and left sides, as well as from the front and back, with an average recording duration of 15 minutes per session.

MediaPipe was used as the computational tool, employing a single-person estimation approach for human pose detection using Computer Vision to identify and track the positions of keypoints on the human body during the performance of routine office tasks, such as typing, customer service, using a cell phone, and handling documents [9]. The data were tabulated quantitatively using Microsoft Excel 2014 and Python. The study complies with Resolution No. 510/2016 of the National Health Council (CNS) and was approved by the UFG Research Ethics Committee for Studies Involving Human Subjects.

A. Methodology

The proposed framework was structured into four sequential stages, as illustrated in Fig. 1: (i) Acquisition and Interface, in which the raw video was received via the Gradio interface and the audio was suppressed; (ii) Preprocessing, involving person detection and facial anonymization; (iii) Biomechanical Core, involving pose estimation and calculation of RULA and REBA scores; and (iv) Summarization via LLM, synthesizing the data into an actionable textual report.

1) Data collection: The dataset consisted of recordings of 22 workers at office workstations with varied configurations of furniture, monitors, and lighting. Video capture was performed using a Samsung S21FE smartphone mounted on a tripod, with the lens positioned between the worker's iliac crest and the armrests of the chair. The videos were recorded from a side view (profile) and an oblique view (approximately 45° relative to the frontal plane), an effective strategy for capturing subtle postural compensations by workers, such as excessive cervical rotation while monitoring secondary screens.

2) Preprocessing and Privacy: This stage consists of three steps. First, the YOLOv8 model [14] was used to detect people by selecting the most reliable bounding box in the scene. Second, the cropped image was fed to the pose estimator to infer body landmarks. Third, a dynamic Gaussian filter was applied to the detected facial region [15], ensuring that no identifiable images are displayed or stored, in compliance

with the Brazilian General Data Protection Law (LGPD, Law No. 13,709/2018). In addition to visual anonymization, the subject's privacy was also protected by removing the audio tracks to prevent the capture of sensitive verbal information in the workplace, in line with the Privacy by Design approach [16], which represented a significant ethical distinction for workplace monitoring applications.

3) RULA and REBA scores: MediaPipe Pose [17] was evaluated as a pose estimator that utilized a topology of 33 three-dimensional landmarks on the human body. This pose estimation model provided coordinates for each anatomical keypoint, also known as landmarks. Visibility and confidence indicators served as filtering criteria: a landmark was included in the calculation of RULA/REBA scores only if its indicator exceeded the threshold of 0.5. Below this threshold, the system reports a detection failure for the frame in question, preventing spurious angles from contaminating the RULA and REBA scores. Thus, the ergonomic scores were obtained through mapping, in which joint angles (actual values) were quantized into discrete thresholds of 20°, 45°, 90°, in accordance with protocol standards, producing the scores that make up the final risk indices.

The RULA and REBA methods were implemented as lookup tables in direct-search structures that faithfully replicated the original scoring matrices. The joint angle between two adjacent body segments, represented by the vectors $\vec{a}$ and $\vec{b}$ formed from the (x, y) coordinates of the landmarks, was calculated using the Euclidean dot product. The calculations were performed frame by frame, generating a time series of scores. The final score was obtained by a weighted average over the processed time series. The methods were implemented in conjunction: RULA for focusing on the upper limbs and neck, and REBA for whole-body analysis, as comparative studies demonstrate that their sensitivities differ depending on the task dynamics [18].

4) Summarization and automatic generation of technical reports: To translate the RULA and REBA scores into guidance accessible to end users (occupational physical therapists and ergonomists), the Llama 3.2 language model was adopted. This is a quantized model optimized for low computational cost and local inference on embedded computers, as shown in Fig. 2.

The model was adapted to the specific context of physical therapy using the context injection technique: the processed statistical data (angular means, standard deviations, maximum scores, and user metadata—age and gender) were structured into a JSON object and injected as grounding into the prompt. The system prompt incorporated strict guardrails that restrict the output to the identification of biomechanical risks based on the provided data, explicitly refraining from providing clinical diagnoses or prescribing physical therapy treatments. This scope limitation was essential to validate the tool as an ergonomics aid and not as a substitute for a healthcare professional.

ERGONOMIC ANALYSIS REPORT (GENERATED BY LLM)

Analysis ID: video_20251120_081301 | Role: marketing_analyst

1. EXECUTIVE SUMMARY

Moderate risk (Average RULA: 4.08). The cervical region is the main target, partial score 2.85 | the highest among segments.

2. TECHNICAL DETAILS

- Average RULA: 3.99 (Max: 5.0) | Average REBA: 4.65
- Neck: 33.56° (±8.15°) --- Score 2.85 [CRITICAL]
- Trunk: 7.33° (±9.95°) --- Score 1.72
- Arm: 31.23° (±9.65°) --- Score 1.89

3. RECOMMENDATIONS

- Adjust monitor height to eye level.
- Active breaks every 50 min.

NOTE: This is an auxiliary tool. You should consult a professional!

Fig. 2. Example of a technical report automatically generated by the Llama 3.2 model. The system translates vector metrics into actionable natural language, remaining within the scope of an auxiliary tool for Occupational Physical Therapy and Ergonomics.

B. Results and Discussion

The characteristics of 22 workers assessed using a medical history questionnaire are presented in Table I. They are categorized by job position, the presence of functional limitations affecting the workers' ability to perform office work, work-related complaints or illnesses, and the main postural problems reported by the workers.

1) Segmental Analysis and Clinical Validation: Table II presents the analysis of joint angles and the local and global RULA and REBA scores obtained using the proposed Framework. The individual analysis of the joint angles yielded the cervical region as the area of greatest ergonomic concern. Although the neck exhibits a relatively low standard deviation ($\sigma = 8.15°$), indicating static posture, the mean cervical flexion is $33.56°$, which is sufficient to raise the risk score to 2.85 — the highest among all segments. This finding corroborates the literature, which points to a significant prevalence of musculoskeletal disorders in the neck-shoulder region among office workers [19].

The forearm exhibited the greatest angular variability in the study ($\sigma = 16.22°$), reflecting the dynamic nature of typing and mouse use activity. The trunk demonstrated high postural stability after settling into the chair (median of $4.46°$), indicating that the greatest chronic risk factor lies in the position of the head relative to the screen, not in the lumbar posture adopted by the worker while performing office tasks.

In general, the global median scores, RULA of 3.65 and REBA of 4.93, place the participants in the "investigation and potential for imminent change" range, aligning with the typically more conservative sensitivity of the automated RULA [6], [20]. These data are important to help occupational therapists recommend specific measures to address RSI and

WMSDs, such as adjusting the chair and monitoring height, taking active breaks and performing stretches to minimize pain complaints among affected workers.

2) Comparative assessment of Goniometry against the proposed automated Framework: Table III shows the comparative joint range of motion (ROM) measurements collected by independent professionals using Goniometry against the proposed Framework, together with the corresponding divergence (ϵ).

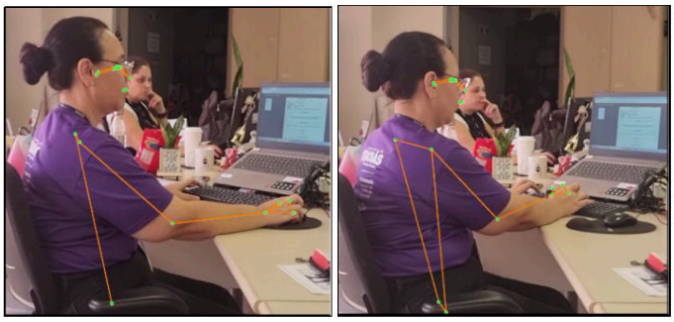

Fig. 3. Keypoints from the MediaPipe tool for estimating the human pose of a female office worker.

Following statistical tolerance criteria, the proposed Framework proved effective in computing joint angle measurements, with errors increasing due to artifacts, such as occluded joints (*e.g.*, ankle, wrist), or artificial landmarks that were inferred by proximal joints (*e.g.*, cervical).

TABLE III
COMPARATIVE JOINT RANGE OF MOTION MEASUREMENTS

Joint angle	**Goniometry (°)**	**Framework (°)**	ϵ (°)
Participant 1			
Neck (cervical)	14	7	7
Shoulder	20	23–25	3–5
Elbow	50–52	49.5–53.5	0.5–3.5
Wrist	12	13.5–18	1.5–6
Lumbar	18	12–14	4–6
Knee	100	89.5–92	8–10.5
Ankle	8–10	7–9	1–2
Participant 2			
Neck (cervical)	36	40–49	4–13

Elbow	10	11–3	1–7
Wrist	8–10	17–30	8–21
Lumbar	34–36	16–17	19
Knee	90	80–75	10–15
Ankle	6	7–10	1–4

3) Automated Framework for Ergonomic Scores Estimation: Regarding the collection of videos for subsequent transcription of the results, the first step was to use MediaPipe Pose to estimate the pose of the anatomical points of interest for assessment in office workers, represented in Fig. 3 by red vectors and green points.

Subsequently, during video data collection, a dynamic Gaussian filter was applied to the detected facial region, ensuring that no image of the worker was identifiable. Next, the system automatically generated summaries and technical reports, with processed statistics (angular means, standard deviations, maximum scores) automatically translated for interpretation by professionals.

From a computational standpoint, this work differs from the state of the art by combining multiple functionalities into a single framework for automated ergonomic assessment,

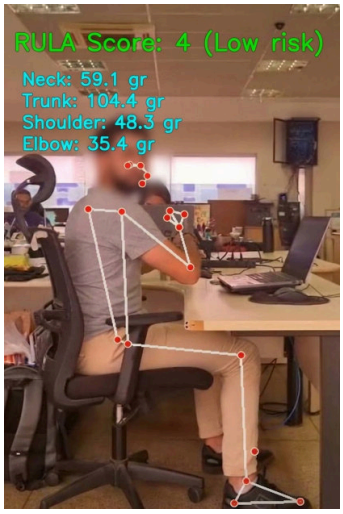

Fig. 4. Representation of the framework in operation: biomechanical skeleton superimposed on the participant with active Gaussian facial anonymization and the RULA score displayed in real time, alongside joint angles by segment.

which integrates: *(i)* a comparative study of pose estimation methods in real-world ergonomic scenarios; *(ii)* a hybrid top-down architecture for pose estimation from videos captured by a single camera; *(iii)* frame-by-frame automation of the RULA and REBA protocols for greater temporal stability; *(iv)* automated anonymization of images and videos compliant with the Brazilian General Data Protection Law (LGPD); *(v)* automatic generation of technical reports through structured prompt engineering using the Llama 3.2 model.

Computer Vision and Generative Artificial Intelligence applications are progressively gaining ground towards the digital transformation of functional and ergonomic assessment of workers. The authors in [21] demonstrated that the implementation of pose detectors on smartphones for classifying physical therapy exercises for the shoulder and lower back achieved 95% accuracy. They also found that a sample size of 7 to 11 patients is sufficient to generate training data that results in efficient classifications.

In [22], it was evaluated the performance of the MediaPipe model for pose estimation in comparison with motion capture (MoCap) systems, concluding that the model's accuracy is highly dependent on the type of exercise and the camera's capture angle, which reinforces the need for standardized data collection protocols in the field of physical therapy.

III. Conclusion

The results revealed in the medical history survey conducted with 22 office workers in the city of Goiania, Brazil, indicated the presence of functional limitations in nearly half of the workers, with evidence of pain and muscle tension in the cervical and lumbar spine and knees.

Regarding the postural abnormalities reported by the workers, a predominance of postural abnormalities in the cervical spine was observed. This study also presented a new proposal for an automated and non-invasive framework for postural and ergonomic analysis of workers in office environments, integrating Computer Vision and Generative Artificial Intelligence. The central contribution lies in the validation of the top-down hybrid architecture in a real-world ergonomic setting, demonstrating that temporal stability is the determining factor for the reliability of the RULA and REBA scores that were automated in this tool. This automated system offers a technical and ethical advantage by implementing facial anonymization prior to biomechanical rendering, ensuring compliance with the Brazilian LGPD legislation.

Segmental analysis revealed that the cervical region was the primary target of physical therapy and ergonomic interventions for office workers in the evaluated dataset, with median overall RULA scores of 3.65 and REBA scores of 4.93.

Future work will focus on hybrid validation using a digital twin protocol to generate a synthetic ground truth with precisely known angles, as well as hand-tracking modules to identify RSI/WMSD risks associated with excessive keyboard and mouse use, and the migration of data to mobile devices.

Resumo*—A Assistência Farmacêutica no Sistema Único de Saúde (SUS) enfrenta os desafios relacionados à garantia do acesso equânime e o uso racional de medicamentos em um cenário de descentralização da gestão. Nesse cenário, o Sistema Nacional de Gestão da Assistência Farmacêutica (Hórus) foi desenvolvido para integrar informações, qualificar os processos de gestão e fortalecer o planejamento das ações farmacêuticas. Este estudo teve como objetivo analisar as fragilidades operacionais e os impactos da implantação do Hórus na gestão da Assistência Farmacêutica no SUS. Para isso, foi realizada uma revisão bibliográfica, complementada pela análise de documentos normativos e da literatura especializada sobre o tema. Os resultados evidenciam que o Hórus proporcionou avanços importantes, como o aprimoramento do controle de estoque, da rastreabilidade de medicamentos e da qualidade das informações utilizadas na gestão. Entretanto, a literatura aponta que sua efetividade ainda é limitada por problemas relacionados à infraestrutura das unidades de saúde, à insuficiência de capacitação dos profissionais, à fragmentação dos sistemas de informação e à permanência de modelos de assistência predominantemente centrados na logística de medicamentos, em detrimento da atenção farmacêutica. Conclui-se que o Hórus constitui uma importante ferramenta para a gestão da Assistência Farmacêutica no SUS, porém seu pleno potencial depende de investimentos contínuos em infraestrutura, qualificação profissional, integração dos sistemas de informação e reorganização dos processos de trabalho, de modo a fortalecer a atuação clínica do farmacêutico e ampliar a qualidade da assistência prestada à população.

***Palavras-chave*—Hórus; Farmácia; Gestão de Farmácias; SUS.**

I. INTRODUÇÃO

A transformação digital na saúde pública brasileira não representa apenas uma mudança de suporte técnico, mas uma estratégia vital para a eficiência do gasto público e a transparência institucional. Em um cenário de recursos limitados, a transição de modelos de gestão manuais para sistemas informatizados torna-se um imperativo para a resolubilidade das ações de saúde e para a utilização estratégica da Tecnologia da Informação (TI) na gestão governamental [5], [9].

Historicamente, a Assistência Farmacêutica (AF) no Brasil foi caracterizada por ações fragmentadas, centralizadas e verticais — exemplificadas pela antiga Central de Medicamentos (CEME) [7], [15] . A promulgação da Constituição de 1988 e a criação do Sistema Único de Saúde (SUS) estabeleceram a saúde como direito de todos e dever do Estado, impulsionando a descentralização do sistema [18], [5], [14]. Contudo, a descentralização transferiu aos municípios a responsabilidade pela gestão direta dos serviços, revelando assimetrias na capacidade administrativa, orçamentária e operacional das gestões locais [18].

Para superar os desafios da descentralização e mitigar as ineficiências na gestão de estoques, a introdução de Tecnologias de Informação e Comunicação (TICs) nos serviços de saúde assumiu papel estratégico [5], [7]. Sistemas de informação de âmbito local constituem-se como recursos estratégicos para democratizar o acesso, aperfeiçoar o controle do gasto público e subsidiar os processos decisórios [5], [11], [2].

Nesse contexto de inovação, o Ministério da Saúde desen-

volveu e disponibilizou gratuitamente, em 2009, o Sistema Nacional de Gestão da Assistência Farmacêutica (Hórus) [7], [5]. O Hórus foi concebido para atuar em todo o território nacional, permitindo o controle de estoque de medicamentos, a rastreabilidade do envio ao consumo final e o monitoramento dos recursos financeiros investidos nas esferas federal, estadual e municipal [5].

No entanto, a simples disponibilização de uma solução tecnológica não garante a efetividade da gestão pública ou a melhoria da atenção à saúde. A literatura demonstra que a implantação de TICs em órgãos públicos municipais enfrenta barreiras estruturais significativas, como escassez de infraestrutura de conectividade, falta de equipamentos adequados, déficit de pessoal qualificado e resistência cultural às transformações nos processos de trabalho [5], [1], [10]. Ademais, subsiste o desafio de integrar a dimensão logística da gestão à dimensão clínica da atenção à saúde, de modo a assegurar que o registro de dados se converta em indicador de qualidade e no uso racional de medicamentos [18], [11].

Considerando que a garantia do acesso sustentável a medicamentos essenciais é condição fundamental para a efetivação do direito à saúde no SUS, torna-se indispensável analisar criticamente o desempenho das ferramentas informatizadas utilizadas no país [18].

II. METODOLOGIA

Este trabalho fundamenta seu referencial teórico em uma revisão bibliográfica, realizada com o propósito de reunir, sistematizar e analisar estudos previamente publicados sobre o Sistema HÓRUS e sua aplicação na gestão da Assistência Farmacêutica no Sistema Único de Saúde (SUS), contribuindo para a contextualização dos resultados e para a fundamentação da discussão apresentada.

A busca bibliográfica foi realizada nas bases Portal de Periódicos CAPES, Biblioteca Virtual em Saúde (BVS) e Scientific Electronic Library Online (SciELO), complementada pela consulta a documentos oficiais do Ministério da Saúde. Para a identificação dos estudos, foram utilizados os descritores e termos relacionados a “Sistema HÓRUS”, “HÓRUS”, “Assistência Farmacêutica”, “Gestão de Medicamentos”, “Sistemas de Informação em Saúde”, “Atenção Primária” e “Sistema Único de Saúde (SUS)”, combinados por meio dos operadores booleanos AND e OR.

Foram realizadas três estratégias de busca. A primeira utilizou a combinação: (”Sistema Hórus” OR ”Hórus”) AND (”Assistência Farmacêutica” OR ”Gestão de Medicamentos”) AND (”Atenção Primária” OR ”SUS”). Nessa estratégia, foram identificados 1 resultado na SciELO, sendo 1 incluído; 12 resultados no Portal de Periódicos CAPES, considerando publicações do período de 2013 a 2026, dos quais 2 foram incluídos; e 6 resultados na BVS, referentes ao período de 2021 a 2023, dos quais 2 foram incluídos, totalizando 19 registros identificados e 5 estudos selecionados.

A segunda estratégia empregou a combinação (”Sistema Hórus” OR ”Hórus”) AND (”Sistemas de Informação em Saúde” OR ”Assistência Farmacêutica”). Foram identificados 26 resultados no Portal de Periódicos CAPES, com recorte temporal de 2012 a 2023, dos quais 3 foram incluídos, e 26 resultados na BVS, dos quais 2 foram incluídos. Essa estratégia resultou em 52 registros identificados e 5 estudos selecionados.

A terceira estratégia utilizou a combinação (”Sistema Hórus” OR ”Hórus”) OR (”Assistência Farmacêutica” OR ”Gestão de Medicamentos”) AND (”Atenção Primária” OR ”SUS”). Na SciELO, foram identificados 145 resultados, considerando o período de 2000 a 2026, dos quais 10 estudos foram selecionados, sendo identificado 1 registro duplicado entre os resultados recuperados.

Ao todo, as três estratégias de busca resultaram em 216 registros identificados (19 + 52 + 145). Após a aplicação dos critérios de seleção e a análise dos resultados, foram selecionados 20 estudos para avaliação na íntegra. Foram considerados elegíveis estudos que abordassem diretamente o Sistema HÓRUS, sua utilização na Assistência Farmacêutica, sua relação com Sistemas de Informação em Saúde ou sua aplicação na gestão de medicamentos no âmbito do SUS e da Atenção Primária à Saúde. Foram consideradas publicações em português ou inglês que apresentassem informações pertinentes aos objetivos da pesquisa.

Foram excluídos estudos que não apresentassem relação direta com o objeto da pesquisa, publicações incompatíveis com os objetivos estabelecidos e registros duplicados. A seleção dos estudos foi realizada mediante análise dos resultados recuperados e posterior avaliação dos trabalhos selecionados em texto completo. O processo de identificação, seleção e inclusão dos estudos está apresentado no Diagrama do processo de seleção dos estudos (Figura 1). Dos 20 estudos avaliados na íntegra, 2 foram identificados como duplicados, resultando em 18 estudos incluídos no escopo da revisão.

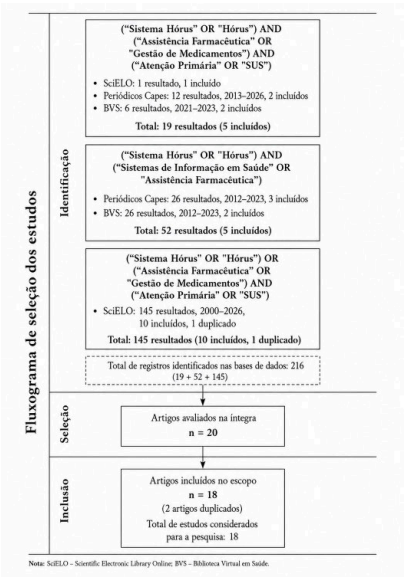

Fig. 1. Fluxograma de seleção dos estudos

Para sistematizar as informações dos estudos incluídos, foi

elaborada uma tabela de caracterização contendo local do estudo, período, amostra, metodologia empregada e principais fragilidades relacionadas ao Sistema HÓRUS identificadas pelos autores (Figura 2). Essa sistematização permitiu comparar os diferentes contextos investigados e identificar aspectos recorrentes relacionados à utilização, implantação e funcionamento do sistema na gestão da Assistência Farmacêutica.

Estudo (Título e Autor)	Local	Amostra	Metodologia	Fragilidades do Hórus Identificadas	Ano
1. Institucionalização da AF em Ananindeua (Torres et al.)	Ananindeua, PA	17 Farmácias Distritais e 3 Especializadas	Pesquisa-ação, exploratória e descritiva	Lacunas no cumprimento de práticas de governança; instabilidade sistêmica.	2021
2. Institucionalização da AF em Benevides (Torres & Soler)	Benevides, PA	31 estabelecimentos de saúde	Exploratória e descritiva (Planejamento Estratégico)	Ausência de ferramentas de controle; sistema operante apenas no componente estratégico.	2023
3. Implantação do HÓRUS nas farmácias do SUS (Dias, K.)	6 municípios (MG, PR, SP)	6 municípios brasileiros	Pesquisa exploratória e de campo (entrevistas/observação)	Falta de internet; déficit de pessoal; lentidão; obrigatoriedade de conexão online.	2013
4. Experiência da estruturação da AF municipal (Azevedo et al.)	Santa Isabel, SP	13 unidades (CS, UBS, ESF, CAF)	Relato de experiência	Lentidão no processamento; necessidade de plataforma offline; problemas de conectividade.	2018
5. HÓRUS: Ferramenta de gestão para AF (Franco et al.)	Iguatu, CE	1 farmácia municipal	Estudo observacional qualitativo	Paralisações frequentes na base nacional em horário comercial; inércia do serviço por falta de preenchimento.	2023
6. Assistência Farmacêutica no SUS (Ribeiro et al.)	Brasil	Revisão bibliográfica	Levantamento bibliográfico	Falta de acesso total à internet nas farmácias e CAF limitando a implantação.	2023
7. Serviço de dispensação de medicamentos (Leite et al.)	Brasil (Nacional)	1.175 farmácias/unidades	Estudo transversal (PNAUM)	Baixa informatização na região Norte (14,3%); falta de integração sistêmica.	2017
8. Caracterização da institucionalização da AF (Souza et al.)	Brasil (Nacional)	507 RAF e 369 SMS	Estudo transversal (PNAUM)	Baixa utilização do Hórus (apenas 16,3% dos que possuem sistema informatizado o utilizam) 11.	2017
9. Gestão da assistência farmacêutica (Gerlack et al.)	Brasil (Nacional)	506 responsáveis pela AF	Estudo transversal (PNAUM)	30% dos municípios sem sistema; menos da metade ligado em rede; falta de uso para controle financeiro.	2017
10. Avaliação da capacidade de gestão da AF (Faraco et al.)	Brasil (Nacional)	600 municípios brasileiros	Quantitativo e transversal (PNAUM)	Fragilidades organizacionais críticas (94% sem CFT); grandes disparidades regionais.	2025
11. AF no Brasil: Análise antropológica (Penaforte, T.)	Brasil (Nacional)	Atas do CNS (1999-2004)	Análise documental antropológica	Tensionamentos entre foco logístico vs. cuidado clínico; lacunas de governança institucional.	2026
12. Avanços e desafios da AF na APS (Costa et al.)	Brasil (Nacional)	Dados gerais do SUS	Estudo avaliativo	Complexidade da gestão descentralizada; disparidades estruturais regionais.	2017
13. Disponibilidade de medicamentos (Mendes et al.)	Brasil (Nacional)	38.812 UBS (PMAQ-AB)	Estudo transversal	Infraestrutura precária (climatização e armazenamento); falta de apoio farmacêutico em unidades.	2014
14. AF na APS: Pactuação interfederativa (Costa et al.)	Brasil (Nacional)	Dados do QUALIFAR-SUS	Estudo avaliativo	Falhas na coordenação entre esferas; necessidade premente de integração de dados nacionais.	2017
15. Acesso a medicamentos e institucionalização (Barros et al.)	Brasil (Nacional)	4.866 usuários e 507 RAF	Estudo transversal (PNAUM)	55,6% dos usuários buscam med. em unidades sem sistema; rede de integração insuficiente 23.	2017
16. Gestão da AF: Controle e farmacoeconomia (Meirelles et al.)	Salto, SP	13 unidades de AF	Relato de experiência	Ineficácia inicial por registros manuais; necessidade de capacitação permanente da equipe.	2015
17. Mudanças na Gestão da AF (Paraíba) (Gomes et al.)	Paraíba (Estadual)	CEDMEX (Componente Esp.)	Estudo descritivo e analítico	Infraestrutura precária e sistema ainda em fase de ajustes operacionais	2013
18. Avaliação do grau de implementação (Inácio, V.)	DSEIs Xavante e Xingu	2 Distritos Indígenas	Estudo de caso múltiplos	Baixa conectividade (internet abaixo do mínimo); falta de RH treinado; banco de dados incompleto para MMH.	2018

Fig. 2. Diagnóstico da AF e fragilidades do Sistema Hórus

III. DESENVOLVIMENTO

A. Histórico e Institucionalização da Assistência Farmacêutica no SUS

A trajetória da Assistência Farmacêutica no Brasil reflete a evolução do próprio sistema público de saúde [16]. A partir da década de 1990, com a aprovação da Política Nacional de Medicamentos em 1998 e da Política Nacional de Assistência Farmacêutica em 2004, a AF passou a ser reconhecida não apenas como um setor de suprimento de insumos, mas como um conjunto de ações voltadas à promoção, proteção e recuperação da saúde [1], [5], [7].

A descentralização das ações de saúde atribuiu novos papéis e responsabilidades aos municípios [1]. Contudo, estudos sobre a caracterização da AF nos municípios brasileiros indicam que a institucionalização desse setor ocorreu de forma heterogênea, desigual e com acentuadas disparidades regionais [16], [6]. A pactuação interfederativa avançou na distribuição de competências orçamentárias e na ampliação da cobertura do fornecimento público de medicamentos, mas a gestão dos serviços nos municípios permaneceu marcada por vulnerabilidades técnicas, operacionais e limitações na autonomia financeira local [18], [8], [6], [4].

O acesso da população aos medicamentos está diretamente associado ao grau de institucionalização, estruturação técnica e organização da AF no nível local [2], [6]. A descontinuidade no suprimento de fármacos, somada às deficiências no armazenamento, no controle de estoques e na distribuição, compromete diretamente a eficácia das diretrizes nacionais de saúde e segurança do paciente. Assim, a informatização e a implantação de sistemas de informação surgiram como propostas centrais para conferir transparência, monitorar os recursos, otimizar a gestão logística e modernizar as estruturas administrativas da saúde pública [5], [7], [11], [3], [9] .

B. O Sistema Hórus: Avanços e Potencialidades de Gestão

O lançamento do Sistema Hórus em 2009 pelo Ministério da Saúde, em parceria com estados e municípios, representou um marco normativo e tecnológico [5], [7]. Conforme destacam Costa e Nascimento Jr [4] e Dias [5], a ferramenta foi concebida como um sistema Web descentralizado e gratuito, destinado a integrar o fluxo de informações da AF em todo o país.

Entre as principais potencialidades e avanços proporcionados pela implantação do Hórus, destacam-se:

- Controle de Estoque em Tempo Real: Permite o rastreamento da entrada e saída de medicamentos nas centrais de abastecimento farmacêutico e nas farmácias das Unidades Básicas de Saúde (UBS) [5], [7], [10].
- Rastreabilidade dos Lotes: Possibilita o acompanhamento detalhado dos lotes e prazos de validade, reduzindo as perdas por vencimento e garantindo a segurança do paciente [1], [5], [10], [12] .
- Visibilidade dos Custos e Agendamento de Atendimentos: Contribui para a transparência do gasto público e para a otimização dos fluxos de atendimento ao usuário [1], [5], [10].
- Apoio ao Planejamento e à Tomada de Decisão: Gera dados agregados que subsidiam a elaboração de estimativas de consumo e a pactuação de compras públicas [5], [7], [10], [12].

Em contextos específicos, como na gestão do Componente Especializado da AF no Estado da Paraíba, a implantação do Hórus demonstrou ganhos significativos no gerenciamento de tratamentos de alto custo, trazendo maior previsibilidade aos estoques estaduais e agilidade no atendimento [9].

C. Fragilidades Estruturais, Operacionais e de Capital Humano

A despeito do arranjo normativo e das avançadas especificações técnicas do Hórus, investigações empíricas realizadas no nível municipal apontam lacunas expressivas entre o modelo ideal concebido e a realidade operacional vivenciada pelos profissionais de saúde nas farmácias do SUS [5], [6], [8], [17], [18].

A análise da implantação do Hórus no Estado do Rio Grande do Sul evidencia que, embora centenas de municípios tenham aderido formalmente ao sistema, a adesão não se traduziu na plena utilização dos seus módulos [1], [5]. As principais fragilidades identificadas compreendem:

- Precariedade da Infraestrutura Tecnológica: A ausência ou instabilidade de conexões de internet nas farmácias públicas inviabiliza o uso continuado do sistema Hórus, que opera na modalidade on-line [1], [5]. A lentidão do sistema e a escassez de computadores adequados geram filas e atrasos no atendimento [1], [5].
- Déficit de Profissionais e Rotatividade: A escassez de farmacêuticos e equipes de apoio e a alta rotatividade de pessoal limitam o alimentação tempestiva dos dados no sistema [1], [5].
- Necessidade de Capacitação Continuada: Os treinamentos ofertados frequentemente revelam-se pontuais e insuficientes frente à complexidade das rotinas de dispensação e às atualizações do software [5], [7], [16].
- Alimentação Incompleta de Dados: A digitação de informações é por vezes negligenciada ou feita com atraso, comprometendo a confiabilidade dos relatórios e anulando a capacidade do Hórus de funcionar como gerador de indicadores gerenciais e assistenciais confiáveis [5].

A dicotomia entre as premissas de planejamento formuladas no nível federal e a capacidade de execução dos governos municipais compromete a consolidação de um modelo unificado de informação assistencial [6], [8].

D. A Tensão entre Tecnologia de Gestão e Tecnologia de Uso: O Papel do Farmacêutico

Uma fragilidade estrutural que perpassa o debate sobre o Hórus refere-se ao foco predominante do sistema na ”Tecnologia de Gestão” (logística, finanças, saldo de estoque) em detrimento da ”Tecnologia de Uso” (cuidado clínico, orientação ao paciente e acompanhamento farmacoterapêutico).

A literatura científica estabelece uma dicotomia crítica entre a ”Tecnologia de Gestão” (logística e abastecimento) e a ”Tecnologia de Uso” (orientação e cuidado clínico) [5], [8]. Por outro lado, enquanto Gomes et al. [9] apontam a eficácia da ferramenta para otimizar controles operacionais de suprimentos, diversos autores alertam para o risco de transformar o profissional farmacêutico em um mero operador de sistema e burocrata do estoque [7], [11].

Quando o ambiente de trabalho da farmácia pública é caracterizado pela alta demanda de usuários, escassez de equipamentos e digitação morosa de cadastros no Hórus, a dimensão relacional do atendimento é sacrificada [1], [5]. A dispensação reduz-se à simples entrega material do fármaco, desprovida da necessária orientação sobre posologia, conservação, efeitos adversos e adesão ao tratamento [11].

Estudos sobre o perfil da atenção primária e o serviço de dispensação na rede básica revelam que orientações clínicas adequadas são indispensáveis para evitar intoxicações, abandono de tratamento e falhas terapêuticas, sobretudo em populações vulneráveis, como idosos e portadores de doenças crônicas [1], [5], [11]. A sobrecarga burocrática provocada por sistemas de informação que não dialogam com a rotina do cuidado atua como uma barreira à consolidação da Atenção Farmacêutica centrada no paciente [11], [14].

Para que os sistemas de informação em saúde no nível local alcancem sua plenitude, a tecnologia deve atuar como meio facilitador do processo de trabalho, promovendo o acolhimento humanizado e a integração interprofissional, e não como um fim burocrático autossuficiente [5], [11], [16].

IV. SÍNTESE CRÍTICA E RECOMENDAÇÕES

A análise da literatura sobre o Sistema Hórus revela que a inovação tecnológica é um elemento necessário, porém insuficiente, para superar as fragilidades históricas da gestão da Assistência Farmacêutica no SUS. A efetividade do sistema depende não apenas de suas funcionalidades, mas também das condições estruturais, organizacionais e humanas existentes nos municípios. Nesse sentido, o aprimoramento da gestão informatizada requer ações articuladas que contemplem infraestrutura, qualificação profissional, qualidade da informação e reorganização dos processos de trabalho.

A Figura 3 sintetiza as principais fragilidades mapeadas e apresenta recomendações de aprimoramento relacionadas a cada uma delas.

DIMENSÃO	FRAGILIDADES IDENTIFICADAS	RECOMENDAÇÕES DE APRIMORAMENTO
Infraestrutura	Instabilidade da internet; falta de computadores e equipamentos nas UBS.	Investimento contínuo em conectividade e renovação do parque tecnológico municipal.
Capacitação	Treinamento pontual; alta rotatividade de pessoal nas farmácias.	Programas permanentes de educação continuada e fixação de profissionais qualificados.
Alimentação de Dados	Subnotificação, registros desatualizados e relatórios não utilizados.	Simplificação da interface do sistema e integração com o Prontuário Eletrônico do Cidadão (e-SUS PEC).
Prática Clínica	Foco exclusivo na logística; sobrecarga burocrática do farmacêutico.	Inclusão de módulos focados no registro do acompanhamento farmacoterapêutico e na dispensação orientada.

Fig. 3. Fragilidades do Sistema Hórus na gestão da Assistência Farmacêutica no SUS e recomendações de aprimoramento. Elaboração dos Autores (2026).

Para conferir maior aplicabilidade prática às diretrizes apresentadas na Figura 2, detalham-se, a seguir, estratégias operacionais de enfrentamento e mitigação articuladas às principais dimensões das fragilidades identificadas. Essas estratégias devem ser compreendidas como proposições de aprimoramento decorrentes da análise realizada, considerando que as limitações observadas são interdependentes e não podem ser enfrentadas exclusivamente por intervenções de natureza tecnológica.

- Infraestrutura e conectividade: Para enfrentar a instabilidade da conexão e a insuficiência de equipamentos nas farmácias públicas, os municípios devem priorizar investimentos em infraestrutura tecnológica e manutenção do parque computacional. A precariedade desses recursos constitui uma barreira direta à utilização contínua do Hórus, podendo ocasionar interrupções, atrasos no atendimento e dificuldades na alimentação tempestiva dos dados. Entre as estratégias possíveis, destacam-se a ampliação e qualificação da conectividade, a manutenção

preventiva dos equipamentos e, quando tecnicamente viável, a adoção de mecanismos que permitam o registro temporário de informações em situações de indisponibilidade de rede, com posterior sincronização. Essas medidas podem contribuir para ampliar a continuidade operacional do sistema e reduzir os impactos das limitações de infraestrutura sobre o atendimento e a qualidade dos registros.

- Capacitação e retenção de profissionais: O enfrentamento dos treinamentos pontuais e da elevada rotatividade exige a institucionalização de programas permanentes de educação continuada, com conteúdos atualizados sobre as funcionalidades do sistema e as rotinas da Assistência Farmacêutica. A literatura aponta que os treinamentos podem ser insuficientes diante da complexidade das rotinas de dispensação e das atualizações do software, enquanto a escassez e a rotatividade dos profissionais dificultam a alimentação tempestiva dos dados. Nesse contexto, recursos de educação a distância podem ampliar o acesso às capacitações e facilitar a atualização das equipes. Paralelamente, estratégias locais de valorização e fixação dos profissionais podem contribuir para preservar o conhecimento acumulado sobre os processos de trabalho e reduzir os impactos da rotatividade sobre a continuidade e a qualidade das atividades desenvolvidas.
- Alimentação e qualidade dos dados: A alimentação incompleta ou tardia das informações constitui uma das principais limitações para o aproveitamento do potencial gerencial do Hórus, uma vez que compromete a confiabilidade dos relatórios e dos indicadores produzidos pelo sistema. O enfrentamento dessa fragilidade requer a padronização dos processos de registro, o acompanhamento sistemático da completude dos dados e a utilização dos relatórios gerenciais como instrumentos efetivos de monitoramento e planejamento. No âmbito tecnológico, a ampliação da interoperabilidade entre sistemas de informação, por meio de interfaces de integração quando tecnicamente viáveis, pode reduzir a duplicidade de registros e a necessidade de digitação manual. Da mesma forma, painéis gerenciais simplificados podem oferecer retorno mais ágil aos gestores, favorecendo a identificação de inconsistências e o uso das informações para subsidiar decisões no nível local.
- Reorientação da prática clínica: A superação do predomínio da dimensão logística e da sobrecarga burocrática constitui um desafio central para que o Hórus contribua efetivamente para a qualificação da Assistência Farmacêutica. Conforme discutido anteriormente, a concentração das funcionalidades na gestão de estoque pode deslocar o trabalho do farmacêutico para atividades predominantemente administrativas, reduzindo o tempo disponível para a orientação e o acompanhamento dos usuários. Nesse sentido, a reorganização dos processos de trabalho e a distribuição de atividades administrativas e operacionais entre os diferentes integrantes da equipe, conforme suas atribuições e competências, podem contribuir para reduzir a sobrecarga do farmacêutico e ampliar sua disponibilidade para atividades de atenção farmacêutica. Adicionalmente, o aprimoramento dos recursos destinados ao registro do acompanhamento farmacoterapêutico e à dispensação orientada pode favorecer a utilização do sistema como instrumento de apoio ao cuidado, fortalecendo a atuação clínica do profissional.

De forma transversal, essas estratégias apontam para a necessidade de superar uma concepção segundo a qual a informatização, por si só, seria suficiente para qualificar a gestão da Assistência Farmacêutica. A tecnologia deve estar articulada às condições concretas de trabalho, à qualificação das equipes e à organização dos serviços, funcionando como instrumento facilitador dos processos de cuidado e de gestão. Essa perspectiva é particularmente importante diante da necessidade de integrar a dimensão logística à dimensão clínica da Assistência Farmacêutica, fazendo com que os dados registrados no sistema sejam convertidos em informações úteis para o planejamento, a tomada de decisão e o acompanhamento dos usuários.

Assim, as recomendações sintetizadas na Figura 1 não devem ser compreendidas como intervenções isoladas, mas como componentes de uma estratégia integrada de aprimoramento do Hórus. O fortalecimento da infraestrutura cria condições para o funcionamento adequado do sistema; a qualificação e a estabilidade das equipes favorecem a continuidade dos registros; a melhoria da qualidade e da interoperabilidade dos dados amplia seu potencial gerencial; e a reorganização dos processos de trabalho permite aproximar a tecnologia da atenção farmacêutica. Em conjunto, essas medidas podem contribuir para que o Hórus ultrapasse sua função de controle logístico e se consolide como instrumento de apoio à gestão e ao cuidado em saúde.

V. CONCLUSÃO

O Sistema Nacional de Gestão da Assistência Farmacêutica (Hórus) representa um inegável avanço na busca por eficiência, rastreabilidade e transparência no uso dos recursos públicos destinados à saúde. As evidências teóricas e empíricas confirmam a sua capacidade de qualificar o controle de estoques e de subsidiar o planejamento em esferas governamentais.

Contudo, a persistência de fragilidades estruturais — sobretudo no nível municipal — demonstra que a tecnologia por si só não resolve os problemas de gestão e de atenção à saúde. A precariedade da infraestrutura física, a escassez de conectividade, a carência de pessoal qualificado e a prevalência de um modelo administrativo burocratizado limitam o potencial do Hórus.

Para que o Hórus e outros sistemas informatizados cumpram integralmente seu papel no SUS, faz-se necessário adotar uma abordagem holística que articule investimentos em infraestrutura de TI, fortalecimento da governança interfederativa e requalificação dos processos de trabalho. Sobretudo, a tecnologia deve ser ressignificada para servir como instrumento de apoio ao cuidado clínico, garantindo que a eficiência

logística resulte, em última instância, no acesso equânime aos medicamentos, na segurança do paciente e na promoção da saúde.

***Resumo*—O Alzheimer é uma patologia que causa demência na população idosa, ela afeta gradualmente as funções cognitivas tais como memória, linguagem e atenção. Com isso, a doença apresenta um impacto que vai além do cognitivo, com uma alta presença de sintomas neuropsiquiátricos. Análises recentes que aplicaram a biblioteca PyCaret à detecção da enfermidade inclinam-se na utilização de classificadores fundamentados em árvores sem ponderar os riscos de superajuste ao lidar com sinais biológicos densos, como o eletroencefalograma (EEG). Este estudo utiliza a biblioteca PyCaret para evidenciar esse viés metodológico, contrastando classificadores baseados em árvores, como LightGBM e Random Forest, com a Logistic Regression. Foi empregada uma base pública do Kaggle: de sinais de EEG, proveniente de registros clínicos publicados no repositório OpenNeuro (ds004504) possuindo 848.640 amostras e 17 variáveis, possuiu a execução do treinamento e a validação dos protótipos por meio do PyCaret, com divisão de 70% dos dados para treino e 30% para teste, foi utilizada validação cruzada K-Folds (5 folds) e as métricas de acurácia, precisão, sensibilidade, especificidade, F1-score e AUC. Conclui-se que a disparidade entre a divisão aleatória (>99%) e o GroupKFold (78,87% no *Random Forest* e 60,65% no *LightGBM*) confirma a presença de *data leakage* no particionamento aleatório por amostras em sinais de EEG.**

***Palavras-chave*—Alzheimer's disease; machine learning; biomedical signal processing; pycaret.**

I. Introdução

A doença de Alzheimer (DA) é uma patologia neurodegenerativa progressiva de demência, frequentemente presente na população idosa [1]. De acordo com a Organização Mundial da Saúde [2], o número global de pessoas com demência deve triplicar até 2050, e no Brasil já são registrados aproximadamente 1,2 milhão de casos, com cerca de 100 mil novos diagnósticos por ano. Ainda segundo [2] essa patologia é desencadeada pelo processamento proteico anômalo no sistema nervoso central, cujo acúmulo de fragmentos neurotóxicos resulta em perda neuronal progressiva em regiões como o córtex cerebral e o hipocampo, suprimindo o reconhecimento sensorial, a memória e o raciocínio [3].

Diante disso, torna-se necessário o diagnóstico prematuro da DA, para que se permita realizar tratamentos em seus estágios iniciais com o objetivo de retardar o avanço da doença. Com isso, a tecnologia vem se tornando uma das principais ferramentas aliadas no auxílio do diagnóstico.

Os trabalhos referentes mostram diferenças metodológicas importantes que restringem a comparabilidade direta com este estudo, como por exemplo, o trabalho de [4], no qual utiliza abordagens lineares no *PyCaret* operando sobre características espaciais pré-extraídas, como o *eLORETA*, para detectar biomarcadores clínicos. Outro trabalho que utiliza o *PyCaret* é o de [5], que tem como objetivo demonstrar o potencial do *PyCaret* em atingir acurácias superiores a 98% no diagnóstico do Alzheimer através do uso de técnicas de explicabilidade expost, como o SHAP, as abordagens focam majoritariamente em dados de prontuário ou registros tabulares. Por fim, o trabalho de [6], utiliza do PyCaret, porém, para investigar a presença da Doença de *Parkinson*, em seu estágios iniciais, como por exemplo,os autores reportaram melhor desempenho de algoritmos de ensemble não lineares, como Gradient Boosting e Extra Trees, na classificação de atributos extraídos de gravações vocais nesse contexto específico, sem apresentar métrica quantitativa ou detalhes de validação que permitam avaliar a robustez desse resultado.

Embora estudos recentes demonstrem o potencial de algoritmos de aprendizado de máquina na classificação da doença de Alzheimer a partir de dados biomédicos, a avaliação de modelos aplicados a sinais EEG exige cuidados metodológicos específicos. Como uma única gravação pode gerar milhares de pontos temporais ou segmentos correlacionados, a divisão aleatória dessas amostras pode fazer com que dados pro-

venientes do mesmo participante sejam incluídos tanto no treinamento quanto no teste. Esse procedimento pode favorecer a aprendizagem de padrões individuais, características da sessão de aquisição ou ruídos específicos, produzindo estimativas artificialmente elevadas de desempenho. Apesar de sua relevância, o impacto do protocolo de particionamento sobre classificadores de Alzheimer baseados em EEG ainda precisa ser investigado de forma sistemática.

Diante dessa lacuna, este trabalho tem como finalidade examinar o desempenho de classificadores de árvore e lineares para a classificação da Doença de Alzheimer a partir de sinais de EEG. O estudo realiza uma avaliação comparativa aplicando dois protocolos distintos de validação cruzada: a divisão aleatória tradicional por amostras (K-Folds, $K = 5$) e a divisão agrupada por participante ($GroupKFold$, $K = 5$) utilizando o identificador (ID) dos sujeitos. Com isso, busca-se demonstrar e quantificar o impacto do vazamento de dados ($dataleakage$) e da memorização de padrões na detecção da patologia.

II. Materiais e métodos

O desenvolvimento deste trabalho consiste na utilização de uma base de dados de classificação binária de sinais de EEG obtida na plataforma Kaggle (https://www.kaggle.com/datasets/thngdngvn/openneuro-ds004504). A base reúne amostras de EEG organizadas por canal, derivadas dos registros de repouso com olhos fechados coletados no 2° Departamento de Neurologia do Hospital Geral AHEPA (Tessalonica, Grécia), e originalmente publicados no repositório OpenNeuro (ds004504). Inicialmente, a coorte da base de dados possui um total de 88 participantes, divididos entre diagnósticos de Doença de Alzheimer (DA), Controle e Demência Frontotemporal, na a classificação binária deste estudo, o grupo de Demência Frontotemporal foi descartado, deixando apenas os grupos de Alzheimer e Controle. A base de dados que foi utilizada possui um total de 848.640 amostras, sendo 512.000 amostras com a manifestação da doença (classe 1), e 336.640 amostras sem a doença (classe 0 - controle). Outrossim, contêm-se 17 variáveis numéricas, das quais 16 são eletrodos de escalpo (sistema internacional 10-20) e a última é a variável alvo para a classificação binária.

É importante destacar que, embora a base de dados derivada do repositório OpenNeuro tenha uma estrutura original de separação por sujeitos, estudos prévios realizaram o particionamento com foco nas janelas temporais de forma aleatória. Como apontado na literatura, a falta de um agrupamento explícito por identificador de participante tende a impedir o isolamento total de dependências temporais entre o treino e teste, reforçando ainda mais a justificativa para a validação agrupada $GroupKFold$.

Mediante a análise dos dados, foi realizado o treinamento e a validação dos modelos por meio da biblioteca PyCaret (v3.3.2). O PyCaret atua como um $wrapper$ em Python para diversas bibliotecas de aprendizado de máquina, como *scikit-learn* (v1.4.2) [7].

A partir do uso do PyCaret, a avaliação dos modelos foi estruturada sob dois protocolos distintos: (1) no **Protocolo Aleatório**, realizou-se a divisão dos dados em 70% para treinamento e 30% para teste via amostragem aleatória simples de janelas temporais, utilizando validação cruzada K-Fold ($K = 5$) no conjunto de treino; (2) no **Protocolo GroupKFold**, aplicou-se a validação cruzada agrupada $GroupKFold$ ($K = 5$) utilizando o identificador único (ID) dos participantes como variável de agrupamento, garantindo que nenhuma amostra do mesmo indivíduo aparecesse simultaneamente no treino e no teste. Os valores apresentados para o protocolo agrupado consistem na média aritmética das métricas obtidas ao longo dos 5 folds. Além disso, foram avaliados cinco algoritmos de Machine Learning: Random Forest, Decision Tree, Logistic Regression, Naive Bayes e LightGBM (v4.6.0). Teve o seu desempenho computado através de métricas consolidadas na literatura: acurácia, área sob a curva (AUC), sensibilidade (recall), especificidade e F1-score, complementados pela análise da matriz de confusão.

Para garantir a clareza e a reprodutibilidade do estudo, os experimentos foram realizados em uma máquina local de sistema operacional Linux, com processador *AMD Ryzen* 3500U, com uma GPU integrada e 20 GB de memória RAM, utilizando Python 3.10.12, *PyCaret* na versão 3.3.2 e com o uso de alguns algoritmos de ML da literatura. O projeto foi desenvolvido integralmente em linguagem Python. O código-fonte completo e a configuração dos experimentos podem ser acessados no repositório do GitHub em: https://github.com/brunopaiva1/project-alzheimer

III. Resultados e Discussão

Esta seção exibe a avaliação comparativa dos cinco classificadores de aprendizado de máquina (Logistic Regression, Naive Bayes, Decision Tree, LightGBM e Random Forest) que foram submetidos a dois protocolos de validação cruzada ($K = 5$): a divisão aleatória por amostras e a divisão agrupada por participante ($GroupKFold$), foi utilizado o identificador único (ID) dos 88 participantes da base de EEG OpenNeuro (ds004504). O conjunto total de dados contendo 848.640 amostras foi particionado por meio do framework PyCaret (v3.3.2).

A. Avaliação Comparativa: Divisão Aleatória vs. $GroupKFold$

Para apurar a hipótese de superajuste e a dependência de padrões do participante, verificou-se uma rodada de experimentos aplicando a validação cruzada agrupada ($GroupKFlod$, $K = 5$), utilizando o identificador único (ID) de cada um dos participantes do conjunto de dados como variável de agrupamento. Esse procedimento busca impedir que janelas temporais de um mesmo paciente pertemçam simultaneamente aos conjuntos de treinamento e teste, sendo os valores dispostos na Tabela I a média aritmética das métricas calculadas entre os 5 folds.

A Tabela I sintetiza a comparação direta entre o protocolo de divisão aleatória por amostras e o protocolo $GroupKFold$ para todos os modelos avaliados.

Tabela I
COMPARAÇÃO DE DESEMPENHO DOS CLASSIFICADORES SOB DIVISÃO ALEATÓRIA E VALIDAÇÃO AGRUPADA POR PARTICIPANTE (*GroupKFold*).

Modelo	Protocolo	Acur. (%)	AUC (%)	Rec. (%)	Esp. (%)	F1 (%)
Random Forest	Aleatório	99,92	**100,00**	99,95	99,87	99,93
	GroupKFold	78,87	91,16	79,32	78,18	80,80
LightGBM	Aleatório	99,87	**100,00**	99,90	99,82	99,89
	GroupKFold	60,65	78,17	52,05	73,73	58,84
Decision Tree	Aleatório	99,46	99,43	99,54	99,34	**99,55**
	GroupKFold	55,32	59,12	53,55	58,01	56,14
Logistic Reg.	Aleatório	83,78	**90,61**	87,60	77,97	86,70
	GroupKFold	75,06	83,15	80,50	66,78	78,41
Naive Bayes	Aleatório	66,62	78,49	51,29	**89,93**	64,96
	GroupKFold	64,47	73,74	54,68	79,35	63,29

B. Random Forest

O algoritmo *Random Forest*, fundamentado em agregação por bootstrap (*bagging*) e seleção aleatória de subconjuntos de atributos, obteve o maior desempenho absoluto sob divisão aleatória (acurácia de 99,92% e AUC de 100,00%). A matriz de confusão registrou os menores índices de erro (126 falsos positivos e 80 falsos negativos para 100.866 TN e 153.520 TP). Contudo, sob o protocolo $GroupKFold$, o modelo apresentou uma redução para 78,87% de acurácia, 91,16% de AUC e 78,18% de especificidade, apresentando, ainda assim, o melhor desempenho entre os modelos avaliados sob esse protocolo.

C. LightGBM

O algoritmo de boosting de gradiente *LightGBM* (v4.6.0) alcançou acurácia de 99,87% e AUC de 100,00% na divisão aleatória. Sua matriz de confusão destacou 254.259 acertos na diagonal principal. Sob a validação agrupada $GroupKFold$, contudo, o modelo sofreu uma degradação severa, caindo para 60,65% de acurácia, 78,17% de AUC, 52,05% de sensibilidade e 73,73% de especificidade, evidenciando sensibilidade à variação de sujeitos entre os conjuntos.

D. Decision Tree

O modelo não paramétrico *Decision Tree* atingiu acurácia de 99,46% e AUC de 99,43% na divisão aleatória, com matriz de confusão contabilizando 100.401 TN e 152.953 TP. Ao aplicar o protocolo $GroupKFold$, observou-se a a menor acurácia entre os modelos avaliados sob o protocolo *GroupKFold*, com queda para 55,32% de acurácia, 59,12% de AUC e 58,01% de especificidade.

E. Logistic Regression

O modelo de *Logistic Regression* obteve acurácia de 83,78% e AUC de 90,61% na divisão aleatória. Sua matriz de confusão no conjunto de teste revelou 78.971 TN e 134.731 TP. Sob $GroupKFold$, a Logistic Regression apresentou menor variação em relação ao protocolo aleatório, registrando 75,06% de acurácia e 83,15% de AUC, indicando maior estabilidade do modelo linear sob o isolamento de sujeitos.

F. Naive Bayes

O algoritmo registrou acurácia de 66,62% e AUC de 78,49% na divisão aleatória, apresentando elevada taxa de falsos negativos (74.527 amostras) devido à premissa de independência condicional dos canais de EEG. Sob $GroupKFold$, o modelo obteve 64,47% de acurácia, 73,74% de AUC e 79,35% de especificidade.

G. Discussão Crítica do Impacto do Particionamento

A expressiva disparidade de desempenho observada entre a divisão aleatória (99% nos modelos de árvore) e a validação $GroupKFold$ aponta para uma forte vulnerabilidade dos modelos não lineares ao particionamento por amostras. Como sinais de EEG de repouso constituem séries temporais densas, a divisão aleatória tende a colocar instâncias temporais correlacionadas do mesmo indivíduo simultaneamente no treino e no teste. A avaliação agrupada por $GroupKFold$ isolou essas dependências por participante, fornecendo estimativas mais realistas sobre o desempenho preditivo dos algoritmos para dados de novos indivíduos.

H. Limitações Computacionais

Para assegurar a reprodutibilidade, as simulações foram executadas em ambiente local Linux com processador AMD Ryzen 3500U, GPU integrada e 20 GB de memória RAM, utilizando Python 3.10.12. Em função das restrições de hardware e memória enfrentadas durante o processamento de 848.640 instâncias com 17 variáveis, algoritmos computacionalmente intensivos como XGBoost, SVM, KNN e CatBoost tiveram sua execução inviabilizada, optando-se por algoritmos com menor pegada computacional suportados pelo PyCaret.

IV. CONCLUSÃO

Este estudo avaliou comparativamente classificadores baseados em árvore e modelos lineares na predição da Doença de Alzheimer a partir de sinais de EEG, aplicando a biblioteca PyCaret sob dois protocolos de validação cruzada. Demonstrou-se experimentalmente que a divisão aleatória por amostras produz estimativas de desempenho excessivamente otimistas (99% para modelos de árvore) devido ao vazamento de informações entre treino e teste.

A aplicação do protocolo $GroupKFold$ baseado no identificador do participante forneceu uma estimativa mais realista da capacidade de generalização para participantes não observados durante o treinamento, evidenciando que algoritmos como o *LightGBM* sofrem severa degradação em sujeitos inéditos (acurácia reduzida para 60,65% e especificidade para 73,73%). O *Random Forest* apresentou o melhor equilíbrio de generalização sob isolamento do sujeito (78,87% de acurácia e 91,16% de AUC). Conclui-se que a validação agrupada por participante é um requisito metodológico indispensável para a avaliação confiável de sistemas de auxílio ao diagnóstico da Doença de Alzheimer.

Como trabalhos futuros, pretende-se aprimorar o protocolo de testes com o $GroupKFold$. As etapas incluirão a realização de ajuste fino de hiperparâmetros sob a validação

agrupada, a aplicação de técnicas de extração de características espectrais no domínio da frequência antes do agrupamento e a avaliação de algoritmos mais complexos, como SVM e XGBoost, em ambiente computacional de alta performance, visando otimizar a capacidade de generalização para indivíduos inéditos.

Abstract - **Este artigo apresenta uma avaliação sistemática de simuladores realistas na educação em saúde, com foco em dispositivos de ausculta, e descreve o desenvolvimento e a análise de um protótipo de baixo custo para a reprodução de sons cardíacos, pulmonares, abdominais e traqueais. O objetivo complementar é prjetar e criar o protótipo abrange a arquitetura de hardware, o mapeamento dos pontos de ausculta e as tentativas de obtenção de sons clínicos. Os resultados ficam prejudicados no que diz particularmente respeito à contaminação por ruído e aos procedimentos de obtenção de sons. A discussão enfatiza a relevância social de simuladores de baixo custo em cenários com recursos limitados. Conclui-se apontando limitações de validação educacional, melhoria na qualidade do som e integração com plataformas digitais.**

Palavras Chave - ***Simuladores de Ausculta, Protótipo, Clínica Sistemática e Validação Educacional.***

I. INTRODUÇÃO

A simulação em saúde consolidou-se, nas últimas duas décadas, como eixo estruturante da formação em medicina, enfermagem, fisioterapia e outras profissões, sendo reconhecida internacionalmente como Simulation-Based Education (SBE).[3][8] Nessa denominação, SBE refere-se a estratégias pedagógicas que utilizam cenários simulados, manequins, dispositivos digitais e ambientes virtuais para treinar habilidades técnicas e não técnicas em condições controladas, com potencial para aumentar a segurança do paciente e reduzir erros clínicos [4][8]. Relatórios recentes sobre centros de simulação na América Latina, elaborados segundo critérios de qualidade da ASPIRE (Association for Simulated Practice in Healthcare) e da Society for Simulation in Healthcare (SSH), mostram que 84% dos centros respondentes são vinculados a universidades, que 71% são de porte médio (menos de dez instrutores) e que a maior concentração se dá em países como Chile (37,5%), Brasil (18,1%) e México (12,7%), evidenciando a expansão da simulação em ambientes acadêmicos [1]. Estudos de mapeamento no Brasil indicam que SBE vem sendo incorporada em praticamente todas as fases da formação, da graduação à pós-graduação e à educação continuada, embora ainda haja lacunas importantes de pesquisa aplicada que orientem sua implementação em nível nacional [3][7].

No interior desse movimento, simuladores realísticos ocupam um lugar singular. Por simuladores realísticos, entende-se dispositivos que buscam reproduzir, com alto grau de proximidade, condições clínicas complexas, seja por meio de manequins de alta fidelidade, seja por meio de sistemas híbridos que combinam hardware, software e ambientes virtuais [4][8]. A literatura distingue duas dimensões centrais nesse campo: fidelidade e realismo. Fidelidade refere-se ao nível de detalhamento com que o simulador reproduz aspectos fisiológicos, anatômicos e de resposta dinâmica do paciente; já realismo diz respeito à percepção subjetiva de "semelhança com a realidade" por parte do usuário, incluindo fatores como ambientação, narrativa clínica e plausibilidade das respostas simuladas [4][8]. Um simulador pode, portanto, ser de baixa fidelidade em termos tecnológicos e ainda assim produzir forte sensação de realismo, se estiver bem contextualizado em um cenário clínico; inversamente, um dispositivo de alta fidelidade técnica pode ser percebido como pouco realista se for utilizado de forma desarticulada do contexto educacional [4][8].

Entre os diferentes tipos de simuladores, aqueles voltados à ausculta cardiopulmonar e abdominal desempenham papel particular. A ausculta é componente central do exame físico, exigindo que o profissional reconheça padrões sonoros complexos, muitas vezes em ambientes ruidosos, e os associe a hipóteses diagnósticas precisas [4][8]. Simuladores de ausculta - doravante denominados "simuladores de ausculta" - permitem que estudantes pratiquem sistematicamente a identificação de bulhas cardíacas, sopros, sons respiratórios normais e adventícios e ruídos abdominais em manequins, com repetição controlada e feedback imediato. Revisões de literatura e ensaios clínicos indicam que o uso de simuladores de ausculta está associado à melhoria da acurácia na identificação de sons e ao aumento da confiança dos estudantes em sua própria capacidade de exame físico, sobretudo quando integrado a programas estruturados de treinamento [4][8].

No Brasil, a expansão da SBE tem sido acompanhada por esforços de caracterização de centros de simulação, programas e práticas pedagógicas. Um consenso recente global sobre simulação em saúde, envolvendo 50 sociedades em 67 países, reforça que práticas de simulação devem estar alinhadas a padrões de qualidade e a agendas de pesquisa que vinculem diretamente o uso de simuladores a melhorias

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

em desfechos de pacientes e na formação de profissionais [8]. Autores brasileiros destacam que, apesar do crescimento de centros de simulação e da fundação da Sociedade Brasileira de Simulação na Saúde (ABRASSIM), ainda há baixa produção de pesquisa específica sobre SBE no país, o que dificulta o estabelecimento de parâmetros nacionais de qualidade e de estratégias de avaliação robustas [3][7]. Nesse contexto, projetos que desenvolvem e analisam simuladores de ausculta de baixo custo, especialmente quando articulados a revisões sistemáticas ou narrativas da literatura, podem contribuir para preencher a lacuna entre pesquisa e prática, oferecendo subsídios para decisões de investimento e desenho curricular [3].

Do ponto de vista da engenharia biomédica, há uma tensão permanente entre o desejo de construir simuladores de alta fidelidade, com respostas dinâmicas sofisticadas e integração plena a plataformas digitais imersivas, e a necessidade de desenvolver dispositivos financeiramente viáveis para instituições de ensino com recursos limitados [3][4]. Simuladores de alta fidelidade, embora potencialmente poderosos, são caros, exigem manutenção intensiva e podem ser subutilizados se não forem acompanhados de estratégias pedagógicas claras [4][8]. Por outro lado, simuladores de baixa e média fidelidade, construídos com componentes mais simples, podem alcançar impacto significativo se forem bem alinhados a objetivos de aprendizagem, especialmente em habilidades básicas como ausculta, exame físico geral e raciocínio clínico inicial [4]. É nesse espaço de transição entre baixa e média fidelidade, buscando alto realismo pedagógico com custo reduzido, que se insere o protótipo de simulador de ausculta de baixo custo analisado neste artigo.

Finalmente, cabe destacar que a gravação e reprodução de sons de pacientes reais em simuladores levanta questões técnicas e éticas relevantes. Do ponto de vista técnico, estetoscópio digital – definido aqui como dispositivo eletrônico de ausculta que capta sons mediante microfone, os converte em sinais digitais e permite armazenamento e reprodução – enfrenta desafios associados a ruído ambiental, artefatos de movimento e limitações de hardware [4]. Do ponto de vista ético, a coleta de sons de ausculta em pacientes reais exige consentimento informado, proteção de dados e reflexão sobre o uso secundário desses registros em contextos educacionais e tecnológicos, especialmente quando há possibilidade de identificação do paciente por características sonoras ou pela associação a prontuários [8]. A discussão aprofundada desses temas, articulada ao desenvolvimento de protótipos acessíveis, é fundamental para que a engenharia biomédica contribua de forma responsável para a democratização da simulação em saúde.

II. Objetivos

O objetivo principal principal é apresentar uma avaliação sistemática de simuladores realísticos na educação em saúde, focando o subcampo da ausculta, e descrever o desenvolvimento de um protótipo de baixo custo para reprodução de sons de ausculta abdominal, cardíaca, pulmonar e traqueal, construído com componentes eletrônicos comercialmente disponíveis e embarcado em manequins de simulação.

III. Metodologia e materiais

A metodologia adotada combina dois eixos complementares: uma revisão narrativa da literatura sobre simuladores realísticos na educação em saúde, com ênfase em simuladores de ausculta, e um estudo de caso de desenvolvimento e análise de um protótipo de baixo custo para reprodução de sons cardíacos, pulmonares e abdominais embarcado em manequins. A opção por revisão narrativa, em vez de revisão sistemática, decorre da necessidade de integrar diferentes tipos de estudos – ensaios clínicos, estudos observacionais, editoriais e trabalhos de engenharia biomédica – em um quadro analítico abrangente, e de acomodar a descrição qualitativa do protótipo em diálogo com a literatura [3][4].

A. Revisão de literaturas

A seleção dos estudos ocorreu em três etapas. Na primeira, títulos e resumos foram tirados para verificar pertinência temática e adequação aos critérios básicos de inclusão. Na segunda, textos completos foram lidos para confirmar o alinhamento ao foco da revisão e para identificar contribuições específicas em termos de tipos de simuladores, contextos de uso, resultados educacionais e debates conceituais.

Na terceira, procedeu-se à síntese narrativa, organizando os estudos em núcleos temáticos: (a) caracterização de centros de simulação e de SBE em âmbito nacional e regional; (b) simuladores de ausculta cardíaca e pulmonar de alta fidelidade; (c) simuladores de baixa e média fidelidade, com destaque para dispositivos de baixo custo; (d) discussões sobre fidelidade, realismo e qualidade em simulação; (e) desafios técnicos e éticos na gravação de sons de pacientes reais [1][3][4][5][8]. A figura 1 apresenta os pontos de ausculta pesquisados para definição de patologias.

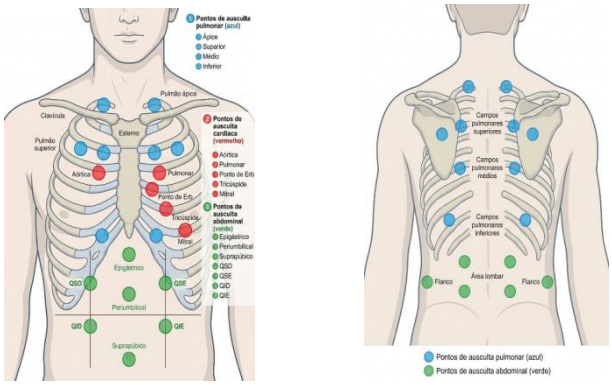

Figura 1 - Pontos de ausculta.

A natureza narrativa da revisão implica que as inferências produzidas têm caráter interpretativo e se baseiam em integração crítica dos estudos, em vez de seguir protocolos de metanálise quantitativa[3][4].

No que diz respeito à caracterização do contexto brasileiro e latino-americano, foram especialmente valorizados estudos que analisam centros de simulação segundo critérios da ASPIRE e da SSH, bem como artigos que discutem a implantação da SBE no Brasil e o papel de associações nacionais como a ABRASSIM [1][3][7]. O trabalho de

caracterização de centros latino-americanos, por exemplo, fornece estatísticas fundamentais: 84% dos centros participantes são universitários, 71% são de porte médio e há distribuição significativa de centros no Brasil (18,1% dos respondentes), o que permite inferir que simuladores realísticos já estão presentes em boa parte dos cursos da área da saúde na região [1]. Um estudo bibliométrico apresentado em reunião da Society for Simulation in Europe, por sua vez, indica que brasileiros são responsáveis por 152 publicações indexadas em simulação em saúde entre 2012 e 2021, sendo a cirurgia o subcampo mais representado (27,3% dos artigos), o que reforça o protagonismo regional e a necessidade de ampliar a produção sobre áreas como ausculta e exame físico [5].

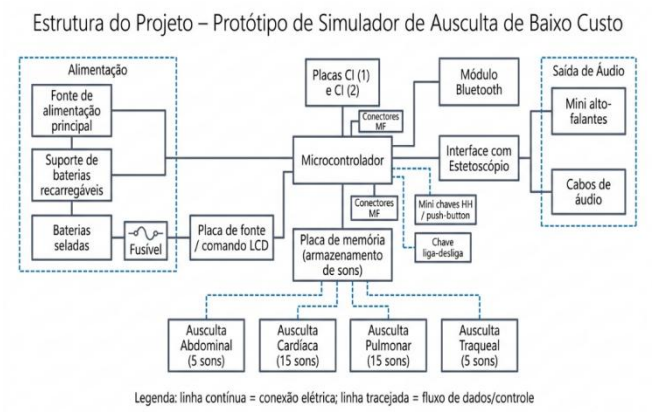
B. Protótipo

O segundo eixo metodológico consiste em um estudo de caso de desenvolvimento de protótipo de simulador de ausculta de baixo custo, cuja concepção foi realizada por conhecimentos da Engenharia Biomédica em parceria com cursos da área da saúde. O dispositivo foi projetado para ser embarcado em manequins de exposição tipo busto e para reproduzir sons de ausculta cardíaca, pulmonar, abdominal e traqueal diretamente na superfície, em pontos pré-definidos. A capacidade de armazenamento é capaz de reproduzir um total de 45 sons, distribuídos em cinco sons abdominais, quinze cardíacos, quinze pulmonares e cinco traqueais, configurados de modo a permitir diferentes cenários clínicos simulados. Cada ponto de ausculta é mapeado em posição anatômica correspondente no manequim - por exemplo, áreas típicas de ausculta das valvas aórtica, pulmonar, tricúspide e mitral, campos pulmonares anteriores e posteriores, quadrantes abdominais e região traqueal cervical – e conectado a mini alto-falantes internos, acionados por lógica de comando central.

Do ponto de vista da engenharia biomédica, o protótipo situa-se, em termos de fidelidade, na transição entre simulador de baixa e média fidelidade. Fidelidade baixa é aqui entendida como dispositivos que reproduzem sons ou sinais fisiológicos de forma estática, sem resposta dinâmica a intervenções do usuário, enquanto fidelidade média se refere a sistemas que, embora não alcancem a sofisticação de manequins de alta fidelidade, incorporam múltiplos pontos de ausculta, diversidade de sons e alguma capacidade de configuração de cenários [4][8]. O núcleo de comando consiste em microcontrolador responsável por gerenciar o acionamento de sons, a seleção de sistemas (cardíaco, pulmonar, abdominal, traqueal), o controle de volume e a interface com usuário por meio de display LCD. As placas de circuito impresso (PCI) foram desenhadas para distribuir sinais aos diferentes alto-falantes internos, conectados a pontos de ausculta através de trilhas e cabos protegidos, garantindo que cada posição anatômica corresponda a um som específico.

O armazenamento dos sons é realizado em placa de memória apropriada, dimensionada para comportar os 45 arquivos de áudio em formato digital, com taxa de amostragem compatível com a reprodução de frequências típicas de sons cardíacos, pulmonares e abdominais.

A figura 2 ilustra o organograma estrutural do projeto.



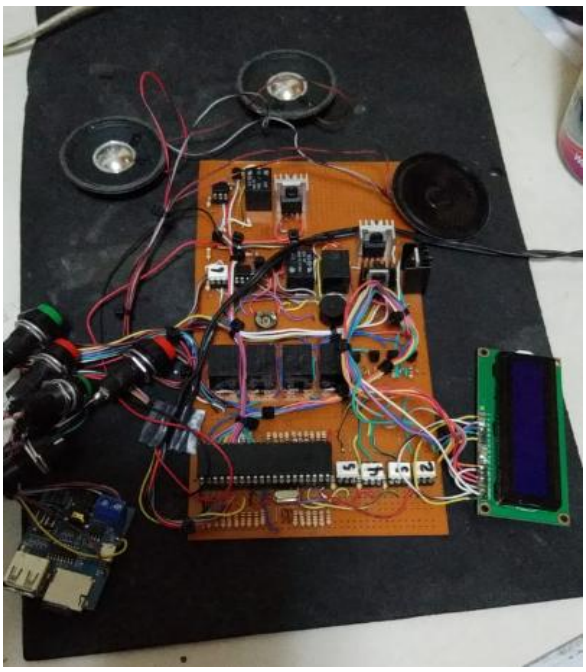


Figura 2 - Organograma da estrutura do projeto

A metodologia de desenvolvimento incluiu etapas de concepção em software de modelagem (CAD), prototipagem física, testes elétricos e acústicos, e ajustes iterativos de posicionamento de alto-falantes e calibração de volume. Foram confeccionados suportes internos para fixação dos alto-falantes em regiões anatômicas dos manequins, com cuidado para evitar vibrações excessivas e para minimizar a propagação indevida de som entre pontos.

Figura 3: Circuito elétrico.

Na concepção do projeto foram considerados a opções de componentes importados e regularmente adquiridos no mercado nacional.

Considerando o objetivo de entrega de um produto de custo reduzido, optou-se para embarcarmos a eletrônica e o sistema de alimentação em um busto manequim plástico adaptado.

O sistema de alimentação de energia utiliza baterias seladas recarregáveis, permitindo uso móvel do simulador em salas de aula e laboratórios sem dependência exclusiva de rede elétrica. Durante os testes, mediu-se temperatura e corrente em pontos críticos da arquitetura para garantir operação segura e evitar aquecimento dos componentes, utilizando multímetros apropriados.

A listagem de material prevê componentes relacionados no Tabela I,

TABELA I - RELAÇÃO DE COMPONENTES POR UNIDADE

ÍTEM	DESCRIÇÃO DO COMPONENTE / EQUIPAMENTO
1	Mini chave HH (Seletora de duas posições)
2	Mini chave push-button (Chave táctil)
3	Chave liga-desliga (Interruptor gangorra comum)
4	Microcontrolador (Arquitetura de mercado de 8 ou 32 bits padrão)
5	Conectores MF (Par de conectores Macho / Fêmea de pinos)
6	Placa de memória (Módulo MicroSD para armazenamento básico)
7	Mini alto-falantes (Pequeno porte para sinalização/áudio básico, 8-9 Ohms
8	Display LCD touch screen (Interface gráfica, tamanho médio 3.5 a 5 16 pol.)
9	Placa de fonte / comando para gerenciamento de display LCD
10	Cabos de áudio blindados (Par de conectores montados por metro)
11	Fusível com caixa (Porta-fusível de proteção com elemento fusível)
12	Fonte de alimentação principal (Estabilizada / Chaveada externa de 12/24V
13	Suporte para baterias recarregáveis (Slot de fixação estrutural)
14	Baterias seladas (Modelo chumbo-ácido regulada por válvula 12V padrão)
15	Componentes e Miscelâneas em geral (Parafusos, espaçadores, fios, solda)
16	Busto manequim (masculino/feminino)
17	Placa de circuito impresso ilhadas (PCBs - parciais)
18	Serviços de mão de obra/fretes/Outros (montagem)

Na Tabela II está relacionado os instrumentos sugeridos e considerados como ideais para realização dos testes e validações dos protótipos.

TABELA II - INSTRUMENTOS PARA TESTES E VALIDAÇÃO

ÍTEM	INSTRUMENTOS SUGERIDOS
1	Multímetro térmico industrial com câmera infravermelha integrada + Kit
2	Licença de software CAD 3D (Assinatura anual corporativa padrão)

IV. RESULTADOS E DISCUSSÃO

Os resultados da revisão narrativa revelam que a simulação em saúde, em suas diferentes modalidades, está amplamente difundida nos cursos da área em âmbito internacional, com crescimento expressivo nas últimas décadas [4][8]. Um levantamento clássico sobre simulação e realidade virtual em educação médica, publicado em periódico brasileiro, indica que, já em meados da década de 2000, uma busca em base internacional com o termo “medical simulation training” retornava mais de quatro mil artigos, com aumento acentuado ao longo dos anos [4]. Esse dado, embora histórico, sinaliza a consolidação da simulação como tema de pesquisa e prática pedagógica em medicina e áreas afins. Mais recentemente, o Global Consensus Statement on Simulation-Based Practice in Healthcare reforça que existem ao menos 50 sociedades de simulação operando em 67 países, apontando para uma infraestrutura global [8].

TABELA III - TABELA COMPARATIVA DE VALORES (05 FABRICANTES - 2026)

Fabricante	Tabela de valores		
	Modelo	Pontos	Preço (R$)
Nasco	Healthcare Auscultation Trainer 2.0 iPad/SmartScope (LF01290)	15 pulmonares 13 cardíacas 5 abdominais	R$ 26.800,00
Sdolf	Simulador c/controle remoto (SD4040)	31 pulmonares 13 cardíacas 0 abdominais	R$ 6.800,00
ProLab	Simulador Avançado de ausculta (SKU-TGD-4025-c)	31 pulmonares 13 cardíacas 0 abdominais	R$ 10.100,00
MedVisioon	Simulador de ausculta MATT	26 pulmonares 26 cardíacas 18 abdominais	R$ 11.000,00
3B Scientific	Simulador de ausculta - SAMBasic - BHS (5022828)	26 pulmonares 37 cardíacas 11 abdominais	R$ 32.000,00
Simulador de "BAIXO CUSTO"	Protótipo	15 pulmonares 15 cardíacas 5 abdominais 5 traqueais	R$ 1.318,00

O desenvolvimento do protótipo foi baseado nas especificações semelhantes aos demais ofertados por outros

fabricantes, guardadas as limitações de custos e modelos. A Tabela III apresenta este comparativo.

No contexto latino-americano, a caracterização de centros de simulação segundo critérios da ASPIRE e da SSH fornece um retrato importante da estrutura e do uso de simuladores realísticos [1]. Entre os centros que responderam ao estudo, 84% são universitários, o que indica forte integração da simulação à formação de graduação e pós-graduação em saúde [1]. A maioria dos centros é de porte médio, com menos de dez instrutores, e há predominância de programas que combinam ensino, pesquisa e educação continuada [1]. Em termos geográficos, Chile, Brasil e México concentram a maior parte dos centros, sugerindo que esses países desempenham papel de liderança regional [1]. Embora o estudo não se concentre exclusivamente em simuladores de ausculta, ele evidencia que recursos realísticos – como manequins de alta fidelidade – fazem parte da infraestrutura desses centros e são usados em treinamento de habilidades clínicas básicas, incluindo exame físico.

No Brasil, artigo recente sobre o avanço da Simulation-Based Education destaca que a simulação foi incorporada à maioria dos cursos de graduação em medicina, enfermagem e outras áreas, bem como a programas de residência e educação continuada [3][7]. Os autores ressaltam, porém, que há déficit de pesquisa nacional robusta que avalie sistematicamente o impacto dos simuladores em desfechos educacionais e clínicos, e que a ABRASSIM, fundada por educadores e pesquisadores em simulação, busca justamente preencher essa lacuna ao incentivar produção de conhecimento aplicada [3][7]. Em particular, poucos estudos brasileiros tratam especificamente de simuladores de ausculta, o que torna relevante a discussão de protótipos de baixo custo nessa área.

Um estudo bibliométrico apresentado em encontro da Society for Simulation in Europe, focado em publicações sobre simulação em saúde na América Latina e Caribe entre 2012 e 2021, indica que a cirurgia é o subcampo mais representado (27,3% dos artigos) e que autores brasileiros respondem por 152 publicações, seguidos por chilenos com 56 [5]. Ainda com resultado, obteve-se o produto final funcionando e ilustrado na figura 5.

Figura 5: Protótipo. Fonte: própria

Como objeto de discussão citamos o fato de a tentativa de efetuar gravações realísticas no Laboratório de Fonoaudioogia da Santa Casa com estetoscópios digitais, porém, não obtivemos resultados audíveis qualitativos com nitidez suficiente para implantarmos nos simuladores para as próximas etapas dos projeto.

V. Conclusões

O protótipo foi concluído e fez parte do fomento de um Projeto do Núcleo de Auxílio a Pesquisa da Faculdade de Ciências Médicas Santa Casa de São Paulo. Esclarecemos que a produção de unidades de montagem de mais unidades para estudos previamente programadas, não ocorreram por razões da não utilização da verba alocada para o projeto e nem termos cronograma de montagem disponível. O produto final entregue ratifica a proposta de produzir um equipamento de baixo custo e com preços finais entre 4% a 20% dos valores dos demais fabricantes.

***Resumo*—O Diabetes Mellitus é uma das doenças crônicas de maior impacto na saúde pública mundial, tornando essencial o desenvolvimento de métodos que auxiliem sua identificação precoce. Nesse contexto, este trabalho avalia o impacto de diferentes técnicas de balanceamento de classes no desempenho de algoritmos de aprendizado de máquina aplicados à predição de diabetes. Foram comparadas as técnicas SMOTE, ADASYN e RandomOverSampler em conjunto com os classificadores Regressão Logística, K-Nearest Neighbors (KNN), Support Vector Classifier (SVC), Random Forest e Multilayer Perceptron (MLP). Os modelos foram avaliados por meio de validação cruzada estratificada de dez dobras utilizando as métricas de acurácia, precisão, recall, F1-Score e AUC-ROC. Além disso, empregou-se a técnica SHAP para interpretar as decisões do modelo de melhor desempenho. Os resultados demonstraram que as técnicas de balanceamento aumentaram significativamente o recall da classe minoritária, porém ocasionaram redução da precisão e do F1-Score na maioria dos modelos. O Random Forest apresentou o comportamento mais consistente entre os cenários avaliados, enquanto o MLP obteve o melhor desempenho no cenário sem balanceamento. A análise por meio do SHAP evidenciou que o nível de glicose, a hemoglobina glicada (HbA1c) e a idade foram as variáveis de maior influência nas predições do modelo. Os resultados indicaram que, embora as técnicas de balanceamento tenham proporcionado melhorias em algumas métricas, não foram observados ganhos consistentes no desempenho dos classificadores para o conjunto de dados utilizado.**

***Index Terms*—Aprendizado de Máquina, Predição, Diabetes, Balanceamento, SHAP.**

I. Introdução

O Diabetes Mellitus (DM) é uma doença metabólica crônica caracterizada pela elevação dos níveis de glicose no sangue em decorrência da produção insuficiente de insulina ou da incapacidade do organismo de utilizá-la adequadamente. A doença representa um importante problema de saúde pública mundial, estando associada a complicações cardiovasculares, renais, neurológicas e visuais que comprometem significativamente a qualidade de vida dos indivíduos [1], [2].

Segundo a International Diabetes Federation (IDF), aproximadamente 537 milhões de adultos vivem com diabetes em todo o mundo, com projeções indicando um aumento para 643 milhões até 2030 e 783 milhões até 2045 [1]. Nesse contexto, estratégias que possibilitem a identificação precoce da doença tornam-se fundamentais para auxiliar o diagnóstico e reduzir os impactos clínicos associados.

Nos últimos anos, técnicas de Aprendizado de Máquina (*Machine Learning* ML), uma subárea da Inteligência Artificial voltada ao desenvolvimento de algoritmos capazes de identificar padrões complexos nos dados e melhorar seu desempenho com base nas informações disponíveis, e têm sido amplamente empregadas na área da saúde [3]. Essas técnicas possibilitam a análise de grandes volumes de dados e a identificação de padrões relevantes, contribuindo para a predição e o apoio à identificação de diferentes doenças [4], [5]. Nesse contexto, diversos estudos demonstram resultados promissores na predição de diabetes utilizando algoritmos como Regressão Logística (LR), *Support Vector Classifier* (SVC), *K-Nearest Neighbors* (KNN), *Random Forest* (RF) e *Multilayer Perceptron* (MLP) [6], [7], [10].

Entretanto, conjuntos de dados clínicos frequentemente apresentam desbalanceamento entre as classes, situação em que a quantidade de indivíduos pertencentes à classe majoritária é significativamente superior à da classe minoritária. Esse cenário pode comprometer o desempenho dos modelos de classificação, favorecendo a identificação da classe mais frequente e reduzindo a capacidade de detecção dos casos positivos [7], o que pode acarretar em um modelo enviesado.

Para minimizar os efeitos do desbalanceamento, técnicas de balanceamento de dados têm sido amplamente empregadas em tarefas de classificação. Como o *Synthetic Minority Oversampling Technique* (SMOTE) que gera exemplos sintéticos da classe minoritária a partir das relações de vizinhança entre as amostras existentes [8]. De forma semelhante, o *Adaptive Synthetic Sampling* (ADASYN) realiza a geração adaptativa de novas amostras, priorizando regiões do espaço de características nas quais a classificação da classe minoritária é mais difícil [9]. Já o *RandomOverSampler* aumenta a representatividade da classe minoritária por meio da replicação aleatória de suas amostras. Essas abordagens buscam reduzir o viés dos modelos em relação à classe majoritária e ampliar a capacidade de identificação dos casos positivos.

Diante desse contexto, este trabalho tem como objetivo avaliar o impacto de diferentes técnicas de balanceamento de classes no desempenho de algoritmos de ML aplicados à

predição de diabetes. Para isso, foram comparados os métodos SMOTE, ADASYN e *Random Over-Sampling* utilizando os classificadores Regressão Logística, KNN, SVC, Random Forest e Multilayer Perceptron (MLP).

II. Trabalhos Relacionados

No trabalho de [11] foi investigada a aplicação de técnicas de ML para a predição de diabetes utilizando um conjunto de dados contendo informações demográficas, hábitos de vida e condições de saúde autorreferidas, que apresenta desbalanceamento entre as classes. Os autores avaliaram diferentes técnicas de balanceamento, incluindo SMOTE-N, ENN, SMOTE-ENN e SMOTE-Tomek, combinadas com algoritmos como *Logistic Regression*, *Random Forest*, *Gradient Boosting* e *AdaBoost*. Além disso, destacaram a importância de aplicar as técnicas de reamostragem apenas no conjunto de treinamento para evitar vazamento de dados. Os resultados mostraram que todas as técnicas de balanceamento aumentaram o desempenho na identificação da classe minoritária, especialmente em termos de recall. Entre as estratégias avaliadas, o ENN apresentou o melhor desempenho quando combinado ao algoritmo *Gradient Boosting*, evidenciando que o tratamento adequado do desbalanceamento pode melhorar significativamente a capacidade de identificação de pacientes com diabetes.

É apresentado em [12] a proposta de uma estrutura escalável e interpretável para a predição precoce de diabetes utilizando ML. O estudo foi realizado com um conjunto de dados do Kaggle contendo 96.146 registros, após a remoção de duplicatas. Os autores aplicaram o SMOTE para balancear as classes e utilizaram a Eliminação Recursiva de Características (RFE) para selecionar as cinco variáveis mais relevantes: idade, IMC, histórico de tabagismo, HbA1c e glicose no sangue. Também utilizaram o LIME para interpretar as previsões dos modelos. Entre os modelos avaliados, o XGBoost apresentou o melhor desempenho, alcançando 96,8% de acurácia e AUC-ROC de 0,973. Além disso, os autores demonstraram que um modelo utilizando apenas cinco características manteve um desempenho semelhante ao modelo completo, reduzindo o custo computacional e aumentando a interpretabilidade.

Por fim, o estudo [13] apresenta uma abordagem para a predição do risco de diabetes utilizando técnicas de Ml baseadas em métodos de *Bagging, Boosting e Ensemble*. O estudo empregou três conjuntos de dados públicos (CDC Diabetes Health Indicators, Early Stage Diabetes Risk Prediction e PIMA Indian Diabetes), aplicando a técnica SMOTE para tratar o desbalanceamento de classes, seleção de atributos, ajuste de hiperparâmetros por meio do GridSearchCV e validação cruzada de cinco dobras. Entre os modelos avaliados, o CatBoost apresentou o melhor desempenho no conjunto de dados do CDC, alcançando acurácia de 91%, enquanto os métodos de *Ensemble* obtiveram acurácia de 98% no conjunto ESDRP. Os autores concluíram que a combinação das técnicas de balanceamento, seleção de atributos e otimização de hiperparâmetros contribui significativamente para o aumento da robustez e da capacidade preditiva dos modelos de ML aplicados à predição de diabetes.

Os estudos analisados demonstram que técnicas de balanceamento de classes, seleção de atributos, otimização de hiperparâmetros e métodos de ML podem contribuir significativamente para o aumento do desempenho dos modelos de ML na predição de diabetes. Entretanto, cada trabalho concentra-se em aspectos específicos, como a comparação de diferentes técnicas de reamostragem, a redução da dimensionalidade, a seleção de atributos ou o desenvolvimento de modelos de ensemble. Em contraste, o presente trabalho tem como foco comparar o impacto de diferentes técnicas de balanceamento na performance de modelos de ML para a predição de diabetes, bem como explicar os resultados por meio da técnica SHAP, contribuindo para uma análise mais transparente e interpretável.

III. Metodologia

Esta seção detalha os procedimentos metodológicos empregados neste estudo. Primeiramente, são apresentados o conjunto de dados utilizado e as etapas de pré-processamento. Posteriormente, descrevem-se as técnicas de balanceamento de classes, os algoritmos de classificação avaliados, a configuração experimental e as métricas de desempenho dos modelos.

A. Conjunto de Dados

O conjunto de dados empregado neste estudo foi o *Diabetes Prediction Dataset*, disponível na plataforma Kaggle. Esses dados compreendem aproximadamente 100 mil registros e nove atributos, que englobam características clínicas e demográficas dos indivíduos. Tais atributos incluem idade, gênero, hipertensão, doença cardíaca, histórico de tabagismo, índice de massa corporal (IMC), hemoglobina glicada (HbA1c), nível de glicose no sangue e a variável alvo, que indica a presença ou ausência de diabetes.

O conjunto de dados é composto por 100.000 registros, cuja distribuição entre as classes é apresentada na Tabela I. Observa-se que 91,5% das amostras pertencem à classe de indivíduos sem diabetes, enquanto apenas 8,5% correspondem à classe de indivíduos com diabetes, caracterizando um cenário de desbalanceamento de classes. Nesse contexto, a classe majoritária possui cerca de 10,8 vezes mais amostras que a classe minoritária, o que pode levar os modelos de classificação a favorecerem a classe mais frequente e, consequentemente, reduzir a capacidade de identificar corretamente os casos positivos.

Tabela I
Distribuição das classes no conjunto de dados.

Classe	Quantidade	Percentual
Sem diabetes	91.500	91,5%
Com diabetes	8.500	8,5%

B. Pré-processamento dos Dados

Inicialmente, realizou-se a análise exploratória dos dados para identificar inconsistências e verificar a qualidade do conjunto de dados. Foram removidos os registros duplicados e constatou-se a inexistência de valores ausentes.

As variáveis categóricas foram convertidas para o formato numérico utilizando a técnica *Label Encoding*. Em seguida, os atributos numéricos foram padronizados por meio do método *StandardScaler*, com o objetivo de reduzir diferenças de escala entre as variáveis e otimizar o desempenho dos algoritmos de ML.

C. Balanceamento das Classes

Considerando o desbalanceamento entre as classes no conjunto de dados, foram avaliadas três técnicas de *oversampling*, isto é, uma técnica que visa aumentar a quantidade de dados das classes minoritárias [14], e é amplamente utilizada na literatura:

- SMOTE (*Synthetic Minority Oversampling Technique*);
- ADASYN (*Adaptive Synthetic Sampling*);
- RandomOverSampler.

Adicionalmente, um cenário sem a aplicação de técnicas de balanceamento foi considerado, permitindo uma comparação direta entre os resultados obtidos com e sem *oversampling*. As técnicas de balanceamento foram aplicadas exclusivamente aos dados de treinamento, preservando a distribuição original do conjunto de teste para evitar viés na avaliação dos modelos. Essa abordagem garantiu a ausência de vazamento de informações entre os conjuntos de treinamento e teste, resultando em uma avaliação mais confiável dos modelos.

D. Modelos de Classificação

Foram avaliados cinco algoritmos amplamente empregados em tarefas de classificação supervisionada:

- LR;
- KNN;
- SVC;
- RF;
- MLP.

Os hiperparâmetros dos classificadores foram otimizados por meio do algoritmo GridSearchCV, utilizando validação cruzada de cinco dobras (*5-fold cross-validation*) e a métrica F1-score como critério de seleção. Os melhores hiperparâmetros encontrados para cada modelo são apresentados na Tabela II.

Tabela II
MELHORES HIPERPARÂMETROS OBTIDOS POR MEIO DO GRIDSEARCHCV.

Modelo	**Melhores hiperparâmetros**
Random Forest	n_estimators=200; max_depth=20; max_features=sqrt; min_samples_split=5; min_samples_leaf=2
Regressão Logística	C=0.1; penalty=l2; solver=liblinear; max_iter=1000
KNN	n_neighbors=7; weights=uniform; metric=euclidean
SVC	C=10; kernel=rbf; gamma=scale
MLP	hidden_layer_sizes=(50,50); activation=relu; solver=adam; learning_rate_init=0.001; alpha=0.001; max_iter=1000

E. Configuração dos Experimentos

O conjunto de dados foi dividido em treinamento e teste na proporção de 80% e 20%, respectivamente, utilizando amostragem estratificada para preservar a distribuição original das classes. Após a otimização dos melhores hiperparâmetros, os classificadores foram avaliados utilizando validação cruzada estratificada de dez dobras (*10-fold Stratified Cross-Validation*), permitindo uma estimativa mais robusta e confiável do desempenho dos modelos.

A Figura 1 apresenta o fluxo experimental adotado neste estudo, desde a preparação dos dados até a avaliação dos modelos de classificação. Para cada técnica de balanceamento, foi construído um pipeline composto pelas etapas de padronização dos dados, aplicação do método de balanceamento e treinamento do classificador correspondente. Essa estratégia garantiu que o balanceamento fosse realizado apenas nos dados de treinamento, evitando vazamento de informação para o conjunto de teste.

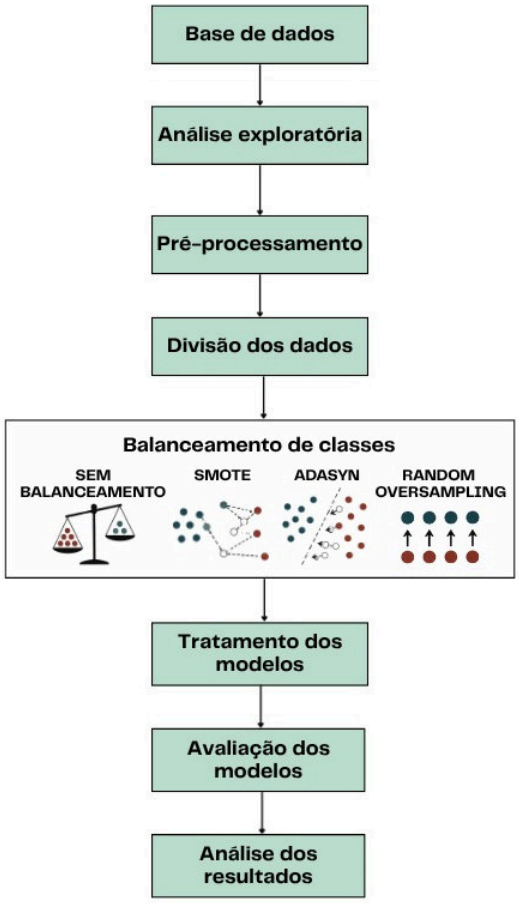

Figura 1. Fluxo experimental da metodologia.

F. Avaliação dos Modelos

O desempenho dos classificadores foi avaliado por meio das métricas de acurácia, precisão, *recall*, F1-Score e área sob a curva ROC (AUC-ROC). Essas métricas foram selecionadas por fornecerem uma avaliação abrangente do desempenho dos modelos, especialmente em cenários de desbalanceamento de classes.

A acurácia mede a proporção total de classificações corretas realizadas pelo modelo. Entretanto, por ser influenciada pela classe majoritária, essa métrica, isoladamente, pode não refletir adequadamente o desempenho em problemas desbalanceados. A precisão indica a proporção de instâncias classificadas como positivas que realmente pertencem à classe positiva, enquanto o *recall* representa a capacidade do modelo de identificar corretamente os indivíduos que possuem diabetes. O F1-Score corresponde à média harmônica entre precisão e *recall*, fornecendo uma medida equilibrada entre ambas. Por fim, a AUC-ROC avalia a capacidade global do modelo em distinguir as classes, independentemente do limiar de decisão adotado.

A análise dos resultados concentrou-se principalmente nas métricas da classe minoritária, uma vez que o objetivo principal é identificar corretamente indivíduos com diabetes, reduzindo a ocorrência de falsos negativos.

G. Explicabilidade do Modelo

A interpretação do modelo de melhor desempenho foi realizada por meio da técnica *SHapley Additive exPlanations* (SHAP), que permite quantificar a contribuição de cada atributo para as predições realizadas pelo modelo. Foram gerados gráficos de importância global das variáveis para identificar os fatores com maior influência na predição de diabetes.

IV. Resultados e Discussão

Esta seção apresenta a comparação entre o desempenho dos modelos nos quatro cenários definidos: sem aplicação de técnicas de balanceamento, com utilização de SMOTE, ADASYN e RandomOverSampler. Como se trata de um problema de predição de diabetes com dados desbalanceados, é importante dar atenção especial à classe minoritária (Classe 1, que é a classe positiva), uma vez que ela representa o principal desafio em problemas de classificação desbalanceada.

Tabela III
Resultados dos modelos sem balanceamento para a classe 1

Modelo	**Acurácia**	**Precisão**	**Recall**	**F1**	**AUC**
Random Forest	0.97	0.96	0.68	0.80	0.97
Regressão Logística	0.95	0.87	0.62	0.72	0.96
KNN	0.96	0.90	0.66	0.76	0.90
SVC	0.96	0.98	0.64	0.77	0.93
MLP	0.97	0.97	0.68	0.80	0.97

A partir dos resultados apresentados na Tabela III, é possível observar que todos os modelos apresentaram acurácia superior a 95% no cenário sem balanceamento para a classe 1. Entretanto, nesse tipo de problema a acurácia isoladamente tende a ser fortemente influenciada pela classe majoritária. Dessa forma, as métricas de precisão, recall e F1-Score da classe minoritária são mais adequadas para a avaliação do desempenho dos modelos.

Os resultados obtidos revelam que o F1-Score dos modelos foi superior sem aplicação de técnicas de balanceamento para a classe minoritária. O modelo MLP apresentou o melhor resultado geral, alcançando F1-Score de 81%, seguido pelo Random Forest com 79% e pelo KNN com 77%. Além disso, a precisão também foi satisfatória para todos os modelos, destacando-se o MLP (98,7%) e o SVC (98,3%). Esses resultados indicam que os modelos foram capazes de identificar corretamente a maioria das instâncias positivas previstas, no entanto, os valores moderados de recall evidenciam uma certa ocorrência de falsos negativos. No caso de cenários médicos, o ideal é minimizar a quantidade de falsos negativos.

Tabela IV
Resultados dos modelos utilizando SMOTE

Modelo	Precisão	Recall	F1	AUC
Random Forest	0.78	0.74	0.76	0.96
Regressão Logística	0.42	0.87	0.57	0.95
KNN	0.49	0.79	0.60	0.90
SVC	0.41	0.88	0.56	0.95
MLP	0.47	0.88	0.61	0.97

A aplicação da técnica SMOTE resultou em um aumento significativo do recall em todos os modelos analisados, conforme apresentado na Tabela IV. Por exemplo, a Regressão Logística aumentou de 63% para 87%, enquanto o SVC passou de 61% para 88%, e o MLP foi de 67% para 88%. Apesar desse ganho na capacidade de detecção da classe minoritária, houve uma redução significativa na precisão e, consequentemente, no F1-Score, indicando que os modelos passaram a ter mais falsos positivos. Esse comportamento é esperado, tendo em vista que geralmente há um trade-off entre a precisão e o recall. Entre os modelos avaliados nesse cenário, o Random Forest apresentou o melhor equilíbrio entre precisão e recall, com F1-Score de 76%, seguido pelo MLP, com 62%.

Tabela V
RESULTADOS DOS MODELOS UTILIZANDO ADASYN

Modelo	Precisão	Recall	F1	AUC
Random Forest	0.71	0.76	0.73	0.96
Regressão Logística	0.31	0.93	0.47	0.95
KNN	0.44	0.82	0.57	0.90
SVC	0.29	0.94	0.45	0.95
MLP	0.38	0.91	0.54	0.97

Os resultados apresentados na Tabela V evidenciam que o balanceamento por ADASYN proporcionou os maiores ganhos de recall entre os métodos avaliados. O recall atingiu 94,6% no SVC, 93,9% na Regressão Logística e 91,9% no MLP, indicando uma elevada capacidade de identificação dos casos positivos de diabetes. Contudo, esse aumento foi acompanhado por uma redução significativa da precisão. O SVC, por exemplo, apresentou queda de precisão de 98,3% para 29,9%, enquanto a Regressão Logística reduziu de 86,7% para 31,5%. Consequentemente, os F1-Scores obtidos com ADASYN foram inferiores aos observados nos demais cenários, indicando que o aumento do número de falsos positivos comprometeu o desempenho global dos classificadores.

Tabela VI
RESULTADOS DOS MODELOS UTILIZANDO RANDOMOVERSAMPLER

Modelo	Precisão	Recall	F1	AUC
Random Forest	0.84	0.71	0.77	0.96
Regressão Logística	0.42	0.87	0.57	0.96
KNN	0.52	0.79	0.63	0.89
SVC	0.42	0.88	0.57	0.96
MLP	0.50	0.85	0.63	0.97

O RandomOverSampler apresentou resultados intermediários entre os métodos avaliados. De forma geral, essa técnica produziu os maiores valores de F1-Score dentre os métodos de balanceamento, superando tanto o SMOTE quanto o ADASYN na maioria dos modelos. O Random Forest teve o maior F1-Score (77,6%), valor próximo ao obtido pelo mesmo modelo sem balanceamento (79%), porém com menos falsos negativos. Resultados semelhantes foram observados para o KNN e para o MLP, cujos F1-Scores foram superiores aos obtidos com SMOTE e ADASYN. Esses resultados sugerem que a simples replicação das amostras da classe minoritária preservou melhor as características originais dos dados quando comparada às abordagens baseadas em geração sintética.

Outro aspecto relevante observado nos experimentos foi o comportamento da métrica AUC-ROC. Apesar das diferenças expressivas entre os valores de precisão, recall e F1-Score, os modelos mantiveram valores elevados de AUC em praticamente todos os cenários avaliados. O Random Forest apresentou AUC-ROC de 0,9646 com SMOTE e 0,9651 com ADASYN, enquanto o MLP alcançou o maior valor observado, com AUC-ROC de 0,9726 utilizando SMOTE. Esses resultados indicam que os classificadores preservaram uma elevada capacidade de distinção entre indivíduos com e sem diabetes, mesmo após as alterações provocadas pelas técnicas de balanceamento.

Ao analisar os diferentes cenários experimentais, observa-se que o Random Forest apresentou o comportamento mais consistente entre os classificadores avaliados. Mesmo após a aplicação das técnicas de balanceamento, o modelo manteve valores elevados de precisão, recall e F1-Score, apresentando menor degradação de desempenho quando comparado aos demais algoritmos. Com SMOTE, o Random Forest obteve F1-Score de 76,4%, enquanto com ADASYN alcançou 73,9% e com RandomOverSampler aproximadamente 77,6%. Esses resultados sugerem maior robustez do modelo frente às alterações na distribuição dos dados. Além de apresentar elevados valores de F1-Score em todos os cenários, o modelo manteve um equilíbrio entre precisão e recall superior ao observado nos demais classificadores.

Os resultados obtidos corroboram estudos da literatura que relatam o aumento do recall após a aplicação de técnicas de *oversampling* em problemas de classificação desbalanceada. Entretanto, também foi observado que o ganho na capacidade de detecção da classe minoritária ocorreu acompanhado de uma redução considerável da precisão, especialmente no cenário com ADASYN.

Esse comportamento evidencia a existência de um compromisso entre a redução de falsos negativos e o aumento de falsos positivos, aspecto que deve ser cuidadosamente considerado em aplicações médicas. Na prática clínica, um aumento no número de falsos positivos pode resultar na realização de exames complementares e em encaminhamentos que, posteriormente, se mostram desnecessários, além de gerar custos adicionais para o sistema de saúde. Por outro lado, em programas de rastreamento do diabetes, esse impacto costuma ser considerado menos preocupante do que a ocorrência de falsos negativos, já que deixar de identificar um paciente com a doença pode atrasar o diagnóstico e o início do tratamento, aumentando o risco de complicações. Dessa forma, a escolha entre priorizar maior sensibilidade ou maior precisão deve levar em conta o objetivo da aplicação do modelo.

De maneira geral, os resultados obtidos indicam que as técnicas de balanceamento não resultaram em melhorias consistentes para o conjunto de dados analisado. Embora tenham aumentado a capacidade dos modelos de identificar exemplos da classe minoritária, esse ganho foi acompanhado por uma redução na precisão, o que impactou negativamente algumas

métricas de desempenho. Esses achados sugerem que, para o conjunto de dados utilizado, o nível de desbalanceamento pode não ter sido suficientemente elevado para justificar a aplicação de técnicas de *oversampling*, uma vez que os classificadores já apresentavam desempenho satisfatório utilizando a distribuição original dos dados.

Tabela VII
MELHORES RESULTADOS OBTIDOS EM CADA CENÁRIO

Cenário	Modelo	F1	Recall
Sem balanceamento	MLP	0.81	0.68
SMOTE	Random Forest	0.76	0.75
ADASYN	Random Forest	0.74	0.76
RandomOverSampler	Random Forest	0.78	0.72

No entanto, como o problema em questão envolve cenários de auxílio à previsão de diagnósticos, é importante tentar reduzir os falsos negativos mantendo um equilíbrio no número de falsos positivos. Desse modo, para situações em que a prioridade seja evitar ao máximo os falsos negativos, cenários com alto recall podem ser mais relevantes. Já quando se busca um equilíbrio entre sensibilidade e precisão, o Random Forest com RandomOverSampler apresenta uma alternativa mais interessante, combinando recall satisfatório com precisão significativamente superior aos modelos com maior sensibilidade.

A. *Análise de Explicabilidade com SHAP*

Com o objetivo de compreender a influência das variáveis nas predições do modelo de melhor desempenho, foi empregada a técnica SHAP. A Figura 2 apresenta a importância global das variáveis, calculada por meio da média dos valores absolutos de SHAP para as duas classes do problema: Classe 0, correspondente aos indivíduos sem diabetes, e Classe 1, correspondente aos indivíduos com diabetes.

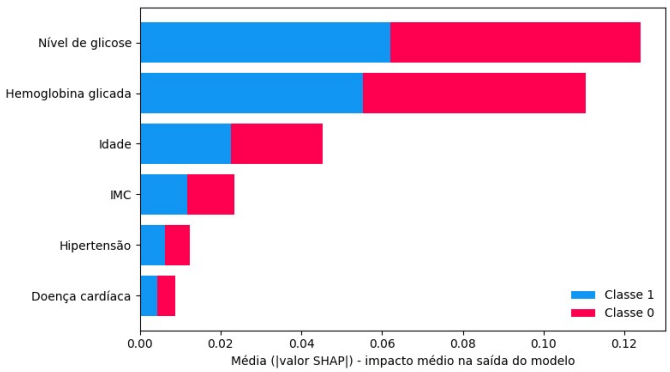

Figura 2. Gráfico SHAP

Conforme apresentado na Figura 2, o nível de glicose no sangue foi a variável com maior impacto nas predições do modelo, seguido pela hemoglobina glicada (HbA1c) e pela idade. Esses atributos apresentaram os maiores valores médios absolutos de SHAP, evidenciando sua elevada contribuição para a classificação dos indivíduos quanto à presença ou ausência de diabetes.

Por outro lado, as variáveis índice de massa corporal (IMC), hipertensão e doença cardíaca apresentaram menor influência nas predições. Embora esses fatores sejam reconhecidos como importantes fatores de risco para o desenvolvimento do diabetes, sua contribuição individual foi inferior à observada para as variáveis diretamente relacionadas ao controle glicêmico, como HbA1c e glicose sanguínea.

Observa-se ainda que nível de glicose no sangue e HbA1c apresentaram elevada contribuição tanto para a classe ”Com diabetes”quanto para a classe ”Sem diabetes”, indicando que o modelo utilizou essas variáveis como principais elementos discriminativos entre as duas classes. Esse comportamento é consistente com a literatura, que reconhece a hemoglobina glicada e a glicose sanguínea como os principais indicadores clínicos para o diagnóstico e acompanhamento do diabetes.

V. CONCLUSÃO

Este trabalho avaliou o impacto de diferentes técnicas de balanceamento de classes no desempenho de algoritmos de ML aplicados à predição de diabetes. Para isso, foram comparados os métodos SMOTE, ADASYN e RandomOverSampler em conjunto com os classificadores Regressão Logística, KNN, SVC, Random Forest e MLP, utilizando validação cruzada estratificada de dez dobras e métricas de classificação adequadas para problemas com desbalanceamento de classes.

Os resultados mostraram que as técnicas de balanceamento aumentaram significativamente a capacidade dos modelos em identificar indivíduos com diabetes, refletida pelo aumento do recall. Entretanto, esse ganho foi acompanhado por uma redução da precisão e, consequentemente, do *F1-Score*, principalmente nos cenários com ADASYN. Ainda assim, em aplicações nas quais a identificação do maior número possível de indivíduos com diabetes seja prioritária em relação à redução de falsos positivos, as técnicas de balanceamento podem representar uma alternativa interessante, uma vez que contribuíram para reduzir significativamente a quantidade de falsos negativos. Entre os modelos avaliados, o Random Forest apresentou o comportamento mais consistente diante das diferentes estratégias de balanceamento, enquanto o MLP obteve o melhor desempenho no cenário sem aplicação de técnicas de *oversampling*.

A utilização da técnica SHAP permitiu interpretar as decisões do modelo, evidenciando que o nível de glicose, a hemoglobina glicada (HbA1c) e a idade foram as variáveis mais relevantes para a predição de diabetes. Esses resultados estão de acordo com o conhecimento clínico disponível na literatura, reforçando a confiabilidade do modelo desenvolvido.

De maneira geral, conclui-se que, para o conjunto de dados utilizado, as técnicas de balanceamento não proporcionaram melhorias no desempenho global dos classificadores, uma vez que o aumento do *recall* ocorreu acompanhado por uma redução significativa da precisão. No entanto, em aplicações médicas nas quais a redução de falsos negativos seja mais importante do que a maximização do desempenho global,

essas técnicas podem representar uma estratégia vantajosa, por favorecerem a identificação de um maior número de indivíduos com diabetes.

Como trabalhos futuros, pretende-se avaliar o desempenho dos modelos em outros conjuntos de dados com diferentes níveis de desbalanceamento, a fim de verificar em quais cenários as técnicas de balanceamento podem proporcionar benefícios. Além disso, pretende-se investigar algoritmos de ML mais recentes, como XGBoost e CatBoost, bem como explorar outras abordagens de explicabilidade, incluindo a técnica LIME, a fim de ampliar a interpretação das predições realizadas pelos modelos.

***Abstract* —** Exposure to pesticides in the work process represents a significant health risk for Endemic Disease Control Agents (EDCAs), potentially leading to alterations in the respiratory system. The present study aimed to analyze respiratory mechanics and pulmonary function in these workers through an integrated assessment, with an emphasis on respiratory oscillometry. This was a cross-sectional, analytical study including 30 individuals, comprising 15 endemic disease control agents and 15 healthy controls. Participants underwent spirometry, body plethysmography, and multifrequency oscillometry (4–32 Hz). Spirometric results demonstrated significant reductions in forced vital capacity (FVC, $p<0.05$) and forced expiratory volume in one second (FEV_1, $p<0.05$) in the EDCA group. Plethysmography revealed a significant reduction in vital capacity (VC, $p<0.01$) and a significant increase in the RV/TLC ratio ($p<0.05$), indicating air trapping. In oscillometric analysis, there was a significant increase in total resistance (R4, $p<0.05$) and central resistance (R20, $p<0.01$), along with a significant reduction in mean reactance (Xm, $p<0.05$) and dynamic compliance (Cdyn, $p<0.05$). Additionally, a significant increase was observed in resonant frequency (fr, $p<0.05$), the area under the reactance curve (Ax, $p<0.01$), and impedance modulus at 4 Hz (Z4, $p<0.05$). These findings contribute to the characterization of respiratory mechanical alterations in this population and are consistent with the underlying pathophysiology. It can be concluded, that respiratory oscillometry is a sensitive tool for identifying alterations in pulmonary mechanics among endemic disease control agents, thereby contributing to improved health monitoring in this workforce.

Keywords: Pesticides; Endemic Disease Control Agents; Oscillometry; Plethysmography; Exposure in the work process.

I. INTRODUCTION

Arboviral diseases, viral pathologies transmitted by arthropod vectors, have become one of the most complex and persistent challenges for global public health in the 21st century [1]. In the Brazilian context, the severity of this scenario is amplified by a combination of rapid and unplanned urbanization, structural deficiencies in basic sanitation, and intense population mobility. These factors, together with anthropogenic climate change, create an ideal environment for the proliferation and spread of the mosquito Aedes aegypti, the biological vector of etiological agents with a high impact on the population [2].

The city of Rio de Janeiro, in particular, has historically stood out as an epicenter of multiple and severe epidemics. Its status as an international tourist destination and its role as a strategic hub within national road and air transport networks facilitate the introduction of exotic viral variants and their subsequent spread into inland regions [3]. Over the past four decades, the state has experienced both endemic and epidemic circulation of Dengue, Zika, Chikungunya, and Yellow Fever, placing a continuous and substantial burden on the Unified Health System (SUS) and requiring uninterrupted, high-cost vector control strategies [3].

The dynamics of these transmission patterns have undergone profound changes due to global warming. Increases in average temperatures and alterations in rainfall patterns accelerate the vector's metabolism and reproductive cycle, expanding its geographic range into previously unaffected areas where viral circulation had not occurred [4]. This phenomenon results in the loss of traditional seasonality, transforming diseases once restricted to warmer periods into year-round threats, thereby requiring continuous surveillance efforts [4]. In response to the spread of arboviral diseases, the

Pan American Health Organization (PAHO) and the Brazilian Ministry of Health recommend integrated strategies that include the extensive use of chemical compounds for vector population control in urban areas [2]. The implementation of these actions, such as fogging/spraying and insecticide application, is governed by technical regulations that establish operational guidelines and health protection measures for workers involved in these activities [2].

In this context, Endemic Disease Control Agents (EDCAs) emerge as the frontline workforce responsible for implementing these public health policies [2]. However, the social relevance of this group contrasts with the chronic precariousness of their working conditions [5]. Historically referred to as "mosquito control workers," these professionals perform their duties under direct exposure to neurotoxic pesticides, such as temephos and other organophosphates and pyrethroids [5, 6]. This exposure often occurs in the absence of adequate provision of personal protective equipment (PPE), without rigorous biological monitoring, and in the context of insufficient and outdated training regarding the toxicokinetics of these compounds [6].

Robust scientific evidence indicates that continuous inhalation and dermal absorption of these toxic agents result in systemic effects [5]. Multicenter studies led by FIOCRUZ in the state of Rio de Janeiro have identified alarming correlations between exposure in the work process and the development of hematological, renal, neurological, and cardiovascular disorders, with the latter affecting up to 46% of the studied population [7]. Within the respiratory system, the prevalence of pathological conditions reaches approximately 19%, suggesting that the inhaled toxic burden compromises airway integrity and pulmonary mechanics in these workers [7, 8].

Considering the pressing need to identify possible respiratory dysfunctions resulting from this exposure, the present study proposes the use of advanced, noninvasive diagnostic methods. In this context, respiratory oscillometry emerges as a highly sensitive tool for assessing respiratory mechanics during spontaneous breathing, enabling the detection of alterations in the resistive and reactive properties of the respiratory system. This technique has been consolidated as a state-of-the-art approach in current clinical practice, allowing the identification of distinct pathophysiological parameters that are complementary to those obtained through conventional tests, such as spirometry and plethysmography [9].

In light of the above, the aim of this study was to analyze respiratory mechanics and pulmonary function through a multimodal approach, integrating respiratory oscillometry, spirometry, and body plethysmography. This assessment sought to identify potential subclinical functional alterations in EDCAs chronically exposed to pesticides, thereby characterizing the possible impact of this toxic burden on pulmonary mechanics.

II. Material and Methods

A. Volunteers

This is a cross-sectional, analytical, and descriptive study. The sample comprised 30 volunteers aged over 18 years, divided into two groups: a control group (CG), consisting of 15 healthy individuals with no history of respiratory or cardiac disease, non-smokers, and without prior COVID-19 or post-COVID-19 sequelae; and an exposed group, consisting of 15 Endemic Disease Control Agents (EDCAs), who were invited to participate through telephone contact in collaboration with Center for Studies on Workers' Health and Human Ecology (CESTEH/ENSP/Fiocruz). Important characteristics of the patient group are observed in Table 1.

Variable	EDCA group (n=15)
Duration of work (years)	26.1 ± 8.5
Duration of direct exposure (years)	24.8 ± 8.3
Primary type of insecticide used	Organophosphates/Pyrethroids
Average frequency of application	5 days/week
Smoking history (pack-years)	9.0 ± 13.8

B. Ethics

All participants provided written informed consent, and the study protocol was approved by the Research Ethics Committee of the Pedro Ernesto University Hospital (HUPE), under CAAE number: 86702825.0.0000.5259.

C. Assessment protocol

Data collection was conducted at the Biomedical Instrumentation Laboratory of the State University of Rio de Janeiro (LIB/UERJ). Participants initially underwent a clinical interview, followed by anthropometric measurements and instructions regarding the procedures for the examinations.

D. Spirometry

All procedures were performed by trained professionals using pre-calibrated equipment. A pneumotachograph-based system was used for spirometric analysis (nSpire Health, Inc., 1830 Lefthand Circle, Longmont, CO 80501). Participants were instructed on the correct execution of respiratory maneuvers, according to the protocols and acceptability and reproducibility criteria established by national guidelines [10]. Forced vital capacity (FVC), forced expiratory volume in the first second (FEV_1), FEV_1/FVC ratio, and forced expiratory flow (FEF_{25-75}%) were analyzed.

E. Plethysmography

For plethysmography examinations, the same equipment used for spirometry was employed, and the examination protocol followed the international guidelines of the ATS [11]. Total Lung Capacity (TLC), Vital Capacity (VC), Residual Volume (RV), and the Ratio between Residual Volume and Total Lung Capacity (RV/TLC) were analyzed. The predicted result for the disease group was used for the statistical test; results from the control group were not included in the comparison.

F. Respiratory oscillometry technique

Respiratory mechanics were further assessed using the respiratory oscillometry technique, with multifrequency analysis ranging from 4 to 32 Hz, using a device developed at the LIB/UERJ, and the results were analyzed using Oscilab 3.0 software [12].

During the examination, participants were instructed to breathe at resting tidal volume while supporting their cheeks

CAPES; CNPq; FAPERJ.

with their hands and wearing a nose clip, in accordance with international standardization guidelines [13]. Respiratory impedance parameters were obtained, including resistance parameters, which assess opposition to airflow in the airways, and reactance parameters, which describe the elastic and inertial properties of the respiratory system.

The resistive parameters analyzed were resistance at 4 Hz (R4), resistance at 20 Hz (R20), and the difference between R4 and R20 (R4–R20). Reactive parameters included mean reactance (Xm), dynamic compliance (Cdyn), resonant frequency (fr), the area under the reactance curve (Ax), and the impedance modulus at 4 Hz (Z4).

All measurements obtained via respiratory oscillometry undergo a quality control procedure based on the coherence function, which allows for the quantification of respiratory variability during measurement. Consequently, only measurements with values above 0.90 are considered valid, while those failing to meet this criterion are discarded.

G. Statistical analysis

Statistical results are reported as mean ± standard deviation (SD) and are presented in tables and box-and-whisker plots. Data analysis was performed using ORIGIN 8.0 software (Microcal Software Inc., Northampton, MA, USA). The distribution of the data was initially assessed using the Shapiro–Wilk test. The statistical analysis employed was the independent samples t-test or the Mann-Whitney U test when comparing two different groups, and the paired t-test or Wilcoxon test when comparing measurements within the same group, as in the case of whole-body plethysmography. A p-value < 0.05 was considered indicative of statistical significance.

Given that this study is exploratory and preliminary in nature, involving a sample of only 15 individuals per group, applying statistical correlation and ROC curve analyses to such a small sample at this stage could yield unstable and unreliable estimates, complicating the interpretation of results; for this reason, we opted not to perform these analyses in the present study, although we recognize that such approaches are relevant and important for future work.

III. RESULTS

Table 1 presents the anthropometric and spirometric data of the studied groups. No statistically significant differences were observed between the EDCA and control groups regarding age, weight, or height; only body mass index (BMI) showed a significant increase ($p < 0.05$).

In the assessment of pulmonary function by spirometry, the EDCA group showed statistically significant reductions in FVC (L) ($p < 0.01$), FVC (%) ($p < 0.05$), FEV_1 (L) ($p < 0.01$), FEV_1 (%) ($p < 0.01$), the FEV_1/FVC (L) ($p < 0.05$), and FEV_1/FVC (%) ($p < 0.0001$). In contrast, $FEF_{25–75}$% did not show a statistically significant difference between groups (p = ns).

Regarding exposure history and lifestyle habits, the exposed group presented a mean duration of direct exposure to pesticides of 26.13 ± 8.49 years ($p < 0.0001$). Concerning smoking status, a mean smoking burden of 9.05 ± 13.79 pack-years was observed in the EDCA group ($p < 0.01$).

Table 1 - Anthropometric and spirometric measurements of the studied groups.

	Control (n= 15)	EDCA (n= 15)	p
Age (years)	59.04 ± 4.86	59.06 ± 8.99	ns
Weight (kg)	80.98 ± 8.80	88.16 ± 15.61	ns
Height (cm)	169.73 ± 5.84	165.13± 6.46	ns
BMI (kg/m2)	27.97 ± 3.43	31.88 ± 4.97	<0.05
Gender (F/M)	5/10	7/8	-
Smoking Load (pack/years)	0	9.05 ± 13.79	-
Exposure period (years)	0	26.13 ± 8.49	-
FEV_1 (L)	3.07 ± 0.44	2.52 ± 0.44	<0.01
FEV_1 (%)	98.54 ± 13.89	84.26 ± 14.37	<0.01
FVC (L)	3.87 ± 0.54	3.19 ± 0.56	<0.01
FVC (%)	98.74 ± 13.48	85.50 ± 15.73	<0.05
FEV_1/FVC (L)	86.32 ± 12.11	78.84 ± 5.54	<0.05
FEV_1/FVC (%)	100.25 ± 7.12	99.01 ± 7.25	<0.0001
FEF_{25-75}(L)	3.14 ± 0.88	2.83 ± 1.17	ns

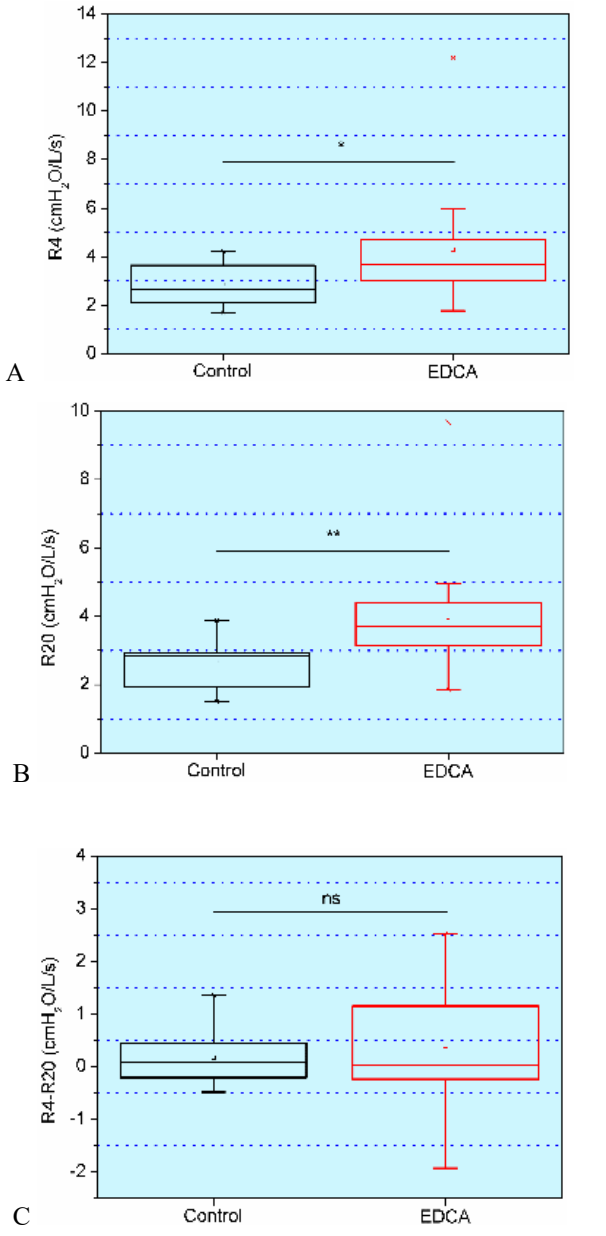
Legend: BMI - Body Mass Index; FEV_1 - Forced Expiratory Volume in one second; FVC - Forced Vital Capacity; FEV_1/FVC - Forced Expiratory Volume in one second to Forced Vital Capacity ratio; FEF - Forced Expiratory Flow; ns - not significant;

Among the 15 volunteers in the EDCA group, nine were classified as normal, four presented a nonspecific ventilatory pattern, one exhibited a mixed disorder, and one demonstrated an obstructive disorder.

Table 2 presents the plethysmographic parameters and their comparison with predicted values for the EDCA group. A patient was unable to undergo plethysmography due to difficulties understanding how to correctly perform the maneuvers. The results showed a significant increase in RV/TLC ($p < 0.05$) and a significant reduction in VC ($p < 0.001$). Residual volume values were higher in the exposed group compared with predicted values; however, this difference did not reach statistical significance (p = ns). Similarly, TLC values were visually lower, but without a statistically significant difference (p = ns).

Table 2 – Plethysmography results and predicted values of the studied groups.

	Predicted (n=14)	EDCA (n=14)	p
TLC (L)	5.63 ± 0.91	5.33 ± 0.93	ns
VC (L)	3.84 ± 0.53	3.26 ± 0.66	<0.001
RV (L)	1.97 ± 0.32	2.17 ± 0.58	ns
RV/ TLC	33.87± 3.02	40.34± 7.63	<0.05



Legend: TLC - Total Lung Capacity; VC – Vital Capacity; RV - Residual Volume; RV/TLC - Ratio between Residual Volume and Total Lung Capacity; n = number of patients evaluated; ns - not significant

Figure 1 presents the resistive results obtained through respiratory oscillometry. A statistically significant increase was observed in R4 ($p < 0.05$; Fig. 1A) and in R20 ($p < 0.01$; Fig. 1B). R4-R20 (Fig. 1C) did not show a statistically significant difference between groups (p = ns).

Figure 2 shows the results related to reactive properties; the EDCAs group showed a significant reduction in Xm ($p < 0.05$; Fig. 2A) and Cdyn ($p < 0.05$; Fig. 2B). In addition, there was an increase in fr ($p < 0.05$; Fig. 2C) and in Ax ($p < 0.01$; Fig. 2D).

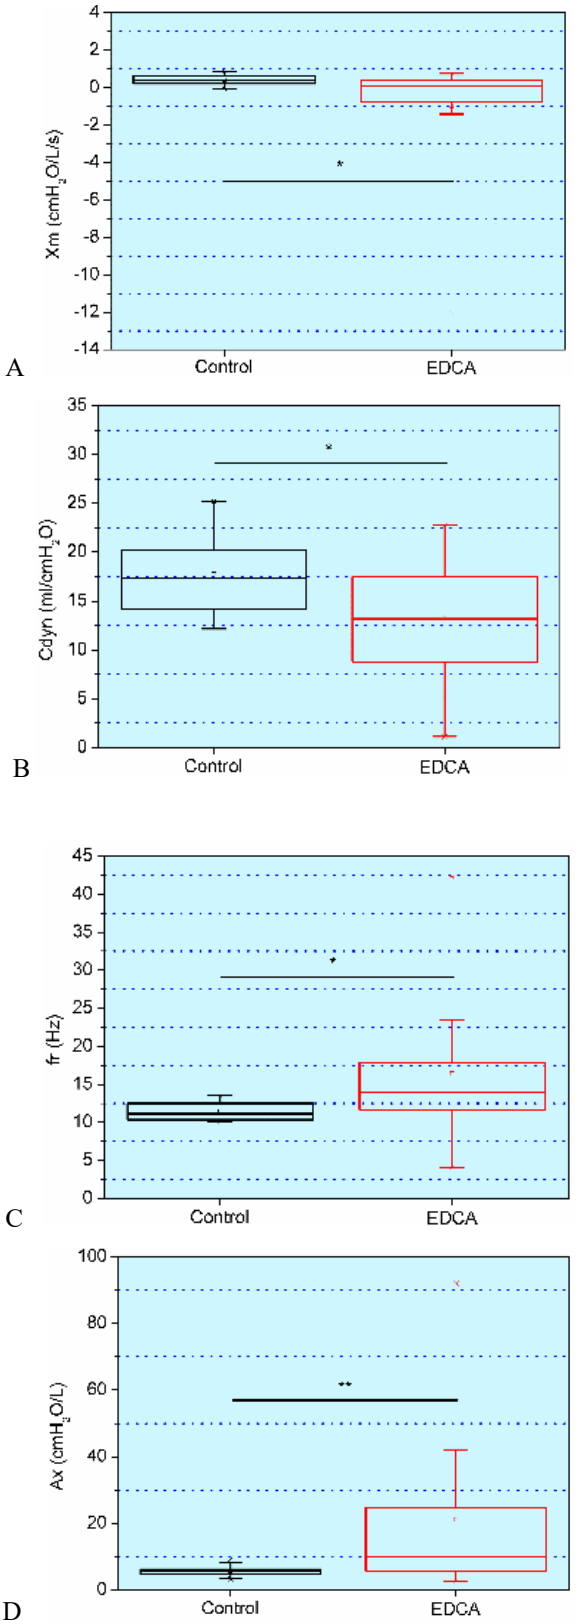


Figure 3 shows that Z4 values (Fig. 3A) were significantly higher in the exposed group compared to the control group ($p < 0.05$).

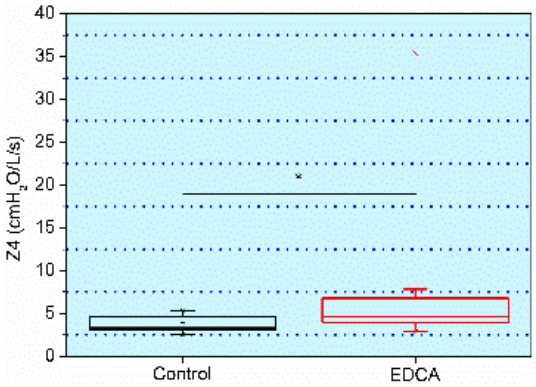
Figure 1 – Comparative analysis of resistive parameters in oscillometry



Legend: R4 – total resistance; R20 – central airway resistance; R4-R20 – difference between R4-R20;

Figure 2 – Comparative analysis of reactive parameters in oscillometry

Legend: Xm – mean reactance; Cdyn – dynamic compliance; fr – resonance frequency; Ax – area under the reactance curve.

Figure 3 – Comparative analysis of the impedance modulus in oscillometry

Legend: Z4 – impedance modulus at 4Hz

IV. DICUSSION

In the description of the anthropometric results (Table 1), no statistically significant differences were observed between the EDCA and control groups with respect to age, body weight, or height, indicating group homogeneity. The EDCA group presented a higher BMI ($p<0.05$). According to the Brazilian Thoracic Society (SBPT) guidelines [10], small variations in BMI within this range do not exert a significant impact on pulmonary volume reduction. Therefore, the similarity in the participants' physical profiles supports the interpretation that the reductions observed in FVC and FEV_1 are not attributable to external mechanical influences related to body weight, but rather to exposure in the work process. These findings are consistent with those reported by Hansen et al. whose prospective study of farmers exposed to organophosphates and carbamates [14]. These results are consistent with an increase in airway obstruction.

The absence of a statistically significant difference in $FEF_{25–75}$% is in line with the findings of Quanjer et al. [15]. These authors pointed out that this parameter presents a high variability, consequently, limited utility as an isolated marker, and the presence of functional impairment is necessary to provide a secure diagnosis. This finding suggests that spirometry alone may underestimate functional alterations in exposed populations.

Regarding lifestyle factors, the mean smoking exposure of 9.05 pack-years in the EDCA group is classified as low. According to the literature [16], in individuals with prolonged exposure to chemical agents, the impact of a low smoking burden is considered secondary when compared with the potential inhalational damage associated with exposure in the work process.

The mean duration of exposure in this population was 26 years of direct contact with pesticides, emerging as the primary determinant of the observed alterations in respiratory mechanics and characterizing a condition of cumulative toxicity that outweighs the effects of low-level smoking exposure.

Body plethysmography (Table 2) enabled a more detailed characterization of the respiratory pattern in this population, revealing the presence of air trapping, as indicated by the increased RV/TLC ratio. According to Beachey [17], this phenomenon is associated with small airway closure. Furthermore, exposure to chemical agents with potential for distal deposition may induce bronchiolar inflammation and impair lung emptying, thereby contributing to increased residual volume [18]. Complementarily, Spiro et al. [19], describe that low-solubility chemical agents are capable of penetrating deeply into the respiratory system, promoting bronchiolar inflammation and impairing lung emptying, which may account for the findings observed in the present study.

The observed increase R4 and R20 (Figures 1A and 1B, respectively) indicates a higher resistive load during breathing, suggesting possible obstruction of more central airways and, consequently, an increase in total respiratory system resistance. This finding may be partially attributed to exposure to chemical agents, as described by Hendrick et al. [20], who reported mechanical impairment affecting the conducting airways even at stages in which workers may not yet present evident clinical symptoms.

These findings are in agreement with the spirometric and plethysmographic results (Tables 1 and 2), which demonstrated significant reductions in FVC and FEV_1, as well as decreased VC and an increased RV/TLC ratio, indicative of ventilatory impairment and air trapping. Although $FEF_{25–75}$% showed only a non-significant downward trend, oscillometric analysis was able to detect alterations suggestive of peripheral airway involvement, highlighting its greater sensitivity in identifying early or subtle functional changes not captured by conventional tests.

According to Cavalcante et al. [21] and Libu et al. [22], respiratory oscillometry demonstrates greater sensitivity in detecting early functional alterations that may be underestimated by spirometry alone. Hansen et al. [14], described that chronic exposure to neurotoxic agents induces sustained cholinergic activity, resulting in bronchoconstriction and mucus hypersecretion throughout the tracheobronchial tree, thereby characterizing a state of cumulative toxicity and underdiagnosed pulmonary impairment. Taken together, these two propositions may support findings of Figures 1A and 1B.

Conversely, although a trend toward increased R4–R20 values was observed in the EDCA group (Figure 1C), no statistically significant difference was found between groups (p = ns). These findings, together with the observation in Figures 1A and 1B, suggests that the main changes in EDCAs may happens in more central airway. This finding may also be attributed to a lack of sensitivity of this parameter to the peripheral changes in the EDCA group. The presence of the peripheral airway's involvement and potential alterations in the ventilatory homogeneity should be interpreted in conjunction with reactance data.

The EDCA group exhibited significant reductions in Xm (Figure 2A) and Cdyn (Figure 2B). These findings indicate decreased ventilatory homogeneity, which may be attributed to small airway involvement, where deposition of chemical agents used in vector control activities may occur. Such alterations impair the mechanical performance of the respiratory system, leading to an uneven distribution of ventilation. According to Kaminski et al. [23], these parameters are sensitive markers of distal airway dysfunction, often not detected by conventional methods. Additionally, studies on interstitial lung diseases have reported similar alterations associated with pulmonary fibrosis, which may lead to bronchostenosis, changes in elastic recoil, and

consequently air trapping, findings consistent with those observed in the present population [24, 25].

The alterations observed in reactive properties, particularly the significant increases in fr (Figure 2C) and the Ax (Figure 2D), support the hypothesis that chemical exposure has affected the small airways, resulting in increased pulmonary stiffness and heterogeneous air distribution. These findings are consistent with the plethysmographic evidence of air trapping observed in this population, as indicated by the elevated RV/TLC ratio (Table 2).

This finding is further strengthened when compared with the studies by Kosak et. al [26] and Moitra et. al [27], which highlight Ax as a highly sensitive marker for detecting peripheral disfunction and loss of elasticity, often outperforming resistance parameters in assessing the severity of obstructive diseases and exposures in the work process.

Taken together, the changes in reactive parameters described in Figure 2 provide clear evidence of abnormalities in peripheral airways and ventilatory homogeneity. Therefore, the absence of significant changes in R4-R20 (Figure 1C) may also be attributed to a lack of sensitivity of this parameter to the peripheral changes in the EDCAs group. It can be speculated that the nature of these abnormal changes in EDCAs are not associated with increased obstruction, but related with elastic properties.

The significant increase in Z4 (Figure 3A) reflects a greater overall opposition to airflow, indicating an increased work of breathing in this population. This parameter is related to the total mechanical load of the respiratory system and may therefore be associated with fatigue and dyspnea, symptoms commonly reported by some volunteers in the EDCAs group [28]. Similar findings have been previously described in studies involving respiratory diseases due to exposure in the work process [24].

Multifrequency respiratory oscillometry analysis enabled the identification of subclinical alterations in respiratory mechanics that were not detected by spirometry alone. These findings demonstrate the sensitivity of respiratory oscillometry in assessing pulmonary mechanics, contributing to a more comprehensive characterization of the alterations observed in EDCAs. These results are consistent with that observed by Parker et al. investigating the short-term ventilatory effects in workers exposed to fumes containing zinc oxide [29].

CONCLUSION

This study provides evidence that EDCAs chronically exposed to pesticides present measurable alterations in pulmonary function and respiratory mechanics when compared with non-exposed individuals.

Spirometric and plethysmographic findings indicate a pattern consistent with ventilatory impairment and air trapping, while oscillometric analysis revealed increased resistive load, reduced reactance, and alterations in parameters associated with peripheral airway dysfunction and respiratory work.

Importantly, respiratory oscillometry proved to be a sensitive tool for detecting early and subclinical changes that may not be fully captured by conventional pulmonary function tests alone. The observed increase in total and central resistance, along with changes in reactance-derived parameters such as fr and Ax, suggests the presence of mechanical alterations affecting both central and peripheral airways, likely related to chronic inhalational exposure to toxic agents.

These findings reinforce the relevance of incorporating advanced, noninvasive techniques such as oscillometry into the routine assessment of workers exposed to respiratory hazards. From a perspective of the exposure in the work process, the results highlight the need for improved preventive strategies, including stricter control of exposure, adequate use of personal protective equipment, and continuous health surveillance programs.

Future studies with larger samples and longitudinal designs are warranted to further elucidate the progression of these alterations and to establish oscillometric parameters as reliable biomarkers for early detection and monitoring of lung injury associated with exposure in the work process in this population, as well as validation using multicenter samples.

ACKNOWLEDGMENT

The authors would like to thank CNPq, FAPERJ and CAPES for their financial support.

We also thank all Endemic Disease Control Agents that participated in this study, and in particular to the federal civil servant unions of the category and to Thaís I. L. C. F. Valença that organized the flow of the studied volunteers.

CONFLICT OF INTEREST

The authors report no conflict of interest.

Prezados Membros da Comissão Temática,

Agradecemos pela oportunidade de submeter uma versão revisada do manuscrito **"*Cold Plasma in Medicine: A Review of Clinical Applications and Underlying Biological Mechanisms*"** para consideração para publicação nos anais do CBEB 2026. Agradecemos também aos revisores pela análise cuidadosa do trabalho e pelos comentários pertinentes, que contribuíram para aprimorar a clareza, a consistência e a apresentação dos resultados. Apresentamos abaixo uma resposta ponto a ponto aos comentários e às questões levantadas pelos revisores, indicando as alterações realizadas no manuscrito e, quando pertinente, esclarecendo as decisões metodológicas adotadas. Também anexamos a versão revisada do manuscrito em um arquivo separado, com todas as alterações destacadas na cor verde. Esperamos que as modificações realizadas tenham esclarecido as questões levantadas durante a revisão e que a versão atualizada atenda aos requisitos do CBEB 2026.

RESPOSTA PARA OS REVISORES

Reviewer #1:

- Uniformizar a classificação metodológica do trabalho como "revisão narrativa" ou "de escopo" em todo o manuscrito — hoje oscila entre "systematic review" (Resumo, seção II) e "narrative review" (Introdução), sem os requisitos de uma revisão sistemática.

  Resposta dos autores: O manuscrito passou a ser classificado, de maneira uniforme, como uma revisão narrativa estruturada. As referências ao trabalho como "revisão sistemática" foram removidas do Resumo, da seção de Métodos e das demais seções do manuscrito.

- Deduplicar os quatro pares de referências repetidas: [7]/[28], [8]/[98], [46]/[90], [47]/[93].

  Resposta dos autores: Os quatro pares de referências duplicadas foram removidos. Posteriormente, todas as citações no texto e as referências bibliográficas foram renumeradas.

- Substituir a citação autor-data solta "(Canady et al.)" pelo número correspondente na lista de referências.

  Resposta dos autores: A citação foi corrigida e substituída pela referência numérica correspondente, atualmente apresentada como [59].

- Detalhar o processo de seleção: data da busca, contagem por base, número de duplicatas e exclusões por etapa (idealmente em fluxograma).

  Resposta dos autores: A seção de Métodos foi ampliada para esclarecer a estratégia de busca, os critérios de elegibilidade, o processo de extração e organização das evidências e a data da última atualização da busca, realizada em 26 de agosto de 2026. Também foi incluído um fluxograma para representar o processo de seleção.

- Reduzir a sobreposição entre Resultados e Discussão, que repetem o mesmo conteúdo por especialidade médica.

  Resposta dos autores: A sobreposição entre Resultado e Discussão foi reduzida.

- Expandir a Conclusão (atualmente 3 frases) com limitações da revisão e direções futuras.

  Resposta dos autores: A conclusão foi expandida.

- Remover o placeholder de template no rodapé.

  Resposta dos autores: o placeholder foi removido.

Reviewer #2:

- Considero apresentar uma tabela de síntese dos 101 estudos, ou pelo menos dos estudos clínicos, contendo aplicação, desenho do estudo, número de participantes, dispositivo/fonte de plasma, gás utilizado, dose ou tempo de exposição, comparador, principais resultados e eventos adversos. Isso permitiria sustentar quantitativamente afirmações como a de que cicatrização de feridas constitui a aplicação clinicamente mais estabelecida, atualmente apresentada principalmente de forma narrativa. Recomendo ainda separar claramente evidências in vitro, animais e humanas, sobretudo em oncologia, pois o próprio manuscrito reconhece que a evidência permanece predominantemente pré-clínica e que ensaios clínicos randomizados de grande escala são escassos. Por fim, incluiria uma avaliação de qualidade metodológica ou risco de viés dos estudos clínicos selecionados e moderaria a conclusão de que CAP possui potencial para "transformar" a prática médica, concentrando-a nas aplicações sustentadas por evidência clínica.

  Resposta dos autores: Após a remoção das referências duplicadas, o manuscrito passou a conter 97 referências únicas. Foram acrescentadas tabelas de síntese dos estudos clínicos com aplicação, desenho, número de participantes, dispositivo, gás, dose ou tempo de exposição, comparador, resultados, eventos adversos e avaliação metodológica. Também foram incluídas tabelas específicas para as principais evidências animais e in vitro. Os Resultados foram reorganizados para separar claramente as evidências humanas, animais e in vitro, especialmente em oncologia, cuja evidência permanece predominantemente pré-clínica. Os estudos clínicos receberam uma avaliação qualitativa do risco de viés. Por fim, a Conclusão foi moderada, destacando que as evidências clínicas mais consistentes estão concentradas no tratamento de feridas e em algumas aplicações dermatológicas, enquanto outras aplicações ainda exigem ensaios clínicos maiores, protocolos padronizados e acompanhamento de segurança em longo prazo.

Comparison Study of Three Different Howland Current Pump Architectures for a Low-Cost EITduino Device

***Abstract*—Electrical Impedance Tomography (EIT) presents a promising, low-cost, and radiation-free alternative to standard anatomical imaging modalities like Computed Tomography. However, ensuring reliable EIT measurements requires a highly stable voltage-controlled current source capable of maintaining high output impedance regardless of load variations. This study evaluates three variations of the Improved Howland Current Pump architecture, a discrete single operational amplifier (TL071), a discrete buffered topology (TL072), and an integrated instrumentation amplifier (AD623), to determine the optimal current injection module for EITduino, an open-source, low-cost EIT device intended for educational and accessible clinical applications. The circuits were modeled using LTspice to assess their frequency response and stability under non-ideal operational conditions across the 10 kHz to 100 kHz frequency spectrum. The evaluation accounted for variable load resistances (100 Ω to 3 kΩ), a 1% resistor mismatch, and a severe parasitic capacitance of 750 pF. Results indicate that the integrated AD623 is severely limited by its 800 kHz gain-bandwidth product, exhibiting significant signal attenuation early in the intended operating range. Furthermore, while the single operational amplifier topology exhibits high-frequency instability under 100 kΩ resistor balancing and a severe cutoff frequency degradation (dropping to the 538 kHz range) under a 20 kΩ balance, the buffered configuration effectively isolates feedback currents and preserves signal integrity. The buffered topology successfully sustained its operational bandwidth near 700 kHz regardless of the balancing resistors utilized and limited maximum current deviation to approximately $\pm 1.5\%$ under resistor tolerance variations. Ultimately, the two-amplifier buffered architecture proved to be the most robust and cost-effective solution, successfully mitigating parasitic degradation and resistor imbalance errors in low-cost EIT instrumentation.**

***Index Terms*—Electrical Impedance Tomography, Howland Current Pump, Bioimpedance, Open-Source Instrumentation, Voltage-Controlled Current Source.**

I. Introduction

Although Computed Tomography (CT) is the gold standard regarding anatomical imaging [1]–[3], its use is limited by the high cost and the use of ionizing radiation.

The safety of continuous exposure of patients and medical staff to ionizing radiation remains a topic of debate in the literature. Several studies support the claim that tomography is safe and does not lead to adverse health effects for patients [4]. On the other hand, other studies suggest the opposite, indicating a notable increase in the incidence of cancer among individuals who have undergone CT scans [4].

Furthermore, the costs associated with acquiring and maintaining a CT scanner are substantial, often exceeding thousands of reais per month and reaching millions over time [5], [6].

Considering the potential risks imposed on patients due to ionizing radiation in conventional CT scans, as well as the high acquisition and maintenance costs, researchers are exploring alternative imaging methods that are safer and more cost-effective. One such approach is Electrical Impedance Tomography (EIT).

EIT can detect and process variations in electrical impedance between different types of tissues in the body [7]. The applied current is minimal and adheres to safety standards for medical devices [7], [8], ensuring that it does not produce the potentially harmful effects associated with high-energy radiation or any noticeable electrical side effects.

In devices of this nature, an electrical current is injected into the patient through an electrode. Such a signal is typically generated by a voltage-controlled current source. To ensure that the generated current presents a high output impedance and constant current for any load, the Howland Current Pump

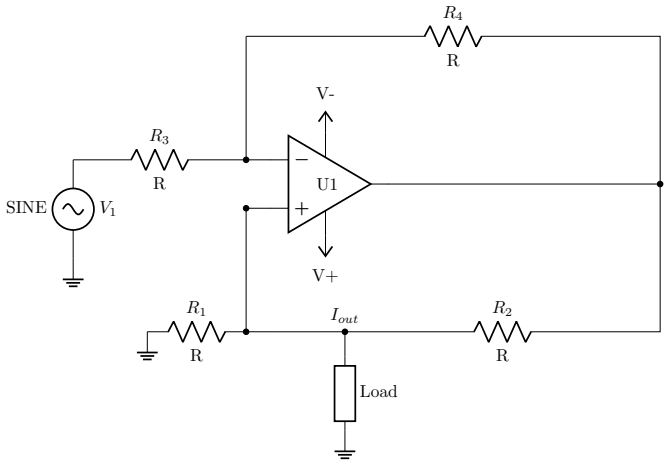

Fig. 1. The diagram shows a generic representation of the Howland pump circuit configuration.

topology is commonly employed [9]–[11], as shown in the diagram of Fig. 1.

The high output impedance is guaranteed by the relationship (1)

$$Z_{\text{out}} = \frac{V_x}{I_{\text{test}}} \tag{1}$$

where Z_{out} represents the output impedance, V_x the voltage at the output node, and I_{test} the theoretical current drained by the external source when $V_{\text{in+}}$ (non-inverting input) and $V_{\text{in-}}$ (inverting input) are grounded. In an ideal source, $I_{\text{test}} \to 0$, resulting in (2)

$$Z_{\text{out}} = \lim_{I_{\text{test}} \to 0} \frac{V_x}{I_{\text{test}}} = \infty \tag{2}$$

which guarantees, therefore, that the output impedance is high.

In this context, the optimization of this circuit is imperative to ensure that, under non-ideal conditions, the device maintains the high output impedance of the current source. Consequently, the present study analyzes three distinct architectures of the Improved Howland Current Pump, aiming at its implementation and improvement in EITduino, an open-source, low-cost EIT equipment, through computational simulations. Such tests were designed to highlight potential signal distortions resulting from resistor imbalance and the presence of parasitic capacitances inherent to the circuit in practical scenarios.

II. Methodology

To ensure the reliability of the current injection module for the EIT system, three voltage-controlled current source topologies were evaluated. The topologies were selected based on technical application notes [12], [13] and were modeled and simulated using LTspice [14]. Additionally, the components selected for the implementation of these circuits prioritized the balance between performance and cost, aligning with the objective of developing a low-cost device.

The evaluated topologies were:

- **Discrete Improved Howland Current Pump:** A single operational amplifier configuration built with discrete components. While effective, this topology relies heavily on precise resistor matching to maintain high output impedance.
- **Discrete Improved Howland Current Pump with Buffer:** A two-amplifier configuration where a buffer is added to the feedback loop. The buffer practically eliminates the feedback current, which simplifies the selection of the feedback resistors, improves output current control, and offers better resilience against parasitic capacitance.
- **Integrated Improved Howland Current Pump:** An implementation utilizing a precision difference amplifier. This topology leverages laser-trimmed internal resistors, virtually eliminating external matching errors and ensuring superior stability with minimal external components.

To assess the robustness of each topology under realistic operating conditions, multiple variables and non-ideal scenarios were simulated:

- **Resistor Balancing Points:** For the two discrete topologies, the performance was evaluated at two distinct nominal balancing resistance values: 20 kΩ and 100 kΩ.
- **Resistor Mismatch and Tolerance:** An intentional imbalance was introduced by changing the value of resistor R2 by $\pm 1\%$ from its nominal value, which, in this case, is considered to be 1 mA or -60 dB.
- **Parasitic Capacitance Analysis:** Parasitic capacitance is recognized as a primary source of error in electrical bioimpedance systems, originating mainly from coaxial cables and electrode-skin interfaces [15]. To evaluate the stability and frequency response of the current pumps under these non-ideal conditions, a severe parasitic capacitance of 750 pF was simulated in parallel with the load. This specific magnitude was chosen based on empirical data from literature, which report average measured parasitic capacitances of 712 ± 128 pF in realistic bioimpedance instrumentation setups [16].
- **Variable Load Resistance:** Tests conducted across 100 Ω, 500 Ω, 1 kΩ, 2 kΩ, and 3 kΩ.

The performance data for each configuration were compiled into comparative tables. The results map each simulated load value against key frequency response metrics: the Limit Frequency (defined as a 1% magnitude drop) and the Cutoff Frequency (-3dB).

III. Results

A. Constructed Circuits

For the implementation of the circuits, resistors with a 1% tolerance were employed, comprising nominal values of 20 kΩ and 100 kΩ. The final configuration of the three assembled circuits is illustrated in Fig. 2, 3, and 4.

For the implementation of the Improved Howland Current Pump topologies, the TL07X family of operational amplifiers was chosen due to its cost-benefit ratio and suitability to the

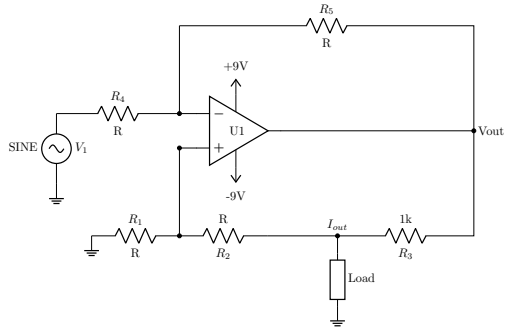

Fig. 2. Schematic of the assembled circuit in the Improved Howland topology using only a single TL071 amplifier.

device's performance requirements. These components present a Gain-Bandwidth Product (GBW) of 5 MHz and a slew rate of 20 V/μs [17], granting them high dynamic characteristics. Such parameters, essential for the stability and precision of said topology, were determining factors for their selection.

On the other hand, the final topology of the Howland Pump incorporated the AD623 instrumentation amplifier. The choice of this component was based on its economic competitiveness against alternatives such as the INA592. However, it should be noted that the AD623 presents technical limitations, having a GBW of 800 kHz (for unity gain) and a slew rate of 0.3 V/μs [18]. Conversely, the differentiator of this component lies in the integration of highly precise internally trimmed resistors, eliminating the need for external components for this purpose, with the exception of the resistor intended to control the output current, denoted by R_S.

For comparative purposes, the topology constructed using the TL071 Improved Howland was altered to accomodate the AD826 to be used as a more robust and ideal standard.

B. Frequency Response (Baseline vs. Parasitic 750 pF)

The frequency response of the Improved Howland Current Pump circuit was evaluated under two distinct resistive balancing conditions: 20 kΩ and 100 kΩ, as detailed in Table I, which specifies the data obtained in the tests for the Improved Howland circuit. A significant divergence between the configurations is observed; the balancing at 100 kΩ exhibits lower attenuation, while the 20 kΩ one presents higher attenuation,

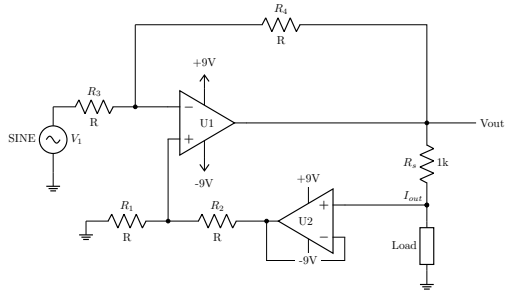

Fig. 3. Schematic of the assembled circuit in the Improved Howland topology using two TL072 amplifiers, one of which is in a buffer configuration for the circuit's feedback.

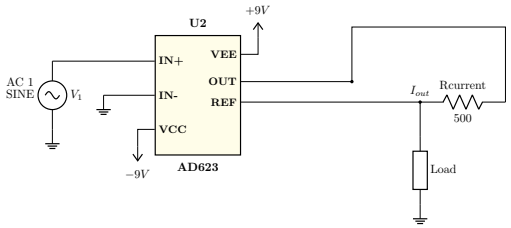

Fig. 4. Schematic of the assembled circuit in the Improved Howland topology using the internal resistors of the AD623 instrumentation amplifier.

this characteristic being particularly prominent at the 1% attenuation limit. Such behavior stems from the use of higher magnitude resistors, which exacerbates the errors associated with bandwidth, instability, and parasitic capacitances, concurrently with the increase in the output impedance of the circuit [12], [13]. Additionally, due to the inherent project needs that determined the use of a less complex amplifier, the limitations of the component become more evident.

As illustrated by Fig. 5, in association with the data from Table II, it is verified that, for lower resistance values, the current magnitude is higher at higher frequencies.

It is observed that the values referring to the 1% gain variation with the balancing at 100 kΩ coincide with the 1% signal attenuation for the circuit balanced at 20 kΩ, around 155 kHz. This fact shows that, in both configurations, the current magnitude variation begins at approximately equivalent frequency thresholds. Additionally, at the frequency of 651.73 kHz, under a load of 100 Ω, a positive variation of 10% in the current magnitude is observed, a characteristic that diverges from the expected ideal behavior for conventional applications of this class of device.

This phenomenon can also be verified when a capacitance is applied in parallel to the load, as can be seen in Table I.

On the other hand, when a more robust amplifier such as the AD826 is used in the circuit, the peaks disappear for both

resistive balancings, as evidenced by Fig. 6, in which no peaks can be seen, even for the lowest load values.

Additionally, this phenomenon is no longer observed upon the insertion of a second amplifier in the positive feedback loop, as evidenced in Table III, which details the values obtained in the test for the Improved Howland topology with Buffer. Such behavior stems from the high input impedance provided by the amplifier in the buffer configuration, which almost entirely suppresses the feedback current [12] [13], resulting in the improvement of the circuit's stability. Furthermore, the feedback current itself acts as a source for several other potential inaccuracies [19] which, in this topology, are mitigated without the need to employ higher magnitude resistors [20]. Thus, the amplification of instabilities that would occur if such resistors were used to perform the same role as the high input impedance provided by the second amplifier in buffer configuration is avoided.

An additional advantage of this configuration, although less expressive, consists of the isolation of the resistor responsible for defining the magnitude of the current directed to the load, a characteristic that considerably facilitates the adjustment of the current if necessary.

In contrast to the other topologies, the Howland Current Pump, when implemented with the AD623 instrumentation amplifier, presents a more pronounced attenuation, besides manifesting itself earlier, even in the base case, as evidenced in Table IV.

This limitation stems from the reduced gain-bandwidth

TABLE III
IMPROVED HOWLAND BUFFER TOPOLOGY: BASELINE AND PARASITIC CAPACITANCE (20 KΩ VS 100 KΩ)

Load	Baseline				Parasitic Capacitance (750 pF)

product (GBW) of the aforementioned amplifier, which is located at approximately 800 kHz for unity gain. On the other hand, the TL071 model presents a GBW of 5 MHz. Consequently, as the input signal frequency approaches the 800 kHz limit, the AD623 becomes unable to follow the waveform variation, resulting in attenuation and other degradations in

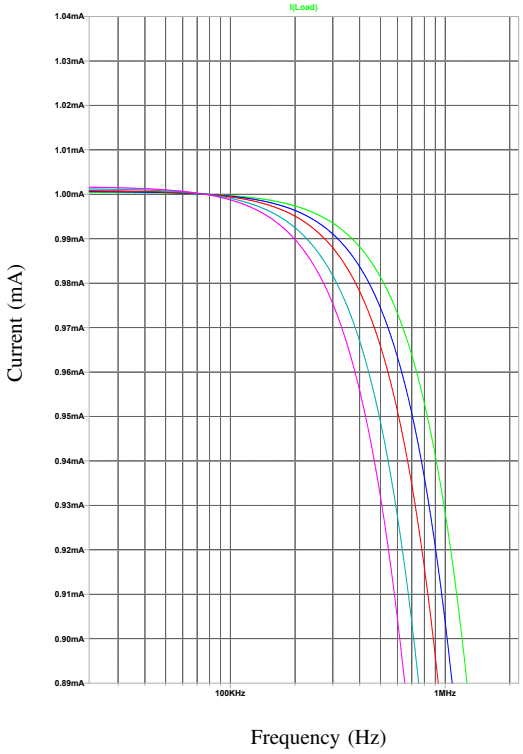

Fig. 6. Attenuation graph of the current generated by the Howland Pump balanced at 100 kΩ using the AD826

TABLE IV
AD623 INTEGRATED TOPOLOGY: BASELINE AND PARASITIC CAPACITANCE

Load (ZL)	Base Condition		Parasitic Capacitance (750 pF)	
	-3dB (Hz)	-1% (Hz)	-3dB (Hz)	-1% (Hz)
100 Ω	694.87 k	325.15 k	660.95 k	269.75 k
500 Ω	497.24 k	106.70 k	286.57 k	41.61 k

2 kΩ	213.78 k	31.60 k	75.38 k	10.77 k
3 kΩ	153.24 k	22.20 k	50.97 k	7.32 k

signal integrity. Additionally, the AD623 exhibits a limited slew rate of 0.3 V/μs, a value significantly lower than the 20 V/μs observed in the TL071.

Furthermore, when comparing the base case with the parasitic capacitance test, an attenuation of approximately 20% is observed for the lowest load values, and about 80% for the highest values for all studied topologies. This discrepancy is attributed to the fact that the insertion of the capacitance in parallel reduces the circuit's output impedance, causing a decrease in the expected frequency response, as in (3)

$$Z_{\text{out}} = \frac{1}{j\omega C_{\text{parasitic}}} \tag{3}$$

where Z_{out} denotes the circuit's output impedance, ω represents the angular frequency, expressed by $2\pi f$, and $C_{\text{parasitic}}$ corresponds to the parasitic capacitance, simulated by the capacitor added in parallel to perform this test. From this equation, the inversely proportional relationship between the output impedance, the capacitance, and the angular frequency becomes evident, so that the increment of the latter two variables necessarily implies the reduction of Z_{out}. Such a property justifies the observed drop in signal amplitude.

In practice, Electrical Impedance Tomography (EIT) systems typically operate in the range of 10 kHz to 100 kHz [7], [16], [20] for the characterization of materials and biological tissues. In this frequency spectrum, Tables I, III, which compile the simulation data of the Howland circuit in the improved and buffered configurations, demonstrate the stability of these topologies. Within them, reduced or negligible attenuations are observed, even under the strong influence of parasitic capacitances [15].

In contrast, Table IV, which reports the results of the topology implemented with the AD623 amplifier [18], reveals significant attenuations for this same operating range (presenting a 1% drop as early as 21 kHz for a 1 kΩ load). Consequently, such an architecture proves to be a less viable alternative for the characterization of biological tissues in the analyzed frequency spectrum.

Regarding integration into a complete EIT acquisition system, scalability introduces hardware limitations. The routing of signals through analog multiplexers inherently adds series resistance and stray capacitance [15]. The simulated 750 pF parasitic capacitance serves as a worst-case baseline for these effects. While the buffered and improved Howland architectures successfully mitigate these parasitic degradations, keeping the system stable [13], [19], [20], future physical implementations for educational platforms like EITduino must carefully design the PCB layout to minimize trace capacitance and crosstalk across multiple electrode channels [11], [15].

C. Sensitivity Analysis (Resistor Mismatch)

Given the integration of high-precision resistors in the AD623 instrumentation amplifier, performing simulations aimed at analyzing the effects of resistive imbalance becomes dispensable. In contrast, the remaining topologies, implemented with nominal 1% tolerance resistors, are subject to variations that can lead to discrepant results in a benchtop environment, distancing themselves from the ideal behavior predicted in simulation.

TABLE V
EFFECT OF $\pm 1\%$ RESISTOR TOLERANCE ON CURRENT OUTPUT AND BANDWIDTH (1 kΩ LOAD AND 20 kΩ RESISTOR BALANCE)

Topology	Max. Deviation	Cutoff Shift (-3dB)
Discrete (TL071)	$\approx \pm 1.5\%$	538 kHz – 549 kHz
Buffered (TL072)	$\approx \pm 1.5\%$	685 kHz – 700 kHz
AD623*	N/A	N/A

* AD623 utilizes internal laser-trimmed resistors.

For the conducted simulations, the sixth step was considered the nominal value, being 1 mA due to the resistor used to define the current, 1 kΩ. According to Ohm's Law

$$I = \frac{V}{R} \tag{4}$$

where I is the nominal value, R is the current-defining resistor with a value of 1 kΩ and V is the voltage set to 1 V, as is the case in all simulations, it can be deduced that

$$I = \frac{1}{1000} = 1 \text{ mA} \tag{5}$$

This specific target of 1 mA was not chosen arbitrarily; it represents the maximum safe current limit for medical applications operating in the 10 kHz to 100 kHz frequency band, ensuring strict adherence to the IEC 60601-1 safety standard [8].

Thus, the difference in attenuation under various resistor mismatches can be analyzed. Tables V and VI present the results obtained for both the 20 kΩ resistive balance (in Table V) and the 100 kΩ resistive balance (in Table VI). No significant discrepancy between them is observed: the maximum deviation for both analyzed topologies is $\approx \pm 1.5\%$ for the 100 kΩ and 20 kΩ balancing.

The attenuation and gain levels can be easily visualized through the graphs generated for the simulations. All graphs have the same scale on the y and x-axes. Fig. 7 and 8 show the results seen in Table V. The maximum and minimum deviations observed in both topologies proved to be effectively equivalent, standing around 1.015 mA for the maximum gain and 0.985 mA for the maximum attenuation. Both alternatives prove adequate for the purpose of this type of instrument, considering that the current value is a parameter employed in

TABLE VI
EFFECT OF $\pm 1\%$ RESISTOR TOLERANCE ON CURRENT OUTPUT AND BANDWIDTH (1 kΩ LOAD AND 100 kΩ RESISTOR BALANCE)

Topology	Max. Deviation	Cutoff Shift (-3dB)
Discrete (TL071)	$\approx \pm 1.5\%$	721 kHz – 734 kHz
Buffered (TL072)	$\approx \pm 1.5\%$	687 kHz – 702 kHz
AD623*	N/A	N/A

* AD623 utilizes internal laser-trimmed resistors.

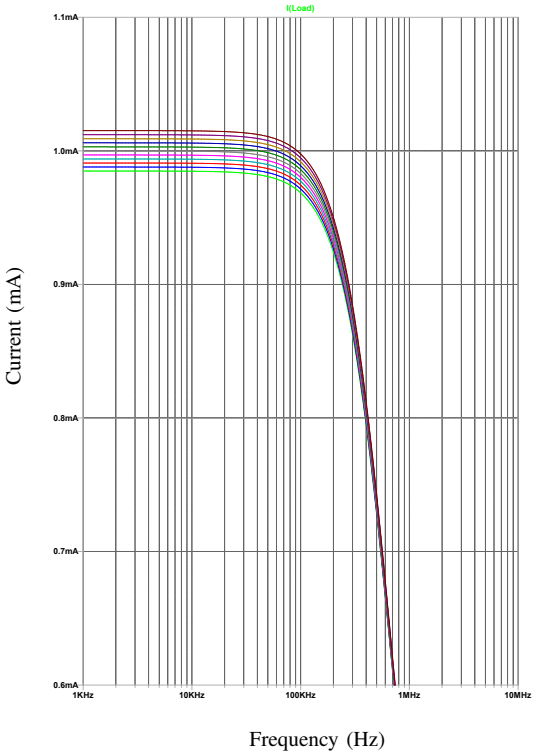

Fig. 7. Sensitivity test graph for the Improved Howland topology utilizing the TL071 Operational Amplifier in a 20 kΩ resistive balance

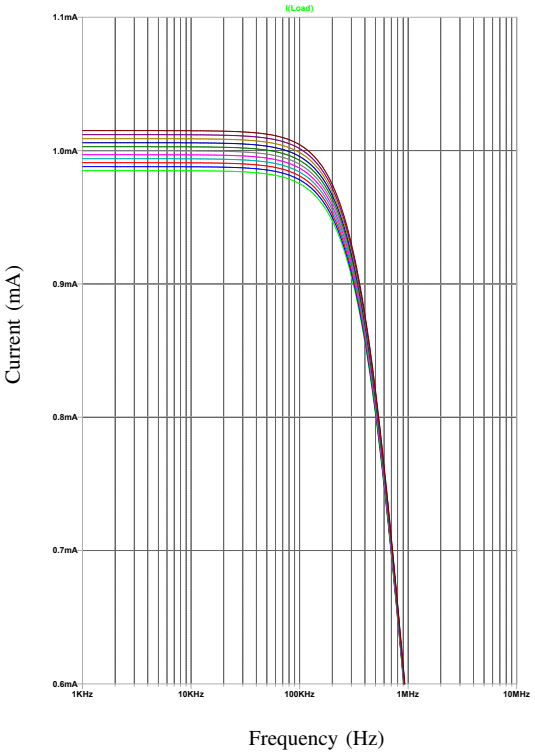

Fig. 8. Sensitivity test graph for the Improved Howland with a buffer topology utilizing the TL072 Operational Amplifier in a 20 kΩ resistive balance

the subsequent image reconstruction steps [7], [20] and the observed variation is not of sufficient magnitude to compromise patient safety, remaining strictly within the normative limits established by the IEC 60601-1 standard [8].

Similarly, Fig. 9 and 10 demonstrate almost the same results. These graphical representations illustrate the data detailed in Table VI. In this scenario, the maximum gain also reached a value of 1.015 mA, and the maximum attenuation was limited to 0.985 mA.

Additionally, a significant difference is observed between the cutoff frequency values of the two resistive balancings evaluated in the topology based on the TL071 operational amplifier. It is noted that this architecture is more susceptible to the low resistance values employed, exhibiting cutoff frequencies in the range of 538 kHz to 549 kHz for the 20 kΩ balancing, and from 721 kHz to 734 kHz for the 100 kΩ balancing.

When comparing these data with the results obtained in the buffered topology (using the TL072 component)–whose values ranged from 685 kHz to 700 kHz for the 20 kΩ balancing, and from 687 kHz to 702 kHz for 100 kΩ–the aforementioned impact becomes evident, corroborating the greater stability of the buffered configuration. This behavior is justified by the introduction of a high-impedance component in the non-inverting feedback loop of this topology [12], [13]. Such an addition acts directly in mitigating parasitic effects and maintaining the output impedance, consequently preventing a decrease in the circuit's cutoff frequency [15], [19], [20].

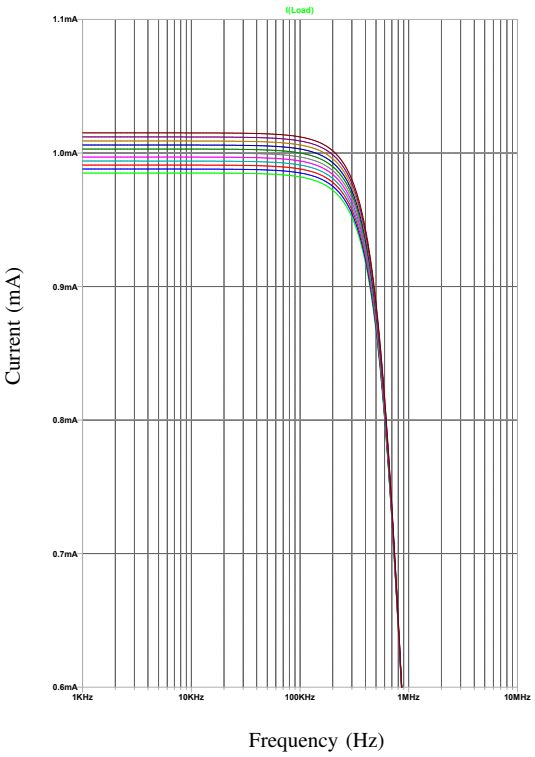

Fig. 9. Sensitivity test graph for the Improved Howland topology utilizing the TL071 Operational Amplifier in a 100 kΩ resistive balance

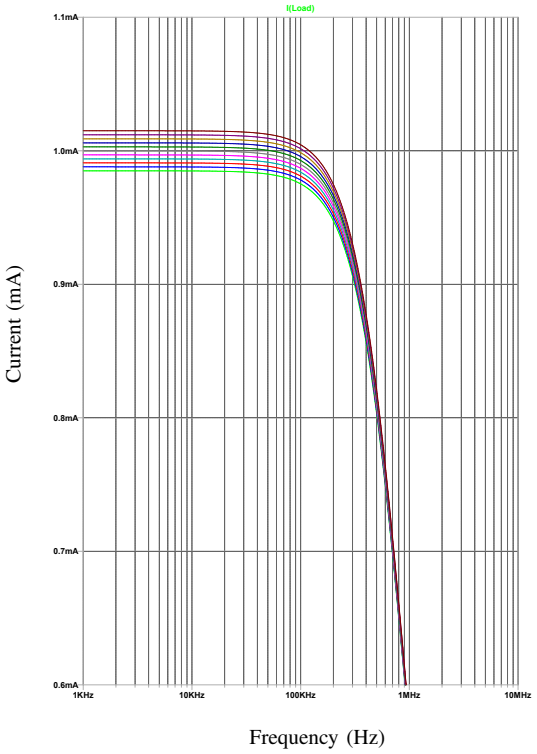

Fig. 10. Sensitivity test graph for the Improved Howland with a buffer topology utilizing the TL072 Operational Amplifier in a 100 kΩ resistive balance

D. Consolidated Results

To facilitate further analysis, a consolidated table was made

TABLE VII
CONSOLIDATED COMPARISON OF THE THREE HOWLAND CURRENT PUMP TOPOLOGIES (1 kΩ LOAD, 20 kΩ RESISTOR BALANCE WHERE APPLICABLE)

Parameter	Discrete (TL071)	Buffered (TL072)	AD623 (Integrated)
GBW / Slew Rate	5 MHz / 20 V/μs	5 MHz / 20 V/μs	0.8 MHz / 0.3 V/μs
-3dB Baseline	540.18 kHz	692.72 kHz	350.69 kHz
-3dB w/ 750 pF	167.75 kHz	175.05 kHz	147.84 kHz
Max. Deviation ($\pm$1% R)	$\approx \pm 1.5\%$	$\approx \pm 1.5\%$	N/A (internal laser-trimmed resistors)
Instability (Peaks)	Yes (+10% at 100 Ω, 651.73 kHz)	No	No (early attenuation)

IV. CONCLUSION

In conclusion, given the design constraints, the measured trade-offs highlight the advantages of the Improved Howland Current Pump topology composed of two operational amplifiers, one of them operating in a buffer configuration. This study evaluated three architectures, a discrete single operational amplifier (TL071), a discrete buffered topology (TL072), and an integrated instrumentation amplifier (AD623), to determine the optimal current injection module for the EITduino device operating within the 10 kHz to 100 kHz frequency spectrum.

This buffered circuit demonstrated high robustness against resistive imbalance and parasitic capacitance, which are critical factors for the proper functioning of the current source. It consistently maintained a highly stable output capable of delivering the nominal 1 mA safe current mandated by the IEC 60601-1 standards for medical applications. The parametric mismatch sweep revealed that while a 1% component tolerance induces an equivalent maximum current deviation of $\approx \pm 1.5\%$ across all resistive configurations, the buffered topology demonstrates superior high-frequency resilience. Unlike the single operational amplifier architecture, which suffers a severe cutoff frequency degradation (dropping to the 538 kHz range) under a 20 kΩ balance, the buffered configuration effectively sustains its operational bandwidth near 700 kHz regardless of the balancing resistors utilized.

Furthermore, the two-amplifier architecture effectively mitigated the problems observed in the other evaluated topologies. Among the overcome limitations, the amplification of high-frequency instabilities and signal peaks associated with the 100 kΩ resistive balancing in the single operational amplifier architecture is notable. The buffered topology successfully isolates feedback currents and preserves signal integrity, even under a severe 750 pF parasitic capacitance representing the stray effects of cables and analog multiplexers.

Additionally, the buffered circuit surpassed the restricted performance of the instrumentation amplifier tested in isolation, whose selection had been primarily guided by its low cost compared to components in the same category. Despite its internal precision, the AD623 was severely limited by its 800 kHz gain-bandwidth product, presenting significant attenuation early in the intended operating range. Ultimately, the buffered Improved Howland topology proved to be the most robust and cost-effective solution for mitigating parasitic degradation and ensuring reliable measurements in low-cost EIT instrumentation.

***Resumo* — A avaliação motora da mão de pessoas com doença de Parkinson (DP) pode se beneficiar de medidas complementares de força, movimento e atividade muscular obtidas durante a realização de uma determinada tarefa. A integração dessas medidas permitiria investigar sua associação com a gravidade do comprometimento motor do paciente. Este artigo apresenta uma proposta de arquitetura para uma manopla instrumentada destinada à avaliação motora da mão de pessoas com DP. A arquitetura compreende subsistemas de estrutura mecânica, medição de força por dedo, medição da preensão global, sensoriamento inercial do tremor, eletromiografia de superfície, aquisição e comunicação de dados, inteligência artificial e interface com o usuário. A organização da arquitetura define as funções e interfaces de cada subsistema, permitindo a implementação através de diferentes componentes. A implementação de uma manopla baseada na arquitetura proposta encontra-se em andamento, com desenvolvimento da estrutura mecânica e dos subsistemas de força por dedo, preensão global e sensoriamento inercial, incluindo eletrônica, programas embarcados e de computador. Essas implementações apoiarão a caracterização dos subsistemas e a posterior validação da arquitetura integrada. A integração temporal dos sinais, a eletromiografia de superfície e a inteligência artificial estão previstas para etapas posteriores. São apresentadas as escolhas técnicas atuais e o planejamento da caracterização metrológica, da integração dos subsistemas e da avaliação com participantes. A contribuição do trabalho consiste na definição da arquitetura multimodal e de uma estratégia de desenvolvimento e validação por etapas. O desempenho diagnóstico e a validade clínica da plataforma ainda não foram estabelecidos.**

Palavras-chave—doença de Parkinson, arquitetura de sistemas, instrumentação biomédica, preensão palmar, avaliação motora.

***Abstract* — Motor assessment of the hand in people with Parkinson's disease (PD) may benefit from complementary measurements of force, movement, and muscle activity obtained during the same task. Integrating these measurements may enable investigation of their association with the severity of motor impairment. This paper presents the proposed architecture of an instrumented handgrip device intended for manual motor assessment in people with PD. The architecture comprises subsystems for mechanical structure, finger force measurement, overall grip force measurement, inertial tremor sensing, surface electromyography, data acquisition and communication, artificial intelligence, and a user interface. Its organization defines functions and interfaces, allowing alternative component choices. Implementation of the handgrip device is ongoing, with development of the mechanical structure and the finger force, overall grip force, and inertial sensing subsystems, including electronics, embedded software, and experimental interfaces. These implementations will support subsystem characterization and subsequent validation of the integrated architecture. Temporal integration of the signals, surface electromyography, and artificial intelligence are planned for later stages. Current technical choices and plans for metrological characterization, subsystem integration, and evaluation with participants are presented. The contribution of this work lies in defining the multimodal architecture and a staged development and validation strategy. The platform's diagnostic performance and clinical validity have not yet been established.**

Keywords—Parkinson disease, system architecture, biomedical instrumentation, handgrip, motor assessment.

I. INTRODUÇÃO

A doença de Parkinson (DP) é uma condição neurodegenerativa progressiva caracterizada pela perda de células do sistema nervoso central, mais especificamente dos neurônios dopaminérgicos na substância negra do mesencéfalo [1]. Mesmo após mais de 200 anos de sua descrição inicial, o diagnóstico clínico da DP permanece um desafio complexo, com amplas implicações para o manejo clínico [2]. A doença caracteriza-se pela presença de manifestações motoras e não motoras múltiplas, incluindo tremor em repouso, bradicinesia, rigidez muscular e instabilidade postural [3,4]. Para tanto, diversas escalas de avaliação têm sido utilizadas para monitorar a DP; dentre as mais tradicionais estão a de Hoehn e Yahr, para graduar o estágio da doença, e a Escala Unificada de Avaliação da Doença de Parkinson (UPDRS – Unified Parkinson's Disease Rating Scale), para avaliar a incapacidade e o comprometimento [4]. No entanto, embora sejam instrumentos padronizados e amplamente utilizados, essas escalas dependem da avaliação clínica de um examinador

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

experiente, estando sujeitas à variabilidade intra e interavaliador, especialmente na avaliação de determinados sinais motores da doença [5]. A revisão da UPDRS patrocinada pela Sociedade de Distúrbios do Movimento (Movement Disorder Society), denominada MDS-UPDRS, constitui a referência clínica prevista para os estudos de validação deste projeto [6].

Nesse contexto, o monitoramento mais objetivo do desempenho motor tem sido favorecido pelo surgimento de dispositivos instrumentados e de biomarcadores digitais que permitem a obtenção de medidas quantitativas por meio de sensores [1]. O avanço das tecnologias digitais em saúde tem possibilitado a incorporação de medidas instrumentais capazes de complementar as avaliações clínicas tradicionais. Entre essas tecnologias, destacam-se os dispositivos vestíveis (wearables), dotados de acelerômetros e giroscópios, utilizados no monitoramento da frequência e da amplitude dos tremores por meio de sensores inerciais. Ali et al. [7], por exemplo, investigaram esses sensores na estimativa da gravidade do tremor essencial, aplicação que não deve ser confundida com validação para a DP.

Entretanto, a avaliação de variáveis cinemáticas, como tremor e movimento, quando realizada sem integrar informações relacionadas à força muscular e à atividade mioelétrica, limita a caracterização geral do desempenho motor. Dessa forma, a análise do desempenho motor pode permanecer fragmentada, exigindo múltiplos equipamentos para avaliação de diferentes domínios motores, o que dificulta a obtenção de uma caracterização integrada da função neuromuscular. Embora já existam propostas de instrumentação multimodal da mão, como a luva apresentada por Li et al. [8], a integração de medidas complementares em uma mesma tarefa de preensão permanece uma questão de projeto a investigar.

Assim sendo, a progressão dos sintomas motores na DP geralmente é acompanhada da redução da força de preensão palmar manual (FPM), que tem sido apontada como um importante biomarcador [9]. Além de ser complementar às avaliações neurológicas, a mensuração da FPM contribui com a Fisioterapia para estabelecimento do programa de exercícios dos pacientes com DP [10]. Em populações idosas, a força de preensão também tem sido associada à velocidade da marcha, indicando uma possível relação entre a função muscular da mão e o desempenho físico global [11].

Adicionalmente, a eletromiografia de superfície (EMG) pode fornecer informações sobre o declínio do desempenho funcional para atividades de vida diária ao identificar alterações na atividade muscular [12]. Entretanto, os exames que combinam EMG e dinamometria exigem frequentemente equipamentos distintos, de alto custo e operação complexa, dificultando a realização de testes rápidos e padronizados em consultórios ou ambientes domésticos. Além disso, a maioria dos dinamômetros comerciais, como o Jamar, mede apenas a força global de preensão da mão, sem discriminar a contribuição individual de cada dedo. Quando utilizados de forma isolada, estes dispositivos podem mascarar déficits motores específicos e assimetrias finas importantes para o diagnóstico precoce [4].

Diante desse contexto, o presente estudo tem como objetivo apresentar uma proposta de arquitetura para uma manopla instrumentada multimodal para aquisição integrada de dados de força muscular, tremor e oscilação da mão e ativação mioelétrica, visando apoiar a avaliação motora da mão de pessoas com DP. O trabalho descreve a divisão da solução em subsistemas, o desenvolvimento em andamento e as etapas previstas para validação da arquitetura. Este é o primeiro relato científico do projeto, cujo pedido de patente já foi depositado. Apesar de estarem presentes na arquitetura, os subsistemas de sincronização entre os módulos, a eletromiografia e a inteligência artificial permanecem como etapas futuras. Sua aplicação ao diagnóstico ou ao monitoramento clínico dependerá de validação específica futura.

II. Solução Proposta

A. Organização funcional da arquitetura

A arquitetura proposta neste trabalho para o desenvolvimento de uma manopla instrumentada destinada à avaliação motora da mão de pessoas com DP é dividida em oito subsistemas (Fig. 1). A estrutura mecânica define a empunhadura, o apoio dos dedos e a transmissão das cargas. Os subsistemas de força por dedo e preensão global medem, respectivamente, os esforços locais de cada dedo da mão e a reação agregada no suporte do dispositivo. O sensoriamento inercial registra aceleração e velocidade angular, enquanto a EMG fornece informações sobre a ativação muscular. Os subsistemas de aquisição e comunicação associam referência temporal aos sinais e os transmitem ao computador. A interface com o usuário e a gestão de dados organizam as sessões, a visualização e o armazenamento das informações. O subsistema de inteligência artificial (IA) utiliza os registros disponíveis para análises multimodais.

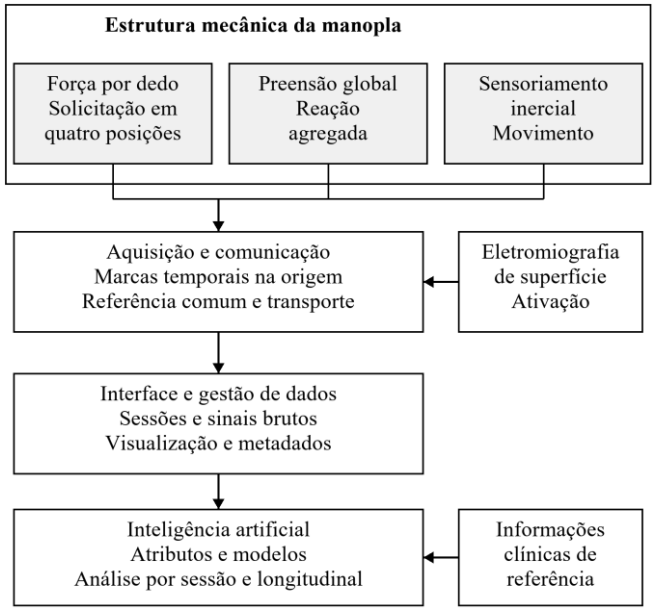

Fig. 1. Arquitetura funcional proposta. As setas representam o fluxo previsto dos dados, não integração já validada. A estrutura mecânica recebe os sensores de força e movimento. O estágio de desenvolvimento está discriminado na Tabela I.

As funções dos subsistemas não dependem de marcas específicas de sensores, conversores ou processadores. Cada módulo deverá informar os canais, grandezas, unidades de medida, taxas, configuração e identificação da calibração. Diferentes transdutores de força, células de carga e unidades inerciais poderão ser utilizados, desde que atendam aos requisitos mecânicos, elétricos e metrológicos. A substituição

de componentes exigirá nova caracterização e verificação das interfaces.

A medição da força por dedo e a medição da preensão global possuem papéis complementares. A primeira tem como objetivo quantificar a contribuição percentual de cada dedo instrumentado para a força total de preensão, tomando como referência a medida fornecida pelo sensor de preensão global, e acompanhar como essas contribuições variam durante a tarefa. Essa análise depende intrinsicamente da calibração dos sensores e da caracterização da transmissão das cargas, pois diferenças entre os caminhos mecânicos e as respostas dos transdutores podem fazer com que a soma das forças individuais difira da força global medida. O sensoriamento inercial por sua vez, fornecerá informações sobre a dinâmica do movimento, enquanto a eletromiografia de superfície (EMG) permitirá investigar sua relação com a ativação muscular. A integração dessas medidas possibilitará estudar a distribuição da força entre os dedos e sua relação com o movimento e a atividade muscular durante a realização de uma tarefa de preensão.

B. Marcação temporal das amostras

Para integrar os sinais dos diferentes subsistemas, a arquitetura contempla uma unidade de aquisição com uma referência de tempo comum, baseada em um contador monotônico, isto é, que avança sem retroceder durante a aquisição. Cada amostra de sinal receberá uma marca temporal nessa unidade, associada ao evento de conversão ou à indicação de que o sensor disponibilizou um novo dado. Nos canais adquiridos sequencialmente por multiplexação, será registrado o instante correspondente a cada conversão, sem considerar simultâneas as medidas de um mesmo conjunto de canais. Quando não for possível identificar diretamente o instante da conversão, será registrado o momento da leitura, e o atraso de conversão, quando caracterizado, será considerado na análise temporal.

Cada registro deverá conter a identificação da sessão, o tipo de sinal e o canal, o número de sequência da amostra, sua marca temporal, o valor bruto e os indicadores de qualidade. As informações de configuração, unidades de medida, calibração e versão do programa serão armazenadas como metadados da sessão. Os dados adquiridos serão mantidos temporariamente em filas, de modo a desacoplar a leitura dos sensores das etapas de transmissão e atualização dos gráficos. Os instantes de chegada dos dados ao computador podem ser utilizados para avaliar a comunicação, mas não substituem a marcação temporal da aquisição, uma vez que estes instantes também refletem os atrasos de transmissão e processamento no computador.

O mecanismo de marcação temporal com referência de tempo comum integra a arquitetura proposta, mas ainda não foi implementado. Sua implementação e validação estão previstas para etapas posteriores ao desenvolvimento descrito neste trabalho.

C. Subsistema de inteligência artificial

O subsistema de inteligência artificial (IA) é concebido como uma camada independente do dispositivo de aquisição, permitindo avaliar diferentes modelos de machine learning sem modificar a cadeia de sensoriamento. Seu funcionamento prevê o uso de dados organizados por sessão de avaliação, incluindo os registros originais dos sensores, as informações de calibração e, quando disponíveis, os resultados de avaliações clínicas de referência. O processamento da informação compreenderá a verificação da qualidade dos registros, a identificação dos trechos correspondentes a cada tarefa e a extração de características dos sinais que servirão como entradas para os modelos. Os resultados por sua vez, deverão ser acompanhados de informações que auxiliem sua interpretação pelo pesquisador ou profissional de saúde. Para o treinamento e a avaliação de modelos supervisionados destinados a estimar aspectos da gravidade motora, serão necessárias avaliações clínicas de referência correspondentes aos registros.

As possibilidades previstas incluem investigar a associação dos sinais com a gravidade do comprometimento motor da mão, identificar padrões de execução das tarefas e acompanhar mudanças entre sessões. A partir dos sinais de força calibrados, poderão ser analisados os valores de pico, a variabilidade da força global, o tempo até atingir o pico e a contribuição percentual de cada dedo instrumentado em relação à força de preensão global, considerando a caracterização da transmissão das cargas. Dos sinais inerciais, poderão ser extraídas medidas de amplitude, frequência dominante e potência em faixas de frequência de interesse. Se os sinais de eletromiografia de superfície (EMG) estiverem disponíveis, poderão ser analisados o envelope do sinal, que representa a variação de sua amplitude ao longo do tempo, e sua relação temporal com a força. As análises conjuntas deverão considerar o alinhamento temporal entre os canais e as limitações de cada subsistema para registrar variações rápidas dos sinais.

Para estimar gravidade motora e identificar padrões de execução, serão comparados modelos de machine learning baseados nas características extraídas dos sinais. Entre os métodos candidatos estão Regularized Regression, Random Forest, Gradient Boosting e Support Vector Machines (SVM), conforme o desfecho e os dados disponíveis. Change-Point Detection poderá apoiar análises entre sessões; Deep Learning dependerá de uma base com quantidade e diversidade adequadas. O método SHAP (SHapley Additive exPlanations) poderá auxiliar a interpretação da contribuição das características para as predições [13], sem estabelecer causalidade.

D. Desenvolvimento atual e etapas futuras

A arquitetura proposta ainda não foi integralmente implementada. O desenvolvimento vem sendo conduzido por subsistema, com montagens experimentais destinadas à caracterização e validação de cada bloco antes da integração do conjunto.

Atualmente estão em desenvolvimento a estrutura mecânica e os subsistemas de força por dedo, preensão global e sensoriamento inercial, com eletrônica, programas embarcados e interfaces experimentais. A leitura e a visualização dos sinais apoiam os testes, mas ainda não demonstram validação metrológica ou integração concluída. A Tabela I apresenta as frentes em andamento e as próximas etapas.

A sequência de desenvolvimento prevê a caracterização e a validação de cada subsistema, seguidas da integração dos fluxos de dados com a referência temporal comum e da avaliação do funcionamento conjunto. A incorporação da eletromiografia de superfície e o desenvolvimento do subsistema de inteligência artificial estão previstos para etapas posteriores.

TAELA I. ESTÁGIO DE DESENVOLVIMENTO DOS SUBSISTEMAS

Subsistema	Situação atual	Próxima etapa
Estrutura mecânica	Montagem experimental em desenvolvimento	Caracterização mecânica e ergonomia
Força por dedo	Quatro canais resistivos e aquisição experimental	Calibração individual e resposta dinâmica
Preensão global	Célula de carga e aquisição experimental	Calibração na montagem e banda útil
Sensoriamento inercial	Aquisição e análise exploratória	Calibração e validação das métricas
Aquisição e comunicação	Programas e placas independentes	Integração e referência temporal comum
Interface e dados	Interfaces específicas em desenvolvimento	Registro multimodal bruto e metadados
Eletromiografia	Subsistema futuro	Projeto da cadeia e segurança
Inteligência artificial	Subsistema futuro	Base rotulada e avaliação de modelos

A validação da arquitetura deverá verificar o atendimento das funções, interfaces e fluxos aos requisitos do sistema integrado. A validação clínica terá objetivos e protocolos próprios e dependerá de estudos com participantes.

III. MATERIAIS E MÉTODOS

A. Abordagem de desenvolvimento

O desenvolvimento adota prototipação e verificação por subsistema, apoiadas por modelos mecânicos, esquemas eletrônicos, programas embarcados e interfaces de aquisição. As configurações a seguir descrevem escolhas experimentais, que não devem ser confundidos com requisitos exclusivos da arquitetura.

B. Construção mecânica

A manopla foi modelada no Fusion 360 com corpo cilíndrico e quatro teclas, correspondentes aos dedos indicador, médio, anular e mínimo. Corpo e teclas foram impressos em plástico ABS por deposição de material fundido através de impressora 3D FDM (do inglês fused deposition modeling). O dedo polegar não possui canal individual de força.

Uma peça de alumínio, também modelada no Fusion 360 e fabricada em centro de usinagem com comando numérico computadorizado (CNC), acomoda os sensores de força por dedo e se acopla à célula de carga de preensão global. Um compartimento interno na base da manopla foi projetado para alojar uma unidade de medição inercial. A Figura 2 apresenta os elementos construtivos e a montagem experimental da manopla.

No interior da manopla, o suporte de alumínio recebe e transmite à célula de carga os esforços aplicados às teclas. A caracterização dessa ligação deverá avaliar a transmissão das cargas, a influência de esforços fora da direção de medição prevista, a interferência entre as posições dos dedos e a repetibilidade das respostas. As dimensões finais, a massa, a faixa admissível de esforço e os mecanismos de proteção contra sobrecarga serão definidos ao longo do desenvolvimento mecânico. A adequação da geometria a diferentes tamanhos de mão também deverá ser avaliada, orientando eventuais ajustes e alternativas de empunhadura a partir de estudos de usabilidade.

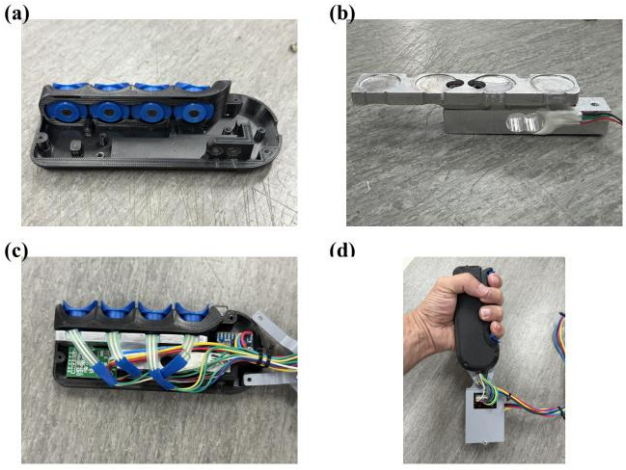

Fig. 2. Montagem experimental: (a) teclas e sensores resistivos; (b) suporte de alumínio e célula de carga; (c) eletrônica e cabeamento; (d) manopla empunhada. Fotografias do desenvolvimento, sem caracterização de ensaio clínico.

C. Aquisição da força por dedo

Para a medição da força exercida por cada dedo, a montagem atual utiliza quatro sensores resistivos de força (FSR, do inglês force-sensing resistors), modelo FSR402. Cada sensor está conectado entre um nó de leitura e o terra, enquanto um resistor de 22 kΩ conecta esse nó à alimentação de 3,3 V, formando um divisor de tensão. Um capacitor de 10 nF liga o nó de leitura ao terra. Um amplificador MCP6004, configurado como seguidor de tensão, reduz a interação entre a impedância do divisor e a entrada do conversor. Sua saída passa por um resistor de 220 Ω, seguido de outro capacitor de 10 nF conectado ao terra, para filtragem do sinal de saída, conforme apresentado na Figura 3.

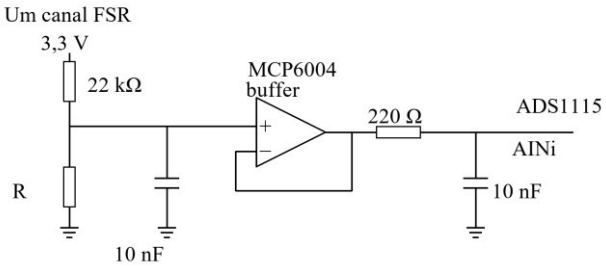

Fig. 3. Condicionamento de um canal FSR na implementação atual. R representa o sensor resistivo. O circuito é repetido para as quatro entradas do conversor ADS1115.

Desprezando o efeito de carga do seguidor de tensão sobre o divisor resistivo, a tensão do canal i é dada por $\mathbf{V_i = V_s R_i/(R_i + R_0)}$, em que $\mathbf{R_i}$ é a resistência do sensor, $\mathbf{V_s = 3{,}3\ V}$ é a tensão de alimentação e $\mathbf{R_0 = 22\ k\Omega}$ é a resistência fixa do divisor. À medida que a força aplicada ao sensor aumenta, sua resistência diminui, reduzindo a tensão medida. A conversão dessa resposta elétrica em força dependerá de curvas de calibração individuais, obtidas com os sensores instalados na manopla, pois a resposta dos FSR depende das condições de aplicação da carga [14].

As tensões dos quatro sensores são digitalizadas por um conversor analógico-digital ADS1115 (ADC, do inglês analog-to-digital converter), que possui resolução nominal de 16 bits e está configurado para uma faixa de ±4,096 V e uma

taxa de 860 conversões por segundo [15]. As quatro entradas são lidas sequencialmente por multiplexação.

Uma placa ESP32 DevKit V1 controla a aquisição e recebe as leituras digitais do ADS1115 pelo barramento I²C (Inter-Integrated Circuit). O ESP32 organiza a aquisição em ciclos nominais de 20 ms, equivalentes a 50 quadros por segundo. A cada ciclo, lê os quatro canais, aplica um filtro de mediana de cinco amostras por canal e converte os resultados em tensão.

O ESP32 envia ao computador, por comunicação serial via USB (Universal Serial Bus), registros CSV (comma-separated values) com o tempo local em milissegundos e as amostras filtradas das quatro tensões. O tempo é obtido no início do ciclo e identifica o quadro, não o instante de cada conversão.

Uma aplicação desenvolvida em Python recebe esses registros e apresenta os valores instantâneos e a evolução temporal dos quatro canais. A implementação utiliza as bibliotecas pySerial para comunicação, PySide6 para a interface gráfica e PyQtGraph para os gráficos. A interface permite visualizar as tensões medidas ou a diferença entre a tensão de repouso de cada canal e sua leitura instantânea. A referência de repouso é estimada durante aproximadamente dois segundos e pode ser redefinida pelo usuário com a manopla em repouso.

A Fig. 4 mostra as diferenças de tensão dos quatro canais durante o acionamento das teclas. Embora a interface use o rótulo “pressão”, os valores estão em volts e ainda não representam força calibrada ou contribuições percentuais para a preensão global.

Fig. 4. Interface Python dos quatro canais FSR. As curvas mostram a diferença entre a tensão de repouso e a tensão medida, em volts, ao longo do tempo.

D. *Aquisição da preensão global*

Complementando as medidas por dedo, uma célula de carga extensométrica registra os esforços transmitidos pelo suporte de alumínio. Seu sinal diferencial em ponte de Wheatstone é digitalizado por um módulo HX711, conversor de resolução nominal de 24 bits, configurado no canal A com ganho 128 [16]. Uma placa ESP32 DevKit V1 recebe as leituras e as transmite ao computador por comunicação serial via USB.

O HX711 está configurado para 10 amostras por segundo. O programa embarcado no ESP32 verifica a disponibilidade de novas leituras e adota intervalo mínimo de 100 ms entre envios. Cada registro contém o tempo local do ciclo, em milissegundos, a leitura bruta e o valor corrigido pela tara, polaridade e fator de escala.

A tara define a referência sem esforço aplicado, e a convenção de polaridade torna positiva a resposta à preensão. Um fator de escala permite converter as leituras numéricas em força, mas deverá ser determinado por calibração com cargas de referência na montagem. Até esse momento, a calibração ainda não foi realizada.

Uma aplicação Python, desenvolvida com as mesmas bibliotecas de comunicação e visualização do subsistema anterior, apresenta na tela do computador: o sinal ao longo do tempo, o valor instantâneo e o pico da sessão. A aplicação permite também selecionar a porta de comunicação serial, executar a tara, ajustar o fator de escala e redefinir o pico. Na Fig. 5, o fator unitário utilizado mantém os valores em contagens corrigidas apenas pela tara e polaridade. O rótulo “unidades calibradas” da interface ainda não representa calibração física concluída, necessária para apresentação do sinal em newtons.

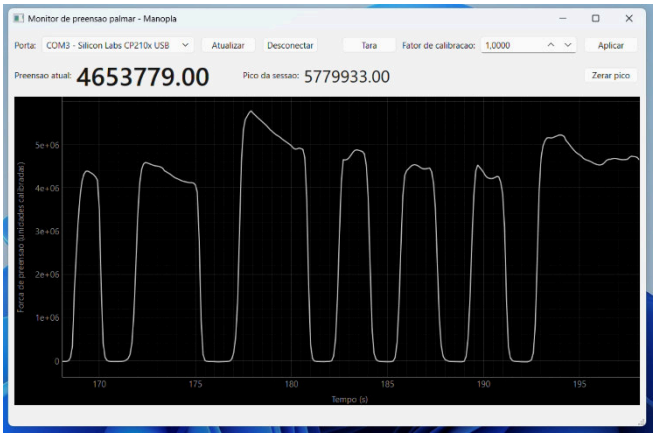

Fig. 5. Interface Python da preensão global, com resposta temporal, valor instantâneo, pico e controles de tara e escala. Os valores são contagens corrigidas, sem conversão para newtons.

E. *Sensoriamento inercial e processamento exploratório*

Complementando as medidas de força, o subsistema inercial tem como objetivo quantificar características dos tremores da mão, como amplitude e frequência, durante as tarefas de preensão. Para isso, registra as acelerações e velocidades angulares da manopla decorrentes dos movimentos transmitidos pela mão. A interpretação desses sinais deverá considerar a influência da empunhadura e do acoplamento mecânico entre a mão e o dispositivo.

A montagem utiliza uma unidade de medição inercial (IMU, do inglês inertial measurement unit) identificada como MPU-9250, da qual são adquiridos três eixos de aceleração e três de velocidade angular. As faixas configuradas são de ±4 g e ±500°/s, respectivamente, com resolução nominal de 16 bits. Uma placa ESP32 DevKit V1, dedicada a esse subsistema na montagem experimental atual, configura o sensor e recebe suas leituras pelo barramento I²C a 100 kHz, com aquisição programada para 100 Hz. Os filtros internos estão configurados para bandas de aproximadamente 44,8 Hz para aceleração e 41 Hz para velocidade angular [17]. Esses valores representam configurações nominais, não resultados de calibração dinâmica do protótipo.

O ESP32 converte as leituras digitais em valores de aceleração, expressos em g, e velocidade angular, em graus

por segundo, utilizando os fatores de escala nominais do sensor. Os dados são transmitidos ao computador por comunicação serial via USB, em registros CSV contendo uma referência de tempo local em milissegundos e os valores dos seis eixos. Essa referência é registrada após a leitura dos dados e ainda não corresponde ao mecanismo de sincronização entre subsistemas previsto na arquitetura.

Assim como nos subsistemas de força, uma aplicação desenvolvida em Python permite acompanhar os sinais durante a aquisição. A implementação utiliza pySerial para comunicação, PySide6 para a interface gráfica, PyQtGraph para visualização e NumPy e SciPy para processamento numérico e filtragem. A aplicação calcula o módulo da aceleração a partir dos três eixos e subtrai o valor de 1 g, produzindo o sinal utilizado na análise exploratória. Sobre esse sinal, aplica um filtro Butterworth passa-faixa de 3 a 12 Hz, configurado com parâmetro de ordem 4 e processamento bidirecional sobre uma janela de até dez segundos.

A partir do sinal filtrado, a aplicação calcula a raiz da média quadrática (RMS, do inglês root mean square) em uma janela de um segundo, utilizada como medida de sua amplitude. Também estima a frequência dominante na faixa analisada por meio da transformada rápida de Fourier (FFT, do inglês fast Fourier transform), aplicada a um trecho de quatro segundos com janela de Hann. Para esse trecho completo, considerando a taxa nominal de 100 Hz, a separação entre os pontos do espectro é de 0,25 Hz.

A interface gráfica apresenta o módulo da aceleração com subtração de 1 g, sua versão filtrada e a evolução do RMS, além dos valores de amplitude e frequência dominante. A Figura 6 ilustra a utilização da manopla com acompanhamento dos sinais na aplicação. As categorias de intensidade exibidas pela interface são baseadas em limiares experimentais definidos no programa e não correspondem a uma classificação clínica validada.

Fig. 6. Manopla em uso experimental e aplicação Python ao fundo, com sinal derivado da aceleração, versão filtrada entre 3 e 12 Hz e amplitude RMS.

F. Organização das unidades de aquisição

Cada um dos três subsistemas anteriormente apresentados utiliza um ESP32 dedicado para facilitar seu desenvolvimento e caracterização independente. Essa escolha permite ajustar circuitos, programas e interfaces sem interferir nos demais módulos, mas não é um requisito da arquitetura. As referências temporais locais descritas anteriormente ainda não implementam sincronização entre subsistemas.

Na integração final, será avaliada a possibilidade de utilização de um único ESP32 para acessar os três subsistemas, centralizar a marcação temporal e comunicar-se com o computador. A decisão dependerá das interfaces disponíveis, dos tempos de leitura e processamento e da capacidade de atender às taxas previstas sem perdas, incluindo a verificação da referência temporal comum.

IV. RESULTADOS E DISCUSSÃO

O principal resultado da etapa pretendida para este trabalho é a definição da arquitetura proposta e sua implementação experimental parcial, composta pela estrutura mecânica e pelos subsistemas de força por dedo, preensão global e sensoriamento inercial, com seus respectivos programas embarcados e interfaces de visualização. Essas implementações permitem acompanhar as respostas dos sensores e apoiar o desenvolvimento de cada subsistema. Entretanto, ainda não estão disponíveis curvas completas de calibração, estimativas de incerteza, medidas de erro de sincronização ou resultados clínicos que permitam considerar o sistema validado.

A organização modular da arquitetura permite avaliar separadamente o comportamento mecânico, a aquisição dos sinais e o processamento dos dados, preparando a integração do conjunto. Conforme descrito na seção anterior, o uso de um ESP32 dedicado a cada subsistema facilita essa etapa, mas os registros atuais ainda não possuem uma referência temporal comum validada. A integração deverá avaliar a possibilidade de centralizar a aquisição em um único ESP32 e implementar o mecanismo de marcação temporal proposto, considerando as diferentes taxas de aquisição e os atrasos de cada canal. A passagem do funcionamento independente para a operação coordenada dos subsistemas será, portanto, uma etapa central da validação da arquitetura.

A contribuição específica da proposta está em reunir, em uma mesma empunhadura, a medição da força por dedo, da preensão global e do movimento da manopla, com previsão de incorporação de EMG e análise por IA. Essa combinação pretende permitir o estudo da contribuição percentual de cada dedo instrumentado em relação à força global e de sua associação com os movimentos observados durante a tarefa. Em relação aos trabalhos sobre modulação da força [18] e luvas multimodais [8], a proposta apresenta uma configuração voltada à investigação da preensão por medidas complementares. Não se afirma, nesta etapa, que essa configuração ofereça maior sensibilidade ou melhor desempenho. O benefício da combinação dos sinais deverá ser investigado por meio da comparação entre análises baseadas em medidas isoladas e conjuntas.

As escolhas da implementação atual também impõem limitações que deverão orientar as próximas etapas. Os FSR exigem calibração individual e avaliação de histerese, fluência e condições de contato mecânico. A medição da preensão global depende da transmissão dos esforços até a célula de carga e da faixa de frequências registrada pelo conversor. As medidas inerciais, por sua vez, podem ser influenciadas pela fixação e orientação do sensor, pelo acoplamento entre a mão e a manopla e pelas opções de processamento. A própria geometria do dispositivo pode alterar a empunhadura e a distribuição dos esforços. Esses fatores deverão ser considerados no projeto mecânico, na caracterização dos sensores e na definição dos protocolos experimentais, sem pressupor que suas influências possam ser compensadas apenas por modelos computacionais [19].

.

V. VALIDAÇÃO PREVISTA E TRABALHOS FUTUROS

A. Caracterização e integração

A validação da proposta será conduzida em etapas, resumidas na Tabela II. Em bancada, cargas de referência serão aplicadas em diferentes níveis e posições, incluindo ciclos de carga e descarga, repetições e manutenção de esforço. Serão estimadas sensibilidade, repetibilidade, histerese, deriva e interferência entre canais. A célula de carga será caracterizada na montagem, com registro da faixa útil e da resposta à sobrecarga prevista em projeto. A IMU será avaliada quanto a escala, orientação e resposta dinâmica com referência apropriada. Cada resultado deverá incluir condições de ensaio e incerteza compatível com a finalidade de medida.

TAELA II. ESTÁGIO DE DESENVOLVIMENTO DOS SUBSISTEMAS

Etapa	Avaliação	Evidência para avançar
Bancada	Carga estática/dinâmica, interferência, deriva, proteção	Curvas e incerteza; faixa de operação documentada
Integração	Referência temporal, sequência, perdas e filtros	Atrasos medidos; lacunas identificadas; dados brutos preservados
Indivíduos Saudáveis	Repetição entre sessões/avaliadores e ergonomia	Confiabilidade e concordância; protocolo executável
Piloto Indivíduos com DP	Estágios I–III, estado medicamentoso, referência clínica	Tolerabilidade e qualidade dos dados; tamanho amostral revisto
Validação	Modelos por participante e avaliação externa	Desempenho com incerteza e domínio de aplicação definido

A integração verificará o contador comum, a correspondência entre marcas temporais e eventos de aquisição, os atrasos de conversão e a continuidade dos registros. Testes específicos de cada cadeia e aquisições prolongadas deverão quantificar defasagens, irregularidades e perdas. Os procedimentos e critérios de aceitação serão definidos antes dos ensaios, conforme as tarefas e características dos sinais que se pretende analisar.

B. Estudos com participantes e análise dos dados

Após os ensaios de bancada, estão previstos estudos de repetibilidade e usabilidade com voluntários saudáveis, seguidos de estudo piloto com pessoas com DP. O planejamento preliminar considera 15 a 30 participantes com DP em estágios I a III de Hoehn e Yahr e um grupo controle, com duas sessões separadas por aproximadamente uma semana. Essa previsão serve à análise de viabilidade; o dimensionamento definitivo dependerá do desfecho primário e da variabilidade observada. O protocolo deverá padronizar postura, mão avaliada, duração, repetições, repouso e instruções, registrando dominância, estado medicamentoso e condições que interfiram na execução.

A avaliação incluirá dinamometria de referência e itens pertinentes da MDS-UPDRS. A repetibilidade será examinada pelo coeficiente de correlação intraclasse; a concordância com a dinamometria, por análise de Bland–Altman, quando as medidas representarem a mesma grandeza, com intervalos de confiança. A associação com as avaliações clínicas será analisada separadamente, preferencialmente com avaliadores cegos aos resultados do dispositivo. Estudos longitudinais exigirão seguimento próprio; diferenças entre pacientes e controles não demonstrarão detecção pré-clínica.

Para a IA, treino e teste serão separados por participante, mantendo suas janelas e sessões no mesmo conjunto. Seleção de atributos, normalização e ajuste dos modelos ocorrerão apenas nos dados de treino, em validação cruzada aninhada. Para regressão serão avaliados erro absoluto médio e raiz do erro quadrático médio; para classificações justificadas pelo protocolo, sensibilidade, especificidade e área sob a curva característica de operação do receptor. Modelos multimodais serão comparados com modalidades isoladas e referências clínicas e demográficas. Os intervalos de confiança deverão respeitar o agrupamento por participante, e conclusões de generalização dependerão de avaliação externa ou temporal.

C. Eletromiografia, segurança e usabilidade

O subsistema de EMG ainda requer desenvolvimento. A cadeia prevista compreende eletrodos de superfície, amplificação diferencial, condicionamento, conversão e integração temporal. Número e posicionamento dos eletrodos, ganho, impedância de entrada, rejeição de modo comum, ruído, banda e taxa de amostragem serão definidos a partir dos músculos e tarefas de interesse. Também serão necessários filtragem antialias, proteção e avaliação da segurança da ligação elétrica com o participante. Nenhuma dessas especificações é apresentada atualmente como implementada.

A análise de riscos será orientada pela norma 14971 da Organização Internacional de Normalização (ISO, do inglês International Organization for Standardization) [20]. Será avaliada a aplicabilidade dos requisitos de segurança elétrica e compatibilidade eletromagnética da série 60601 da Comissão Eletrotécnica Internacional (IEC, do inglês International Electrotechnical Commission) [21], [22]. Não se declara conformidade nesta etapa. Serão considerados fixação, esforço excessivo, aquecimento, limpeza, contato com a pele, isolamento e correntes de fuga, inclusive nas conexões ao computador. A alimentação em baixa tensão não dispensa a avaliação do conjunto.

Avaliações iterativas com profissionais e usuários deverão examinar conforto, diferentes tamanhos de mão, lateralidade, facilidade de uso e higienização. Estudos com participantes dependerão de aprovação ética e consentimento, com pausas e critérios de interrupção por desconforto. Os dados deverão ser protegidos e vinculados a identificadores de pesquisa. O papel pretendido da plataforma é apoiar investigação e avaliação funcional; indicações diagnósticas ou terapêuticas dependerão de validações específicas posteriores.

VI. CONCLUSÃO

Este trabalho apresentou a arquitetura de uma manopla para aquisição multimodal durante tarefas de preensão e descreveu a implementação experimental da estrutura mecânica e dos subsistemas de força por dedo, preensão global e sensoriamento inercial. A organização modular permite avaliar diferentes componentes e desenvolver cada subsistema antes de sua integração.

As próximas etapas compreendem a caracterização metrológica, a integração temporal, a incorporação de EMG e o desenvolvimento da IA. A validação do conjunto e os estudos com participantes deverão estabelecer os limites de medição e a utilidade da plataforma para avaliação motora na DP, ainda não demonstrados nesta etapa.

***Resumo*—Este artigo analisa a estratégia e-SUS Atenção Primária (e-SUS APS) sob o paradigma da Engenharia de Sistemas de Saúde (ESS), integrando evidências de uma década de evolução do Prontuário Eletrônico do Cidadão (PEC). Através de um estudo descritivo e exploratório baseado em uma Síntese Técnico-Científica Multimetodológica, investigou-se a trajetória de informatização das Unidades Básicas de Saúde (UBS) no Brasil. Observou-se que a adesão ao PEC saltou de 8.930 unidades em 2017 para 26.091 em 2022, cobrindo 59,93% da rede primária. Os resultados demonstram que a robustez do sistema advém de uma arquitetura escalável e da aplicação de metodologias de User Experience (UX), embora persista a fragmentação com sistemas nacionais de vigilância, onde 15 de 31 sistemas ainda não possuem unificação de interfaces. Conclui-se que a Engenharia Biomédica é o pilar necessário para garantir a interoperabilidade semântica via RNDS e a transição do PEC de um registro burocrático para um ecossistema de suporte à decisão clínica.**

***Palavras-chave*—e-SUS APS, Engenharia de Sistemas de Saúde, Prontuário Eletrônico do Cidadão, Interoperabilidade, Engenharia Biomédica.**

I. Introdução

A criação do Sistema Único de Saúde (SUS), pela Constituição de 1988, consolidou a saúde como um direito universal e dever do Estado, fundamentado nos princípios de universalidade, integralidade e equidade [6]. Dentro dessa estrutura, a Atenção Primária à Saúde (APS) atua como centro ordenador e a porta de entrada preferencial da Rede de Atenção à Saúde (RAS), desempenhando papel crucial na redução de internações por condições sensíveis e na coordenação do cuidado no território [2].

Historicamente, a gestão da informação no SUS foi marcada por uma profunda fragmentação, caracterizada por "ilhas de informática" e dezenas de Sistemas de Informação em Saúde (SIS) heterogêneos e não integrados [4]. Essa desarticulação forçava o registro redundante de dados, gerando retrabalho para os profissionais e resultando em bases de dados consolidadas com baixa qualidade e confiabilidade, o que dificultava a análise epidemiológica e a tomada de decisão gerencial [4] [3].

Para enfrentar esses desafios, o Ministério da Saúde instituiu, em 2013, a estratégia e-SUS Atenção Primária (e-SUS APS) [7]. O objetivo central foi reestruturar o Sistema de Informação em Saúde para a Atenção Básica (SISAB), rompendo com a lógica milenar de dados puramente consolidados para adotar o registro clínico individualizado, fundamentado no Cartão Nacional de Saúde (CNS) [1]. O núcleo tecnológico dessa transformação é o Prontuário Eletrônico do Cidadão (PEC), uma ferramenta projetada para apoiar o processo de informatização das Unidades Básicas de Saúde (UBS), integrar ferramentas de apoio à decisão clínica e permitir o compartilhamento de informações entre serviços [1] [6].

Sob o paradigma da Engenharia de Sistemas de Saúde, o e-SUS APS transcende a definição de um simples software para se tornar um ecossistema sócio-tecnológico complexo [8]. Sua sustentabilidade depende da integração harmônica

entre infraestrutura tecnológica, governança de dados sensíveis e processos assistenciais dinâmicos [3]. Nesse cenário, a Engenharia Biomédica emerge como disciplina estratégica, atuando na mediação entre as demandas clínicas e as soluções tecnológicas [5]. A contribuição da engenharia é vital para transitar da mera "implantação" (disponibilização técnica) para a efetiva "incorporação" tecnológica, processo que envolve a adaptação contínua do sistema às necessidades do usuário e a garantia da segurança do paciente [5].

Ao completar uma década de implementação em 2023, o PEC consolidou-se como a principal ferramenta de registro eletrônico no Brasil, cobrindo a maioria dos municípios [2]. Contudo, a escalabilidade nacional trouxe novos desafios de interoperabilidade e resiliência de sistemas distribuídos [4] [10]. Este artigo analisa essa trajetória sob a ótica da engenharia, discutindo como a aplicação de princípios de requisitos, arquitetura de dados e padrões semânticos pode superar os gargalos que ainda fragmentam o cuidado no SUS [3].

II. Metodologia

Este trabalho caracteriza-se como um estudo descritivo e exploratório, com abordagem mista (quanti-qualitativa), fundamentado em uma síntese técnico-científica multimetodológica [1]. A investigação foi estruturada para analisar o e-SUS APS não apenas como uma ferramenta isolada, mas sob o paradigma da Engenharia de Sistemas de Saúde, que exige a compreensão das interações entre componentes tecnológicos, processos assistenciais e governança de dados [8]. As etapas desse desenvolvimento metodológico do artigo estão detalhadas na figura 1.

Fig. 1. Fluxograma da metodologia de estudo multimetodológica aplicada no artigo. Elaboração dos autores (2026).

A. Coleta de Dados e Fontes de Evidência

A coleta de dados abrangeu o período de 2013 a 2026, de modo a contemplar o histórico de consolidação do e-SUS APS e as diretrizes de interoperabilidade mais recentes estabelecidas para a Rede Nacional de Dados em Saúde (RNDS). O processo baseou-se em três eixos principais :

1. Dados Secundários Oficiais: Foram extraídas informações da base de dados da Secretaria de Atenção Primária à Saúde (SAPS), incluindo indicadores de adesão nacional ao PEC, informatização das Unidades Básicas de Saúde (UBS) e registros de envio de dados ao Sistema de Informação em Saúde para a Atenção Básica (SISAB) [2] [6].

2. Análise Documental com Critérios de Elegibilidade: Para o levantamento documental, adotou-se como critério de inclusão portarias ministeriais, manuais técnicos e normativas oficiais que regem a infraestrutura do e-SUS APS e a interoperabilidade na RNDS publicadas entre 2013 e 2026. Foram excluídos rascunhos de guias e documentos de consulta pública não homologados. A amostra final compreendeu 15 documentos técnicos estratégicos, incluindo as Portarias nº 1.412/2013 e nº 2.983/2019, o Plano Diretor de Tecnologia da Informação (PDTI) e os manuais técnicos do sistema das versões 3.2 a 5.2. [1] [9] [12].

3. Revisão Científica e Seleção de Literatura: Realizou-se uma busca bibliográfica nas bases LILACS, SciELO, PubMed e nos anais do XXIX Congresso Brasileiro de Engenharia Biomédica (CBEB). Os critérios de inclusão contemplaram artigos originais e revisões que abordavam usabilidade, arquitetura, integração ou impacto assistencial do e-SUS APS e do PEC. Foram excluídos trabalhos duplicados e estudos sem foco direto em sistemas de informação da Atenção Primária [13].

Para a análise temporal da adesão ao e-SUS APS, distinguem-se duas métricas complementares extraídas de bases de dados secundárias da Secretaria de Atenção Primária à Saúde (SAPS/MS):

Informatização Efetiva por PEC (2022): Refere-se à proporção de Unidades Básicas de Saúde (UBS) ativas com o Prontuário Eletrônico do Cidadão (PEC) instalado localmente e enviando dados regularmente ao SISAB, totalizando 26.091 UBS (59,93% do parque instalado), segundo dados do CNES/SAPS de dezembro de 2022.

Cobertura do Ecossistema e-SUS APS (2024): Expressa a taxa de adesão institucional global (97,6% das UBS), abrangendo unidades com PEC local, PEC Nuvem e sistemas próprios integrados cadastrados no Programa Informa e-SUS APS, com base no Painel e-Gestor AB (primeiro semestre de 2024).

B. Modelagem Sistêmica, Avaliação LCIM e Análise de Dados

Para traduzir o funcionamento do e-SUS APS sob a ótica da engenharia, aplicou-se a técnica de Modelagem de Modelo Lógico, baseada no referencial de Thurston e Ramaliu [1].Este modelo permitiu decompor o sistema em Estrutura (Insumos), Processos (Atividades) e Resultados e Impactos. Destaca-se

que as propostas de arquitetura e modelos de integração apresentados neste trabalho constituem modelagens conceituais sistêmicas e analíticas, e não validações empíricas testadas em bancada experimental.

- Estrutura (Insumos): Hardware, conectividade e pessoal qualificado [1].
- Processos (Atividades): Registro clínico via SOAP (Subjetivo, Objetivo, Avaliação e Plano) e fluxo de dados assistenciais [1].
- Resultados e Impactos: Redução do retrabalho, unificação de cadastros e ampliação da capacidade clínica [1].

A análise quantitativa foi realizada por meio de estatística descritiva, utilizando a classificação do IBGE para caracterização de espaços rurais e urbanos, visando identificar desigualdades regionais na maturidade digital assistencial [7]. A avaliação da interoperabilidade seguiu os critérios de conformidade com o padrão HL7 FHIR e a integração com os 31 Sistemas Nacionais de Informação em Saúde (SNIS) identificados na literatura [14].

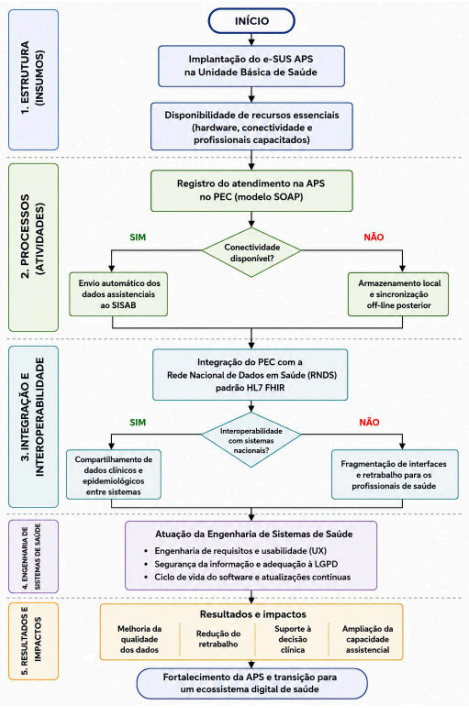

Fig. 2. Modelo lógico e fluxo sistêmico do e-SUS APS sob a perspectiva da Engenharia de Sistemas de Saúde. Elaboração dos autores (2026).

C. Aspectos Éticos e de Integridade

A avaliação do estágio de integração entre o e-SUS APS e os 31 Sistemas Nacionais de Informação em Saúde (SNIS) mapeados na literatura foi realizada de forma objetiva mediante a construção da Matriz de Interoperabilidade baseada no Levels of Conceptual Interoperability Model (LCIM). A pontuação dos sistemas nos quatro níveis do LCIM - Técnico/Fundacional (T), Sintático/Estrutural (S), Semântico (Se) e Organizacional (O). Foi realizada por meio de análise documental sistemática e triangulação de evidências secundárias (manuais de integração, documentação de APIs publicadas pelo DATASUS/MS e literatura técnico-científica), adotando-se uma escala ordinal de 0 a 4:

0 (Inexistente): Ausência de evidências técnicas ou documentais de integração.

1 (Inicial): Integração incipiente, dependente de exportações manuais ou dados em lote.

2 (Parcial): Trocas pontuais e parciais de dados com escopo restrito.

3 (Avançado): Integração estruturada com adoção de padrões e uso regular.

4 (Completo): Integração plena, padronizada e institucionalizada no fluxo de trabalho.

Com base nessas pontuações, calculou-se para cada sistema o Índice de Maturidade de Interoperabilidade (IMI), expresso em percentual (0 a 100 %), conforme a equação (1):

IMD (%) = [(T + S + Se + 0) / 16] * 100

Os sistemas foram subsequentemente categorizados em quatro Níveis de Maturidade: Muito Alto (IMI maior que 80 %), Intermediário (50 % menor que o IMI e menor ingual que 80 %), Baixo (25 % menor que o IMI e menor igual a 50 %) e Muito Baixo (IMI menor igual a 25 %).

TABELA M– Matriz de Interoperabilidade dos 31 Sistemas Nacionais de Informação em Saúde com o e-SUS APS (PEC) segundo o LCIM.

Nº	Sistema Nacional (Órgão Gestor)	Níveis de Interoperabilidade (LCIM)				Índice de Maturidade (0–100)	Nível de Maturidade

LEGENDA DOS NÍVEIS DE INTEROPERABILIDADE (LCIM)

0 – **Inexistente:** Não há evidências de integração.
1 – **Inicial:** Integração incipiente ou pilotos isolados; dependência de processos manuais.
2 – **Parcial:** Integração parcial com trocas limitadas de dados ou sem padronização consistente.
3 – **Avançado:** Integração estruturada com padrões adotados e uso regular.
4 – **Completo:** Integração plena, padronizada e institucionalizada no processo de trabalho.

CÁLCULO DO ÍNDICE DE MATURIDADE (IMI)

$$IMI = \frac{(T + S + Se + O)}{16} \times 100$$

Onde:
T = Técnico/Fundacional;
S = Sintático/Estrutural;
Se = Semântico;
O = Organizacional.

CLASSIFICAÇÃO DO NÍVEL DE MATURIDADE (IMI)

- **Muito Alto (81–100):** Interoperabilidade consolidada e institucionalizada.
- **Intermediário (51–80):** Interoperabilidade em desenvolvimento.
- **Baixo (26–50):** Integração limitada e não sistematizada.
- **Muito Baixo (0–25):** Ausência ou integração incipiente.

Elaborado pelos autores (2026).

Por utilizar exclusivamente dados secundários e anônimos de acesso público, este estudo está dispensado de apreciação pelo Comitê de Ética em Pesquisa, conforme a Resolução CNS 510/2016 [1]. A análise técnica manteve a neutralidade frente aos modelos de desenvolvimento (b-thinking) adotados pelos laboratórios parceiros do Ministério da Saúde [6].

O marco fundamental da infraestrutura de interoperabilidade no SUS foi a consolidação da Rede Nacional de Dados em Saúde (RNDS), fundamentada no padrão internacional HL7 FHIR. No entanto, a integração efetiva de interfaces com os demais Sistemas Nacionais de Informação em Saúde (SNIS) ainda enfrenta desafios de maturidade heterogênea. Para avaliar objetivamente o estágio de integração do e-SUS APS com os 31 SNIS mapeados, aplicou-se a matriz baseada no Levels of Conceptual Interoperability Model (LCIM), cujos resultados detalhados e pontuações por nível (Técnico, Sintático, Semântico e Organizacional) estão consolidados na Tabela M.

As propostas arquiteturais apresentadas neste estudo possuem caráter teórico e conceitual, sendo elaboradas a partir da análise da literatura científica e da documentação técnico-institucional selecionada. Dessa forma, os modelos propostos não correspondem a implementações em ambiente real nem foram submetidos a testes ou validações empíricas pelos autores. Sua finalidade é representar cenários possíveis de integração e apoiar a discussão sobre a evolução do ecossistema e-SUS APS. São propostas conceituais derivadas da análise, não resultados de uma implementação experimental.

D. Limitações do Estudo

Reconhecimento da Natureza do Estudo e Limitações:

Cumpre ressaltar, quanto à natureza metodológica do presente trabalho, que a análise do ecossistema e-SUS APS e a mensuração do Índice de Maturidade de Interoperabilidade (IMI) fundamentam-se exclusivamente no levantamento de dados secundários e na análise documental sistemática de portarias, normativas, manuais técnicos e documentações de APIs publicadas pelo Ministério da Saúde e DATASUS. Dessa forma, a classificação de não-integração ou de baixa maturidade atribuída aos sistemas nacionais de informação decorre estritamente do enquadramento desse arcabouço normativo, documental e arquitetural disponível até o presente momento. A caracterização de tais barreiras operacionais não constitui resultado de testes técnicos de interoperabilidade direta, como simulações de rotas de API, análises de pacotes em ambiente de homologação ou testes de bancada experimental.

III. Resultados

A. Evolução do e-SUS APS

O e-SUS APS consolidou-se como a principal ferramenta de registro eletrônico no Brasil. A adesão demonstrou crescimento acelerado após a instituição do programa Informatiza APS em 2019, que vinculou o financiamento à qualificação dos dados enviados ao SISAB [2] [3]. Esse cenário impulsionou a transformação digital do Sistema Único de Saúde (SUS), otimizando a gestão local e o monitoramento das políticas públicas de saúde. Como resultado, o sistema passou a subsidiar de forma mais robusta o planejamento estratégico e a continuidade do cuidado aos usuários na rede pública, fortalecendo a integração e a transparência das informações em saúde em todo o território nacional.

Tabela I
Evolução da adesão ao PEC nas Unidades Básicas de Saúde (2017–2022)

Região	UBS com PEC (2017)	UBS com PEC (2022)	Crescimento (%)
Norte	631	2.247	256,10%
Nordeste	2.618	12.245	367,72%
Centro-Oeste	1.014	2.201	117,06%
Sudeste	2.724	7.002	157,04%
Sul	1.943	2.396	23,31%
Brasil (Total)	8.930	26.091	192,17%

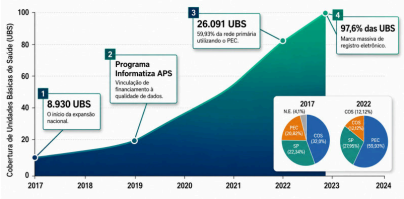

Fig. 3. Curva de crescimento e marcos de adesão nacional ao PEC (2017 - 2024). Elaboração dos autores (2026).

Os dados integrados da Tabela 1 e da Figura 3 revelam que a expansão do PEC não ocorreu de forma imediata ou homogênea no território nacional. Enquanto a região Nordeste apresentou o incremento mais acentuado em termos absolutos e percentuais (367,72%), saltando de 2.618 para 12.245 UBS conectadas, a região Sul manteve um crescimento gradual (23,31%), reflexo de uma cobertura assistencial previamente estabelecida. Esse avanço descentralizado resultou no marco histórico de 2024, atingindo 97,6% de cobertura nacional e consolidando a transição do modelo de Coleta de Dados Simplificada (CDS) para o Prontuário Eletrônico do Cidadão (PEC) sendo considerado o canal principal de melhoria no sistema de saúde da APS.

A evolução observada entre a taxa de 59,93% de informatização efetiva por PEC em 2022 (26.091 UBS) e a cobertura de 97,6% atingida em 2024 reflete uma transição metodológica e estrutural na infraestrutura da Atenção Primária. Em 2022, a métrica refletia primariamente a instalação local do software PEC em servidores físicos municipais, processo limitado por barreiras de conectividade e aquisição de hardware. A aceleração verificada até 2024 justifica-se por três fatores indutores:

(i) a consolidação do Programa Informa e-SUS APS, que vinculou os repasses financeiros federais de custeio ao envio contínuo de dados;

(ii) a expansão da modalidade PEC Nuvem e de sistemas municipais próprios interoperáveis via APIs REST/Thrift; e

(iii) a disseminação de aplicativos móveis com sincronização assíncrona (e-SUS Território), viabilizando o registro digital em áreas remotas.

Dessa forma, o incremento temporal traduz a passagem de um modelo focado na infraestrutura física local para uma cobertura ampliada do ecossistema de dados da APS.

- Mudança de Paradigma (2025): Em junho de 2025, o Sistema de Informação para a Atenção Primária à Saúde (SIAPS) substituiu oficialmente o antigo Sistema de Informação em Saúde para a Atenção Básica (SISAB) como a plataforma central da APS digital. Essa transição visou superar gargalos de performance e latência que limitavam a análise de dados em tempo real nas décadas anteriores. O novo sistema focou principalmente em uma arquitetura de melhor usabilidade e confiabilidade, possuindo integração nativa com a Rede Nacional de Dados em Saúde (RNDS) [6]. Esse ecossistema atingiu cerca de 60 milhões de downloads e 29 milhões de usuários ativos mensais no aplicativo Meu SUS Digital em 2025 [6].
- Perspectiva 2026: O Guia de Informática em Saúde de 2026 já define a interoperabilidade semântica via FHIR R4 (Fast Healthcare Interoperability Resources, Release 4) como o padrão estável e obrigatório para mandatos nacionais, consolidando a RNDS como o repositório de mais de 2,8 bilhões de registros clínicos [11].

B. Arquitetura e Engenharia de Sistemas de Saúde

A arquitetura do PEC evoluiu para suportar a complexidade de 5.570 municípios. Inicialmente baseado em H2, o sistema migrou para PostgreSQL e Oracle, garantindo escalabilidade nacional [6]. O desenvolvimento adota a metodologia b-thinking, que integra desenvolvimento ágil, User Experience (UX) e privacy by design [6]. O registro clínico é estruturado no formato SOAP (Subjetivo, Objetivo, Avaliação e Plano) [1].

C. O Paradoxo da Cobertura em Saúde e o Retrabalho Assistencial na Ponta

A análise integrada dos indicadores de expansão e maturidade revela uma importante assimetria estrutural na saúde digital brasileira: uma alta taxa de cobertura de implantação do PEC (97,6%) não se traduz, necessariamente, em uma interoperabilidade real de dados clínicos na rotina diária[1]. Embora a expansão do ecossistema e-SUS APS tenha sido praticamente universalizada no parque instalado das Unidades Básicas de Saúde (UBS), a troca fluida e automatizada de dados com os demais Sistemas Nacionais de Informação em Saúde (SNIS) permanece altamente fragmentada[1] [6].

A aplicação da matriz LCIM demonstra quantitativamente esse paradoxo: enquanto a cobertura física do sistema atinge patamares universais, a interoperabilidade de alta maturidade (nível Muito Alto, IMI maior que 80%) restringe-se a apenas 5 dos 31 sistemas mapeados (16,1%), limitando-se ao núcleo cadastral básico (como CADSUS e CNES)[cite: 1, 5]. Por outro lado, 16 dos 31 sistemas analisados (51,6%) situam-se nas faixas de maturidade Baixa e Muito Baixa (IMI menor igual que 50%), operando de forma isolada e sem comunicação automatizada com o prontuário eletrônico[1] [5].

Na rotina diária das equipes de Saúde da Família, esse isolamento do bloco de 16 sistemas (que inclui o e-SUS Notifica, SIVEP-Gripe, SI-Malária, SISLEISH, SIPNI e BPA-i) impacta diretamente os profissionais de saúde na ponta, gerando um expressivo gargalo de retrabalho assistencial[1] [5]

- Dupla Digitação e Sobrecarga Burocrática: Ao realizar um atendimento clínico ou procedimento (como a notificação de um caso suspeito de arbovirose ou o registro vacinal), o profissional de saúde é obrigado a registrar a evolução clínica no PEC e, em seguida, reescrever as mesmas informações sociodemográficas e epidemiológicas em portais e sistemas web paralelos da vigilância em saúde[1] [5].
- Carga Cognitiva vs. Tempo de Atendimento: A necessidade de navegar por múltiplas interfaces com diferentes credenciais de acesso consome um tempo precioso do atendimento, reduzindo a disponibilidade de tempo efetivo para a escuta qualificada, anamnese e exame físico do paciente.
- Riscos à Qualidade dos Dados e Subnotificação: A repetição manual do lançamento de dados em interfaces distintas aumenta exponencialmente o risco de erros de transcrição e divergências de cadastro. Ademais, em momentos de sobrecarga de demanda na UBS, a rotina burocrática força os profissionais a postergar ou omitir o preenchimento nos sistemas secundários isolados, gerando subnotificação e comprometendo a fidelidade dos indicadores epidemiológicos nacionais.

Portanto, o avanço da saúde digital na Atenção Primária não pode mais ser medido apenas pela distribuição e cobertura física de software[1] [6]. Superar o retrabalho dos profissionais da ponta exige que a Engenharia de Sistemas de Saúde direcione esforços para a interoperabilidade semântica e sintática via padrões como o HL7 FHIR R4 na RNDS, assegurando que o dado registrado uma única vez no PEC alimente de forma transparente e assíncrona todo o ecossistema público de saúde[1] [5].

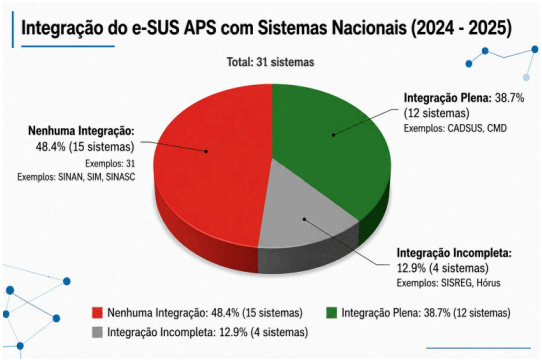

Fig. 4. Situação de integração de interfaces entre o e-SUS APS e os Sistemas Nacionais de Informação em Saúde (SNIS) do ano de 2024 a 2025 [4]. Elaboração dos autores (2026).

Como observado na Figura 4, a respeito do avanço na cobertura técnica, a persistência de 15 dos 31 sistemas nacionais (48,4%) operando com severas barreiras de integração

demonstra que o ecossistema de saúde digital brasileiro ainda opera em silos de informação. Para a Engenharia de Sistemas de Saúde, este dado reforça a urgência da implementação de padrões semânticos e da RNDS para superar o retrabalho dos profissionais na ponta e garantir a integridade dos dados clínicos.

D. Contribuições da Engenharia de Sistemas de Saúde

A Engenharia de Sistemas de Saúde pode contribuir para a sustentabilidade e eficiência dos processos nas instituições de saúde, especialmente por meio da integração entre aspectos clínicos, tecnológicos e de gestão. Nesse contexto, um estudo de caso realizado em 2025 no Hospital Monsenhor Walfredo Gurgel (HMWG), em Natal/RN, relatou um incremento de 23,47% no faturamento por Autorização de Internação Hospitalar (AIH) após a substituição de fluxos analógicos por processos apoiados em prontuário digital [18]. No período analisado, o faturamento passou de 19,4 milhões de reais para 23,9 milhões de reais ao longo de oito meses [18]. Esse resultado sugere uma possível associação entre a qualificação dos registros clínicos e a melhoria dos processos de faturamento; entretanto, por se tratar de um único estudo de caso, não permite estabelecer relação causal nem generalizar esse efeito para outras instituições. A Engenharia de Sistemas atua com suma importância na transição da implantação (instalação técnica) para a incorporação (processo dinâmico de treinamento e adaptação) [5]. As principais contribuições incluem:

- Engenharia de Requisitos: Adaptação das interfaces para cenários de baixa conectividade, resultando em aplicativos móveis com sincronização offline (e-SUS Território) [6].
- Segurança e Resiliência: Implementação de autenticação forte (MFA) e criptografia para proteção de dados sensíveis conforme a LGPD [13].
- Ciclo de Vida de Software: Gestão de atualizações para correção de falhas e adequação a novas políticas como o Previne Brasil [6].

E. Perspectivas Futuras

Como perspectiva futura, a evolução do ecossistema e-SUS APS pode envolver a investigação de recursos de Inteligência Artificial (IA) e modelos de linguagem aplicados aos registros clínicos, visando ampliar o potencial de apoio à decisão clínica. Nesse contexto, Modelos de Fundação (FMs) e Large Language Models (LLMs) constituem possibilidades tecnológicas a serem avaliadas em estudos futuros, especialmente quanto à capacidade de processar informações clínicas não estruturadas [15]. O GatorTron, por exemplo, é apresentado na literatura como um modelo de linguagem clínica desenvolvido para processamento de textos médicos [16]. Entretanto, sua utilização no e-SUS APS não foi implementada nem avaliada experimentalmente neste estudo, sendo apresentada apenas como possibilidade de investigação futura.

A Figura 5 apresenta um cenário conceitual de integração de tecnologias associado às perspectivas da Saúde 4.0 no SUS. Nesse cenário prospectivo, a interoperabilidade semântica, os

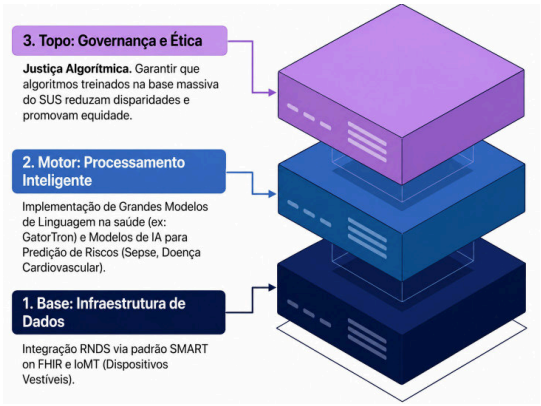

Fig. 5. Cenário conceitual e perspectivas futuras para a Saúde 4.0 no ecossistema do e-SUS APS. Estruturação analítica sem validação empírica direta no presente trabalho. Elaboração dos autores (2026).

padrões de integração e os mecanismos de governança constituiriam elementos fundamentais para eventual incorporação de recursos de IA, LLMs e dispositivos de Internet das Coisas Médicas (IoMT). Padrões como SMART on FHIR poderiam ser investigados como mecanismos de integração entre aplicações e sistemas de informação em saúde [17]. Nesse cenário hipotético, modelos de fundação e LLMs, incluindo o GatorTron, poderiam ser investigados para tarefas de processamento e interpretação de informações clínicas não estruturadas [16]. A efetividade, segurança, desempenho e aplicabilidade desses modelos no contexto do e-SUS APS dependeriam de avaliações experimentais específicas, que não fazem parte do escopo deste estudo.

De forma prospectiva, dispositivos vestíveis e biossensores poderiam ser investigados como fontes adicionais de dados para o ecossistema de saúde digital, incluindo informações de monitoramento contínuo, como glicemia e frequência cardíaca. A eventual integração desses dados ao fluxo de cuidado do PEC dependeria de estudos de viabilidade, interoperabilidade, segurança, privacidade e validação clínica.

Ressalta-se que a arquitetura apresentada na Figura 5 possui caráter conceitual e prospectivo, não constituindo uma arquitetura implementada ou validada experimentalmente pelos autores. Dessa forma, sua utilização como estratégia de apoio à decisão clínica permanece como hipótese para pesquisas futuras, devendo ser precedida por avaliações técnicas, clínicas, éticas e de segurança.

IV. Conclusão

Ao completar sua primeira década, o e-SUS APS consolidou-se como um dos maiores bancos de dados de saúde primária do mundo, atingindo uma cobertura nacional de 97,6% das UBS em 2024 [11] [12]. Entretanto, os resultados deste estudo indicam que a efetividade plena desse ecossistema ainda é limitada pela fragmentação de interfaces, onde 15 de 31 sistemas nacionais de informação permanecem isolados, gerando retrabalho e inconsistência de dados [13] [14]. A Engenharia de Sistemas de Saúde emerge como o elo científico

capaz de converter esse volume massivo de registros em conhecimento clínico aplicado, utilizando a RNDS e padrões semânticos robustos como o HL7 FHIR R4 [4] [11].

Nesse contexto, o papel do Engenheiro Biomédico como 'profissional de interface' é determinante: ele atua na zona de convergência entre as complexas demandas assistenciais e o rigor dos requisitos técnicos, sendo o agente capaz de viabilizar a transição da mera implantação física para a efetiva incorporação tecnológica [15]. Sua intervenção garante que o prontuário eletrônico transcenda a função de repositório burocrático para tornar-se um ecossistema dinâmico de suporte à decisão clínica, atuando como pilar de sustentabilidade institucional e de segurança do paciente [15] [16].

Em última análise, a transformação digital do SUS não deve ser reduzida a um processo de informatização técnica; trata-se de um projeto político-técnico de fortalecimento da cidadania sanitária, orientado pela justiça algorítmica e pelo compromisso inalienável com a equidade em saúde para todos os brasileiros [10].

***Abstract*—We present a binary ictal-vs-non-ictal classifier for neonatal scalp EEG, trained and evaluated *cross-patient* with strict Leave-One-Subject-Out (LOSO) over all 79 term neonates of the Helsinki dataset. A compact EEGNet-style CNN is trained on 8 s windows with a clean three-expert consensus ground truth and an aggregation that separates the 39 seizure-bearing subjects from the 40 consensus-negative ones (ranking metrics over the former; specificity and false-alarm rate over all). The full 79-fold study was run at scale on the NPAD supercomputer (NVIDIA V100 GPUs). The detector reaches a pooled AUROC of ≈ 0.81 (best configuration 0.807), a cross-patient baseline; post-hoc event-level scoring with causal, real-time-compatible smoothing already detects $\approx 79\%$ of seizures at ≈ 3.5 false alarms/h, and inference takes ≈ 1.8 ms per 8 s window on a CPU, well within real time for bedside use. As secondary analyses we ablate two input-representation choices usually assumed rather than measured, the montage (referential 19-channel vs. bipolar "double-banana") and per-recording z-score normalization, and add a second, channel-mixing CNN as a control: z-score helps both montages modestly, the two montages reach a comparable pooled AUROC and trade sensitivity for specificity, and the normalization benefit is specific to the compact EEGNet rather than universal. Future work will focus on optimizing this model to run on our custom, low-cost microprocessed EEG hardware within an Artificial Intelligence of Things (AIoT) framework, helping to universalize neonatal neurological care.**

***Index Terms*—neonatal EEG, seizure detection, cross-patient, leave-one-subject-out, EEGNet, convolutional neural network, electroencephalography.**

I. Introduction

In the neonatal intensive care unit (NICU), electrographic-only seizures are among the most frequent neurological manifestations. Because nearly 50% of these events in the first days of life are entirely subclinical, continuous EEG monitoring remains the only reliable method for their identification. This reality strongly motivates the development of automated EEG-based detection systems to support real-time bedside clinical decisions. In this work, we propose a seizure detection classifier grounded in three guiding principles. First, cross-patient generalization: a model is only clinically useful if it performs on babies it has never seen, since neonatal seizure morphology is highly subject-specific. We therefore enforce Leave-One-Subject-Out (LOSO) evaluation, ensuring that no window from the test subject ever appears in training. Second, class-aware metrics: with a rare positive class, a trivial "all-negative" classifier would score high accuracy while detecting nothing, so we report sensitivity, specificity, AUROC (area under the receiver operating characteristic curve), AUPRC (area under the precision–recall curve), and false positives per hour (FP/h), the metric that governs alarm burden in the NICU. Third, comparability: results are benchmarked against established neonatal baselines, specifically Temko *et al.* [3] (support vector machines) and O'Shea *et al.* [4] (fully convolutional networks).

The contribution of this paper is not the proposal of a new architecture, but a leak-free cross-patient neonatal seizure classifier on the full public Helsinki cohort: a compact EEGNet trained and tested under strict 79-fold LOSO, with aggregation separating seizure-bearing from consensus-negative subjects. Around this baseline, we introduce two controlled secondary analyses of input-representation choices that are often assumed rather than empirically measured: the EEG *montage* (referential vs. bipolar) and the input *normalization* (raw vs. per-recording z-score). These are quantified on identical LOSO splits over the public Helsinki neonatal EEG dataset [1], [2], alongside a second architecture included as a generalization control. Finally, further work is currently underway to optimize this model for resource-constrained embedded systems (e.g., using TinyML frameworks), paving the way for low-cost, real-time edge computing at the neonatal bedside.

II. Related Work

Automated neonatal seizure detection has a substantial history. Early systems combined hand-engineered features with classical classifiers: Temko *et al.* [3] trained a support vector machine over spectral, temporal, and information-theoretic features and established a strong patient-independent baseline, and Tapani *et al.* [6] showed that time-varying EEG correlation features further improve detection. The field then moved to deep learning on raw EEG: O'Shea *et al.* [4] proposed a

[†]These authors contributed equally to this work.

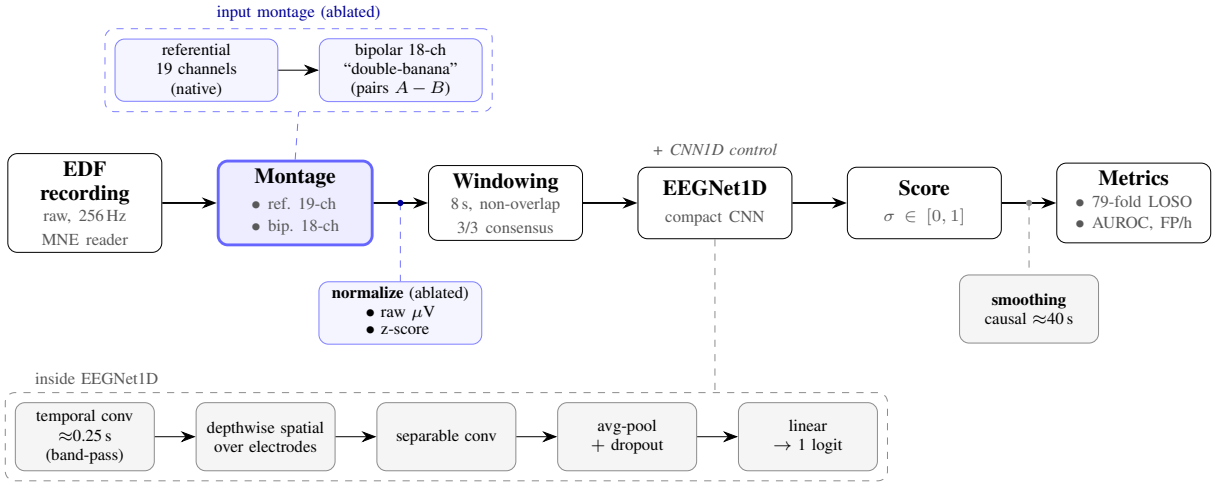

Fig. 1. End-to-end processing pipeline: a 256 Hz EDF recording is converted to the referential or bipolar montage, optionally per-recording z-scored, sliced into non-overlapping 8 s windows, and classified by `EEGNet1D` into a per-window score aggregated under 79-fold LOSO. The insets expand the bipolar “double-banana” derivations (top) and the `EEGNet1D` stages (bottom). Input *montage* and *normalization* are the 2×2 ablated factors.

fully convolutional network that matched or exceeded the feature-based SVM without manual feature engineering, while Ansari *et al.* [7] combined convolutional networks with a heuristic classifier. The clinical viability of such algorithms was assessed by Pavel *et al.* [8] in a multicentre randomised trial. Most recently, Hogan *et al.* [9] showed that scaling a convolutional network to more than 50,000 h of annotated EEG attains expert-level detection, showing that data scale, not only architecture, drives performance. Deep learning on EEG more broadly is surveyed by Roy *et al.* [10]. Compact, EEG-specific architectures such as EEGNet [5], originally designed for brain–computer interfaces, offer a low-parameter alternative that is attractive in the data-limited, leakage-sensitive neonatal setting. A parallel line replaces task-specific supervision with self-supervised pre-training on large unlabelled EEG corpora, through contrastive Transformer encoders [11] or tokenized foundation models pre-trained on thousands of hours of recordings [12]. These are the high-capacity counterpart to the compact model studied here, and Section V returns to the trade-off.

Our work sits in this raw-EEG CNN line, with the emphasis on the evaluation protocol rather than on the network: a cross-patient *baseline* over the full public cohort, around which we measure two *input-representation* choices (the recording montage and the per-recording amplitude normalization) that prior work typically fixes implicitly. To our knowledge this combination, on this dataset, has not been reported.

III. Materials and Methods

Fig. 1 summarizes the full processing pipeline; the stages are detailed below.

A. Dataset

The Helsinki neonatal EEG seizure dataset [1], [2] comprises 79 term neonates recorded in the NICU of Helsinki University Hospital at 256 Hz, with a referential 10–20 montage (∼19 EEG electrodes plus ECG and respiration). Seizures are annotated per second by three independent experts; annotation column j (0-based) corresponds to file `eeg{j+1}.edf`. The data are released under CC BY 4.0; the full set of 79 EDFs is ≈4.33 GB.

Treating a second as ictal only when all three experts agree (the project’s ground truth), 39 of 79 subjects have seizures (46 by majority ≥2/3; 58 by any expert), with ≈10.9 h of total consensus seizure time. The ictal fraction is high relative to scalp-EEG seizure corpora, which makes the positive class comparatively well represented and the cross-patient task tractable. Fig. 2 shows an example recording with its consensus annotation and the two 8 s window classes the model must separate.

a) EDF heterogeneity: The 79 EDF files are not uniform: some are plain EDF (electrode suffix `-REF`), others are declared EDF+C yet contain no “EDF Annotations” signal and use a lowercase `-Ref` suffix, and the physical channel order varies between subjects. The strict reader `pyedflib` rejects the EDF+C-without-annotations files outright, so we read every recording with MNE (`mne.io.read_raw_edf`), verified to reproduce `pyedflib`’s output to $\sim 10^{-13}\,\mu$V on a file both can read. Channel names are normalized case-insensitively and reordered to a fixed canonical order, so per-subject ordering is irrelevant downstream.

B. Labels and windowing

Each annotation CSV is read with its header skipped, so data-row i is second i. The three expert columns are summed per second and thresholded at consensus ($= 3$); contiguous ictal seconds are collapsed into half-open intervals $[s, e)$. Signals are sliced into 8 s windows at 256 Hz (2048 samples), the window length of the dominant neonatal baselines. A window spanning $[t_0, t_1)$ is labelled ictal when it overlaps any

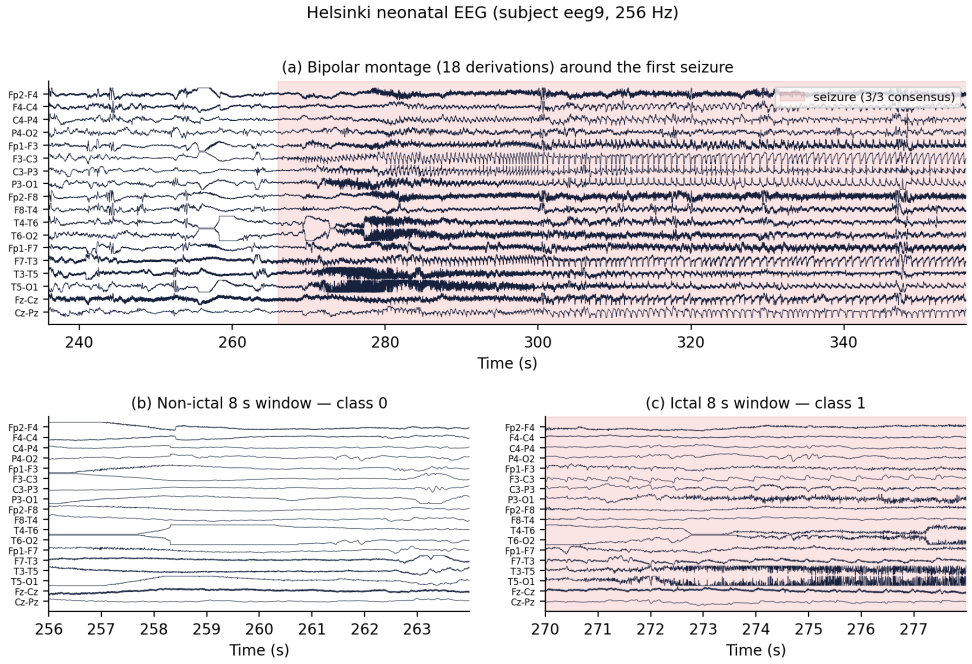

Fig. 2. Example data and the two classes (subject `eeg9`, bipolar "double-banana" montage, 256 Hz; traces per-channel scaled for display). **(a)** A 120 s segment around the first seizure onset, the red span marking the 3/3-consensus ictal interval. **(b)** A non-ictal 8 s window (class 0). **(c)** An ictal 8 s window (class 1); each 8 s window is one input.

consensus interval,

$$y = \mathbb{1}\left[\exists\,[s, e) \in I : t_0 < e \ \wedge\ t_1 > s\right], \tag{1}$$

where I is the set of consensus intervals. The full-cohort study uses non-overlapping windows (stride = window) for both training and evaluation, which avoids double counting at evaluation and, given this corpus's high ictal fraction, makes overlap-as-augmentation unnecessary; the validation gate alone (Table I) used a 4 s stride (50% overlap). Treating the label as intervals rather than a per-second mask makes window labelling independent of window length and robust to CSV padding.

C. Input montages (ablated)

Two montages are compared on identical splits. The referential montage uses the 19 native electrodes (Fp1, Fp2, F3, F4, C3, C4, P3, P4, O1, O2, F7, F8, T3, T4, T5, T6, Fz, Cz, Pz) as recorded, the simplest baseline. The bipolar montage is the longitudinal "double-banana" (18 derivations), each a difference of two referential electrodes obtained by a pure re-montage function:

Fp2–F4, F4–C4, C4–P4, P4–O2, Fp1–F3, F3–C3, C3–P3, P3–O1,
Fp2–F8, F8–T4, T4–T6, T6–O2, Fp1–F7, F7–T3, T3–T5, T5–O1,
Fz–Cz, Cz–Pz.

Fig. 3 maps these derivations onto the scalp. This is the representation of clinical practice and the neonatal literature, emphasizing local gradients and attenuating common-reference noise, which is why we include it in the ablation rather than assuming it helps. To keep the montage identical across subjects, a derivation is emitted only when both of its electrodes survive the across-cohort intersection. The same network accepts 19 or 18 channels with no code change. Both montages derive from the same time samples, so they are two views of one recording (Fig. 4).

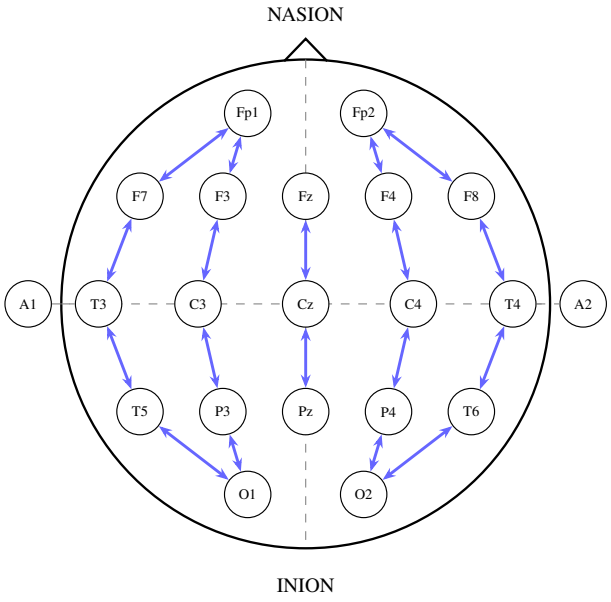

Fig. 3. Scalp map (top view, 10–20 system): the 19 referential electrodes (circles) and the 18 bipolar "double-banana" derivations (blue arrows); A1/A2 are auricular references. Adapted from Fig. 1 of [1].

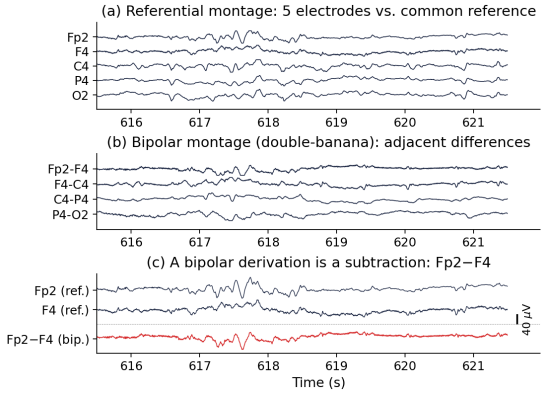

Fig. 4. Referential and bipolar montages of the *same* 6 s ictal segment (`eeg9`). **(a)** Five referential electrodes of the right-medial chain (Fp2, F4, C4, P4, O2). **(b)** Their four bipolar derivations (Fp2–F4, F4–C4, C4–P4, P4–O2). **(c)** The subtraction in real microvolts: Fp2–F4 (red) is the referential Fp2 minus F4, attenuating the common-mode component.

D. Input normalization (ablated)

EEG amplitude scale varies markedly between neonates and recordings (electrode impedance, age, pathology). We ablate two scalings: raw microvolts, and a per-recording, per-channel z-score, in which each channel c of recording r is standardized using only its own statistics,

$$\tilde{x}_{c,t} = \frac{x_{c,t} - \mu_c^{(r)}}{\sigma_c^{(r)}}, \tag{2}$$

where $\mu_c^{(r)}, \sigma_c^{(r)}$ are computed within recording r only (a constant channel, $\sigma \approx 0$, is left centred to avoid division by zero). Being a per-channel affine rescaling, the z-score discards only this nuisance amplitude scale while leaving the waveform *morphology*, the rhythmic shape that signals a seizure, intact. Because the statistics never cross subjects, the z-score introduces no LOSO leakage, in contrast to a global standardization, which would let the held-out subject influence the training scale.

E. Model and training

The classifier, which we refer to in code as `EEGNet1D`, is our PyTorch reimplementation of the published EEGNet architecture [5]; it is not a new network. We keep EEGNet's canonical design and hyperparameters (F_1=8 temporal filters, depth multiplier D=2, dropout 0.25) and adapt only the output to a single binary logit (used with `BCEWithLogitsLoss`); the one data-dependent choice is the temporal kernel width (≈0.25 s, i.e. 64 samples at 256 Hz). An input window (C, T) is reshaped into a single-channel $(1, C, T)$ map so that temporal and spatial filtering separate, and three stages follow (Fig. 1): a *temporal* convolution of width ≈0.25 s applied per electrode, acting as a learned band-pass filter bank; a *depthwise spatial* convolution spanning all electrodes at once, collapsing the electrode axis; and a *separable* convolution for higher-level temporal structure. Average pooling and dropout follow the last two, and a linear layer maps the flattened features to one logit per window. That flattened size is computed dynamically, so the same architecture serves the 19- and 18-channel montages without modification. The whole network has only 2433 parameters (≈10 KB in fp32), small enough for microcontroller memory.

Training uses Adam (lr $= 10^{-3}$, batch 64), 15 epochs per fold. The strong class imbalance is handled automatically by weighting the positive class in the loss,

$$\text{pos_weight} = n_{\text{neg}}/n_{\text{pos}}, \tag{3}$$

computed per fold from the training split, so the minority (ictal) class is up-weighted without resampling or discarding data. Hyperparameters are fixed a priori (no nested cross-validation) to avoid tuning leakage in the LOSO loop, and model initialization is seeded per fold for reproducibility. The model is compute-bound (the depthwise/grouped convolutions do not benefit from tensor cores, so fp32 was empirically faster than mixed precision here); with each of the eight ablation conditions run as one independent GPU job, the full 79-fold study completes in about three hours of wall-clock.

F. Evaluation: LOSO and metric aggregation

For each held-out subject i, the model trains on the concatenation of all other subjects and scores subject i (structural anti-leakage). Per-fold metrics are sensitivity, specificity, AUROC, AUPRC, and false positives per hour (FP/h).

A central methodological choice of this work is *how* these per-subject metrics are aggregated across the cohort, because a naive cohort mean is misleading. Of the 79 neonates, only 39 have seizures under the consensus rule and 40 are consensus-negative. Such a test subject contains a single class, for which a ranking metric such as AUROC (and likewise AUPRC and per-subject sensitivity) is mathematically *undefined*. We therefore partition the aggregation by what each metric can measure:

- *AUROC, AUPRC, sensitivity* are averaged *only* over the 39 seizure-bearing subjects, where the positive class exists; the 40 single-class subjects yield *nan* and are excluded from these means.
- *Specificity and FP/h* are averaged over *all 79* subjects, because the 40 consensus-negative recordings are precisely where false alarms can occur and are thus what make the false-positive rate representative; excluding them would flatter the model.

We additionally report a *pooled* AUROC (every fold's window scores concatenated into one ranking) as a threshold-free headline that does not depend on this partition.

Three estimation levels are kept distinct throughout. *Window-level* metrics score each 8 s window independently and underlie Table II; the threshold-dependent ones (sensitivity, specificity, FP/h) use a fixed operating point of 0.5 on the sigmoid output, with no per-subject or per-fold calibration. *Subject-level* estimates are those per-fold values aggregated as above, each mean carrying its across-fold sample standard deviation (ddof = 1). *Event-level* metrics score whole seizures after causal post-processing and are reported separately (Section IV-B).

G. Reproducibility

The pipeline is the `neoseiz` Python package (windowing, model, training, evaluation, EDF/data I/O, and the LOSO runner) developed test-first with 59 passing unit/integration tests covering windowing, both channel counts, consensus parsing, the real-recording read, z-score behaviour, both architectures, LOSO anti-leakage and aggregation, and the real-time streaming path. For the full study, all 79 subjects are windowed once into a single in-RAM `float32` array (≈9 GB peak resident per job) and each fold gathers mini-batches by vectorized indexing (no per-sample data loader), keeping the GPU saturated. The full study was run on UFRN's NPAD supercomputer, one NVIDIA Tesla V100 (16 GB) GPU per condition under Slurm, with PyTorch 2.6 (CUDA 12.4) and Python 3.12; each condition took about 2–3 h for its 79 folds and all eight ran concurrently; all reported numbers are from these NPAD runs. The pipeline was developed and prototyped on a commodity desktop (NVIDIA RTX 5060 Ti, PyTorch 2.11/CUDA 12.8). MNE, NumPy, SciPy and scikit-learn complete the stack.[1]

IV. Results

A. Validation gate

Before committing GPU time to the full study, a six-subject gate verified pipeline correctness on a deliberately diverse subset: `eeg3` (no consensus seizures, exercising the specificity / *nan* path), `eeg4` (an EDF+C file with the `-Ref` suffix, exercising the MNE reader), and `eeg5`, `eeg7`, `eeg9`, `eeg13` (seizure-bearing), totalling 8567 windows (Table I). Subject leakage was provably absent (per fold, $n_{\text{train}} + n_{\text{test}}$ equals the cohort total, e.g. $8567 - 1102 = 7465$ for `eeg3`); the consensus-negative subject correctly yielded *nan* sensitivity/AUROC while still contributing specificity and FP/h; the heterogeneous EDF headers were read correctly; and all aggregate quantities were finite. The gate was an implementation check only: no hyperparameter, threshold or architectural choice was selected from it, all hyperparameters being fixed a priori from the published EEGNet configuration [5]. The six subjects remain ordinary members of the 79 folds of the full study, so the gate cannot bias the reported estimates.

TABLE I
VALIDATION-GATE SUBSET AFTER 8 S WINDOWING (4 S STRIDE). "HOURS" IS THE RECORDING DURATION USED FOR FP/H.

Subject	Windows	Ictal	Non-ictal	Hours
`eeg3` (no cons. sz.)	1102	0	1102	1.23
`eeg4` (EDF+C)	855	214	641	0.95
`eeg5`	959	794	165	1.07
`eeg7`	912	160	752	1.01
`eeg9`	886	220	666	0.99
`eeg13`	3853	314	3539	4.28
Total	8567	1702	6865	9.53

B. Full-cohort results

We then ran the full study over all 79 subjects under strict 79-fold LOSO, sweeping the 2×2 design (montage $\times$ normalization) as four independent runs. The cohort yielded exactly 39 seizure-bearing subjects under the consensus rule, matching Section III-A and confirming the labelling pipeline at scale (Table II).

TABLE II
FULL-COHORT 79-FOLD LOSO, 2×2 ABLATION (15 EPOCHS). CELLS ARE THE ACROSS-FOLD MEAN WITH ITS SAMPLE SD AS A SUBSCRIPT; AUROC/AUPRC/SENSITIVITY OVER THE 39 SEIZURE SUBJECTS, SPECIFICITY AND FP/H OVER ALL 79. POOLED AUROC RANKS EVERY FOLD'S CONCATENATED SCORES AT ONCE AND HAS NO FOLD-LEVEL SD. BEST MEAN PER COLUMN IN **BOLD**.

Montage	Norm.	AUROC	AUPRC	Pooled	Sens.	Spec.	FP/h
ref.	raw	$0.677_{\pm.18}$	$0.458_{\pm.32}$	0.758	$0.371_{\pm.31}$	$\mathbf{0.894}_{\pm.18}$	$\mathbf{43.3}_{\pm80}$
ref.	z-score	$0.731_{\pm.15}$	$0.485_{\pm.33}$	**0.807**	$0.442_{\pm.32}$	$0.872_{\pm.20}$	$48.0_{\pm79}$
bip.	raw	$0.662_{\pm.19}$	$0.437_{\pm.33}$	0.728	$0.400_{\pm.34}$	$0.862_{\pm.23}$	$51.8_{\pm80}$
bip.	z-score	$\mathbf{0.745}_{\pm.16}$	$\mathbf{0.517}_{\pm.35}$	0.786	$\mathbf{0.527}_{\pm.36}$	$0.834_{\pm.20}$	$63.1_{\pm79}$

a) A cross-patient baseline: The headline result is the cross-patient detector itself: a compact EEGNet reaches a pooled AUROC of 0.807 in its best configuration (referential + z-score) and ≈ 0.81 across the standardized conditions (Table II), on all 79 neonates with no window of the test subject ever seen in training. The per-subject spread behind these means is wide, and is detailed below.

b) Effect of normalization: As a secondary analysis, per-recording z-score raises the *pooled* AUROC of both montages, by $+0.049$ for referential ($0.758 \rightarrow 0.807$) and $+0.058$ for bipolar ($0.728 \rightarrow 0.786$), and lowers no ranking metric (Fig. 5; Table II); the largest AUPRC gain is again bipolar's ($0.437 \rightarrow 0.517$). The effect is largest where the raw input is weakest: raw bipolar, whose recording-dependent dynamic range z-score regularizes, is the lowest configuration and gains the most. A subject-paired Wilcoxon test confirms the effect per subject for *both* montages, while neither montage contrast is significant ($p \geq 0.34$; see *Paired significance*). Among these input-representation choices it is thus normalization, not montage, that moves the needle, and even that is a modest effect.

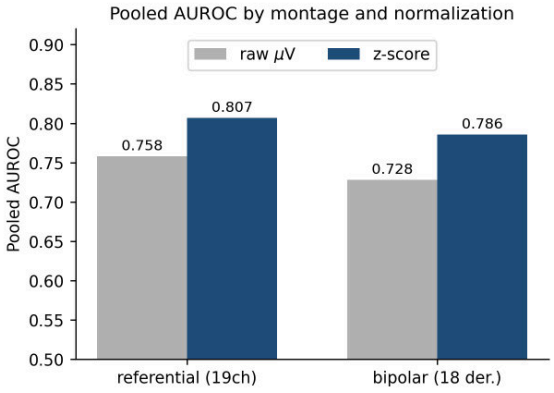

Fig. 5. Per-recording z-score raises the pooled AUROC of both montages.

c) Effect of montage: a sensitivity/specificity trade-off: Once standardized, the two montages reach a comparable pooled AUROC (0.807 referential vs. 0.786 bipolar) and differ mainly in operating character (Fig. 6).

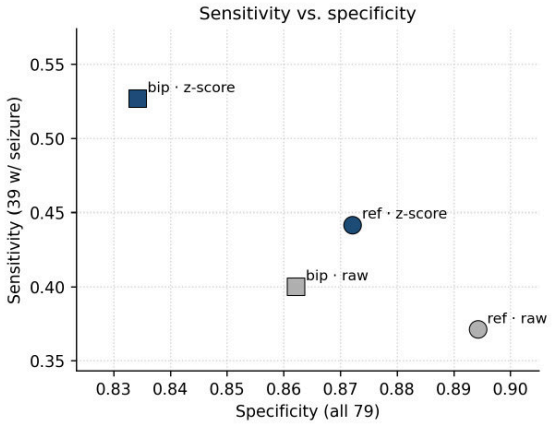

Fig. 6. Under z-score, the montages trade sensitivity (bipolar) against specificity and false-alarm rate (referential).

Bipolar + z-score is the most sensitive (0.527 vs. 0.442) and has the highest seizure-subject mean AUROC (0.745), at the cost of more false alarms (63.1 vs. 48.0 FP/h) and lower specificity. Referential is the more conservative montage (fewer false alarms) and edges the best pooled AUROC. The clinically preferable montage therefore depends on whether the use case rewards catching more seizures or suppressing false alarms.

d) Paired significance: Because the four conditions score every subject on the same LOSO split, the per-subject metrics are paired and admit a subject-level Wilcoxon signed-rank test (Table III), a guarantee the cohort means of Table II cannot give. The normalization effect on per-subject AUROC is significant for *both* montages (median $+0.059$, $p = 0.007$ for bipolar; $+0.034$, $p = 0.020$ for referential), while neither montage contrast is significant under either normalization ($p \geq 0.34$). Normalization is thus the one input-representation factor with a measurable per-subject effect, and even it is modest; the montage differences live within cross-patient noise, a caution against over-reading small differences in cohort-mean tables.

TABLE III
SUBJECT-PAIRED WILCOXON SIGNED-RANK TEST ON PER-RECORDING AUROC (39 SEIZURE SUBJECTS). Δ IS THE PER-SUBJECT DIFFERENCE A − B; p IS TWO-SIDED.

Contrast (A vs. B)	median ΔAUROC	p
Norm., ref.: z-score vs. raw	$+0.034$	**0.020**
Norm., bip.: z-score vs. raw	$+0.059$	**0.007**
Montage, z-score: bip. vs. ref.	$+0.026$	0.42
Montage, raw: bip. vs. ref.	-0.015	0.34

e) Generalization across architectures: To test whether the normalization effect belongs to the input representation or to `EEGNet1D` specifically, we re-ran the full 2×2 ablation with a structurally different compact network: a plain 1D-CNN (`CNN1D`) that mixes all electrodes in its first layer and uses batch normalization throughout. The cross-patient task stays tractable (Table IV), but the normalization effect does *not* carry over: `CNN1D`'s bipolar z-score-minus-raw gap is -0.014 (vs. $+0.058$ for EEGNet), because batch normalization already absorbs the recording-dependent amplitude that z-score otherwise removes. The z-score benefit is therefore *architecture-mediated*, not a universal property of the montage. Notably `CNN1D` at raw referential reaches the highest pooled AUROC of the whole study (0.824, above EEGNet's best 0.807). Repeating the bipolar conditions under a changed seed and epoch budget moved their pooled AUROC by up to 0.05, so a gap of this size does not establish a ranking and the ≈ 0.81 figure is best read as a baseline band.

TABLE IV
GENERALIZATION CONTROL: POOLED AUROC OF THE 2×2 ABLATION FOR `EEGNet1D` AND A STRUCTURALLY DIFFERENT `CNN1D` (CHANNEL-MIXING 1D-CNN), 15 EPOCHS.

Montage	Norm.	EEGNet	CNN1D
ref.	raw	0.758	**0.824**
ref.	z-score	**0.807**	0.786
bip.	raw	0.728	0.782
bip.	z-score	0.786	0.768
bipolar gap (z-score − raw)		$+0.058$	-0.014

f) Pooled ROC curves: Fig. 7 overlays the threshold-free pooled ROC of all four conditions: the two z-score curves reach pooled AUROC $\approx$ 0.79–0.81, above their raw counterparts (0.758 and 0.728), and the montages become close once standardized (0.807 vs. 0.786).

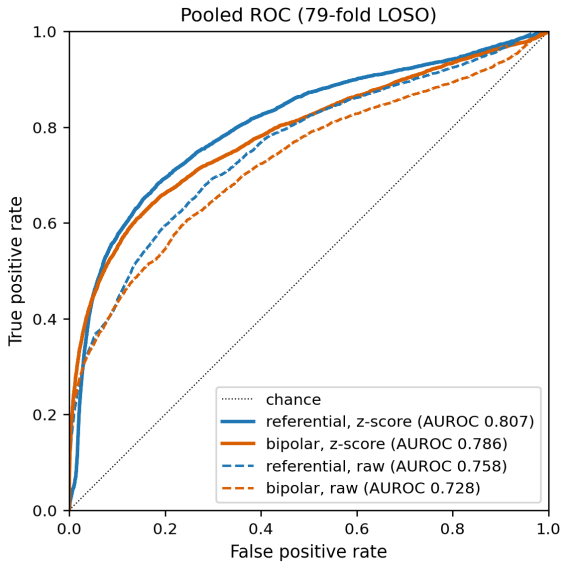

Fig. 7. Pooled ROC of all four conditions (every fold's window scores concatenated): montage by colour (referential blue, bipolar orange), normalization by line style (z-score solid, raw dashed); the legend reports the pooled AUROC.

g) Cross-patient spread: Aggregates hide wide per-subject variation, the defining difficulty of cross-patient neonatal detection. Under referential + z-score, per-subject AUROC ranges from 0.97 (`eeg31`) down to 0.34 (`eeg15`): some neonates' seizure morphology is simply not represented by the other 78, the cost of never training on the test subject.

h) Consensus-negative subjects and the false-alarm rate: The 40 subjects without consensus seizures carry the false-alarm estimate. Under referential + z-score their mean specificity is 0.908 ± 0.181, above the 0.836 ± 0.218 of the 39 seizure-bearing subjects, and their FP/h averages 41.6 with a median of 3.7. The distance between mean and median is itself the finding: over all 79 subjects FP/h has median 13.4 (IQR 1.1–54.3) against a mean of 48.0, and five subjects alone produce 36% of all false positives, so the cohort-mean FP/h is driven by a few outlying recordings and the median is the more representative summary. The estimate is also conservative, because of these 40 subjects only 21 carry no seizure annotation from any expert: the other 19 have seizures marked by one or two of the three (7 of them by a majority), so part of what is counted here as a false alarm is non-consensus seizure activity.

i) Sensitivity by seizure burden: Detection is unevenly distributed across the 39 seizure-bearing subjects and tracks how much seizure each one carries. Grouping them by total consensus ictal time, per-subject sensitivity rises from 0.305 ± 0.281 below 5 min ($n = 12$) to 0.477 ± 0.323 between 5 and 30 min ($n = 19$) and 0.564 ± 0.319 above 30 min ($n = 8$), with per-subject AUROC in the same order (0.693, 0.730, 0.790). The association holds across the cohort (Spearman $\rho = 0.38$, $p = 0.018$ for sensitivity; $\rho = 0.31$, $p = 0.055$ for AUROC). Low-burden neonates, whose seizures are few and brief, therefore account for most of what the detector misses, which is where a larger and more diverse seizure cohort would help first.

j) Event-level detection: The window-level FP/h above is pessimistic: it counts every false 8 s window separately, whereas a clinician cares whether each seizure *event* is caught and how many *separate* alarms occur per hour. We therefore score post-hoc at the event level, with no retraining: a causal (past-only, real-time compatible) 40 s moving average smooths each subject's window scores, detections are merged across gaps < 30 s and short (< 16 s) ones dropped, and a true seizure counts as detected if a predicted event overlaps it within a 30 s collar. Reference events are the contiguous ictal runs of the window labels, so consensus intervals closer together than one window merge and the 343 raw consensus intervals become 315 scored events. For the best configuration (referential + z-score) the detector then flags 78.7% of those 315 events at 3.5 false alarms/h at a score threshold of 0.30, tunable along the same scores (60.6% at 1.9 FP/h at 0.50, or higher sensitivity at more alarms). No threshold search was performed against a clinical protocol; these are two points of one curve. The per-window $\approx$ 48/h thus collapses to a few alarms/h once counted as events, the single largest step toward the neonatal baselines and one needing no change to the model. (The causal smoothing alone also lifts pooled AUROC by $+0.02$ to $+0.03$.)

k) Inference cost: The detector is light enough for the bedside (Fig. 8). A single 8 s window (EEGNet, 19 channels, batch 1) is classified in $\approx$1.8 ms on a commodity CPU and $\approx$1.7 ms on the GPU, far inside the 8 s the window spans. At batch 1 this tiny network is launch-bound rather than compute-bound, so the two are within noise; the GPU's edge is throughput, not single-window latency: $\approx$26,000 windows/s in batch versus $\approx$170/s on the CPU. A single commodity machine can therefore score many neonates in real time and a GPU is optional, which with the causal smoothing above makes real-time NICU monitoring realistic.

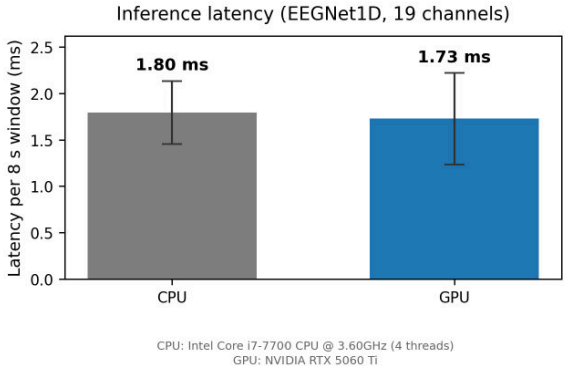

Fig. 8. Inference latency per 8 s window for the 2433-parameter EEGNet1D ($\approx$10 KB; 19 channels, batch 1; mean $\pm$ sd over 200 runs).

V. Discussion

These cross-patient numbers are a baseline rather than a ceiling: several deliberate simplifications leave clear headroom. *(i) Fixed 15-epoch budget:* fixed a priori, with no early stopping; a larger budget would mainly lift the raw configurations toward the standardized ones. *(ii) Post-processing not yet fully tuned:* the event-level threshold and the merge/collar parameters are not calibrated per the protocols of the cited baselines. That remaining tuning, rather than the architecture, is most of the gap to Temko [3] and O'Shea [4] ($\approx$0.95–0.97 AUC). *(iii) Fixed 0.5 operating point:* sensitivity, specificity and FP/h use an uncalibrated threshold; the pooled ROC/AUROC are threshold-free and are the fairer headline. *(iv) No overlap augmentation:* an intentional scope limit for this iteration. *(v) No Transformer or self-supervised comparison:* the foundation-model line [11], [12] is the natural high-capacity counterpart, but it targets a different deployment regime. The constraint here is a detector that fits beside acquisition and video streaming on an ESP32/ARM node, which the 2433-parameter network meets at $\approx$10 KB, and a fair benchmark of pre-trained encoders would need their pre-training corpora rather than the Helsinki set alone. *(vi) No hardware-in-the-loop measurement:* every timing reported here comes from desktop CPU and GPU. Power draw, memory under the full acquisition pipeline and long-term robustness on the target board are not measured, and the $\approx$10 KB figure is a parameter-

storage estimate rather than a deployed footprint. Architecture itself is no longer a single point: the `CNN1D` control above shows the normalization finding is EEGNet-specific, which is itself part of the contribution.

a) Clinical reading: The two best configurations sit at opposite ends of a clinically meaningful axis, referential + z-score the more conservative and bipolar + z-score the more sensitive. Since the event-level false-alarm rate is already within a small factor of the cited baselines, the next iteration should calibrate that operating point rather than chase AUROC.

b) Toward literature comparability: The gap to Temko [3] and O'Shea [4] is largely one of protocol: both smooth the window scores, score detections at the *event* level, and report a calibrated rather than fixed threshold. Applying that post-processing here already closes much of the distance with no change to the model, and a per-protocol calibrated threshold and collar would close more. The `CNN1D` control provides a convolutional comparison on these identical splits; a like-for-like Temko-style SVM on the same splits is the natural next experiment and is left as immediate future work.

VI. Conclusion and Future Work

On all 79 babies of the Helsinki dataset, under leak-free 79-fold LOSO and class-aware aggregation, a compact EEGNet gives a cross-patient seizure-detection baseline at pooled AUROC ≈ 0.81 (best 0.807). Two secondary ablations frame the input representation: z-score helps both montages modestly and significantly per subject, the montages are comparable once standardized, and a channel-mixing CNN gains nothing from z-score, so that benefit is architecture-mediated. For the model itself, future work will: (i) extend the event-level operating point introduced here with per-protocol calibrated thresholds and collars, the cheapest path to literature-comparable numbers; (ii) increase the epoch budget with early stopping; (iii) compare against a classical Temko-style SVM baseline on the identical LOSO splits; and (iv) scale the cohort to larger, ideally multicentre data, since performance is bounded by seizure-subject diversity (39 of 79) rather than by window count [9].

This work is a first step toward a low-cost NICU AIoT video-EEG system built by our group (Center for Child Neuroprotection). At ≈ 1.8 ms per window on a CPU there is headroom for a hybrid ESP32+ARM design, the ESP32 handling low-power acquisition and telemetry while ARM processors run TinyML-compressed pipelines for on-device detection and video streaming. In parallel we are collecting vEEG from preterm neonates in a Brazilian NICU, to adapt the model to a setting with a different disease prevalence and a less stable electrical grid.

***Abstract*—This article presents a systematic review on the development of wearable tactile assistive devices for people with hearing impairment (DHH). The research analyzes 41 articles focused on technological solutions to mitigate the absence of sound perception, improving situational awareness and safety. The results indicate a transition from theoretical clinical studies to practical systems based on Edge Computing and microphone arrays. It is concluded that the architecture preferred by users is bimodal, utilizing haptic feedback as an immediate attention alert and visual feedback for semantic and directional confirmation. The study also discusses current technical challenges, such as battery management, latency, and social acceptance.**

***Index Terms*—Deaf and Hard-of-Hearing, Sensory Substitution, Vibrotactile Feedback, Sound Source Localization, Sound Awareness, Assistive Technology, Systematic Review.**

I. Introduction

Hearing plays a fundamental role in human communication and environmental perception, being crucial for cognitive and social development, as well as personal safety. It is estimated that about 20% of the global population lives with some degree of hearing loss, and World Health Organization projections indicate that, by 2050, approximately 2.5 billion people will have some form of hearing impairment [42]. For Deaf and Hard-of-Hearing (DHH) individuals, restricted access to the sound world imposes significant daily challenges. The absence of this perception directly compromises situational awareness, making it difficult to recognize imminent alerts such as sirens, horns, fire alarms, or verbal calls, which substantially increases the risk of accidents in urban environments.

Although traditional assistive technologies, such as Hearing Aids (HAs) and Cochlear Implants (CIs), have revolutionized the rehabilitation of thousands of people, they still present technical limitations. In addition to the high cost and the need for surgical intervention in the case of CIs, users frequently report severe difficulties in understanding speech in noisy environments and in spatially localizing sound sources. The inability to accurately identify the direction of a sound-especially those coming from blind spots, such as behind the user-remains an unresolved problem for these conventional prostheses.

Given this scenario, researchers have explored approaches based on sensory substitution to mitigate such deficiencies. This technique consists of compensating for the impaired sense by using remaining sensory channels, notably vision and touch. The use of haptic technology, which employs mechanical actuators to transmit sound information through vibrations on the skin, has emerged as a promising solution. Due to the tactile system's high sensitivity to intensity variations and temporal rhythmic patterns, wearable devices (such as wristbands, glasses, belts, or vests) can provide vital spatial cues. Furthermore, the literature points out that multimodal integration-combining haptic feedback as an immediate alert and visual feedback as directional or semantic support-is highly accepted by users, assisting in the rapid identification of danger without overloading cognitive load.

With the advancement of electronic miniaturization and the employment of Artificial Intelligence processing directly at the edge (*Edge Computing*), combined with the use of *microphone arrays*, it has become possible to design much more robust assistance systems. Such systems seek not only to alert the user that a noise has occurred but also to inform them about what is sounding and where it is coming from. Given the rapid expansion of these innovations, it becomes necessary to systematically evaluate the technical parameters, usability, and efficacy of these tools in the context of auditory accessibility.

II. Methodology

This Systematic Literature Review (SLR) was conducted in adherence to the PRISMA 2020 (*Preferred Reporting Items for Systematic Reviews and Meta-Analyses*) guidelines.

1) Information Sources and Search Strategy: The electronic search was executed across major peer-reviewed databases and digital publishers: IEEE Xplore, ACM Digital Library, SpringerLink, MDPI, Elsevier/ScienceDirect, PNAS, and the Journal of the Acoustical Society of America (JASA). The literature retrieval covered all indexed publications up to 2025 (spanning from 1982 to 2025). The unified Boolean search strategy was formulated across three core facets: (i) target population/hearing impairment, (ii) acoustic processing/event detection, and (iii) haptic/vibrotactile feedback:

> *Generic search string: ("hearing aid" OR "hearing assist*" OR "assistive listening device" OR "cochlear implant" OR "hearing impairment" OR "hearing loss" OR "deaf" OR "hard of hearing" OR "auditory prosthesis" OR "sensory substitution" OR "hearing impaired" OR "audiology" OR "otology" OR "hearing disorder" OR "hearing deficits") AND ("sound" OR "acoustic" OR "audio" OR "speech" OR "music" OR "auditory" OR "sound localization" OR "sound source localization" OR "acoustic source localization" OR "direction of arrival" OR "DOA" OR "angle of arrival" OR "AOA" OR "sound source detection" OR "azimuth estimation" OR "sound test" OR "audio fingerprint" OR "omnidirection" OR "feature extraction" OR "speech processing" OR "acoustic perception" OR "auditory perception" OR "auditory scene analysis" OR "binaural hearing" OR "acoustic signal" OR "soundscape") AND (vibrotactile OR tactile OR vibration OR haptic OR "vibrotactile feedback" OR "somatosensory" OR "kinesthetic feedback" OR "vibrotactile stimulation" OR "electrotactile") AND ("wearable" OR "wearable*" OR "body-worn" OR "on-body" OR "body-mounted" OR "wearable device*" OR "wearable sensor*" OR "wearable technology" OR "smart textile*" OR "e-textile*" OR "bracelet*" OR "wristband*" OR "smartwatch" OR "smart-watch" OR "head-worn" OR "earable*")*

2) Deduplication and Screening Pipeline: Initial search yields were aggregated into reference management software (Zotero). Automated deduplication was performed by matching digital object identifiers (DOIs) and normalized title-author metadata, followed by manual adjudication (e.g., resolving duplicate workshop and conference pre-prints).

Eligibility screening followed a two-phase independent double-blind evaluation conducted by two independent reviewers, based on predefined criteria. Inclusion focused on acoustic-to-tactile/haptic technologies for sound source localization (I1), sound classification (I2), and related assistive research (I3, I4).

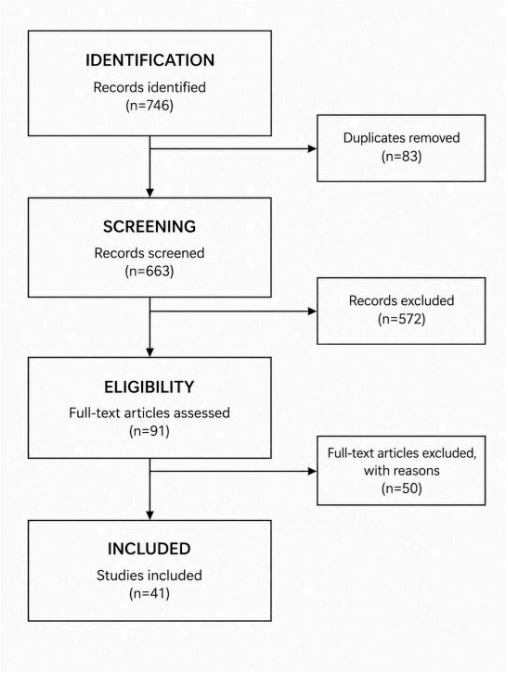

Fig. 1. PRISMA Flow Diagram.

Conversely, studies were excluded if they lacked a haptic component, did not address hearing impairment, or did not use environmental sounds (E1–E3). Non-article documents, outdated technologies, insufficient technical data, irrelevant research, or papers outside English, Portuguese, or Spanish were also excluded (E4–E8).

Disagreements during screening were resolved via structured consensus meetings or adjudicated by a third independent reviewer. Inter-rater reliability was measured using Cohen's kappa coefficient ($\kappa = 0.84$), indicating strong agreement. A final corpus of 41 unique primary studies met all criteria and was synthesized. The detailing of all stages of identification, screening, and eligibility can be visualized in the PRISMA flow diagram (Fig. 1).

3) Limitations and Risk of Bias Assessment: This review faces potential publication bias, as studies reporting positive outcomes in assistive technology are more frequently published than null or negative trials. Furthermore, by restricting the search to peer-reviewed academic literature to ensure scientific rigor, gray literature, proprietary technical reports, and commercial patent databases (e.g., USPTO, WIPO) were excluded, which may omit relevant market-ready implementations and industrial designs.

III. Results

The initial evaluation of the collection of 41 articles reveals that the literature on tactile and visual assistive devices for people with hearing impairment is a field that is still incipient, yet with the potential for rapid expansion.

A clear temporal trend is observed: the vast majority of publications on wearable devices and sound processing is concentrated in the last decade. This growth was strongly driven by the miniaturization and cost reduction of portable

TABLE I
PRISMA SYSTEMATIC ELIGIBILITY AND INCLUSION AUDIT ACROSS PRIMARY STUDIES ($N = 41$)

Reference	Target Condition (DHH/CI/NH)	Acoustic Processing	Tactile/Haptic Modality	Empirical Evaluation	Peer-Reviewed	Eligibility Decision
Chelladurai et al. [1]	DHH	VR Spatial Sound	Head Haptic Ring	Localization Time	Yes	Included (Axis 1)
Buhat et al. [2]	DHH	YAMNet SED	Wristwatch / Headband	Accuracy (Indoor/Outdoor)	Yes	Included (Axis 3)
Michaud et al. [3]	DHH (Targeted)	Microphone Array / DOA	SmartBelt (Waist)	MAE (2.9°) / Selection	Yes	Included (Axis 1)
Sun et al. [4]	Deaf Cyclists	Bandpass Filtering	Smart Helmet	In-situ Functional Test	Yes	Included (Axis 2)
Wong et al. [5]	Able-bodied (Targeted DHH)	Speech Feature Mapping	Forearm Tactile Sleeve	Psychophysical Trials	Yes	Included (Axis 5)
Kim et al. [6]	DHH	SED (BGRNN) + TDOA	Haptic Vibration (Home)	Classification / Conversion	Yes	Included (Axis 4)
Israr et al. [7]	Deaf / NH	Formant Extraction	Multi-finger Display	Absolute Identification	Yes	Included (Axis 5)
Rahman & Fattah [8]	DHH	Active Noise / Speech Rec.	Smart Glass Binaural Cue	Functional Verification	Yes	Included (Axis 3)
Rahul et al. [9]	Deaf-Blind	Speech Recognition	Dynamic Braille Ring	User Translation Trials	Yes	Included (Axis 4)
Singh et al. [10]	DHH / Headphone Users	10-Layer CNN / MFCC	Headphone Vibration	Accuracy (Clean/Noisy)	Yes	Included (Axis 2)
Nakata et al. [11]	DHH	Frequency-to-Vibration	Headphone / Hat Haptics	Localization / Sound Type	Yes	Included (Axis 3)
Orzech et al. [12]	Hearing Loss	Systematic Methodology	Haptic Review	Usability / Feasibility	Yes	Included (Axis 5)
Abhiram et al. [13]	Hearing Impaired Drivers	Sequential CNN	Microvibrator Glove	Real-time Siren Alert	Yes	Included (Axis 2)
Fletcher et al. [14]	CI Users / NH	Tactile Intensity Differences	Tricep / Palmar / Dorsal	Sensitivity (TID Thresholds)	Yes	Included (Axis 5)
Mirzaei et al. [15]	DHH	VR Sound Localization	Haptic + LED Feedback	Localization Speed	Yes	Included (Axis 1)
Fletcher [16]	Hearing-Impaired	Electro-haptic Audio	Wrist Haptics	Perceptual Review	Yes	Included (Axis 5)
Fletcher & Zgheib [17]	CI / Hearing Aid Users	Signal Compression / DSP	Wrist-Worn Haptics	Localization Error (degrees)	Yes	Included (Axis 1)
Fletcher et al. [18]	CI Users	Electro-Haptic Dual Stim.	Wrist Tactors	Localization Task	Yes	Included (Axis 1)
Mirzaei et al. [19]	DHH	3D Spatial Audio	EarVR (Headset Haptics)	Completion Time / Accuracy	Yes	Included (Axis 1)
Goodman et al. [20]	DHH	Multimodal Sound Awareness	Smartwatch Tactons	Wizard-of-Oz In-situ	Yes	Included (Axis 5)
Sakuma et al. [21]	Hearing Impaired	Julius Keyword Engine	Back Haptic Actuators	Recognition / Localization	Yes	Included (Axis 3)
Kim et al. [22]	DHH	Multi-label BGRNN	12-Tactor Sleeve	F1-Score / MOS Trials	Yes	Included (Axis 2)
Yağanoğlu & Köse [23]	DHH / NH	Audio Fingerprint (AF)	Fingertip Vibration	Real-Time Accuracy (94%)	Yes	Included (Axis 2)
Fletcher et al. [24]	Simulated CI	Low-frequency Tactile	Fingertip Transducer	Speech-in-Noise Recovery	Yes	Included (Axis 5)
Yağanoğlu & Köse [25]	DHH / NH	ReliefF + SVM / k-NN	Fingertip Actuators	Direction Accuracy (98%)	Yes	Included (Axis 3)
Desloge et al. [26]	DHH / NH / Simulated	Auditory Gap Thresholds	Vibrotactile (Finger)	Quantitative Psychophysics	Yes	Included (Axis 5)
Russo et al. [27]	DHH / NH	Timbre / Waveform	Voice Coils (Back)	Discrimination Trials	Yes	Included (Axis 5)
Israr et al. [28]	Hearing Assumed	Consonant Contrast Coding	3-Digit Tactual Display	Psychophysical Index	Yes	Included (Axis 4)
Aker et al. [29]	NH	Audio-Tactile Congruence	Haptic Actuator	Preference Rating	Yes	Included (Axis 5)
Chin et al. [30]	DHH (Targeted)	EfficientNet / STFT	Wrist Vibrator	Edge AI / Offline Accuracy	Yes	Included (Axis 2)
Kidd Jr. et al. [31]	CI Users / NH	Triple Beamformer	Binaural Acoustic/Tactile	Speech Identification	Yes	Included (Axis 1)
Spiegel et al. [32]	Tinnitus Observers	Audio-Visual-Somatosensory	Somatosensory	Randomized Control Trial	Yes	Included (Axis 5)
Plant [33]	Profoundly Deaf	Speech / Env. Sounds	Tactile Transducer	Word/Sound Recognition	Yes	Included (Axis 4)
Shimoyama [34]	Hearing Impaired	Sound Tracking / Interaural	Dual Vibrators (Shoulders)	Angle Error ($< 5°$)	Yes	Included (Axis 1)
Paisa et al. [35]	CI Users	Multi-instrument Segregation	Vibrotactile Furniture	Qualitative / Observational	Yes	Included (Axis 4)
Mirzaei et al. [36]	DHH	3D Sound in VR	Haptic Suit / Ear Motors	Task Completion Time	Yes	Included (Axis 1)
Fletcher [37]	CI / Hearing-Impaired	Music Enhancement	Haptic Stimulation	Systematic Evaluation	Yes	Included (Axis 5)
Guilleminot & Reichenbach [38]	NH / Simulated	Syllabic Rate Audio	Vibrotactile (Fingertip)	EEG / Psychophysics	Yes	Included (Axis 5)
Honda et al. [39]	DHH	Acoustic Pressure / DSP	Ontenna (Hair/Ear/Sleeve)	User Experience Trials	Yes	Included (Axis 4)
Sofack et al. [40]	Single-Sided Deafness	Vibrotactile Stimulation	Skin Mechanoreceptors	Cortical EEG / ERP	Yes	Included (Axis 5)
Dupin et al. [41]	Normal Sensing	Haptic Coupling	Bimanual Tactors	Psychophysical Index	Yes	Included (Axis 5)

Note: The eligibility decision indicates the thematic axis (Axis 1 to 5) assigned to each primary study, as defined in Section III.

microcontrollers (such as Raspberry Pi, Arduino, and ESP32), by the advancement of *Deep Learning* algorithms capable of operating locally (*Edge Computing*), and by the popularization of Virtual Reality (VR) environments, which created yet another environment that requires inclusion. Although there are foundational studies from previous decades on the psychophysical capacity of the skin to discriminate frequencies, modern application is mostly focused on the *design* of embedded systems for everyday use.

Regarding technological maturity (*Technology Readiness Level* - TRL), the field is predominantly composed of proofs of concept and academic prototypes tested in controlled environments with small groups. However, there are notable exceptions that have overcome the prototyping barrier. The biggest example identified is the *Ontenna* [39], developed in Japan, which evolved into a mass-manufactured commercial product, adopted in more than 80% of schools for the deaf in the country for teaching rhythm and programming.

The user demands that were the focus of the analyses were divided into two main directions (often complementary): the classification of important sound events (active alerts about sirens, horns, and calls); and the three-dimensional spatial localization of the source (ensuring safety and situational awareness).

Fig. 2. Prototype of the *Ontenna* device, a wearable acoustic sensory interface designed to be attached to the hair, earlobe, or clothing. It uses a condenser microphone to capture ambient sound and converts its characteristics into real-time tactile and visual feedback through 256-stage vibrations and LED light intensities [39].

The analysis of the selected publications revealed five thematic axes of research, categorized by the objective of the interaction between the user and the environment.

The first axis covers devices focused strictly on spatial localization (nine articles identified). The central objective of these projects is situational and navigational awareness (*Direction of Arrival* - DoA), without a focus on sound classification. Examples include instrumented belts (*SmartBelt* [3]), bracelets for spatial enhancement of unilateral cochlear implant users, and spatial mapping in Virtual Reality (*EarVR* [19]).

The second axis encompasses devices that act as sound classifiers (six articles). They monitor the environment to notify the user about specific events, such as doorbells or horns, through pattern recognition and residential IoT monitoring, delegating the spatial identification to the user themselves after the alert.

A more complex category, representing an advanced minority (five studies), focuses on hybrid devices that integrate localization and classification. Projects such as *AICanHear* [2] and *Smart Glass* [8] use AI (*Edge Computing*) to recognize the nature of the sound and microphone arrays to point out its origin, being vital for identifying threats in blind spots, such as the rear approach of vehicles.

The fourth axis moves away from notification systems to explore the direct conversion of sound (six articles). Here fall the "tactile vocoders" and devices for musical appreciation, such as the *Ontenna* [39] and multisensory concert furniture [35]. They do not emit simplified alerts, but translate the raw sound wave or phonemes directly into physical stimuli for the skin.

Finally, the largest portion of the collection (fifteen articles) concentrates on fundamental research and reviews. These are clinical and neuroscientific studies that investigate the psychophysics of touch, vibrotactile perception thresholds, and *cross-modal* plasticity, the reorganization of the auditory cortex in deaf individuals to process somatosensory stimuli, validating the foundational theory for the construction of the aforementioned engineering solutions.

To synthesize these five axes in greater technical depth, the results are organized into three core pillars: (A) Spatial Localization (Axes 1 and 3), (B) Sound Event Detection (Axes 2 and 3), and (C) Sensory Transduction and Response Interfaces (Axes 4 and 5).

A. Spatial Localization and Direction of Arrival (DoA)

Studies within this category (encompassing Axis 1 and hybrid architectures from Axis 3) focus primarily on restoring horizontal spatial awareness and estimating the direction of arrival (DoA) of acoustic sources. Hardware configurations generally rely on multi-microphone arrays (such as wearable belts or glasses) using time-difference-of-arrival (TDoA) and generalized cross-correlation (GCC-PHAT) algorithms, head-mounted binaural interaural level/time difference (ILD/ITD) beamformers, or direct spatial audio integration within virtual reality (VR) engines.

Quantitative performance is reported across heterogeneous paradigms, reflecting distinct physical and virtual setups. In wearable physical devices, accuracy is commonly evaluated via angular error metrics, such as Mean Absolute Error (MAE $= 2.90^\circ$ in *SmartBelt* [3]) or real-time dynamic tracking error below 5° [34]. Clinical trials involving cochlear implant (CI) users quantify performance through root-mean-square (RMS) localization error, demonstrating significant error reductions after training with electro-haptic wrist stimulation (e.g., from 47.2° to 22.7° [18] and 25.2° to 22.6° [17]). Conversely, virtual reality studies assess efficiency through task completion time (e.g., *EarVR* [19], [36], *SoundHapticVR* [1]), showing that localized haptic cues significantly accelerate target search times and spatial identification in immersive environments.

To enable an objective comparison across spatial hearing technologies, Table II synthesizes the quantitative performance of directional systems across both standalone spatial trackers (Axis 1) and hybrid localization-classification architectures (Axis 3), as visually conceptualized in the intersection diagram in Fig. 3. The table reports standardized metrics such as task completion time in VR, root-mean-square (RMS) angular error, directional classification accuracy, and non-standardized outcomes.

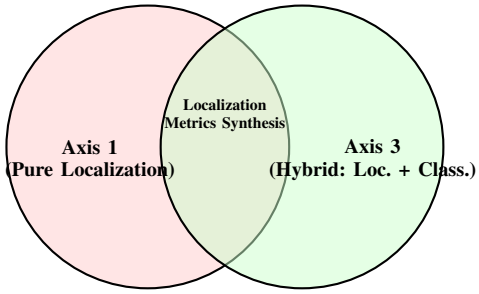

Fig. 3. Venn diagram highlighting the scope of the quantitative synthesis, focusing on spatial localization and direction-of-arrival metrics across standalone spatial trackers (Axis 1) and hybrid localization-classification systems (Axis 3).

B. Sound Event Detection (SED) and Semantic Classification

The second pillar consolidates systems engineered to automatically recognize and classify specific acoustic events (Axis 2) and hybrid systems coupling classification with spatial localization (Axis 3). Evaluating quantitative performance metrics across these implementations is essential for establishing an objective baseline, moving beyond qualitative feasibility to assess real-world viability. Methodological implementations range from classical DSP thresholding and speech keyword-spotting engines to support vector machines (k-NN/SVM) and deep neural architectures (e.g., CNNs, BGRNNs, and edge-deployed EfficientNet ensembles).

To address the functional trade-offs and substantial methodological heterogeneity identified in the literature, Table III synthesizes the quantitative and experimental performance of sound event classification systems, highlighting the intersection between standalone classifiers and hybrid architectures

TABLE II
QUANTITATIVE PERFORMANCE METRICS FOR SPATIAL SOUND SOURCE LOCALIZATION SYSTEMS (AXES 1 AND 3)

Reference	Tracking / Processing Method	Acoustic / Spatial Input	Localization Performance (Metric)	Spatial Setup / Tracking Range	Feedback Modality / Interface	Participants (N and Profile)
Axis 1: Pure Spatial Localization Systems						
Chelladurai et al. [1]	Multi-channel Audio Spatializer	3D Virtual Sound (Meta Quest)	Time: approximately 9 seconds (Accuracy: 89.81%)	360° continuous (4.0 m radius)	LRF Voice-Coil Ring (Head)	$N = 25$ (DHH)
Michaud et al. [3]	GCC-PHAT / TDoA Lookup	8-Microphone Array	MAE = 2.90° (Selection: 92.3%)	360° horizontal (2.0 m distance)	15-Motor SmartBelt (Waist)	$N = 2$ (Bench evaluation)
Mirzaei et al. [15]	Real-time Stereo Energy Balance	3D Spatial Audio (Unreal Engine)	Time: 17.53 ± 1.25 s (Haptic+LED)	Left / Right visual hemifield	2 Ear Vibro-motors + 2 LEDs	$N = 20$ (10 DHH, 10 NH)
Fletcher & Zgheib [17]	Linked Multiband Compression	BTE HRTF (Speech Noise)	RMS: 25.2° (Pre) → 22.6° (Post-train)	11 locations (−75° to +75°)	Dual-wrist HVLab Vibrometers	$N = 32$ (Normal-hearing)
Fletcher et al. [18]	Electro-haptic ILD Extraction	BTE HRTF (Speech Envelope)	RMS: 47.2° (Audio) → 22.7° (Post-train)	11 loudspeakers (−75° to +75°)	Dual-wrist Vibrometers + CI	$N = 12$ (CI users: 7 uni, 5 bi)
Mirzaei et al. [19]	Real-time Stereo Level Tracking	3D Spatial Audio (Google Resonance)	Time: 14.7 ± 1.8 s (EarVR) vs. 29.6 s (None)	6 directions (3D VR enclosed room)	EarVR (2 Ear Coin Motors)	$N = 40$ (20 DHH, 20 NH)
Kidd Jr. et al. [31]	Triple Binaural Beamforming	16-MEMS Microphone Array	Group Mean Error ≈ 15° (Triple 90°)	Horizontal plane (−90° to +90°)	Binaural headphone simulation	$N = 6$ (Normal-hearing)
Shimoyama [34]	Short-time Phase Difference / ITD	Binaural Ear Microphones	Dynamic tracking error < 5°	Omnidirectional (2.0 m platform)	2 Shoulder Transducers (Vest)	$N = 1$ (Simulated deprivation)
Mirzaei et al. [36]	4-Directional Wireless Mapping	3D Spatial Audio (Unreal Engine)	Time: 21.41 s (Ears) vs. 27.05 s (No suit)	4 main positions (Front/Back/L/R)	Haptic VR Suit (2–4 Motors)	$N = 20$ (DHH participants)
Axis 3: Hybrid Systems (Spatial Localization + Sound Event Classification)						
Buhat et al. [2]	Loudness Thresholding / TDoA	4-Electret Array + Grove Sensors	Accuracy (indoors): 56.67% (F/R), 50.00% (B), 53.33% (L)	4 cardinal directions (Indoor/Outdoor)	Wristwatch (LCD + RGB LEDs + Motor)	$N = 13$ (DHH participants)
Rahman & Fattah [8]	Dynamic Binaural Cues (ITD Peak)	5-Microphone Array (1 Front, 4 Sides)	Direction error ≈ 5–15% (with ≥ 3 microphones)	Horizontal plane (0° to 330°, 30° steps)	Smart Glass (3-Color LEDs + 2 Motors)	-
Nakata et al. [11]	4-Channel Micro-Array TDoA	CRESCENT-031 Direction Board	$t(2) = -0.277, p = 0.808, d = -0.204$	6 directions (0°, 60°, . . . , 300°)	Beret Haptuators / Headphone Motors	$N = 3$ (DHH Levels 2 and 3)
Sakuma et al. [21]	CSP Cross-power Spectrum Phase	2-Microphone Array	Accuracy: $87.0 \pm 11.0\%$ (Horn), $86.0 \pm 15.6\%$ (Voice)	5 rear directions (−90° to +90°, 45° steps)	Neck-worn Collar (5 Vibration Motors)	$N = 10$ (Isolated hearing)
Yağanoğlu & Köse [25]	ReliefF + SVM / k-NN Classifier	4 Microphones (Orthogonal)	Accuracy: 98.0% (1 m), 94.0% (4-dir), 91.0% (8-dir)	4 to 8 directions (1–4 m distance)	2 Fingertip Motors + 4 Directional LEDs	$N = 56$ (6 DHH, 50 NH)

depicted in Fig. 4. As detailed in the table, performance metrics vary considerably, encompassing overall accuracy, F1-scores, and error rates—with non-accuracy or qualitative evaluations (where parameters not explicitly disclosed are denoted as NR, *Not Reported*). Furthermore, temporal reporting reveals substantial disparities between input temporal windowing and end-to-end response delays, while participant cohorts diverge across deaf and hard-of-hearing (DHH) individuals, normal-hearing (NH) control groups, and subjective MOS evaluations.

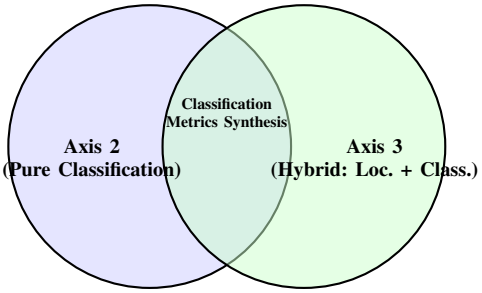

Fig. 4. Venn diagram highlighting the scope of the quantitative synthesis, focusing on classification and sound event detection metrics across standalone classifiers (Axis 2) and hybrid localization-classification systems (Axis 3).

C. Sensory Transduction and Response Interfaces

The third pillar addresses how acoustic information is physically conveyed to the mechanoreceptors of the body, encompassing direct sound-to-haptic substitution (Axis 4) and foundational psychophysical investigations (Axis 5), as synthesized in the taxonomic mapping in Fig. 5. The selection of actuation technology dictates the directional precision, frequency fidelity, and acoustic resolution of the assistive device:

- **Mixed (Visual and Low-Resolution Haptic):** The majority of basic alert systems adopt conventional vibration motors (coin type or Eccentric Rotating Masses - ERM) combined with LEDs or *displays*. Vibration works as an attention trigger, while vision confirms the urgency and directionality (e.g., *SI-LERT* [13]).
- **Exclusively Haptic (High Fidelity):** To relieve the visual load or transmit greater sound complexity, advanced systems adopt *Haptuators* (Linear Actuators) or *Voice-coil* transducers (e.g., *SoundHapticVR* [1]). They mechanically replicate the nuances of the audio wave (frequency, texture, and continuous volume).

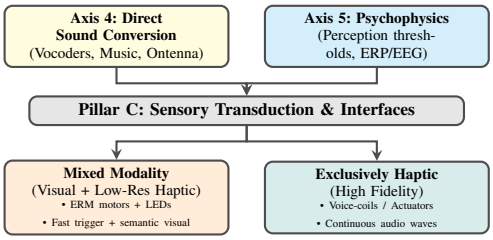

Fig. 5. Taxonomic synthesis of Pillar C (Sensory Transduction and Response Interfaces), mapping Axes 4 and 5 into mixed bimodal and exclusively haptic paradigms.

Beyond discrete alerts, continuous transduction models and psychophysical studies (Axes 4 and 5) explore sensory limits, speech formant and gap discrimination [5], [7], [26], [28], cortical plasticity [38], [40], and spectral compression for musical timbre [27], [29], [35], [37], [39]. However, complex vibratory encoding (*tactons*) often causes sensory overload and high cognitive load. Consequently, bimodal architectures—pairing intuitive haptic triggers with immediate visual confirmation—emerge as the preferred design paradigm for situational awareness and usability.

IV. DISCUSSION

From this research, the understanding is consolidated that haptic feedback (or electro-haptic stimulation) is a powerful resource to compensate for the limitations of traditional medical prostheses, especially in the restoration of spatial awareness, in the improvement of speech rhythm tracking in noisy environments, and in the reintegration of musical perception. However, usability research strongly demonstrates that the architecture preferred by users is not exclusively tactile, but rather **bimodal (haptic and visual)** [15]. Vibration acts masterfully as an immediate *push notification*, while the visual complement (LEDs or screens) informs the exact identity of the noise, minimizing the need to memorize complex vibratory patterns.

This architectural preference is strongly supported by the findings of Goodman et al. [20], in which 13 participants expressed significant concerns regarding visual-only interfaces due to the risk of missing critical acoustic events; as one

TABLE III
QUANTITATIVE PERFORMANCE METRICS FOR SOUND EVENT DETECTION AND CLASSIFICATION SYSTEMS (AXES 2 AND 3)

Reference	Model / Classifier	Feature Extraction	Classification Performance	Temporal Window / Latency	Target Sound Classes	Number of Test Participants
Axis 2: Standalone Sound Event Detection and Classification Systems						
Sun et al. [4]	Amplitude Threshold / DSP	Bandpass Filtering (ADC)	Qualitative bench verification	NR / NR	1 class (Vehicle horns)	-
Singh et al. [10]	10-Layer CNN	MFCC ($O(n \log n)$)	Accuracy: 99.54% (Clean), 91.00% (Noisy NAWED)	1.0 s window (50% overlap) / NR	20 attention/emergency words	-
Abhiram et al. [13]	Sequential CNN	MFCC + Chroma + Mel Spectrogram	NR	7.0 s standardized window / NR	2 classes (Emergency sirens vs. noise)	-
Kim et al. [22]	Multi-label BGRNN	Noise-reduced Spectrogram + TDOA	F1-Score: 84.2%	NR / NR	14 home sound classes (polyphonic)	$N = 14$ (MOS evaluation)
Yağanoğlu & Köse [23]	Audio Fingerprint (AF)	Spectrogram Peak Hashing	Accuracy: 98.0% (Clean), 94.0% (SNR 20 dB), 90.0% (15 dB)	NR / 1.9 s	8 sound classes (indoor and outdoor)	$N = 55$ (5 DHH, 50 NH)
Chin et al. [30]	EfficientNet + Fuzzy Ensemble	STFT Spectrograms	Accuracy: 97.05% (Offline), 95.22% (Edge AI)	1.5 s window / NR	7 classes (4 vocalizations, 3 sirens)	-
Axis 3: Hybrid Systems (Semantic Classification + Spatial Localization)						
Buhat et al. [2]	YAMNet (MobileNetV1)	Spectrogram (Google AudioSet)	Accuracy: 70.48% (Indoor), 63.33% (Outdoor)	NR / NR	8 classes (Sirens, horns, dog, baby...)	$N = 13$ (DHH participants)
Rahman & Fattah [8]	Template Matching	Amplitude/Frequency Envelope	BER analysis	NR / NR	Speech keywords, horns, dog bark	-
Nakata et al. [11]	Frequency Mapping	FFT $\rightarrow$ Linear IFFT	$t(2) = 3.90, p = 0.0599, d = 3.00$	NR / NR	15 daily sound sources (6 categories)	$N = 3$ (DHH participants)
Sakuma et al. [21]	Julius Speech Engine	Keyword Recognition	Accuracy: $68.6 \pm 13.8\%$	NR / NR	5 sound keywords (Table 1 patterns)	$N = 7$ (Participants)
Yağanoğlu & Köse [25]	SVM / k-NN	L_{max} + Zero Crossing Rate (ZCR)	Accuracy: 95.0% (Normal voice), 91.8% (Shouting)	NR / 0.68 s classification response time	Voice levels (Shouting vs. Normal speech)	$N = 56$ (6 DHH, 50 NH)

participant remarked, *"I'm not going to be looking at my watch every two minutes when I'm out and about"* [20]. In contrast, when evaluating a simple vibration feedback mechanism, participants emphasized its efficacy in *"alerting to a situation"* and serving as a stimulus to *"trigger you to look at your watch"* [20], although user feedback indicated that vibration intensity should be customizable [20]. Conversely, for more complex systems encoding specific acoustic events into distinct vibration patterns (*tactons*), critical usability bottlenecks emerge—particularly in time-sensitive or hazardous scenarios [20]. As noted by a participant in the same study: *"I had to wait and wait and then the vibration had finished and by the time I finished decoding what it was [...] I'd missed whatever happened"* [20]. Furthermore, relying exclusively on intricate tactile patterns can substantially increase cognitive load and lead to mental fatigue over extended periods, as highlighted in the systematic review by Orzech et al. [12] (citing Wang et al.): *"If I have to wear it [...] for a long time, I will likely have sensory overload"* [12]. Taken together, these studies corroborate that the most effective and usable design paradigm is a bimodal architecture—employing an adjustable, low-complexity vibratory cue strictly as an asynchronous attention trigger, while delegating semantic classification to an immediate visual display [12], [20].

Furthermore, despite these theoretical and prototypical advances, the transposition of these solutions into daily life encounters critical engineering and usability challenges:

1) **Battery Management and Autonomy:** The continuous processing of audio and the triggering of mechanical motors demand high energy. While the market requires at least 14 hours of daily autonomy, many prototypes hit time limits or rely on heavy *power banks*, although BLE technologies and adaptations in *smartwatches* (such as the *Buzz*) are already starting to overcome this bottleneck. [11], [16]
2) **Processing Time and Latency:** The speed of capture and response is a matter of safety. The latency of mechanical motors added to the processing time of neural networks can exceed several seconds in some models. The use of *Edge Computing* is the main bet to mitigate cloud delay. For continuous stimuli, however, delays in the millisecond range are usually tolerated by the brain thanks to cross-modal temporal recalibration. [23], [30], [37]
3) **Physical Coupling and Comfort:** Vibratory effectiveness depends on constant and firm contact with the skin. The need for mechanical pressure (velcro, elastics) can generate long-term discomfort. Furthermore, flaws in mapping the sound dynamic range can transform a loud ambient noise into an uncomfortable tactile shock. [14], [35], [36]
4) **Cognitive Load and Fatigue:** In noisy environments, the constant reception of tactile notifications generates mental exhaustion and can distract the user from their peripheral visual stimuli. The use of complex *tactons* also requires great decoding effort. The need for highly customizable AI systems becomes evident, allowing the user to apply silencing filters or set alerts only for critical sounds. [12], [20]
5) **Social Acceptance and Aesthetics:** The psychological comfort of the user is a major factor for the adoption of the solution. Devices that are intrusive or too robust suffer strong rejection for stigmatizing the disability in public. Solutions embedded in conventional devices, such as *smartwatches* and *smartphones*, show the highest rates of social acceptance. [12], [16], [20]

A. Conceptual Framework and Proposed Architecture

To bridge the empirical gaps identified in this systematic review—particularly regarding energy efficiency, cognitive load, and usability—and aligned with preliminary field insights from the Ceará Institute of Education for the Deaf (ICES), we propose a conceptual bimodal assistive architecture. It is important to emphasize that this section presents a prospective design proposal aimed at guiding future prototyping and real-world validation, rather than an empirically validated outcome of the literature review itself. The architecture is organized into two decoupled layers: mobile-based Edge AI processing and a low-complexity wearable haptic-visual interface.

1) Processing and Personalization Layer on Mobile Devices: Unlike approaches in the literature that concentrate digital signal processing (DSP) and Machine Learning (ML) inference exclusively on dedicated wearable hardware, which increases energy consumption and device cost, a decentralized approach is proposed. Audio processing is delegated to the user's mobile phone through a dedicated application.

This choice is justified by three critical factors:

- **Hardware Availability:** It leverages the computational capacity of an underutilized device that the user already carries daily;
- **Algorithmic Adjustment and Flexibility:** Artificial Intelligence frameworks for mobile devices are used, allowing the local execution of pre-trained classification models with the flexibility for the user to register and calibrate new personalized acoustic signatures (e.g., specific domestic alerts, their own name...);
- **User Interface (UI):** Facilitates the customization of sensitivity profiles and sound categories in an intuitive way.

2) Embedded Haptic and Visual Actuation Layer: The physical interface with the user consists of a microcontrolled bracelet based on the ESP32-S3 SoC, integrated with the cell phone via the *Bluetooth Low Energy* (BLE) protocol. To mitigate the usability barriers pointed out by ICES experts, the tactile feedback paradigm was reformulated.

Instead of encoding complex messages through multiple spatial or frequency vibration patterns, whose learning curve is steep and prone to interpretation errors if a pulse is missed, the device uses a single eccentric rotating mass (ERM) motor acting strictly as an *attention trigger* (asynchronous alert).

Once the user's attention is awakened by the tactile stimulus, the semantics of the message are transmitted visually by a matrix of four multicolored LEDs (RGB). Each color or luminous pattern represents a sound macrocategory (e.g., danger alerts, domestic events, interpersonal calls), drastically reducing the cognitive load necessary for decoding the stimulus.

Furthermore, in line with the *feedback* obtained from users, the immediate spatial localization mapping (Direction of Arrival - DoA) was temporarily discarded in the hardware. The device prioritizes the immediate alert of the event's occurrence, delegating the search for the sound source to the user's natural visual scanning, which optimizes the global response time of the system and reduces the complexity of the embedded circuit.

3) Engineering Challenges and Future Validation: As real-environment testing with end-users is still in the planning phase, the validation of this architecture presents co-design and engineering challenges that need to be investigated, such as:

1) **Temporal Determinism and Latency:** Evaluate the impact of task scheduling in multitasking mobile operating systems (Android/iOS) on the total pipeline delay (*audio capture* $\rightarrow$ *AI inference* $\rightarrow$ *BLE transmission* $\rightarrow$ *peripheral activation*), ensuring that the total time does not compromise safety in critical scenarios.
2) **Ergonomics and Physical Robustness:** Analyze the acceptance of the bracelet in continuous use, considering biomechanical and environmental factors such as thermal dissipation, moisture (sweat), and mechanical comfort of the vibrations on the skin.

V. Conclusion

This systematic review evidenced that the development of assistive devices for Deaf and Hard of Hearing individuals is in a period of rapid expansion, driven by the miniaturization of *hardware* and local processing with artificial intelligence (*Edge Computing*). The focus of innovations has migrated from purely clinical testing to the creation of practical wearable systems that solve two fundamental demands: the spatial localization of sound sources (using arrays of multiple microphones) and the acoustic classification of urgent events (employing neural networks and sound feature extraction).

For the transmission of information, haptic feedback is consolidated as an effective pathway for sensory augmentation. The literature proves that tactile stimulation restores spatial awareness, assists in urban safety, improves speech comprehension in noisy environments, and returns engagement in musical appreciation. However, the most efficient architecture, and the one preferred by users, is the bimodal one: vibration operates as an immediate alert, while visual feedback provides semantic and directional details, drastically reducing the cognitive load.

Despite the expressive potential for inclusion, the transition from the laboratory to the market requires overcoming practical technical challenges, above all the optimization of battery consumption, the reduction of mechanical latency, and the guarantee of comfort during continuous contact with the skin; but projects like the *Ontenna* [39] show that it is possible to make this transition. Furthermore, for future work, it is essential to prioritize personalization through adjustable algorithmic filters, avoiding sensory overload for the user in noisy environments. It is concluded that integrating these assistive technologies into already consolidated social devices, such as *smartwatches* and smart glasses, appears to be an extremely promising path to minimize stigmas and revolutionize the autonomy and quality of life of the DHH community.

***Abstract*—The Specific Absorption Rate (SAR) is the primary parameter used to estimate the deposition of radiofrequency energy during magnetic resonance imaging (MRI). It is critical for patient safety, especially in individuals with impaired thermoregulation. This work proposes and experimentally validates a phantom-based approach to optimizing MRI protocols to reduce SAR while maintaining the predefined quantitative image-quality criteria. Initially, a retrospective analysis of clinical SAR distributions was conducted using DICOM header data from brain and lumbar spine examinations to identify sequences with the highest estimated RF energy deposition. The clinical protocols were then optimized by adjusting acquisition parameters such as flip angle, echo train length, Low SAR mode, and, when necessary, sequence replacement. Image quality was quantitatively assessed using the signal-to-noise ratio, geometric distortion, spatial resolution, and percentage of image uniformity. The findings revealed a quadratic relationship between SAR and the flip angle (R^2 = 0.994) and an approximately linear relationship between SAR and the length of the echo train (R2 = 0.999). Six brain sequences that initially exceeded the operational SAR limit were successfully optimized to values below 1.06 W/kg while meeting the predefined quantitative image-quality acceptance criteria. This experimental approach provides a systematic framework for implementing low-SAR MRI protocols. It may support the development of MRI protocols with reduced estimated RF energy deposition for patients who require stricter control of SAR.**

***Index Terms*—Image Quality, Magnetic Resonance Imaging, Phantom, Protocol Optimization, Specific Absorption Rate.**

I. Introduction

Magnetic resonance imaging (MRI) is one of the leading imaging modalities in contemporary clinical practice, widely used because of its high contrast resolution and the absence of ionizing radiation. Despite this favorable safety profile, the interaction between electromagnetic fields used for image acquisition and biological tissues can result in the deposition of energy as heat, mainly from radiofrequency (RF) pulses [1]–[3].

In this context, the Specific Absorption Rate (SAR) is the primary parameter used to indirectly estimate the energy absorbed by tissues during an MRI examination [4]. SAR is used by regulatory bodies such as the Food and Drug Administration (FDA) and the International Electrotechnical Commission (IEC) to define operational safety limits, generally set at 2.0 W/kg for the whole body and 3.2 W/kg for the head in normal operating mode [5], [6]. Although these limits are considered safe for the general population, patients with impaired thermoregulation—such as elderly people, sedated patients, and those with cardiovascular or metabolic disease—may be more susceptible to RF-induced heating, even within regulatory limits [2], [4], [7]–[9].

Since SAR is not measured directly during examination but is estimated from models that incorporate transmitted RF power, coil characteristics, and acquisition parameters, changes to these parameters simultaneously affect both energy deposition and image quality [1], [10]. Among the main factors involved are the angle of flip (FA), repetition time (TR), echo train length (ETL), the type and duration of RF pulses, as well as the electrical properties and volume of the irradiated tissue [2], [3], [7], [11]–[14]. Consequently, SAR-reduction strategies are mainly based on optimizing these parameters by decreasing FA, increasing TR, reducing ETL, using sequences less dependent on refocusing pulses, and employing automated vendor-provided tools [2], [7], [12], [13], [15]. However, such modifications may compromise fundamental image quality parameters, including signal-to-noise ratio (SNR), contrast-to-noise ratio (CNR), spatial resolution, and tissue contrast, thereby making MRI protocol optimization a trade-off between safety and diagnostic performance.

In this context, the use of phantoms is a well-established experimental approach that standardizes acquisition conditions, eliminates the biological variability inherent in *in vivo* studies,

and enables reproducible quantitative assessments of image quality. Phantoms are widely used in quality control programs and in the development of magnetic resonance protocols, allowing an objective evaluation of quality metrics and other characteristics of the physical image [15], [17]–[20].

Although there are studies that address SAR-reduction strategies, few present an experimental phantom-based approach to protocol optimization that combines the characterization of SAR distribution in clinical protocols with a quantitative evaluation of the impact on image quality under controlled experimental conditions [18], [21].

Given this gap, the present work aimed to propose an experimental approach for optimizing MRI protocols with reduced SAR and to validate it experimentally, using a phantom and quantitative image quality metrics. Specifically, the work sought to characterize the distribution of SAR across clinical protocols, identify the sequences that contribute most to energy deposition, evaluate the influence of key acquisition parameters on SAR, and verify whether the proposed optimization can reduce the estimated RF energy deposition reported by the MRI system while preserving objective indicators of image quality.

II. Materials and Methods

A. Materials

The work was conducted in the diagnostic imaging service of a reference hospital, using a 1.5 T MRI system (Canon Medical Systems, Vantage Elan MRT-2020) with gradients up to 33 mT/m and a slew rate of 125 mT/m/ms [22].

The system is equipped with a 16-element quadrature (QD) whole-body coil, with a maximum root-mean-square (RMS) power of 12 kW and a bandwidth of 63.7 MHz ± 275 kHz [22]. A photograph of the equipment is shown in Fig. 1.

Fig. 1. Canon Vantage Elan 1.5 T magnetic resonance imaging system installed at Hospital de Base do Distrito Federal.

The surface coil used were a head coil (Octave Speeder Head, model MJAH-167A). The image of the coil is shown in Fig. 2.

Images were acquired using routine clinical protocols on the manufacturer's MRI homogeneity test phantom and the

Fig. 2. RF coil used head coil.

American College of Radiology (ACR) phantom. The ACR phantom (180 mm, Konex®) is filled with an aqueous solution of sodium chloride and nickel chloride, with electrical properties equivalent to those of biological tissues [20]. The phantom was used as the standard object in all experimental acquisitions. Two images of the ACR phantom are shown in Fig. 3, with the axial view on the left and the profile view on the right.

Fig. 3. 180-mm Konex® ACR MRI phantom used in the work.

The images were processed using ImageJ software (National Institutes of Health, USA).

This work was approved by the Research Ethics Committee (CEP) of the Hospital das Clínicas of the Federal University of Goiás, under approval report number 7.654.997 and Certificate of Presentation for Ethical Appraisal (CAAE) number 86149824.2.0000.5083.

B. Methods

1) Experimental design: This work is a quantitative, experimental, paired-design study in which standard clinical MRI protocols were compared with their SAR-protocol-reduced, optimized versions. All acquisitions were performed on the same MRI system and with the same test object, ensuring control of external variables and enabling direct analysis of changes resulting exclusively from adjustments to acquisition parameters.

It is important to note that the present study was designed as a phantom-based technical validation, aimed at isolating the effect of acquisition parameter adjustments on objective, quantitative image-quality metrics under controlled conditions. Blinded radiologist evaluation, while valuable, applies to the assessment of diagnostic image quality in patient examinations.

2) Retrospective SAR distribution: Before the experimental stage, a retrospective analysis of SAR values extracted from the DICOM header (tag 0018,1316) was performed to characterize the empirical SAR distribution for each clinical protocol (brain and lumbar spine).

This step was used to estimate the mean values and dispersion of the SAR under real clinical conditions. The distribution by patient, protocol, and sequence type was important, since the literature does not provide a systematic characterization of these distributions, a fundamental step to identify the sequences that contribute the most to overall SAR within a specific protocol.

To determine the number of patients per protocol, a pilot collection of 12 examinations per group was first conducted to estimate the variability of the SAR values obtained [16]. From this preliminary sample, descriptive measures—including the mean and standard deviation—were calculated and used to estimate the required sample size. A significance level of 5% ($\alpha = 0.05$) and a statistical power of 80% ($1-\beta = 0.80$) were adopted, in accordance with widely used recommendations in the literature [24]. The sample size was estimated using the two-sample independent means test, as described in [27], indicating a minimum of 30 patients per protocol.

3) Aquisition: The SAR value reported by the system is based on estimates from the internal manufacturer related to the power absorbed by the tissues ($P_{absorbed}$) and the body mass of the patient (m), which can be expressed in simplified form as [10]:

$$SAR = \frac{P_{absorbed}}{m} \tag{1}$$

Routine clinical protocols for the brain and lumbar spine were first performed in standard settings. The sequences selected for optimization were identified. Then, the acquisitions were performed with progressively adjusted parameters to reduce the SAR. However, as much as possible, the equivalent contrast characteristics and spatial resolution were maintained. Each sequence was acquired in triplicate, allowing estimation of intra-system variability and greater statistical consistency of the measurements obtained.

4) Protocol optimization and SAR control: The reduction in SAR was achieved by adjusting the acquisition parameters, including FAs, ETLs, excitation, and reconstruction parameters, and, when necessary, by replacing sequences. The equipment's automatic SAR-reduction function ("Low SAR") was used as an initial step, followed by incremental manual optimizations. The general work workflow is shown in Fig. 4.

5) Operational SAR criterion: The SAR acceptability criteria adopted in this were defined as operational limits specific

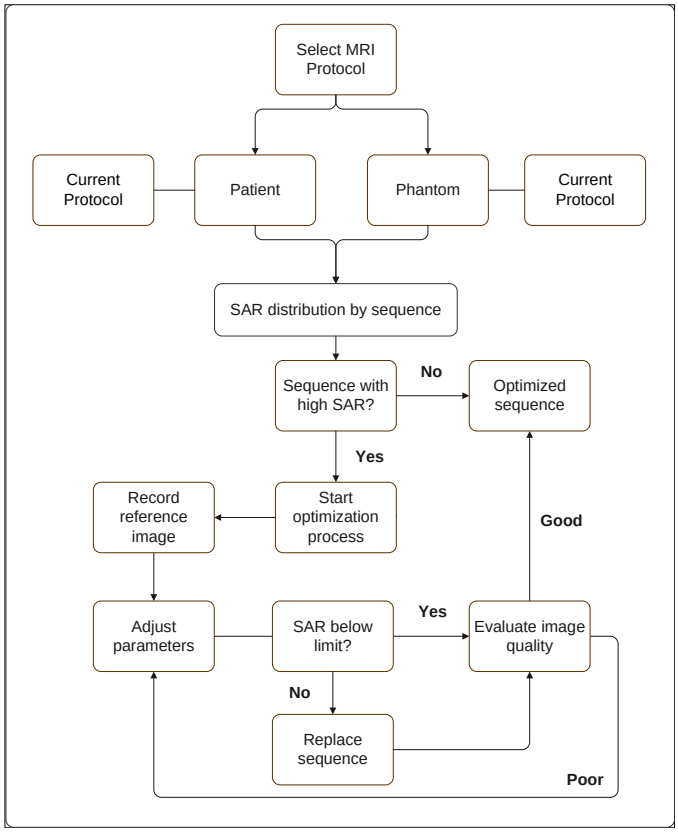

Fig. 4. Workflow for protocol optimization.

to the scenario of impaired thermoregulation. Because the study was motivated by the need to provide an additional thermal safety margin for patients with potentially impaired thermoregulation, a conservative operational SAR criterion was defined a priori.

The physiological literature supports the need for additional caution in patients with impaired thermoregulation, but does not establish a specific percentage reduction in the regulatory SAR limits for this population [7]. Accordingly, rather than being derived from a specific physiological threshold, the 67% reduction adopted in the present study was defined a priori as an operational criterion of the experimental design for the purposes of this study. This criterion was used to establish the operational SAR thresholds adopted for protocol optimization and should not be interpreted as a physiologically established threshold, a regulatory limit, or a universal recommendation. The resulting operational limits are shown in Table I:

TABLE I
OPERATIONAL SAR CRITERION

Protocol	***SAR (W/kg)***
Brain (Head SAR)	$\leq 1,06$
Lumbar Spine (Whole-Body SAR)	$\leq 0,66$

6) Test-object acquisition and experimental control: All acquisitions were performed using the homogeneity MRI

phantom and the ACR phantom, positioned at the equipment isocenter in a standardized manner. The same experimental setup was maintained for both the standard and optimized protocols, ensuring geometric consistency and reproducibility of the measurements.

7) Image quality evaluation: The image quality was quantitatively assessed from DICOM images using ImageJ software. The following parameters were analyzed: SNR, spatial resolution, geometric distortion, and percent image uniformity (PIU). For SNR, equation (2) was used [14], [17], [19], [23], [25]:

$$SNR = 0,655\frac{MPV_{ROI}}{\sigma_{air}} \tag{2}$$

Where MPV_{ROI} is the mean pixel value in a region of interest (ROI) and σ_{air} is the standard deviation within an ROI located in air.

Geometric distortion was obtained using equation (4) [23]:

$$\text{Distortion} = \frac{\text{Distance}_{nominal} - \text{Distance}_{measured}}{\text{Distance}_{measured}} \tag{3}$$

And image uniformity was assessed using equation (5) [20], [23]:

$$PIU = 100\left[1 - \frac{MPV_{\text{Max}} - MPV_{\text{Min}}}{MPV_{\text{Max}} + MPV_{\text{Min}}}\right] \tag{4}$$

Where MPV_{Max} and MPV_{Min} correspond to the mean pixel value in an ROI positioned in the region of highest intensity and in an ROI positioned in the region of lowest intensity, respectively.

ROIs were positioned in a standardized manner, following the ACR phantom guidelines to ensure consistency between acquisitions.

8) Image acceptance criteria: Optimized protocols were considered acceptable when they simultaneously met the image quality criteria defined relative to the reference protocol and the operational SAR criterion, as shown in Table II.

TABLE II
IMAGE QUALITY PARAMETERS AND RESPECTIVE ACCEPTANCE CRITERIA.

Parameter	*Desviation*
SNR	$\geq 75\%$ of reference value
Distortion	$\leq 2\%$
Spatial Resolution	Maintenance of the smallest resolved pattern
PIU	$> 85\%$

9) Statistical analysis: Data were analyzed using descriptive statistics (mean and standard deviation). The design was paired to compare the reference and optimized protocols.

The evaluation of results was based on the percentage variation of the image quality parameters and the compliance with the predefined acceptance criteria.

III. RESULT

A. SAR distribution in clinical protocols

The 30 brain and 30 lumbar spine examinations available for each clinical protocol were analyzed to characterize the distribution of SAR values associated with routinely used clinical protocols. Fig. 5 shows this distribution.

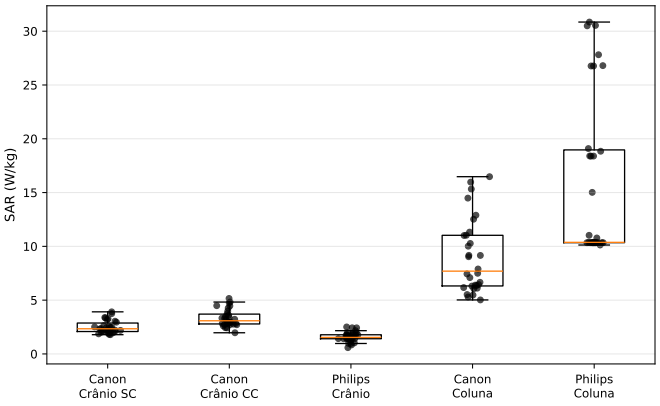

Fig. 5. Statistical distribution of SAR values for brain protocols with and without contrast on the Canon system, the brain protocol on the Philips system, and the lumbar spine protocol on both systems (SC = without contrast; CC = with contrast).

The mean (μ), median, standard deviation (σ), interquartile range (IQR), and minimum and maximum values are shown in Table III. In particular, the SAR recorded in the DICOM header (tag 0018,1316), shown in Fig. 5 and Table III, corresponds to the whole-body SAR (WB SAR).

For the retrospective clinical analysis, SAR values were obtained from DICOM tag (0018,1316), corresponding to whole-body SAR. In contrast, during the experimental optimization stage, the SAR value displayed by the MRI system was recorded according to the anatomical region and acquisition being evaluated.

TABLE III
DISTRIBUTION OF SAR VALUES FOR THE BRAIN AND LUMBAR SPINE PROTOCOLS

Protocol[a]	$\mu \pm \sigma$ **(W/kg)**	**Median (IQR)**	**Min - Max**
Canon Brain SC	2,50 $\pm 0,59$	2,34 (2,08-2,87)	1,79-3,91
Canon Brain CC	3,33 $\pm 0,80$	3,08 (2,79-3,70)	1,97-5,16
Philips Brain	1,59 $\pm 0,46$	1,54 (1,41-1,78)	0,58-2,51
Canon LS[b]	9,01 $\pm 3,42$	7,70 (6,32-11,03)	5,02-16,48
Philips LS[b]	15,98 $\pm 7,60$	10,37 (10,34-18,97)	10,12-30,85

[a]Sample size of 30 patients per protocol
[b]Lumbar Spine.

The largest contributions were observed in the spin echo (SE) and fast spin echo (FSE) based sequences, while the gradient echo (GRE) and fast GRE (FGRE) sequences showed the lowest values, as shown in Figs. 6 and 7.

When grouped by sequence family, the FSE and SE acquisitions showed the highest mean SAR values, as shown in Fig. 8.

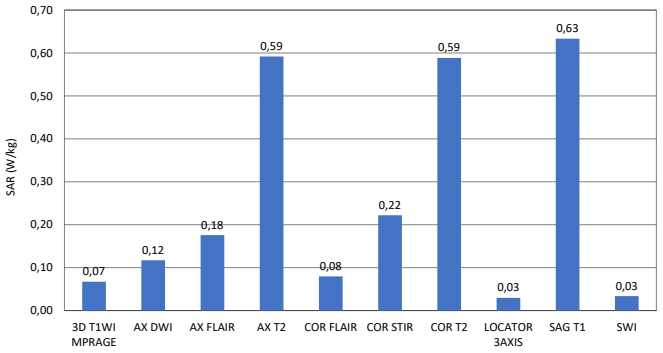

Fig. 6. SAR distribution for the sequences used in the brain protocol.

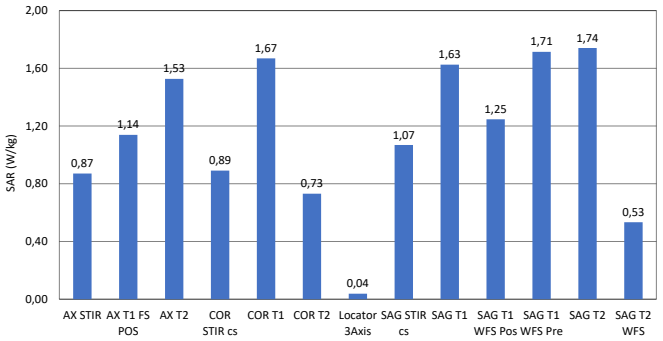

Fig. 7. SAR distribution for the sequences used in the lumbar spine protocol.

B. SAR Reduction strategy

The influence of the main acquisition parameters on SAR was experimentally evaluated using an FSE sequence representative of the clinical brain protocol. SAR exhibited an approximately quadratic dependence on FA ($R^2 = 0.994$) and an approximately linear dependence on ETL ($R^2 = 0.999$).

Activation of the Low SAR mode resulted in reductions ranging from 19% to 63%, depending on the evaluated sequence, as shown in Tables IV.

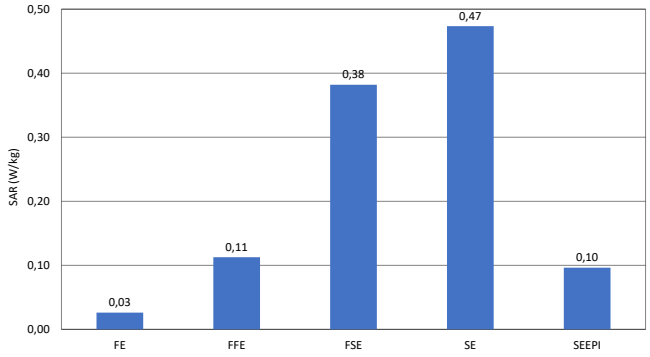

Fig. 8. SAR values grouped by MRI sequence type, for the brain protocol.

TABLE IV
SAR REDUCTION ASSOCIATED WITH THE USE OF THE LOW SAR MODE FOR SPECIFIC SEQUENCES WITHIN THE BRAIN PROTOCOL

Sequence	Original SAR (W/kg)	*Low SAR* (W/kg)	Mean Reduction (%)
FLAIR[a]	0.572	0.462	19.23
3D T1[a]	0.260	0.175	32.69
STIR[a]	1.019	0.771	24.34

C. Protocol Optimization

Six of the fourteen sequences evaluated in the brain protocol exceeded the adopted operational limit of 1.06 W/kg, as shown in Fig. 9.

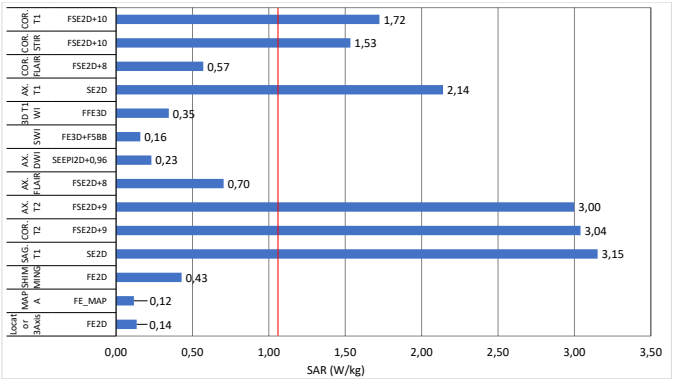

Fig. 9. Estimated SAR values for each sequence of the brain protocol used in clinical routine. The vertical line indicates the SAR = 1.06 W/kg threshold.

After optimizing acquisition parameters, all evaluated sequences achieved SAR values below the operational limit, as shown in Fig. 10.

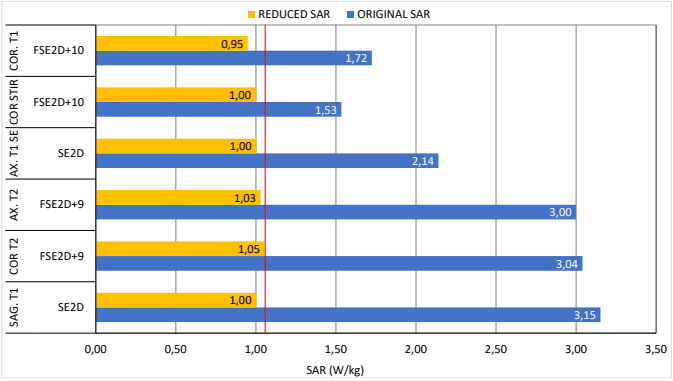

Fig. 10. Estimated SAR values per sequence before optimization (blue) and after optimization (yellow) for the brain protocol.

Table V presents eight sequence configurations. Although only six sequences were optimized, the SAG. T1 and COR. T1 sequences are presented with two optimization alternatives (Adjustments 1 and 2), for a total of eight configurations. For

TABLE V

each, the original and modified parameters are presented, along with the respective SAR values and acquisition times. In this work, the optimized sequence, "Adjustment 1," was adopted to construct Table VI.

D. Impact on Image Quality

The SNR evaluation results are shown in Fig. 11.

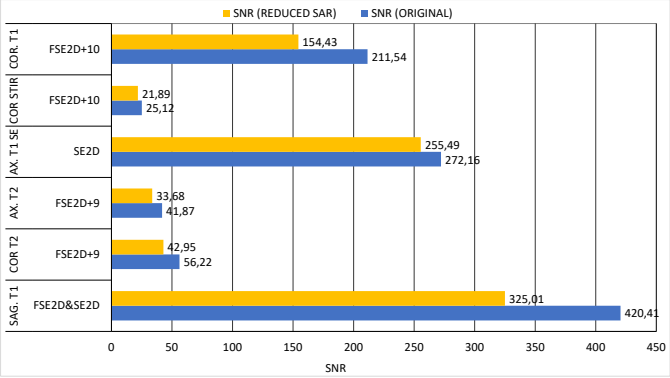

Fig. 11. Signal-to-Noise Ratio (SNR) for the brain protocol sequences before (blue) and after (yellow) SAR reduction.

Since SAR is related to the estimated RF energy deposition and SNR represents the quality of the signal obtained, the SNR/SAR ratio was used as a performance index to estimate the amount of useful signal obtained per unit of estimated RF energy deposition. Although not a standardized metric, this index provides a simple measure of the RF energy efficiency of the evaluated protocols, determined as:

$$\text{Efficiency} = \frac{SNR}{SAR} \tag{5}$$

Table VI presents the efficiency values calculated for the sequences analyzed before and after optimization of the acquisition parameters.

TABLE VI
EFFICIENCY CALCULATED FOR THE SEQUENCES ANALYZED BEFORE AND AFTER OPTIMIZATION

SEQ.	**Original Efficiency**	**Reduced Efficiency**	**Gain**
COR. T1	122.7	162.7	32
COR. STIR	16.4	22.0	34
AX. T1 SE	127.2	255.2	101
AX. T2	14.0	32.7	134
COR. T2	18.5	35.7	93
SAG. T1	133.4	325.0	144

IV. DISCUSSION

Characterization of the SAR distribution in clinical protocols showed that RF energy deposition is not uniform across MRI sequences, a finding also reported in [2], [15], with the brain protocol exhibiting lower SAR values than the other protocol.

The highest contributions to total SAR were observed in SE- and FSE-based sequences for the brain protocol and in FSE for the lumbar spine protocol, which is expected due to the repeated use of refocusing pulses, in agreement with the literature [13]. Although this mechanism is well known from a physical perspective, few studies provide a quantitative assessment of the individual contribution of each sequence within complete clinical protocols.

It was also observed that only a subset of the sequences included in the clinical protocols represented most of the energy deposition. This result demonstrates that optimization can be directed toward the critical sequences while preserving sequences with already low SAR contributions. This approach simplifies the implementation of low-SAR protocols in the clinical routine and minimizes unnecessary changes to the overall quality of the examination.

The observed quadratic behavior confirms the expected physical model, since the transmitted RF power is proportional to the square of the transmit RF field amplitude (B1) and FA is directly related to that amplitude. This result agrees with [13], which identified FA reduction and TR increase as

among the most effective strategies to reduce SAR during clinical examinations, and complements these findings by quantitatively demonstrating this relationship under controlled experimental conditions.

The ETL also had a direct influence on the RF energy deposition, showing approximately linear behavior. This result can be explained by the increase in the number of refocusing pulses applied within each TR, which increases the RF duty cycle and, consequently, the total energy transmitted to the patient. Although effective in reducing SAR, decreasing ETL should be used with caution, as it can increase total acquisition time and alter image weighting characteristics, as demonstrated in [28].

The results showed that the automatic low-SAR mode is an efficient initial strategy to reduce RF energy deposition. Although the internal implementation of the Low SAR mode is proprietary, experimental observations indicate that its activation is associated with changes in RF transmission parameters, such as B1+rms, BW, and TR, resulting in substantial reductions in estimated SAR. However, the observed adjustments varied across sequences. It suggests that the manufacturer's optimization strategy depends on the specific characteristics of each sequence, indicating that its effectiveness varies across sequences. In some sequences, the reduction achieved was sufficient to meet the established operational limit, while in others additional adjustments to acquisition parameters were required.

The results showed that moderate FA reductions of around 120° substantially reduced estimated RF energy deposition while maintaining image quality parameters within the predefined acceptance criteria. Only more intense FA reductions produced significant reductions in SNR, indicating that there is an operational range within which SAR can be optimized without significantly compromising the evaluated quantitative image quality parameters.

Image uniformity remained within the acceptance criteria, while geometric distortion remained within the limits recommended by the MRI quality control guidelines. Similarly, no relevant changes were observed in the spatial resolution of the evaluated sequences. These indicate that the strategies used primarily affected the efficiency of RF excitation while preserving other physical characteristics that determine image quality.

One of the most relevant aspects of this work was the characterization of the distribution of SAR in clinical protocols for the brain and lumbar spine. In contrast to ionizing radiation-based modalities, widely accepted reference values for SAR distribution across MRI protocols are not yet established. Thus, the results presented here can serve as operational indicators for local optimization processes, objectively identifying the sequences that contribute most to RF energy deposition and enabling more efficient targeting of optimization efforts. Furthermore, this characterization establishes a quantitative reference for future comparisons among equipment, protocols, and manufacturers.

A. Energy efficiency of the protocols

In all six evaluated sequences, optimization resulted in increased RF energy SNR-to-SAR efficiency index. This behavior indicates that the reduction in estimated RF energy deposition was disproportionate to the loss in signal intensity, resulting in a higher SNR per unit of deposited RF energy. From a physical perspective, this result demonstrates that the proposed strategy not only reduces SAR but also improves the SNR-to-SAR efficiency index of RF power utilization. An aspect particularly relevant to protocols designed for patients with greater susceptibility to thermal effects.

B. Clinical application

Beyond the implications of the experimental approach presented here, the results have potential applications in clinical routine. As discussed, the proposed approach may support the development of low-SAR protocols for MRI services caring for patients at increased risk of thermal effects. It includes patients who may have increased susceptibility to RF-induced heating, including individuals with impaired thermoregulation or other clinical conditions requiring additional thermal safety considerations. However, clinical diagnostic equivalence was not assessed in the present study.

C. Limitations

This work has some limitations that should be considered when interpreting the results. First, the evaluations were performed on a single 1.5 T MRI system, so generalization of the results to equipment from other manufacturers or with different field strengths should be made with caution. Although the retrospective SAR distribution included equipment from different manufacturers, the experimental optimization stage was conducted exclusively on a Canon system. Future studies should therefore replicate the proposed workflow on MRI systems from different manufacturers and at higher field strengths, particularly 3 T, where RF energy deposition and spatial variations in SAR may represent greater challenges.

Once the technical feasibility of SAR reduction is established under controlled phantom conditions, as demonstrated here, a natural next step would be a clinical validation study involving blinded radiologist scoring of diagnostic image quality and inter-rater agreement in patient examinations.

Finally, the SAR values used in the optimization were estimated by the MRI system rather than directly measured. No direct measurements of phantom temperature or RF energy deposition were performed. Therefore, the proposed approach should be interpreted as an optimization strategy based on the SAR estimates provided by the MRI system, rather than as a direct assessment of tissue heating or thermal dose.

V. Conclusion

This work proposed and experimentally validated an approach for optimizing magnetic resonance imaging protocols using a phantom and quantitative image quality assessment. This experimental strategy was based on characterizing the

SAR distribution in clinical protocols and identifying the sequences that contribute the most to RF energy deposition. The influence of the main acquisition parameters was evaluated, and the performance of the optimized protocols was assessed.

The heterogeneity of the SAR distribution enables objective prioritization of sequences for optimization. The reduction in FA was the most effective strategy. It was complemented by using the Low SAR mode and ETL adjustment. When necessary, sequence replacement complemented optimization, bringing all sequences initially above the operational limit into compliance with the established criteria.

The reduction in estimated RF energy deposition was accompanied by limited quantitative changes in image quality. Although some sequences showed a decrease in SNR, the uniformity, spatial resolution, and geometric distortion values remained within the acceptability criteria. Additionally, the optimized protocols showed greater RF energy efficiency.

The main contribution of this work was to demonstrate that characterizing the SAR distribution in clinical protocols enables the objective identification and optimization of sequences with the highest estimated RF energy deposition, thereby reducing SAR without compromising quantitative image quality criteria. The proposed experimental approach provides a structured and reproducible framework that may be adapted for implementation and further validation across different MRI services and systems.

ACKNOWLEDGMENT

The authors thank Hospital de Base do Distrito Federal and Hospital São Francisco de Assis for providing access to their magnetic resonance imaging systems, the Graduate Program in Electrical and Computer Engineering at the Federal University of Goiás for its academic support, and Cerrad Consultoria em Física Médica e Radioproteção for providing the ACR phantom used in the experimental evaluations.

***Abstract*— Human gait analysis is an important technique for assessing, diagnosing, and monitoring certain conditions and biomechanical patterns. Some diseases and disabilities can influence gait dynamics. Individuals with Trisomy 21 (T21) have reduced speed and quality of postural reactions, which leads to compensatory movement patterns. Therefore, analyzing linear gait measurements allows for the objective identification of kinematic patterns that may be altered, enabling comparison of these patterns after therapy and enhancing the therapeutic approach. This study aims to provide a instructions for using the Kinovea software to evaluating linear gait measurements.**

Keywords—Gait Analysis, Trisomy 21, Kinovea

I. Introduction

Gait analysis is an important technique for assessing, diagnosing, and monitoring certain conditions and biomechanical patterns. Despite individual differences, the gait of typically developing individuals is consistent and rarely changes [1].

However, certain genetic conditions, diseases, and disabilities can influence gait dynamics. Individuals with Trisomy 21 (T21) have reduced speed and quality of postural reactions, which leads to compensatory movement patterns during the phases of gait. Therefore, the analysis of linear gait measurements allows for the objective identification of kinematic patterns that may be altered, enabling comparison of these patterns after the therapy, as well as optimizing the therapeutic [2].

Some authors have reported that individuals with T21 may compensate for their congenital mechanical instability by performing specific motor responses, such as increasing muscle activation or executing co-contraction patterns [3][4][5].

Given our understanding of the musculoskeletal changes that modify the pattern of linear gait measurements, as well as joint stiffness in individuals with T21, the objective and quantified analysis of these changes proposed in the manual can assist in the development of therapeutic interventions with specific, measurable, achievable, relevant, and temporally defined objectives, as described in the SMART method [6].

II. Objectives

Provide instructions for using the Kinovea software to evaluate linear gait measurements.

Establish a standardized method for determining the following parameters: stride length and average gait speed.

III. Kinovea: Analiysis Software

This is a free app that provides tools for analyzing 2D motion using spatiotemporal, angular, and linear parameters, as well as distances and frame-by-frame coordinates, of which can be analyzed with or without markers.marcadores.

IV. Filming

A. Camera Position

The camera used for filming must be positioned horizontally, as shown in Figure 1, in a fixed location at an angle of approximately 90°, positioned perpendicular to the participant at a distance of 2.5 meters and at a height of 1 meter above the ground [7]. The camera cannot be moved while recording. In the example that will be presented, a 12 megapixel smartphone camera with a frame rate of 60 Hz was used.

B. Guidelines for Filming the Walk

It is recommended to place a marker on the subject's lateral malleolus, as shown in Figure 2. Preferably, the subject should be wearing their usual shoes or be barefoot. Markers may include: Post-it notes secured with tape, adhesive labels, or dermatographic pens, as shown in Figure 2.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

Fig. 1. How to position de camera

Fig. 2. Marker Positions

Fig. 3. Calibration Measurement Model

C. *Video Calibration Templates*

We suggest that the calibration measurement be 100 centimeters horizontally. To include this reference in the video, you can use various tools such as adhesive tape, a measuring tape, or two objects positioned to simulate the standard calibration measurement, as shown in Figure 3.

The calibration measurement should be near or part of the path that the individual will walk, as shown in Figure 3.

V. Linear Measurements of the Walk

A. *Video Selection*

To measure linear gait parameters (stride length and speed) through gait video analysis, the video must be recorded in the sagittal plane, and it must be possible to visualize four initial ground contacts and the marked anatomical point: the lateral malleolus.

B. *Analysis of Walking Variables*

The variables analyzed in the walking video are:

COMP-P1: stride length 1.

COMP-P2: stride length 2.

COM-P3: stride length 3.

Δs: distance traveled by the individual from the starting point to the end point.

Δt: time taken by the individual to travel from the starting point to the end point.

V: average walking speed.

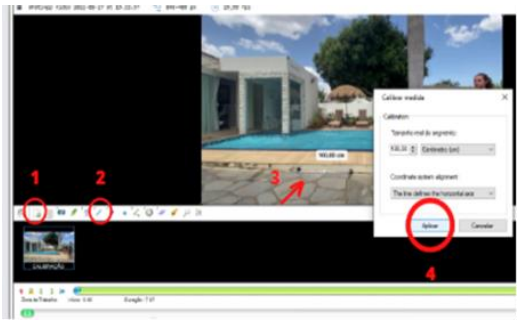

Fig. 4. System Calibration

C. *Calibration of Walking in the Sagittal Plane.*

1- When loading the video, click the button to add a new image frame and select a frame before the first Initial Contact, Figure 4.

2- Select the “line” button. Draw a horizontal line from the beginning to the end of the standard measurement for calibration, which, in Figure 4, is represented by two objects on the ground that represent the actual distance of 100 cm.

3- After drawing the line, right-click on it and select the “Calibrate” button, Figure 4.

4- Set the measurement to 100 centimeters and click “Apply,” Figure 4.

D. *Selection of Initial Contact Frames*

1- Drag the navigation bar and stop at the Initial Contact (IC) phases of the gait, referring to the same lower limb, because we will be working with stride length.

2- Click the icon to add a new image frame and select the frame for the Initial Contact phase, Figure 5.

3- To save the names of the selected frames, simply double-click on the frame to name it, Figure 5.

You must select the frames for the first four Initial Contacts (CI1, CI2, CI3, CI4), Figure 5. This will result in the following: CALIBRATION, CI1, C12, CI3, CI4, Figure 5.

The numbers following the names correspond to the time at which the individual made that initial contact. Therefore, in CI1 the time was 2.07 s, and in CI2 the time was 1.36 s, which is the difference between the times for CI2 and CI1, since the software displays the time continuously. In CI3, the time was 1,27 seconds, that is, the difference between CI3 and CI2, and in CI4, the time was 1,37 seconds, that is, the difference between CI4 and CI3.

The time is automatically saved in the frames, Figure 6. However, it is necessary to calculate these subtractions.

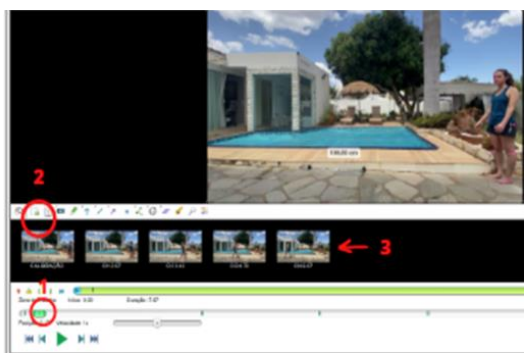

Fig. 5. Frame Selection in the System.

Fig. 6. Frames.

Fig. 7. Calibration Grid Adjustment.

E. Calibration Grid Adjustment

1. After selecting the frames, click on the initial contact frame 1, Figure 7.
2. Click "Tools" and then "Coordinate System"; after these commands, the calibration grid will appear, Figure 7.
3. Select the icon on the navigation bar, position the cursor in the center of the calibration grid, and drag the grid so that the 0 is aligned with the individual's lateral malleolus, Figure 7.
4. Verify that the positioning is correct, Figure 7.

F. Measuring Stride Length 1.

1. To obtain the length of Stride 1, you must be on the CI2 frame, as this frame corresponds to the start of Stride 2 and the end of Stride 1, Figure 8.

2. Select the line button, Figure 8.

3. Draw a horizontal line from the point where the lateral malleolus was located in CI1 (in this case, we adjusted the calibration grid for CI1 to point 0 on the calibration grid) to the point where the lateral malleolus is located in CI2. Then, the line will extend from point 0 on the calibration grid to the individual's lateral malleolus. This will give you the length (COMP) of stride 1 (P1) in centimeters, in Figure 8, this is represented by 140,41 centimeters.

To save the image, right-click and save as: COMP-P1-INDIVIDUALABBREVIATION-MID or MIE (side evaluated).

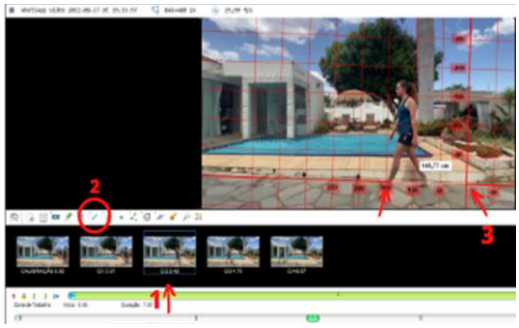

Fig. 8. Measuring Stride Length 1.

G. Measuring Stride Length 2

Para To analyze the length of stride 2, you must first mark the location of the lateral malleolus at the start of stride 2.

To do this, we will use a tool in the application called "marker"

1. Click the "marker" button, Figure 9.
2. Position the marker over the lateral malleolus, Figure
3. Right-click on the marker, click "visibility," and then click "always visible," Figure 9.

This way, when you move to the next frame, the marker will be visible to make it easier to measure the length of the next stride. The markers will be visible in the video as shown in Figure 10.

To Measure Stride Length 2:

1. You must be on the CI3 frame, as this corresponds to the start of stride 3 and the end of stride 2, Figure 11.
2. Select the line icon, Figure 11.
3. Draw a horizontal line from the point where the lateral malleolus was located (as defined by the marker) to the point where the lateral malleolus of CI3 is located, Figure 11.

This will give you the length (COMP) of stride 2 (P2) in centimeters, in Figure 11, this is represented by 134,95 centimeters.

To save the image, right-click and save as: COMP-P2-INDIVIDUALINITIALS-MID or MIE (side evaluated).

Fig. 9. Adding the Marker.

Fig. 10. Markers.

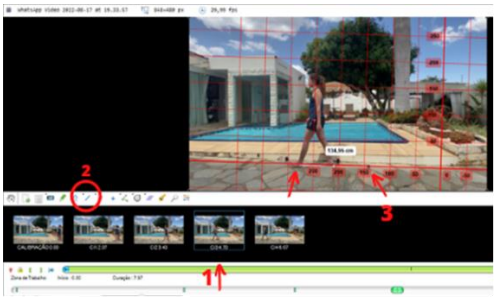

Fig. 11. Measuring Stride Length 2.

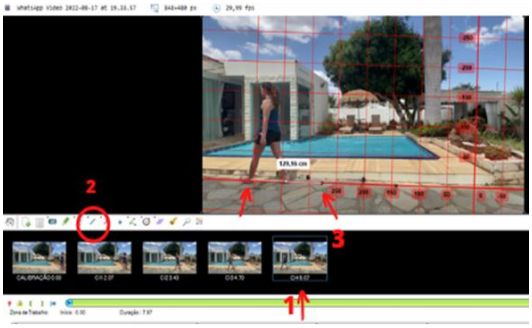

Fig. 12. Measuring Stride Length 3

H. Measuring Stride Length 3

1. To obtain the length of Stride 3, you must be in the CI4 frame, as this frame corresponds to the start of Stride 4 and the end of Stride 3 (Figure 12).

2. Select the line button (Figure 12).

3. Draw a horizontal line from the point where the lateral malleolus was located (as defined by the marker) to the point where the lateral malleolus of CI4 is located, Figure 12.

This will give you the length (COMP) of stride 3 (P3) in centimeters, in Figure 12, this is represented by 129,55 centimeters.

To save the image, right-click and save as: COMP-P3-INDIVIDUALINITIALS-MID or MIE (side evaluated).

I. Walking Speed

To calculate the average walking speed (VM), you need to determine the distance (Δs) traveled by the individual and the time (Δt) taken to move that distance.

J. Calculation of Displacement (Δs)

1. Stay on the CI4 frame, Figure 13.
2. Select the line tool, Figure 13.
3. Draw a line from point "0" on the grid, which marks the start of the displacement, to the individual's lateral malleolus, which marks the end of the displacement, Figure 13.

To save the image, right-click and save as: DISTANCE-INDIVIDUALINITIALS-MID or MIE (side evaluated).

This will give you the (Δs) in centimeters. In our example, the distance traveled was 404.91 centimeters, Figure 14.

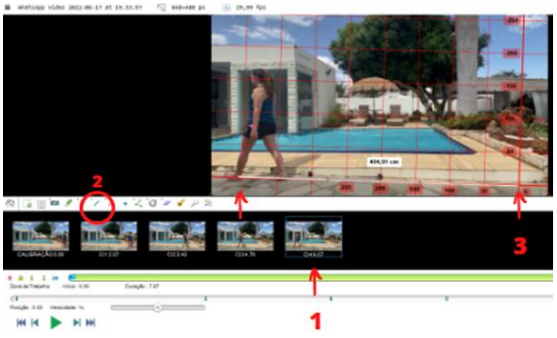

Fig. 13. Guide for determining Displacement (Δs).

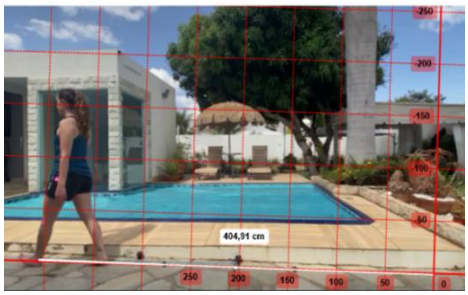

Fig. 14. Obtaining the Displacement (Δs).

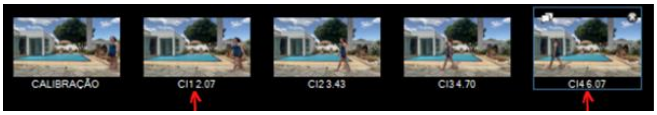

Fig. 15. Obtaining the Time (Δt)

K. Calculating the Time (Δt)

To calculate the time, subtract the time the individual arrived at CI1 from the time they arrived at CI4, as illustrated in Figure 15.

This will give you (Δt) in seconds. In our example, the time was 6,07 s – 2,07 s, or 4,0 s.

L. Calculating Average Speed

To calculate the average speed, we will convert Δs from centimeters to meters, dividing the value in meters by 100, as indicated in equation (1).

$$\Delta s\ (m) = \Delta s\ (cm) / 100 \quad (1)$$

We will divide Δs, measured in meters (m), by Δt, measured in seconds (s), using the following formula:

$$V = \Delta s / \Delta t \quad (2)$$

VI. Conclusion

The use of quantitative protocols for assessing human gait directly impacts the quality of care. The use of Kinovea, a free and accessible tool, for these analyses democratizes this quality. The existence of a detailed protocol helps frontline professionals effectively apply best practices in assessment.

***Abstract*—The use of Large Language Models (LLMs) in healthcare opens promising perspectives for clinical decision support; however, privacy and infrastructure constraints drive interest in open-source models executed locally and offline. This experimental study evaluated and compared the impact of Retrieval-Augmented Generation (RAG) architecture on the cognitive performance and computational efficiency of four LLM architectures specialized in the medical domain (Bio-Medical-Llama-3.1-8B, LlaMA-3.1-8B-Medical, Llama-3.2-3B-Instruct, and Qwen2.5-3B-instruct) during the resolution of complex clinical scenarios of Diabetes Mellitus. Inferences were performed in a restricted deterministic computational environment (8 GB VRAM) using the GGUF quantization format (4-bit and 8-bit). Evaluation was based on balanced subsets of 200 questions extracted from the MEDQA and MedMCQA benchmarks. The results revealed a counterintuitive behavior compared to cloud-operated systems: the introduction of RAG, in this setup, caused a degradation of clinical accuracy across almost all scenarios, accompanied by a substantial operational penalty. The LlaMA-3.1-Med-8B model achieved the highest accuracy observed in direct inference (66.5% on MedMCQA; 58.0% on MEDQA), dropping to 58.5% and 49.5% respectively under the RAG condition. From a software engineering perspective, context expansion (up to 4,000 characters) acted as distracting noise for the selective attention mechanisms of compact networks, a pattern consistent with the lost-in-the-middle effect described in the literature, and created a bottleneck in the GPU–CPU bus bandwidth due to partial layer offloading, increasing average latency by up to 34 times and substantially reducing the tokens-per-second (TPS) rate. We conclude that, under the specific configuration evaluated, the standard single-corpus RAG pipeline substantially increased computational cost and frequently reduced clinical accuracy, indicating a trade-off that requires further characterization across alternative retrieval strategies and hardware environments.**

***Index Terms*—Large Language Models, RAG, Diabetes Mellitus, Restricted Hardware, Computer Engineering.**

I. Introduction

Diabetes Mellitus (DM) represents one of the greatest global public health challenges, requiring individualized and multidisciplinary decision-making based on a growing volume of guidelines and therapeutic data [1]–[4]. In parallel, the recent advancement of Large Language Models (LLMs) has opened new horizons for clinical decision support, demonstrating high performance in medical reasoning tasks [5], [6]. However, operational and regulatory constraints regarding the protection of sensitive data, such as LGPD and HIPAA, limit the use of commercial cloud APIs, driving institutional interest in open-source models executed locally and offline.

Despite progress in compact biomedical models, their probabilistic architecture is still prone to factual hallucinations and failures when applying rigid quantitative diagnostic thresholds [7]. To mitigate these flaws, Retrieval-Augmented Generation (RAG) architecture emerges as a strategy to ground answers directly in explicitly validated external documentary sources [8], [9]. The potential of this approach in the medical field and in diabetes education has demonstrated gains in accuracy and reductions in hallucinations [10], [11].

However, gaps remain in the literature regarding the practical impact of RAG on compact medical LLMs executed locally under severe hardware constraints. Injecting additional contexts introduces search and re-ranking stages that directly alter crucial operational metrics such as latency and token generation speed, making it necessary to evaluate the trade-off between cognitive gains and their respective computational costs.

To contribute toward filling this gap, this study aimed to evaluate and compare the impact of RAG architecture on the cognitive performance and computational efficiency of different open-source, offline-executed LLMs specialized in the medical domain during the resolution of structured complex clinical scenarios focused on Diabetes Mellitus and related metabolic disorders.

II. Methodology

This experimental study aimed to evaluate and compare the impact of RAG architecture on the performance of offline-executed LLMs focused on the medical field. Four medical-specialized LLM architectures were evaluated and subjected to subsets of questions extracted from the MEDQA and MedMCQA international benchmarks, which are widely used to assess biomedical knowledge and automated clinical reasoning [12], [13].

A. Execution Environments and Evaluated Models

Inferences were performed locally in a deterministic computational environment (configured with temperature $t = 0.0$ and $top_p = 1.0$) to mitigate the stochastic variability of the responses. The pipeline was structured in Python, using the

llama_cpp library for the orchestration and execution of the quantized models in GGUF format.

To enhance the technical rigor and academic fluidity of the methodology, the selection of the open compact LLM architectures was based on the state-of-the-art models featuring high efficiency and specialized fine-tuning in the biomedical and clinical domains. Four models based on the Llama 3.1, Llama 3.2, and Qwen 2.5 families were selected, operating at scales of 3B and 8B parameters.

To enable strictly deterministic local execution and mitigate the severe video memory (vRAM) constraints typical of consumer hardware environments, all architectures were evaluated using the GGUF (GPT-Generated Unified Format) encapsulation and quantization format. Weight compression was performed using block-based advanced quantization algorithms (k-quants and i-quants), reducing the original 16-bit floating-point representation to hybrid 4-bit and 8-bit representations. This strategy dramatically reduced the memory footprint and the bandwidth required for data transfer without causing substantial degradation in the models' cognitive and semantic capabilities.

The inference pipeline integrated the llama_cpp library with low-level optimizations at the computational kernel level:

- Flash Attention: Implementation of block-based selective attention mechanisms that optimize reading and writing traffic in the GPU cache memory.
- Active KV Cache Offload: Strictly configured with type-2 keys and values in 16-bit floating-point precision, keeping the context history highly faithful and stable.
- Dynamic Layer Allocation (GPU Split): Adaptive management of network topology in the video memory. For smaller-scale models (3B), full layer offloading to vRAM was applied. For larger models (8B), a hybrid allocation restricted to 22 layers on the GPU was implemented, managing the remainder on the host CPU to avoid Out of Memory (OOM) failures.

Detailed technical specifications for each neural network model, including their distribution files, parameter volumes, and clinical specializations, are consolidated in Table I.

The diversity among the chosen quantization methods establishes a robust baseline for evaluating how the RAG architecture behaves against subtle losses induced by weight compression when solving complex clinical cases of Diabetes.

B. Datasets and Thematic Filtering Criteria

The performance evaluation used two established benchmarks in the medical artificial intelligence literature:

- MEDQA: Questions based on the United States Medical Licensing Examination (USMLE).
- MedMCQA: Multiple-choice questions from India's medical entrance examinations (AIIMS and NEET PG).

Since the scope of the paper was delimited to the study of Diabetes, the original datasets underwent a filtering process based on keyword co-occurrence. A question was included in the test subset only if it presented at least two simultaneous terms (co-occurrence ≥ 2) belonging to the following extended English list: *diabetes, glycemia, insulin, glucose, glycated hemoglobin,* and *hba1c*.

After applying the filter, a simple random sampling (with a fixed randomness seed, random_state $= 42$) selected balanced subsets of 200 questions per dataset to compose the final inference test for each model.

C. Inference Pipeline Architecture

The experiment was divided into two distinct experimental conditions: Direct Inference (Without RAG) and Enriched Inference (With RAG).

1) Condition 1: Direct Inference (Zero-Shot Without RAG): In the first stage, prompts were submitted to the models containing only the professional role instruction (*System Prompt*), the clinical question, and the four available options (A, B, C, D). The model was configured with a strict token limit (max_tokens $= 1$) and instructed to return strictly the letter corresponding to the correct alternative.

2) Condition 2: Inference with RAG Support: In the second stage, a RAG pipeline was implemented, consisting of a dense vector search coupled with a re-ranking algorithm:

- Indexing and Vector Database: The knowledge base (comprising International Diabetes Guidelines) was previously chunked and stored in a local vector database using the Qdrant Client.
- Dense Vector Search: For each dataset question, the query was converted into a dense vector using the local embedding model *sentencetransformers/paraphrase-multilingualmpnetbasev2* via the *fastembed* library. The system performed a cosine similarity search in Qdrant, retrieving the 4 most relevant text chunks (chunk_limit $= 4$) while respecting a cap of 4,000 characters.
- Re-ranking: The retrieved fragments were submitted to a local re-ranking model (*ms-marco-MiniLM-L-12-v2* via *flashrank*). The top 2 chunks resulting from the re-ranking were selected and dynamically injected into the final prompt.
- Enriched Prompt: The model received the context from the medical guidelines before the question block, responding under the same token constraints as the previous stage.

D. Knowledge Base for the RAG

The sources composing the knowledge base for the RAG represent some of the most critical, comprehensive, and updated clinical guidelines globally for the diagnosis, management, and treatment of Diabetes Mellitus and its associated comorbidities. This documentary base included the *Standards of Care in Diabetes — 2026* by the American Diabetes Association [2]; the *Clinical Practice Guideline: Developing a Diabetes Mellitus Comprehensive Care Plan — 2022 Update* [14]; the *Consensus Statement: Algorithm for Management of Adults With Type 2 Diabetes — 2026 Update* [15]; the British guideline *NICE Guideline NG28: Type 2 Diabetes in Adults: Management* [16], along with its respective update factsheet [17]; the *Clinical Practice Guideline: The Use of*

TABLE I
TECHNICAL SPECIFICATIONS AND TOPOLOGY OF THE EVALUATED LLM MODELS FOR THE RESOLUTION OF STRUCTURED COMPLEX CLINICAL SCENARIOS FOCUSED ON DIABETES MELLITUS AND RELATED METABOLIC DISORDERS

Model (.gguf file)	Params	Quantization	Architecture / Clinical Specialization
Bio-Medical-Llama-3.1-8B.i1-Q4_K_M	8B	Q4_K_M (i1)	Llama 3.1 base; supervised fine-tuning (SFT) focused on general biomedical knowledge and scientific literature terms.
LlaMA-3.1-8B-Medical.Q4_K_M	8B	Q4_K_M	Llama 3.1 base; fine-tuning geared toward clinical medical reasoning, diagnostics, and practical internal medicine management.
Llama-3.2-3B-Instruct-Medical-Conversational.Q8_0	3B	Q8_0	Llama 3.2 base; ultra-compact model with instructional tuning focused on history-taking and conversational medical interactions.
Qwen2.5-3B-instruct-medical-finetuned.Q4_K_S	3B	Q4_K_S	Qwen 2.5 base; optimized for high-density information medical tasks under severe computational hardware restrictions.

Advanced Technology in the Management of Persons With Diabetes Mellitus [18]; the joint guideline *Guideline for the Diagnosis and Management of Nonalcoholic Fatty Liver Disease (NAFLD)* [19]; and the integrated *Comprehensive Clinical Practice Guidelines for Medical Care of Patients with Obesity* [20]. Together, these documents form the core of modern, multidisciplinary diabetes management, covering prevention, early diagnosis, the intensive use of biotechnologies, and organ protection (heart, kidneys, and liver), managing the disease far beyond blood glucose metrics.

E. Evaluation Metrics

The performance of both approaches was measured and consolidated through three fundamental metrics: Clinical Accuracy (%), Average Latency per Question (s), and Tokens per Second (TPS).

The generated textual responses were normalized using regular expressions (Regex) to extract the predicted letter (A, B, C, or D) for subsequent cross-checking against the official answer key (*correct_answer*). Cases with inconclusive outputs were automatically classified as "INVALID".

III. RESULTS

Experimental results reveal a counterintuitive behavior regarding the use of Retrieval-Augmented Generation (RAG) architectures in compact LLMs executed locally. Contrary to the gains typically observed in large-scale cloud-operated models, the dynamic injection of clinical guidelines was associated with measurable penalties in both cognitive performance (accuracy) and computational efficiency (latency and token throughput) under the configuration evaluated.

A. Cognitive Performance (Accuracy)

Table II consolidates the accuracy data obtained across both benchmarks (MEDQA and MedMCQA) under the two experimental conditions: Direct Inference (Without RAG) and Enriched Inference (With RAG).

The only scenario that showed a marginal gain was the Llama-3.2-3B-Instruct model on the MedMCQA dataset (+1.00%). In contrast, the Qwen2.5-3B model exhibited the sharpest degradation, losing 11.00% accuracy in the same benchmark. A possible interpretation, further examined in the Discussion, is that the long text fragments retrieved via RAG acted as context distraction for the compact 3B and 8B parameter architectures, reducing their ability to extract the correct answer from the expanded prompt.

TABLE II
CLINICAL ACCURACY METRICS ACROSS EXPERIMENTAL CONDITIONS FOR THE RESOLUTION OF STRUCTURED COMPLEX CLINICAL SCENARIOS FOCUSED ON DIABETES MELLITUS AND RELATED METABOLIC DISORDERS

Model	Dataset	w/o RAG (%)	with RAG (%)	Delta (%)
Bio-Medical-8B	MEDQA	55.50	47.00	–8.50
Bio-Medical-8B	MedMCQA	64.00	62.00	–2.00
LlaMA-3.1-Med-8B	MEDQA	58.00	49.50	–8.50
LlaMA-3.1-Med-8B	MedMCQA	66.50	58.50	–8.00
Llama-3.2-3B-Inst	MEDQA	47.50	43.00	–4.50
Llama-3.2-3B-Inst	MedMCQA	56.00	57.00	+1.00
Qwen2.5-Med-3B	MEDQA	39.00	32.50	–6.50
Qwen2.5-Med-3B	MedMCQA	38.00	27.00	–11.00

B. Computational Performance and Efficiency (Latency and TPS)

Infrastructure costs and local processing times were markedly affected by the RAG architecture (Table III). The inclusion of vector search steps in Qdrant and re-ranking via the Ranker (*ms-marco-MiniLM-L-12-v2*) resulted in a substantial increase in response times.

TABLE III
COMPUTATIONAL EFFICIENCY: LATENCY AND TOKEN THROUGHPUT FOR THE RESOLUTION OF STRUCTURED COMPLEX CLINICAL SCENARIOS FOCUSED ON DIABETES MELLITUS AND RELATED METABOLIC DISORDERS

Model / Dataset	Lat. w/o RAG (s)	Lat. with RAG (s)	TPS w/o RAG	TPS with RAG
Bio-Med-8B (MEDQA)	4.65	51.05	0.24	0.05
Bio-Med-8B (MedMCQA)	1.48	49.64	0.86	0.09
LlaMA-8B (MEDQA)	4.75	51.60	0.24	0.05
LlaMA-8B (MedMCQA)	1.53	49.94	0.84	0.09
Llama-3.2-3B (MEDQA)	4.34	39.75	0.26	0.07
Llama-3.2-3B (MedMCQA)	1.21	38.51	1.05	0.12
Qwen2.5-3B (MEDQA)	1.88	24.73	0.61	0.10
Qwen2.5-3B (MedMCQA)	0.57	23.78	2.26	0.17

While direct inference (Without RAG) enabled agile responses (ranging from 0.57s to 4.75s), the enriched pipeline elevated the average latency to thresholds between 23.78s and 51.60s per question. Concurrently, the Tokens per Second (TPS) rate declined consistently across all scenarios, underscoring the impact of processing dense contexts (up to 4,000 characters) on hardware with shared resources. This reinforces the engineering challenge of enabling real-time clinical decision support systems under strictly offline execution.

IV. Discussion

The analysis of the experimental results reveals two highly relevant patterns for medical informatics: (a) a consistent performance hierarchy among the evaluated architectures in the direct inference scenario (Without RAG); and (b) a consistent reduction of clinical accuracy in seven of the eight model–benchmark pairs evaluated following the introduction of the Retrieval-Augmented Generation (RAG) architecture, accompanied by a substantial increment in latency. These phenomena express the complex trade-off involved in the local execution of large language models (LLMs) on consumer hardware with severe video memory limitations (8 GB of VRAM).

A. Performance in Direct Inference (Without RAG)

In the scenario without RAG, the LlaMA-3.1-8B-Medical and Bio-Medical-Llama-3.1-8B models (8 billion parameters, quantized in Q4_K_M) outperformed the smaller architectures, achieving accuracies of 58.0% and 55.5% on MEDQA, and 66.5% and 64.0% on MedMCQA, respectively. These values align with the literature: Singhal et al. [6] documented that the native Llama-3.1-Instruct-8B reaches 58.7% on MedQA and 56.0% on MedMCQA, and demonstrated that parametric scale and medical pre-training density are the primary predictors of accuracy. For instance, Med-PaLM 2 reaches up to 86.5% on MedQA, outperforming its predecessor by more than 19 percentage points. This benchmark, subsequently expanded for resolving complex clinical scenarios with structured justifications at the medical expert level [21], demonstrates that current maximum cognitive proficiency in medicine still depends on robust proprietary cloud architectures.

The Qwen2.5-3B-instruct-medical-finetuned.Q4_K_S model delivered the poorest performance: 39.0% on MEDQA and 38.0% on MedMCQA, values close to a random guess rate (25% for 4 choices). Two mechanisms explain this deficiency. First, the representational capacity limitations inherent to 3-billion-parameter models are insufficient to capture the causal relationships required by complex clinical reasoning [22]. Second, there is evidence that specialized fine-tuning may have induced catastrophic forgetting; studies indicate that refining models on restricted biomedical corpora tends to overfit the network to the domain, sacrificing general logical capabilities and self-correction mechanics required by benchmarks like MEDQA [22].

All models scored 8 to 12 percentage points higher on MedMCQA compared to MEDQA. This asymmetry reflects structural differences between the benchmarks: MEDQA is based on United States Medical Licensing Examination (USMLE) questions, featuring long clinical vignettes and advanced multidisciplinary reasoning [12]; MedMCQA, derived from the Indian AIIMS/NEET PG medical entrance exams, spans over 194,000 questions across 21 disciplines, but features shorter prompts and less logical articulation complexity [13]. The higher rate of tokens per second (TPS) on MedMCQA, alongside latencies of 0.57 to 1.53 s versus 1.88 to 4.75 s on MEDQA, confirms that more compact inference contexts accelerate processing.

B. Performance Degradation with the RAG Architecture

The most prominent finding of this experiment is the reduction in accuracy observed in almost all scenarios following the introduction of RAG: regressions of 6 to 11 percentage points for the 8B models and up to 11 percentage points for the Qwen2.5-3B, with latency rising from under 5 s to 24–51 s per question (a 10- to 34-fold increase). This behavior, counterintuitive relative to large-scale cloud systems, is consistent with mechanisms described in recent literature.

This negative variation may be partially explained by the ”lost in the middle” effect, formalized by Liu et al. [23], which demonstrates that language models exhibit a U-shaped attention bias, processing information located at the extremes (beginning and end) of the prompt more effectively than in the middle region. In the evaluated pipeline, the structural arrangement of the elements (base instruction + context block + question block) was deliberately designed to reflect the standard logical chaining of computer-assisted systems, positioning the retrieved chunks from Qdrant in the center of the prompt. It is plausible that this layout contributed to the observed accuracy degradation through a mechanism analogous to the lost-in-the-middle effect; however, as this was not the primary focus of the present study, the experiment did not vary the position of the retrieved context within the prompt, nor did it directly probe attention weights or internal model representations. This explanation should therefore be regarded as a plausible hypothesis rather than a confirmed causal mechanism, and warrants targeted investigation in future work. Additionally, as observed by Xiong et al. [11] in the MIRAGE benchmark, medical literature indicates that significant accuracy gains in complex clinical scenarios often demand the combination of a diversified corpus and multi-stage retrieval; thus, the methodological choice of a corpus strictly focused on Diabetes guidelines served as an analytical boundary, highlighting operational challenges in providing the discriminative framing necessary for multiple-choice tasks under constrained hardware conditions.

Additionally, Du et al. [24] demonstrated that simply increasing input length substantially degrades the reasoning capacity of LLMs, regardless of retrieval quality and even in the absence of distracting information—an architectural limitation previously unrecognized. Under the employed hardware configuration (8 GB VRAM, 32 GB RAM), the 8B models operated with partial layer offloading between the

GPU and RAM (*GPU split / CPU offload*). The attention window expanded by the RAG context (up to 4,000 characters per injection) imposed heavier matrix operations on weights quantized at reduced precision. The latency profile observed is compatible with a bandwidth bottleneck in the GPU–CPU bus, although this study did not collect hardware telemetry or separate timing measurements for retrieval, re-ranking, and inference stages, and this attribution therefore remains to be confirmed.

The Qwen2.5-3B model manifested the worst-case scenario: declining from 38.0% to 27.0% on MedMCQA (-11 pp) and displaying a residual TPS of 0.10–0.17 tokens/s with RAG. This is compatible with the injected context exceeding its effective attention window under Q4_K_S quantization, although the present design does not allow this mechanism to be isolated from the effects of quantization itself.

One of the main limitations of this experimental study relates to the constraints of the computational hardware used for offline execution (8 GB of VRAM), which necessitated the application of advanced quantization algorithms (such as Q4_K_M, Q4_K_S, and Q8_0) to enable model encapsulation in GGUF format. Although this strategy mitigates Out of Memory (OOM) errors, compressing the original 16-bit floating-point weights to hybrid 4-bit and 8-bit representations can induce subtle losses in the native semantic and cognitive capacities of the architectures. Furthermore, the evaluation was restricted to a RAG pipeline based on a single corpus of clinical guidelines focused strictly on Diabetes Mellitus and metabolic disorders, limiting the generalization of the findings to broader multidisciplinary medical scenarios and preventing analysis of how compact 3B and 8B parameter architectures would respond to mitigation strategies for the lost-in-the-middle effect, such as altering the positioning of the context block within the prompt or diversifying across multiple document retrievers.

V. Conclusion

It can be concluded that, contrary to the benefits widely documented in the literature for large-scale models executed in the cloud, the introduction of Retrieval-Augmented Generation (RAG) architecture in compact local models under severe hardware restrictions (8 GB of VRAM) led to a reduction of clinical accuracy in almost all evaluated scenarios, accompanied by a substantial operational penalty. The LlaMA-3.1-Med-8B model established itself as the top-performing architecture overall in the study, reaching 66.5% accuracy on MedMCQA in direct inference (native systems). However, under the RAG pipeline, this metric declined to 58.5%, a reduction of 8 percentage points.

This behavior is consistent with context expansion via document injection acting primarily as distracting noise for the selective attention mechanisms of smaller-scale networks. From a computational perspective, the approach was associated with a bottleneck in the GPU–CPU bus bandwidth attributable to partial layer offloading, substantially increasing average latency and reducing token throughput.

Given this scenario, under the specific conditions evaluated — a single, restricted document corpus, a fixed prompt structure, and severe hardware constraints (8 GB VRAM) — the standard RAG pipeline substantially increased computational cost and frequently reduced clinical accuracy relative to direct inference. These findings characterize the specific configuration tested and should not be generalized as establishing the categorical infeasibility of RAG-based approaches for real-time care applications in operational environments with resource and connectivity constraints (DIL Environments). Before such a conclusion can be drawn, and before these technologies can become reliable and operable tools in daily medical practice, future research should systematically evaluate: (a) alternative RAG configurations, including the number of retrieved documents, context window size, chunking strategies, hybrid retrieval methods, context compression techniques, caching mechanisms, and reordering of retrieved blocks within the prompt to mitigate peripheral attention bias; (b) approaches that directly test the lost-in-the-middle hypothesis — such as attention-weight analysis — to determine whether it accounts for the observed degradation or whether the underlying architecture itself requires enhancement; (c) alternative quantization schemes, larger-parameter models, and dedicated hardware optimization to enable strictly local execution without sacrificing the complex clinical reasoning required to manage high-information-density pathologies such as Diabetes Mellitus; and (d) validation across other hardware environments and clinical domains beyond Diabetes Mellitus.

Acknowledgment

The authors would like to thank the Department of Army Education and Culture (Departamento de Educação e Cultura do Exército - DECEx), the Coordination for the Evaluation and Development of Military Higher Education in the Army (Coordenadoria de Avaliação e Desenvolvimento da Educação Superior Militar no Exército - CADESM), and the Captain's Career School (Escola de Aperfeiçoamento de Oficiais - EsAO) for their valuable support throughout the course of this work. We also acknowledge Pro-Research Project (Projeto Pró-Pesquisa), from CADESM, for their financial support, which made this research possible.

***Abstract*—The Endoscopy Department at the *Beneficência Portuguesa* Hospital in São Paulo, Brazil, has a structure comprising 18 beds for pre- and post-examination procedures, 14 beds for preparation for hospital colonoscopy with the right to an accompanying person, and six examination rooms. This infrastructure was renovated in 2018 and included the acquisition of 97 new endoscopes of different types. Despite annual preventive maintenance performed on these devices, the number of breakdowns has increased significantly: 15% in 2023 and 28% in 2024, resulting in increased costs for corrective maintenance. The objective of the present study was to develop an interpretable and operationally applicable prioritization model for Clinical Engineering practice, applying Multicriteria Decision-Making methodology, using variables routinely available in the hospital maintenance management system. The model aims to prevent possible failures, optimize clinical engineering resources, and avoid interruptions in the use of equipment, increasing its availability. The mathematical model was applied to a sample of 24 video-bronchoscopes from the Endoscopy Department of the *Beneficência Portuguesa* Hospital.**

***Keywords*—Endoscopes evaluation, technical evaluation, economic evaluation, prioritization of preventive maintenance.**

I. INTRODUCTION

Health Technology Assessment (HTA) is a multidisciplinary process that uses explicit methods to determine the value of health technology at different points in its lifecycle. The purpose is to inform decision-making to promote an equitable, efficient, and high-quality health system [1]. Hospital-Based Health Technology Assessment (HB-HTA) is a specific context within and for HTA in hospitals. It is an evidence-based approach that considers a particular technology in a hospital setting, for moving the assessment closer to the point of care, where technologies' impacts and benefits can be directly assessed [2]. HB-HTM encompasses tasks related with health technology management processes, such as preventive maintenance [3].

The *Beneficência Portuguesa* Hospital (BP), located in São Paulo, Brazil, is one of the largest private healthcare centers in the country. The institution has 721 beds and an extensive inventory of medical equipment that supports healthcare services across a wide range of clinical specialties [4]. Among its diagnostic units, the Endoscopy Department stands out, comprising 18 beds for pre- and post-procedure care, 14 beds dedicated to hospital colonoscopy preparation with accommodation for a companion, and six examination rooms [5].

In 2018, this infrastructure underwent a major modernization process through a comprehensive renovation and restructuring, which included the renewal of the technological park of endoscopic equipment. An endoscope is a device used for the direct visualization of internal structures of the human body and play a fundamental role in minimally invasive diagnostic and therapeutic procedures [6]. As part of this modernization initiative, 97 new endoscopes of different types were acquired, including [video] gastroscopes, colonoscopes, bronchoscopes, and duodenoscopes, among others.

Currently, the criterion used to determine whether an endoscope undergoes preventive maintenance is time-based, following the manufacturer's recommendations, which define the annual maintenance interval. Despite the annual preventive maintenance performed on these devices, the number of failures and damages has increased significantly over the years: 15% in 2023, and 28% in 2024. This trend has resulted in a substantial increase in corrective maintenance costs.

In this context, the Hospital's Clinical Engineering Department has intensified efforts to investigate the causes of these failures and to identify solutions aimed at reducing the frequency of corrective maintenance and the associated costs. Therefore, the objective of the present study was to develop an interpretable and operationally applicable model for Clinical Engineering practice, using variables routinely available in the hospital maintenance management system. The proposed model aims to prevent potential failures, optimize clinical engineering resources, and avoid interruptions in equipment use, thereby increasing equipment availability. The model was applied to a sample of 24 video-bronchoscopes from the Endoscopy Department of the *Beneficência Portuguesa* Hospital.

Although several studies have proposed indicators to support maintenance management in healthcare technology, most approaches evaluate technical or economic aspects separately [7–11]. The contribution of the present work lies in the integration of failure frequency, downtime, preventive and corrective maintenance history, equipment age, depreciation, and maintenance costs into a single Global Indicator designed to support preventive maintenance prioritization. The integration of technical reliability and economic burden into a single indicator allows maintenance prioritization beyond conventional time-based scheduling approaches. Unlike conventional time-based maintenance policies recommended by manufacturers, the proposed framework combines operational reliability and economic impact, allowing maintenance decisions to be guided by evidence obtained from real

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

equipment performance data. This approach provides a practical decision-support mechanism for Clinical Engineering departments operating in data-constrained hospital environments.

Unlike predictive maintenance approaches based on large datasets and machine learning algorithms, the proposed model was designed for hospital environments where historical maintenance information is available, but data volume may be insufficient for advanced predictive analytics.

II. Methodology

Multicriteria Decision-Making (MCDM) methodology has been widely applied to support decision-making processes involving multiple and often conflicting criteria. By assigning relative importance to technical, operational, and economic factors, MCDM approaches enable the prioritization of alternatives through a transparent and reproducible evaluation framework [12]. In Health Technology Management, these methodologies have been used to prioritize medical equipment according to variables such as failure frequency, maintenance costs, equipment age, utilization rate, technological obsolescence, and clinical criticality, thereby supporting more efficient allocation of maintenance resources and improving equipment availability [13].

A. Definition of Variables

Variables related to the technical and economic aspects of the endoscopes were defined. It is important to note that these variables have a qualitative domain, which is used by the technical staff of the Hospital's Cinical Engineering Department (CED) to assess medical devices. However, in order to develop the mathematical model proposed in this work, it was necessary to map the qualitative domain into the interval [0,1] to obtain a quantitative domain. Each variable was assigned a weighting factor according to its importance in the evaluation, based on the experience of the CED technical staff. The weighting factors assigned to each variable were defined according to their perceived influence on equipment availability, maintenance burden, and operational continuity. Variables directly associated with service interruption and equipment reliability, such as failure frequency and downtime, received higher weights because they have immediate consequences for clinical workflow and patient care. In contrast, variables with a more indirect influence, such as manufacturer brand, received lower weights.

B. Indicators Development

Once the variables and their corresponding weights were defined, two indicators were established: technical and economic. The resulting numerical value was interpreted through a qualitative scale indicating the technical (or economic) condition of the evaluated medical device. Subsequently, a mathematical expression combining both indicators was developed to obtain a global indicator for an overall assessment of the device.

The qualitative intervals adopted for the interpretation of the indicators were established according to maintenance management practices currently used by the CED. The selected thresholds were intended to distinguish equipment with satisfactory operational performance from those requiring increased preventive attention. Although these intervals are based on institutional experience, they provide a practical framework for decision-making and facilitate the translation of quantitative indicator values into actionable maintenance strategies.

C. Mathematical Model Validation

The mathematical model was validated using a sample of 24 video-bronchoscopes from the Endoscopy Department. All technical and maintenance-related information, including failure history, downtime, preventive and corrective maintenance interventions, and associated costs, was extracted from the Genesis® Hospital Maintenance Management System [14], the official computerized maintenance management system (CMMS) used by the Clinical Engineering Department. The model outputs were then compared with the actual maintenance scenario observed during 2024 to evaluate the consistency and practical applicability of the proposed prioritization framework in a real hospital environment.

Additionally, a sensitivity analysis was performed. The purpose of this analysis was to evaluate the robustness of the prioritization framework against moderate changes in the relative importance assigned to the technical and economic components. The Global Indicator was recalculated considering a ±10% variation in the weighting coefficients of both indicators used in the model.

III. Results

A. Technical Indicator

Six variables (x_i) were defined [15]. Each associated with a relevance factor (ρ_i) as shown in Table 1.

TABLE I. Technical variáables and its relevance factor

x_i	Description	ρ_i
x_1	Failure frequency	1.0
x_2	Days out of use	1.0
x_3	Types of failures	0.9
x_4	Preventive maintenance interventions	0.8
x_5	Equipment age (years)	0.7
x_6	Brand	0.2

The technical indicator (I_T) [15] incorporates the six variables and their corresponding weighting factor into a mathematical function, as shown in (1).

$$I_T = \sum_{i=1}^{6} \rho_i x_i \quad (1)$$

Where: x_i is the variable, i= {1, …, 6}
ρ_i is the weighting factor for each variable.

The result of the technical indicator (I_T) was bounded within the interval [0,1]. A normalization factor (N) was therefore calculated using the expression (2).

$$N = \sum_{i=1}^{6} \rho_i M_{imáx} \quad (2)$$

Therefore, I_T is defined by (3):

$$I_T = \frac{\sum_{i=1}^{6} \rho_i x_i}{N} \quad (3)$$

Qualitative scale. It was defined with three technical conditions corresponding to the overall state of the equipment (Table II). Equipment classified as *Good*, indicates the need for one preventive maintenance intervention per year. Those rated as *Regular*, preferably require two preventive maintenance interventions per year. Finally, equipment classified as *Poor,* due to its less satisfactory technical condition, requires three preventive maintenance interventions per year. The definition of the intervals was established by the Clinical Engineering Department based on its technical expertise and practical experience [15].

TABLE II. QUALITATIVE SCALE FOR I_T INTERPRETATION

Result (I_T)	Technical condition	Preventive maintenance priority	Interpretation (No. interventions)
[0.0, 0.3]	Good	Low	1 a year
[0.31, 0.6]	Regular	Medium	2 a year
[0.61, 1.0]	Poor	High	3 a year

B. Economic Indicator

Variables: Five variables were defined, as presented in Table III, from which two partial economic indicators (I_{E1} e I_{E2}) were derived [16].

TABLE III. ECONOMIC VARIABLES

x_i	Variables	Description
x_7	CPM	Cost of preventive maintenance
x_8	CCM	Cost of corrective maintenance
x_9	CNE	Cost of a new endoscope
x_{10}	EA	Equipment age (years)
x_{11}	CAQ	Endoscope acquisition cost

Partial Economic Indicator 1 (I_{E_1}). This indicator represents the ratio between the total costs of both, preventive maintenance (CPM) and corrective maintenance (CCM), and the cost of a new equipment unit (CNE). It reflects the financial impact of technical interventions relative to the equipment replacement value. It is defined by equation (4) [16].

$$I_{E1} = \frac{(CPM+CCM)}{CNE} \quad (4)$$

Partial Economic Indicator 2 (I_{E2}). It expresses the depreciation of the equipment over time relative to its acquisition cost. Equation (5) represents the accumulated economic value loss as a function of the equipment age [16].

$$I_{E2} = \left(\frac{CNE-\text{CAQ}}{CAQ}\right)\left(\frac{EA}{EA_{highest}}\right) \quad (5)$$

Where: $Ea_{highest}$, is the highest age observed in the sample.

Economic Indicator (I_E). It is obtained through the weighted combination of the two partial indicators (Eq. 6) [16].

$$I_E = \frac{1{,}0\ (I_{E1})+0{,}7(I_{E2})}{1{,}7} \quad (6)$$

The weights 1.0 and 0.7 were defined based on the greater relevance of maintenance cost in the economic analysis, since it is directly influenced by the frequency of preventive interventions, whereas depreciation is considered a secondary factor in this process.

Qualitative scale. The interpretation of the numerical value of I_E was defined in three qualitative ranges, corresponding to the economic condition of the equipment (Table IV). This classification guides the recommended number of annual preventive maintenance interventions, following a criterion analogous to that adopted for the technical indicator (I_T). Thus, higher values of (I_E) indicate a greater likelihood that the equipment will require more preventive interventions, ranging from one to three maintenance actions per year according to the defined intervals [16].

TABLE IV. QUALITATIVE SCALE FOR I_E INTERPRETATION

Interval I_E	Economic condition (Priority)	Interpretation (No. interventions)
[0.0, 0.25]	Low cost	1 a year
[0.26, 0.5]	Medium cost	2 a year
[0.51, 1.0]	High cost	3 a year

C. Global Indicator

In the composition of the Global Indicator (I_G), the two indicators (I_T and I_E) were weighted in order to integrate the operational performance and cost–benefit aspects of each endoscope into a single evaluation. The mathematical expression that defines the I_G is presented in Eq. (7) [16].

$$I_G = 0{,}6\ (I_T) + 0{,}4\ (I_E) \quad (7)$$

The value of I_G ranges within the interval [0,1]. Values approaching 1 indicate high priority for preventive maintenance, as they represent equipment with higher technical and/or economic impact in the context of maintenance management. It is important to note that the interpretation of the I_G results, follows the same criteria defined in Table IV.

D. Mathematical Model Validation

The mathematical model was applied to a sample of 24 video-bronchoscopes, including both adult and pediatric devices. The results for each case are presented below.

E. Technical Evaluation

According to the qualitative scale for the I_T interpretation (Table II) the results indicated that five video-bronchoscopes were in *Good* technical condition, six were classified as *Regular*, and thirteen as *Poor*.

For video-bronchoscopes in *Good* technical condition ($I_T \leq 0.3$), observed that B_1 (Table V), provides excellent image resolution and has a large diameter suitable for adult use. Devices B_2, B_3, and B_4 are used for pediatric examinations. The Endocopy. Considering that the demand for pediatric procedures is relatively low, these devices are usually kept in reserve storage, which explains their high technical rating. B_5 is typically used only when the other devices are unavailable for operation. Its high rating is therefore associated with its low utilization rate during the analyzed period.

TABLE V. RESULTS OF THE TECHNICAL (I_T), ECONOMIC (I_E) AND GLOBAL (I_G) EVALUATIONS OF 24 VIDEO-BRONCHOSCOPES

Video-bronchoscope	I_T	I_E	I_G	Priority
B_1	0.18	0.09	**0.15**	
B_2	0.18	0.09	**0.15**	
B_3	0.18	0.09	**0.15**	**Low**
B_4	0.18	0.05	**0.16**	
B_5	0.23	0.13	**0.16**	
B_6	0.36	0.09	**0.25**	
B_7	0.39	0.15	**0.30**	
B_8	0.40	0.21	**0.32**	
B_9	0.49	0.11	**0.34**	
B_{10}	0.46	0.17	**0.34**	
B_{11}	0.55	0.10	**0.37**	**Medium**
B_{12}	0.63	0.15	**0.44**	
B_{13}	0.63	0.25	**0.48**	
B_{14}	0.77	0.04	**0.48**	
B_{15}	0.63	0.29	**0.49**	
B_{16}	0.73	0.20	**0.52**	
B_{17}	0.73	0.24	**0.53**	
B_{18}	0.73	0.24	**0.53**	
B_{19}	0.73	0.26	**0.54**	
B_{20}	0.75	0.23	**0.54**	**High**
B_{21}	0.73	0.27	**0.54**	
B_{22}	0.73	0.31	**0.56**	
B_{23}	0.75	0.32	**0.58**	
B_{24}	0.73	0.49	**0.63**	

In the *Regular* classification ($0.3 < I_T \leq 0.6$), video-bronchoscopes B_6, B_9, B_{10}, and B_{11} were identified as devices used for pediatric examinations. (with low demand). B_6 obtained a score of 0.36, because of preventive maintenance was not performed. B_9, B_{10}, and B_{11} each underwent one corrective maintenance intervention, which led them also to fall into the same category. B_7, which is used for conventional adult examinations, iobtainde a somewhat atypical classification, because it is the only device of its model within this category. Nevertheless, it received this rating because it required only one corrective maintenance intervention and remained out of service for approximately two months. B_8 is dedicated to procedures that combine video-bronchoscopy with ultrasound diagnostics. It received this classification because it is used in very few cases and, when operated, its handling is performed by specialists. It should also be noted that the device remained out of service for only two days.

Finally, the video-bronchoscopes classified as *Poor* ($I_T > 0.61$) are used for adult patients and all of them underwent at least one corrective maintenance intervention (B_{22} and B_{23} required two corrective interventions), did not receive preventive maintenance. The device with the shortest downtime remained out of service for 137 days, which justifies this classification. Within this group, B_{16} is noteworthy, as it is a pediatric video-bronchoscope. It received this rating because it remained out of service during all year (365 days) and did not undergo preventive maintenance, which explains its low classification. Another case is B_{14}, this device is dedicated to procedures combining bronchoscopy and ultrasound diagnostics, and its prolonged absence from service was due to the need for high-cost imported components.

The remaining video-bronchoscopes classified as *Regular* and *Poor* are consistent with these results, as they include biopsy channels and are widely used in adult examinations, which represent the most common procedures in the department

F. Economic Evaluation

According to the qualitative scale for the I_E interpretation (Table IV), the overall results were as follows: 14 video-bronchoscopes were classified with *Low* cost, seven with *Medium* cost, and one with *High* cost (Table V). It should be noted that the first three devices received a low classification because they required few corrective maintenance interventions, resulting in lower total maintenance costs. It was also observed that device B_9 is the only video-bronchoscope with a larger diameter—typically used exclusively in adult patients—and, due to its limited use, it rarely undergoes corrective maintenance, which consequently results in lower maintenance costs.

Among the devices classified with *Medium* cost ($0.25 < I_E \leq 0.50$), are predominantly video-bronchoscopes with intermediate and large diameters used in adult examinations across different anatomical conditions. For devices classified with *High* cost ($I_E > 0.50$), as expected, a higher corrective maintenance cost corresponds to this index value. In particular, the highest maintenance cost ($ 16,200 USD) was associated with device B_{24}, which was therefore classified with the highest cost. It is also noteworthy that the maintenance cost of this device corresponds to approximately 65% of its acquisition cost, indicating that its replacement should be considered.

In general, it can be observed that there is an inverse relationship between the technical condition and the economic condition. That is, the better the technical condition of the device, the lower the maintenance cost. The same applies to the preventive maintenance priority for the device. The better the device's technical condition, the fewer preventive maintenance interventions it requires.

G. Global Evaluation

To obtain the global evaluation (priority), equation (7) was applied to the 24 video-bronchoscopes. The results reveal a clear stratification of the equipment into three maintenance-priority categories, with 25% of the devices classified as low priority, 37.5% as medium priority, and 37.5% as high priority (Table V). The gradual increase in I_G values and the absence of abrupt fluctuations suggest a consistent prioritization framework capable of distinguishing different levels of maintenance need, as can be seen in the preventive maintenance priority ranking based on the Global Indicator (Fig. 1). Notably, nine devices were classified as high priority ($I_G > 0.50$), indicating a substantial proportion of the fleet with elevated technical and economic maintenance requirements. These findings demonstrate that the proposed model can effectively support preventive maintenance planning by identifying equipment requiring increased attention and enabling a more efficient allocation of Clinical Engineering resources.

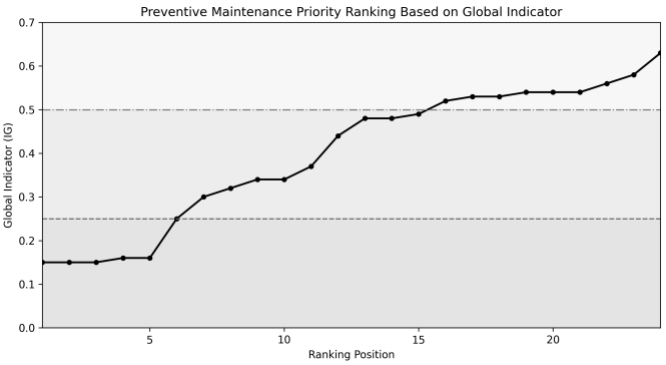

Fig. 1. Preventive maintenance priority ranking based on the Global Indicator.

To better understand the interaction between technical performance and economic impact, the three indicators developed in this study were evaluated jointly. The Technical Indicator (I_T) assesses operational reliability based on maintenance history and equipment condition, whereas the Economic Indicator (I_E) reflects the relative maintenance cost and aging burden of each device. By combining these two dimensions, the Global Indicator (I_G) provides a balanced assessment of preventive maintenance needs This comparison also provides indirect evidence of the consistency of the proposed model, since equipment with poorer technical conditions generally tend to exhibit higher economic impact and, consequently, higher global priority scores.

The values of I_T, I_E, and I_G for the evaluated video-bronchoscopes are compared in Fig. 2. An overall increasing trend can be observed among the three indicators, suggesting a relationship between technical deterioration and economic burden. Devices with higher technical scores generally exhibited higher economic scores, indicating that increased failure frequency, downtime, and maintenance interventions are associated with greater maintenance costs. The Global Indicator follows a similar pattern because it integrates both dimensions through a weighted approach, providing a balanced assessment of equipment condition.

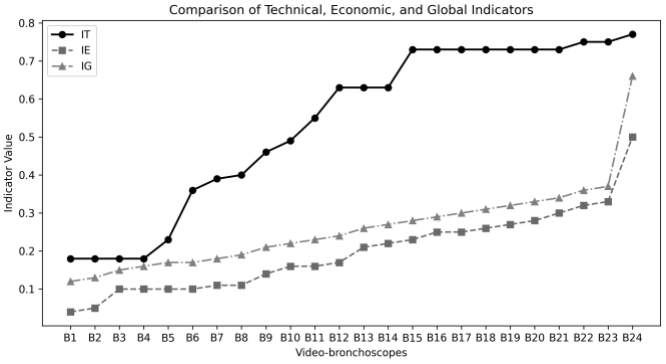

Fig. 2. Comparative profile of the Technical Indicator (IT), Economic Indicator (IE), and Global Indicator (IG) for the evaluated video-bronchoscopes.

These results support the rationale of combining technical and economic factors into a single decision-making index capable of prioritizing preventive maintenance actions more effectively than conventional time-based maintenance schedules.

H. Model Sensitivity

The result of the sensitive analysis is shown in Table VI. In general, the variations in I_G values were proportional and relatively small across all evaluated devices. As expected, increasing the weights (+10%) resulted in a corresponding increase in I_G values, whereas reducing the weights (–10%) produced lower scores. However, these changes did not substantially modify the overall distribution of the equipment, or the prioritization structure generated by the model.

From a maintenance management perspective, the results indicate that the proposed methodology exhibits satisfactory stability under moderate perturbations of the weighting coefficients. Devices with low I_G values, such as B1–B5, remained within the lowest-priority group under both scenarios, while equipment with higher IG values, particularly B22–B24, consistently occupied the highest positions in the ranking. Although some devices located near the classification thresholds experienced slight variations in their scores, the overall prioritization pattern remained largely unchanged. Notably, video-bronchoscope B24 maintained the highest maintenance priority in all scenarios, with IG values ranging from 0.61 to 0.66, confirming the consistency of the model in identifying critical equipment. These findings suggest that the proposed prioritization framework is not excessively dependent on a specific set of weighting coefficients and that the resulting maintenance decisions are reasonably robust to moderate uncertainty in expert-defined parameters.

TABLE VI. SENSITIVITY RESULTS OF THE GLOBAL INDICATOR IG

Video-bronchoscope	I_G	I_G (+10%)	I_G (-10%)
B_1	0,15	0,16	0,14
B_2	0,15	0,16	0,14
B_3	0,15	0,16	0,14

B_{23}	0,58	0,62	0,54
B_{24}	0,63	0,66	0,61

IV. Discussion

The proposed prioritization model differs substantially from the preventive maintenance strategy currently adopted in the institution, which is based primarily on fixed annual intervals recommended by equipment manufacturers. While time-based maintenance schedules assume homogeneous equipment degradation, the proposed model incorporates actual operational performance, maintenance history, and economic impact. Consequently, it enables differentiated maintenance planning according to the specific condition of each device, potentially improving resource allocation and reducing unnecessary interventions.

A. Limitations of the Study

Some limitations of this study should be acknowledged. First, the model was validated using a relatively small sample of 24 video-bronchoscopes from a single hospital department, which limits the generalizability of the findings.

Second, the weighting coefficients and qualitative classification thresholds were established using expert judgment and institutional experience then, future studies should complement using more advanced uncertainty assessment techniques, in order to provide a more comprehensive evaluation of parameter uncertainty and further strengthen the methodological validity of the proposed model.

Third, some variables may present partial correlation, particularly downtime, failure frequency, and corrective maintenance cost. However, these variables were intentionally preserved because each reflects a distinct operational dimension relevant to Clinical Engineering decision-making.

Therefore, the results should be interpreted as evidence of practical applicability rather than definitive predictive performance. Future research should evaluate the model using larger datasets, additional equipment categories, and multicenter environments.

V. Conclusion

The results obtained from the evaluation of 24 video-bronchoscopes suggest that the proposed technical, economic, and global indicators provide a practical framework for supporting preventive maintenance prioritization in Clinical Engineering. The model demonstrated the ability to distinguish equipment with different operational and economic profiles using information routinely available in the hospital maintenance management system. Although the validation was limited to a single equipment category and hospital department, the findings indicate the potential usefulness of indicator-based maintenance planning as a complement to conventional time-based maintenance policies.

The development of the Global Indicator (I_G), with weights of 0.6 assigned to the technical aspect and 0.4 to the economic aspect (Eq. 7), allowed the analysis to balance operational reliability and maintenance cost, prioritizing equipment safety and availability while maintaining financial Sustainability. Therefore, it can be concluded that the Global Indicator model developed in this study, significantly contributes to improve the management of preventive maintenance for medical equipment. Its continuous application may promote a more strategic, indicator-driven management approach, reducing costs, optimizing resources, and increasing the technological availability of hospital units. Furthermore, future studies are recommended to extend the application of the model to other sectors and types of equipment in order to validate its effectiveness in different contexts and enhance its use as a decision-support tool in Clinical Engineering. Future work will also evaluate AI-based predictive maintenance approaches to further improve maintenance planning and resource allocation.

***Abstract*—Infrared thermography (IRT) is an increasingly used technique to assess the functional conditions of masticatory structures. In this exploratory case study, IRT was used to monitor the orofacial thermal patterns of a 60-year-old patient with sequelae of a right mastoid fracture, before and immediately after a multimodal physiotherapy session. Five consecutively captured thermograms, obtained with a FLIR E40 camera over the temporomandibular joints (TMJs) and anterior temporal muscles, bilaterally, were analyzed. The analysis included arithmetic average of the point temperatures, sample standard deviations, and pre-post differences accompanied by Type A uncertainty. The differences were 0.22 ± 0.14 °C in the right TMJ, 0.50 ± 0.11 °C in the left TMJ, 0.28 ± 0.16 °C in the right temporal muscle, and 0.26 ± 0.10 °C in the left temporal muscle. ± indicates the standard uncertainty Type A (k = 1), estimated under the adopted calculation assumptions. A reduction in the average was observed in the four regions, with similar magnitudes in the temporal regions and distinct magnitudes in the TMJs. The pain score on the Visual Analogue Scale went from 8 to 0 and the mouth opening from 37 to 40 mm. In this case, the monitoring associated the regional description of thermal changes with the variability of the captures and the uncertainty of the differences, adding quantitative information to the clinical documentation of the session.**

Keywords — Infrared thermography; Temporomandibular dysfunction; Mastoid fracture; Measurement uncertainty.

I. INTRODUCTION

Temporomandibular disorders (TMD) are a group of musculoskeletal and neuromuscular conditions that affect the temporomandibular joint (TMJ) and the structures of the masticatory system. Their etiology is multifactorial, involving physical, behavioral, and emotional factors; a history of trauma is part of the clinical evaluation context [1].

Infrared thermography (IT) offers a quantitative and non-invasive record of cutaneous thermal distribution. Studies in TMD investigate temperature differences at facial anatomical points and their relationship to the clinical condition [2]. Bilateral assessment allows describing how temperatures are distributed between corresponding regions, while recordings at different times document their changes throughout the course of treatment.

Infrared thermography (IRT) is a non-invasive tool used to investigate musculoskeletal pain management [3]. Thermal recording of a multimodal session adds regional information to pain and mouth opening measurements. By associating the magnitude of changes with the variability of captures, metrological analysis provides an explicit basis for interpreting the observed differences.

The aim of this study was to monitor orofacial thermal patterns before and immediately after a multimodal physiotherapy session in a patient with sequelae of mastoid fracture, describing the differences between the average point temperatures of the TMJs and anterior temporal muscles and estimating the Type A uncertainty associated with these differences.

The absolute skin temperature can be influenced by environmental factors, such as the use of distances greater than 50 cm between the target and the device in image acquisition protocols [4].

II. MATERIALS AND METHODS

A. Experimental configuration

This exploratory case study, with one participant (N = 1), one intervention session, and two acquisition points, without a control condition, was conducted in accordance with REBEc. Thermographic data collection was approved by the Research Ethics Committee of the Clementino Fraga Filho University Hospital and the Faculty of Medicine of the Federal University of Rio de Janeiro (UFRJ) under CAAE 78605524.3.00005257, and the physiotherapy intervention performed at the HUCFF general outpatient clinic was approved under CAAE 05063218.7.0000.5257. The patient signed informed consent to participate in the study and for the use of her thermographic data.

The 60-year-old participant presented with a history of fracture of the right mastoid process and reported bilateral pain in the temporomandibular joints (TMJs), masticatory muscles, and cervical region. The Fonseca questionnaire showed a score of 95/100, corresponding to a severe TMD classification according to the instrument. The physical examination revealed reduced range of motion in the oral

We thank CNPq, CAPES, and FAPERJ for their financial support.

cavity, lateral deviation, cervicogenic balance deficit, and headache.

She underwent a 60-minute physiotherapy intervention using temporomandibular joint (TMJ) and cervical spine mobilization, cervical traction, and laser therapy (4 J/cm² per point) applied to three points of the masseter muscle and three points of the TMJ, totaling 24 J/cm² of accumulated fluence.

B. Acquisition and definition of the analyzed quantity

The test environment (room) was maintained at a temperature between 21°C and 23°C, in accordance with the International Thermography Protocol (IACT), with a relative humidity of approximately 50%, and thermographic images were acquired at a standardized distance of 50 cm before (Pre) and immediately after (Post) the intervention (Fig. 1).

Fig. 1. Scenario for capturing thermographic images with a distance of 50 centimeters between the camera and the base of the chair.
Source: Author

The experimental setup utilized a FLIR E40 infrared camera (Teledyne FLIR LLC/United States) operating at 60 Hz, with a thermal sensitivity of 0.07 °C, emissivity of 0.98, and an integrated real resolution of 160 x 120 pixels. Five consecutive readings were obtained per region of interest (ROI), before and after the intervention. The immediate post-intervention corresponds to the evaluation at the end of the session; the exact interval until the first capture is not specified in the described protocol.

The image acquisition process respected the 10-minute acclimation period. The patient was instructed to avoid using cosmetics, creams, or lotions on the areas being evaluated on the day of the examination.

The ROIs were right TMJ (TMJ D), left TMJ (TMJ L), right anterior temporal (Temporal D), and left anterior temporal (Temporal L). The anatomical regions were manually delimited, with the cursor reading the point identified as having the highest temperature in each region. The measurand was the average of the five point temperatures selected per ROI and time point. This average summarizes the captures, not all the pixels of the ROI. The participant is the clinical unit; the captures are technical repetitions to describe the variability of acquisition.

In Fig. 2, temperature values were extracted from the standardized anatomical hot spot cursor (white cross) in each thermogram. Pain intensity (Visual Analogue Scale - VAS) and mouth opening amplitude were measured before and after the intervention.

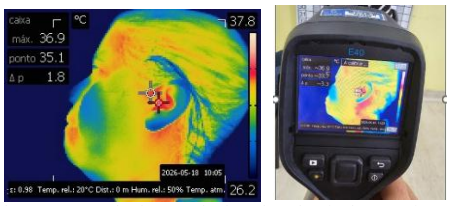

Fig. 2. Thermograms before and after the physiotherapy intervention, respectively.

C. Descriptive analysis and Type A uncertainty

For each ROI and time point j (pre or post), the arithmetic average of nj = 5 temperatures and the sample standard deviation sj were calculated, with divisor nj − 1. The Type A standard uncertainty of the average, uj, was estimated by the dispersion of the catches [5, 6]:

$$\overline{T}_j = \frac{1}{n_j}\sum_{i=1}^{n_j} T_{ij}\,; \quad u_j = \frac{s_j}{\sqrt{n_j}} \quad (1)$$

The difference was defined as $\Delta T = \overline{T}pre - \overline{T}post$; positive values indicate a reduction in average temperature. The comparison was performed between the averages of the acquisition blocks, since the protocol records five captures at each time point, without documented correspondence between pre- and post-acquisition pairs. The calculation hypotheses adopted were independent readings and stability within each block, with uncorrelated pre- and post-acquisition averages.

$$u_A(\Delta T) = \sqrt{u_{pré}{}^2 + u_{pós}{}^2} \quad (2)$$

Eq. (2) combines the variance components of the two time points. In the Type A uncertainty balance, the contribution of each phase was calculated by the ratio between uj² and the sum of the pre and post components, multiplied by 100. The covariance between the pre and post average was considered zero in the calculation model.

The expanded Type A uncertainty, U95,A, and the range ΔT ± U95,A were calculated with an approximate nominal coverage of 95%, using the distribution of the effective degrees of freedom of Welch–Satterthwaite [5]:

$$\nu_{eff} = \frac{(u_{pré}{}^2 + u_{pós}{}^2)^2}{\frac{u_{pré}{}^4}{4} + \frac{u_{pós}{}^4}{4}} \quad (3)$$

$$U_{95,A} = k\,u_A(\Delta T); \quad k = t_{0,975;\,\nu_{eff}} \quad (4)$$

The expansion assumes approximately normal fluctuations, in addition to the previous assumptions. The intervals are individual, referring to the session and restricted to the evaluated Type A components. To complement the regional description, the differences between the right and left averages were calculated. The analyses used the 40 available readings, without excluding any values, with rounding only at the end of the calculations.

III. RESULTS

Average temperatures decreased in all four ROIs (TABLE I and Fig. 3). The reductions were 0.50 °C in ATM E and 0.22 °C in ATM D. During storms, the magnitudes were similar: 0.28 °C on the right and 0.26 °C on the left.

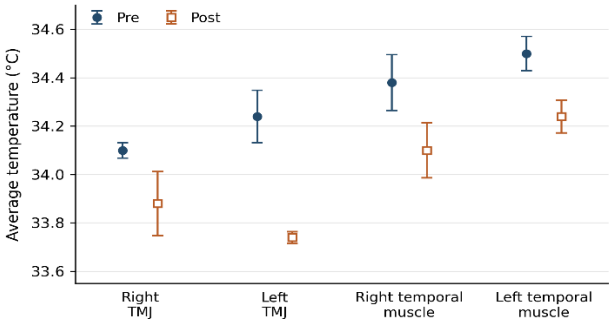

Fig. 3. Average point temperatures before and after the session. Bars: Type A standard uncertainty of the average (k = 1). The pre-post differences and their expanded uncertainties are presented in Table II.
Source: Author

In the TMJs, the side with the higher average shifted from the left in the pre-test to the right in the post-test, maintaining the magnitude of the lateral contrast observed at 0.14 °C. In the temporal lobes, the left average remained higher than the right: a difference of 0.12 °C in the pre-test and 0.14 °C in the post-test.

The dispersion between captures was specific to each ROI and time point. In ATM D, the DP went from 0.071 to 0.295 °C; in ATM E, from 0.241 to 0.055 °C. In the temporal phases, the DPs remained close between pre- and post-capture. In the Type A variance balance of the difference, the post-capture period accounted for 94.6% in ATM D and the pre-capture period for 95.1% in ATM E. In the temporal phases, the contributions of the two phases ranged from 47.9% to 52.1% (TABLE I).

TABLE 1. AVERAGE CAPTURE TEMPERATURES AND TYPE-A COMPONENTS

ROI	Phase	Average (°C)	SD (°C)	$u_A(\bar{T})$ (°C)	Type A Share (%)
TMJ R	Pre	34,10	0,071	0,032	5,4
	Post	33,88	0,295	0,132	94,6
TMJ L	Pre	34,24	0,241	0,108	95,1
	Post	33,74	0,055	0,024	4,9
Temporal R	Pre	34,38	0,259	0,116	50,8
	Post	34,10	0,255	0,114	49,2
Temporal L	Pre	34,50	0,158	0,071	52,1
	Post	34,24	0,152	0,068	47,9

n = 5 per ROI and time point. SD: sample standard deviation. $u_A(\bar{T})$: Type A standard uncertainty of the average. Type A share: contribution of each phase to the estimated variance of the pre-post difference, according to Eq. (2). R: right; L: left
Source: Author

The standard Type A uncertainties of the differences ranged from 0.098 to 0.162 °C, and the expanded uncertainties from 0.23 to 0.37 °C. In the adopted model, the ranges of the left ROIs remained positive; those of the right regions included zero (TABLE II).

In the clinical evaluation, the pain score on the VAS went from 8 to 0 and the mouth opening increased from 37 to 40 mm, a difference of 3 mm.

TABLE II. PRE-POST DIFFERENCES AND TYPE A UNCERTAINTIES

ROI	ΔT(°C)	uA(ΔT)(°C)	U95,A(°C)	Nominal range of 95% (°C)
TMJ R	0,22	0,136	0,36	[−0,14; 0,58]
TMJ L	0,50	0,110	0,30	[0,20; 0,80]
Temporal R	0,28	0,162	0,37	[−0,09; 0,65]
Temporal L	0,26	0,098	0,23	[0,03; 0,49]

U95,A = k × uA(ΔT). Effective degrees of freedom ek, respectively: ATM D, 4.46 and 2.67; ATM E, 4.41 and 2.68; Temporal D, 8.00 and 2.31; Temporal E, 7.99 and 2.31. Individual intervals restricted to the Type A model, under the assumptions of Section II-C.
Source: Author

IV. DISCUSSION

Monitoring documented a reduction in averages across all four regions, with the greatest decrease in the left TMJ and similar magnitudes in the temporal bones. The description by structure locates the changes in the orofacial pattern: in the TMJs, there was a reversal of the side with the higher average; in the temporal bones, the relationship between the sides was approximately preserved. These aspects maintain the anatomical information of the findings within the context of sequelae of mastoid fracture.

The combined presentation of average, dispersions, and uncertainties situates each change in relation to the variability of catches. In the Type A model, the reductions in left-hand ROIs were more clearly defined, with entirely positive intervals. In the right-hand regions, the intervals express greater uncertainty regarding the magnitude and sign of the difference. Thus, the regional interpretation simultaneously considers the observed average reduction and the uncertainty of its estimate.

The balance quantifies the contribution of pre- and post-processing blocks to the estimated variance of the difference. In ATM D, the post-processing includes one reading of 34.4 °C and four between 33.7 and 33.8 °C, all maintained. In ATM E, the pre-processing component predominates, while the temporal components show balanced proportions. Identifying the blocks with the greatest influence on uncertainty guides the documentation of acquisition times and the selection of reading points in future applications. The components describe the variability between captures, without separating instrumental and physiological causes.

The reduction in reported pain and the increase in mouth opening provide clinical context to the thermal records. The literature on TI in TMD examines patterns dependent on the condition and region evaluated [2]. In this study, individual follow-up brings together, in the same session, anatomical information, temperature variation, and clinical measurements. Its contribution is to present this immediate evolution in a quantitative way, maintaining the individuality of the case and the combined nature of the intervention.

The findings describe one participant and one multimodal session, without control or follow-up. Lateral differences are descriptive. The independence and stability of the captures are calculated hypotheses: the timing of the readings, the contours of the ROIs, and the cursor permanence are not

detailed in the described protocol. A positive temporal dependence may increase the uncertainty of the average. Calibration, drift, radiometric adjustments, and repositioning were not quantified separately; U95,A expresses the component evaluated from the captures. Subsequent studies should document these factors and expand the uncertainty balance to assess the consistency of monitoring between sessions.

V. CONCLUSION

In the case study, monitoring documented reductions in average point temperatures of 0.22 to 0.50 °C, with a greater drop in the left atmospheric pressure zone and similar magnitudes during storms. The bilateral description and the Type A uncertainty balance characterized the changes and the contribution of each phase to its uncertainty. Under the adopted assumptions, the standard uncertainties of the differences ranged from 0.10 to 0.16 °C.

Thermal recording added regional information to observations of pain and mouth opening. Continued use in larger samples, with repeated sessions, follow-up, controlled comparisons, and evaluation of isolated techniques, will allow investigation of the relationship with standardized clinical outcomes and the applicability of orofacial monitoring.

***Abstract*— The assessment of respiratory mechanics using oscillometry-derived parameters has gained increasing interest as a complementary tool to spirometry in chronic obstructive pulmonary disease (COPD). In particular, loop-derived parameters based on resistance and reactance may provide additional insights into intrabreath mechanical behavior. Therefore, the present study aimed to evaluate the areas of respiratory system impedance, volume, and flow loops and investigate their association with spirometric parameters, as well as their potential diagnostic value in patients with COPD. This study analyzed loop-derived parameters obtained from respiratory oscillometry, including area of resistance-volume (ARV), resistance-flow (ARV′), reactance-volume (AXV), and reactance-flow (AXV′) loops. Correlation analyses were performed to assess associations with spirometric parameters. Diagnostic accuracy was evaluated using receiver operating characteristic (ROC) curve analysis. Reactance-derived parameters were significantly higher in COPD patients ($p<0.05$) and showed moderate diagnostic accuracy (AUC=0.751), as well as significant moderate to excellent correlations with spirometric variables (R=0.830). In contrast, resistance-derived parameters did not show significant correlations and demonstrated lower diagnostic performance (p=0.888). From this, reactance-based loop parameters showed stronger associations with spirometric impairment and higher discriminatory performance in the studied sample and may provide additional information on alterations in respiratory mechanics compared to resistance-derived measures. These findings suggest a potential role of oscillometry, particularly reactance-derived indices, as a complementary tool to spirometry in the evaluation of COPD.**

Keywords—COPD, oscillometry, reactance, resistance, loop analysis.

I. INTRODUCTION

Chronic Obstructive Pulmonary Disease (COPD) is among the three leading causes of death worldwide, with the majority of deaths occurring in low- and middle-income countries [1, 2]. It is characterized by persistent respiratory symptoms, as well as significant airflow restriction due to abnormalities in the airways and alveoli. These characteristics are usually caused by exposure to harmful gases and particles, with smoking being the main risk factor for developing the disease. It is a preventable and treatable disease, and the most commonly reported symptoms are dyspnea, cough, and discomfort [3].

Airflow limitation is usually measured by spirometry [3]. This pulmonary function test is considered the gold standard, but requires great effort and cooperation from individuals, which can temporarily cause changes in bronchomotor tone, consequently varying the quality of the test results [4, 5].

Respiratory oscillometry involves applying pressure oscillations to the mouth using an external device, allowing the patient to breathe spontaneously while the resistive and elastic properties of the respiratory system are analyzed. The examination requires only passive cooperation from the patient, and forced expiratory maneuvers are not necessary [6]. Thus, it is a method that emerges to complement traditional approaches to assessing pulmonary function, offering additional parameters for the analysis of ventilatory mechanics. Through this technique, it is possible to measure the impedance of the respiratory system (Zrs), composed of two main elements: resistance (Rrs) and reactance (Xrs) [6].

Zrs expresses the total mechanical load imposed on the respiratory system during ventilation, encompassing resistive, elastic, and inertial components of the respiratory system [7, 8]. Rrs reflects the total energy dissipation in the respiratory system, encompassing not only airway resistance but also the properties of lung tissues and the chest wall. Thus, it represents the total respiratory resistance, capturing both the friction related to airflow and the tissue resistive factors. In turn, Xrs expresses the accumulation of energy in the respiratory system [6].

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

Investigating the dynamic behavior of respiratory impedance throughout the breathing cycle may provide additional physiological information that is not captured by conventional time-averaged oscillometric parameters [9]. Since mechanical properties of the respiratory system vary between inspiration and expiration, particularly in conditions associated with airflow limitation such as COPD [9], the analysis of selected breathing cycles may reveal subtle changes in airway mechanics and ventilatory heterogeneity.

Respiratory system behavior throughout the breathing cycle can be evaluated using loop representations derived from physiological signals, such as flow-volume loops. The flow-volume loop represents the relationship between airflow and lung volume, with inspiratory and expiratory flows displayed on the y-axis and the corresponding lung volumes on the x-axis. Different patterns observed in this curve are associated with obstructive and restrictive respiratory conditions and may assist in their identification and localization [10].

Despite the well-established role of spirometry in the assessment of COPD, its limitations, especially the need for effort and cooperation from the patient, drive the search for alternative or complementary methods. In this context, respiratory oscillometry emerges as a promising technique, allowing the assessment of respiratory mechanics during spontaneous breathing.

Although conventional oscillometric parameters have been widely studied, the analysis of intrabreath dynamics, particularly through loop-derived parameters, remains relatively underexplored. These loop representations may provide additional insights into the nonlinear and dynamic behavior of the respiratory system, especially in conditions such as COPD, where expiratory flow limitation and small airway dysfunction play a central role.

These types of loop-derived parameters have been previously explored in the literature, particularly for the assessment of dynamic changes in respiratory mechanics in different conditions [11-13]. However, the clinical applicability and diagnostic value of these loop-derived parameters are not yet fully established, and studies addressing this topic are limited.

Thus, this preliminary and exploratory study aimed to evaluate the areas of respiratory system impedance, volume, and flow loops and investigate their association with spirometric parameters, as well as their potential diagnostic value in patients with COPD.

II. Materials and Methods

A. Monofrequency respiratory oscillometry

In monofrequency respiratory oscillometry, the assessment was performed by applying pressure oscillations at a single frequency. These analyses were used to evaluate Zrs in real time, enabling the detection of variations in airway caliber during the respiratory cycle [6].

The impedance analyzer was developed in our Laboratory, and followed the most recent international recommendations [6]. A sinusoidal pressure signal at a frequency of 6 Hz *was* applied, generated by a power amplifier coupled to an 8-inch speaker, producing a peak-to-peak pressure amplitude probe signal of 2.0 cmH_2O. Pressure variations (P) were captured by a low-pressure transducer (Honeywell 176PC) [14].

The examination was performed in a seated position, with a nose clip, with the individual breathing normally through a disposable mouthpiece with cheek compression by the individual themselves with their palms. The hands holding the cheeks prevent the upper airways from interfering with the respiratory impedance measurement, ensuring that the examination reflects only the behavior of the intrathoracic respiratory system. During the procedure, participants breathed through a mouthpiece connected to a flow (V′) transducer (PT-36 Jaeger-Tonnies). These signals obtained were processed using Fourier Transform (F) to calculate the total respiratory Zrs [Zrs = F(P)/F(V′)] [14], allowing the measurement of the resistance and reactance at 6 Hz.

The software for data acquisition and Zrs processing was developed on the LabVIEW 2018 platform (National Instruments, Austin, TX). We used a Dell Inspiron 137000 series notebook as the hardware platform, equipped with a touch screen, Intel Core i5 processor, 4 GB of RAM and a 456 GB hard drive [14]. Zrs estimates were obtained at 20 Hz.

Each examination lasted a minimum of 35 s and a maximum of 150 s. Exams containing artifacts or irregular breathing were identified using visual inspection and the criteria described in [15] and excluded from analysis.

At least two acceptable examinations were performed. During the maneuvers, graphs of the resistance and reactance curves were provided, with a signal indicating a Coherence Function (CF) > 0.90 as the criterion for accepting the curve. From the examination performed, 5 stable respiratory cycles were selected to perform the average analysis of the Zrs Loops.

The following loop-derived parameters were analyzed: area of resistance-volume loop (ARV), area of resistance-flow loop (ARV′), area of reactance-volume loop (AXV), and area of reactance-flow loop (AXV′). These parameters were obtained from the integration between resistance (R6) and reactance (X6) at 6 Hz with volume (V) and flow (V′) throughout the respiratory cycle, reflecting intrabreath variations in respiratory mechanics [11].

B. Study population

This case-control study included individuals diagnosed with COPD and healthy control subjects, and was approved by the Research Ethics Committee registered under number 87550225.0.0000.5259.

Selected participants were referred to the Biomedical Instrumentation Laboratory of the State University of Rio de Janeiro, provided they met the eligibility criteria and signed the Informed Consent Form. In addition, volunteers were informed of the need to discontinue the use of cigarettes, alcoholic beverages, short-acting bronchodilators for 6 hours and long-acting bronchodilators for 12 hours prior to the pulmonary function test.

Upon arrival at the Laboratory, they underwent a 10-15 minute rest period for the administration of a standard questionnaire, clinical evaluation, and anthropometric measurements. Following this, respiratory oscillometry and spirometry tests were performed. After this stage, salbutamol aerosol was administered to assess the bronchodilator response, and after 20 minutes, the pulmonary assessment was performed

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

again. For the analyses presented in this study, only post-bronchodilator oscillometric and spirometric measurements were considered.

The control group consisted of individuals ≥ 18 years of age, with no history of smoking, respiratory or cardiac diseases, no history of respiratory infections in the last thirty days, and with spirometry and oscillometry tests compatible with normality. In the COPD group, individuals ≥ 18 years of age were included, with no history of respiratory infections in the last thirty days and with a previous diagnosis of COPD based on the criteria of the Global Initiative for Chronic Obstructive Lung Disease (GOLD), where the FEV_1/FVC ratio is < 0.7 after the use of a bronchodilator [3]. Individuals with a history of mild Coronavirus Disease 2019 (COVID-19) were eligible for both groups, provided they did not have persistent respiratory symptoms and fully met the inclusion criteria established for each group.

C. Spirometry

A computerized system equipped with a pneumotachograph (nSpire Health, Inc., Longmont, CO, USA) was used to perform spirometry. The procedure followed the acceptability and reproducibility criteria established by the Brazilian Thoracic Society (SBPT) and the ATS/ERS [16-18]. For data analysis, reference equations proposed by Pereira were applied for spirometry [19].

Participants were evaluated in a seated position, with the head in a neutral position, breathing through a mouthpiece with a bacterial filter and using a nose clip to occlude the nostrils.

They were instructed to breathe normally for 3 seconds, followed by a maximal inspiration and a forced expiration until the end of expiration. In cases of severe obstruction, forced expiration may last longer than 15 seconds. Therefore, although 6 seconds is the minimum recommended duration, curves lasting longer than 10 seconds are still considered acceptable in the presence of significant obstruction [20].

After obtaining three acceptable maneuvers, with at least two being reproducible, the parameters were analyzed based on the flow–volume and volume–time curves.

The spirometric parameters analyzed in the present study included the forced vital capacity (FVC) that represents total volume of air exhaled during a forced expiration initiated from a maximal inspiration; Forced Expiratory Volume in one second (FEV_1), which represents the volume of air exhaled in the first second of the forced expiratory maneuver; FEV_1/FVC corresponds to the ratio between the volume exhaled in the first second and the forced vital capacity; Forced Expiratory Flow between 25% and 75% ($FEF_{25–75}$) represents the mean forced expiratory flow obtained during the intermediate phase of the forced vital capacity; $FEF_{25–75}/FVC$ corresponds to the ratio between the mean forced expiratory flow during the intermediate portion of the forced vital capacity and the forced vital capacity itself, expressed as absolute or percentage values [20].

D. Statistical analysis

Results were expressed as mean ± standard deviation (SD) with descriptions in tables and graphs. The sample distribution characteristics were evaluated using the Shapiro-Wilk test. For normally distributed data (parametric), the independent t-test was applied. For non-normally distributed data (non-parametric), the Mann-Whitney test was used.

Pearson (parametric method) and Spearman (nonparametric method) correlation analyses were also performed to assess the associations between Zrs loops and pulmonary function parameters. These analyses were conducted using GraphPad Prism 8 (GraphPad Software, La Jolla, CA, USA). Correlation coefficients ranging from 0 to 0.25 (or 0 to −0.25) were considered small or negligible; from 0.25 to 0.50 (or −0.25 to −0.50), fair; from 0.50 to 0.75 (or −0.50 to −0.75), moderate to good; and values exceeding 0.75 (or −0.75) were considered very good to excellent [21].

Diagnostic accuracy, sensitivity, specificity, and cutoff values were evaluated using receiver operating characteristic (ROC) curve analysis. Diagnostic accuracy was assessed by calculating the area under the curve (AUC), where values between 0.50 and 0.70 indicate low accuracy, 0.70 to 0.90 indicate moderate accuracy, and values between 0.90 and 1.00 indicate high accuracy [22].

According to Goedhart et al. [23], a cutoff value of 0.70 was considered appropriate to characterize a clinically useful discriminator. In the present study, a minimum AUC value of 0.75 was adopted as the criterion for adequate diagnostic accuracy. ROC analyses were performed using MedCalc 12 (MedCalc Software, Mariakerke, Belgium).

Differences with $p \leq 0.05$ were considered statistically significant, and the analyses and graphs were performed using the Origin® 8.0 program (Microcal Software Inc., Northampton, Massachusetts, United States).

III. RESULTS

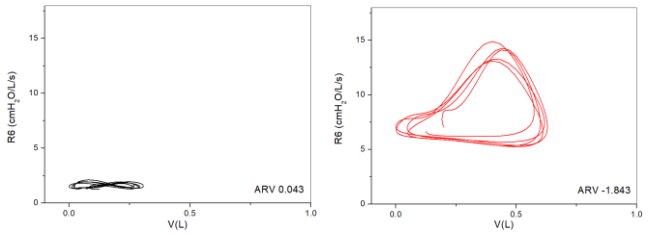
A. Studied volunteers and spirometric evaluations

In total, 30 individuals were included, 15 in the control group and 15 in the COPD group (4 with mild, 3 with moderate, 4 with severe, and 4 with very severe obstruction). The biometric and spirometric parameters of the studied groups are presented in Table 1.

Table 1: Biometric and spirometric parameters of the studied groups.

	Control (n=15)	COPD (n=15)	p
Age (years)	54.86 ± 10.63	66.86 ± 3.88	<0.001
Weight (kg)	79.33 ± 10.04	72.46 ± 9.49	ns
Height (cm)	169.50 ± 10.76	165.33 ± 6.56	ns
BMI (kg/m^2)	27.74 ± 3.78	26.55 ± 3.61	ns
Pack-years	0	77.65 ± 38.70	<0.0001
Gender (F/M)	*7 / 8*	*3 / 12*	-
R6 ($cmH_2O/L/s$)	3.06 ± 1.15	4.62 ± 1.67	0.00666
FVC (L)	3.93 ± 1.02	2.64 ± 1.02	0.00184
FVC (%)	97.06 ± 13.61	69.29 ± 22.88	0.00369
FEV_1 (L)	3.22 ± 0.84	1.56 ± 0.80	<0.0001
FEV_1 (%)	99.47 ± 11.75	52.62 ± 24.73	<0.0001
FEV_1/FVC (%)	81.96 ± 5.30	57.06 ± 10.81	<0.0001

COPD – Chronic Obstructive Pulmonary Disease; BMI - Body Mass Index; FEV_1 - Forced Expiratory Volume in one second; FVC - Forced Vital Capacity; n= number of patients evaluated; ns - nonsignificant.



XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

Regarding biometric parameters, no statistically significant differences were observed between the groups in terms of body weight, height, and BMI. However, age showed a significant difference ($p<0.001$), with the COPD group being characterized by older individuals.

In addition, the smoking history was significantly higher in the COPD group when compared to the control group ($p<0.0001$). The mean resistance at 6 Hz (R6) was significantly higher in the COPD group compared to the control group ($p<0.01$). All spirometric parameters showed significant differences between the groups, indicating significantly reduced lung function in the COPD group compared to the control group (Table 1).

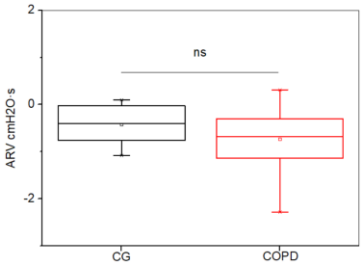
B. Respiratory System Impedance Volume and Flow Loops Areas

To illustrate the behavior of intrabreath oscillometric loops, representative examples from a healthy control and a patient with COPD are presented. In the control subject, the resistance–volume loops exhibit a compact and nearly closed configuration, with minimal separation between inspiratory and expiratory phases, with limited intrabreath variability in resistance (Figure 1A). In contrast, the COPD patient demonstrates markedly expanded and distorted loops, with a clear separation between inspiratory and expiratory trajectories, resulting in an open-loop configuration. This pattern indicates increased intrabreath variability in resistance during the respiratory cycle (Figure 1B).

(A) **(B)**

Fig. 1 Representative resistance–volume loops in a control subject (A) and in a COPD subject (B).
R6 – Resistance *at* 6 Hz; V – Volume; ARV - Area of Resistance Volume Loop.

Although the COPD group showed a visual tendency toward lower mean values (Figure 2), there was no significant difference in ARV between the groups.



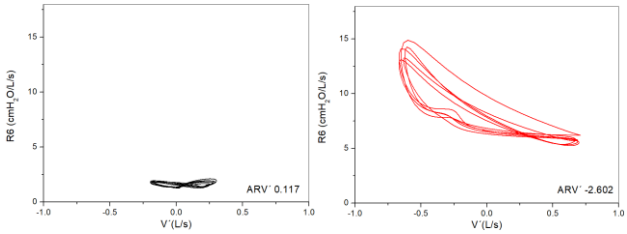


Fig. 2 Comparison of ARV between control group and COPD patients.
ARV - Area of Resistance Volume Loop; CG – Control Group; COPD – Chronic Obstructive Pulmonary Disease; ns – nonsignificant.

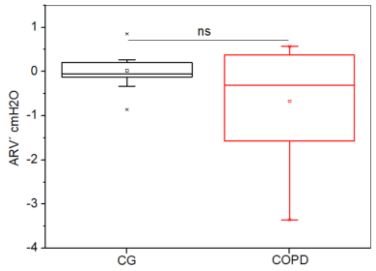
Consistent with the patterns observed in resistance-volume loops, the control subject represented in resistance-flow loops also presented a more compact form, with minimal separation between the phases of the respiratory cycle (Figure 3A).

In contrast, this pattern becomes more pronounced in COPD, where the patient exhibits broader and more dispersed loop patterns, with a clear separation between inspiratory and expiratory phases (Figure 3B).

(A) **(B)**

Fig. 3 Representative resistance–flow loops in a control subject (A) and in a COPD subject (B).
R6 – Resistance at 6 Hz; V′ – Flow; ARV′ - Area of Resistance Flow Loop.

Although the COPD group also exhibited a visual tendency toward lower mean values compared to the control group (Figure 4), no statistically significant difference was observed in ARV′ between the groups.



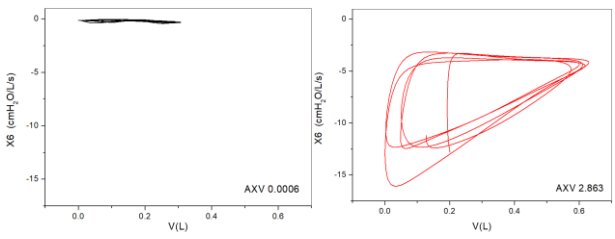


Fig. 4 Comparison of ARV′ between control group and COPD patients.
ARV′ - Area of Resistance Flow Loop; CG – Control Group; COPD – Chronic Obstructive Pulmonary Disease; ns – nonsignificant.

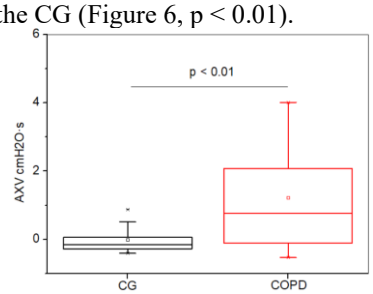
In reactance–volume loops, the control subject exhibited a narrow configuration closely aligned near zero values, indicating minimal variation throughout the respiratory cycle (Figure 5A). Conversely, in COPD, a markedly expanded loop with more negative reactance values and greater separation between inspiratory and expiratory phases was observed (Figure 5B).

(A) **(B)**

Fig. 5 Representative reactance–volume loops in a control subject (A) and in a COPD subject (B).
X6 – Reactance at 6 Hz; V – Volume; AXV - Area of Reactance Volume Loop.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

While resistance-based loops showed limited differences between groups, a distinct pattern emerges when reactance is analyzed. AXV was significantly higher in patients with COPD compared to the CG (Figure 6, $p < 0.01$).



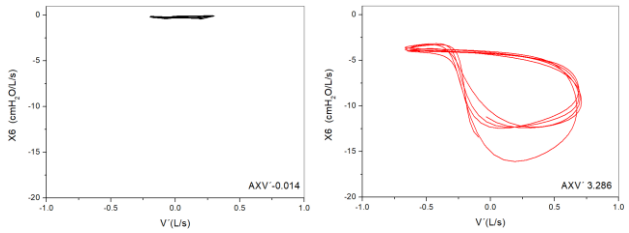


Fig. 6 Comparison of AXV between control group and COPD patients. AXV - Area of Reactance Volume Loop; CG – Control Group; COPD – Chronic Obstructive Pulmonary Disease.

Extending this observation to flow-dependent behavior, reactance–flow loops provide additional insight into the dynamic aspects of respiratory mechanics. In the control subject, the reactance–flow loop remained compact, with a nearly linear trajectory and minimal phase separation between inspiratory and expiratory branches (Figure 7A). However, in COPD, a markedly distorted loop with evident phase separation between inspiratory and expiratory trajectories was observed (Figure 7B), indicating altered dynamic behavior during the respiratory cycle.

(A) **(B)**

Fig. 7 Representative reactance–flow loops in a control subject (A) and in a COPD subject (B).
X6 – Reactance *at* 6 Hz; V′ – Flow; AXV′ - Area of Reactance Flow Loop.

The comparative analysis revealed that AXV′ was significantly higher in patients with COPD compared to the control group (Figure 8, $p < 0.05$).

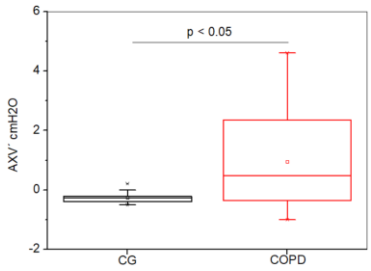

Fig. 8 Comparison of AXV′ between control group and COPD patients. AXV′ - Area of Reactance Flow Loop; CG – Control Group; COPD – Chronic Obstructive Pulmonary Disease.

C. *Correlation Between Impedance Loops and Pulmonary Function Parameters*

Correlation analyses between Zrs loops and spirometry are presented in Table 2. No significant correlations were observed between ARV and any spirometric variables. Similarly, ARV′ did not show significant correlations with spirometry parameters.

In contrast, AXV demonstrated significant moderate to excellent inverse correlations with all spirometric variables. AXV′ also showed significant inverse correlations with most spirometric parameters, except for FEF_{25-75}/FVC %, which showed a significant positive correlation, and for FVC%, which did not show a significant correlation.

D. *Diagnostic Accuracy*

The diagnostic accuracy of Zrs loops is presented in Table 3. Overall, reactance-derived parameters showed higher diagnostic performance in the present sample compared to resistance-derived measures. AXV demonstrated moderate diagnostic accuracy (AUC = 0.791), while AXV′ also showed moderate performance (AUC = 0.751), both with higher sensitivity and specificity.

In contrast, ARV and ARV′ showed lower diagnostic accuracy (AUC = 0.622 and 0.618, respectively), with reduced sensitivity despite high specificity, showing lower discriminatory performance in the present sample.

Table 2: Correlation coefficient (r) and correlation significance level (p) of the oscillometry parameters in relation to the spirometry. Significant correlations are highlighted in bold.

		FVC %	FVC	FEV_1 %	FEV_1	FEV_1/FVC	FEF_{25-75}	FEF_{25-75}/FVC %	FEF_{25-75}/FVC

IV. Discussion

The results regarding biometric parameters demonstrated that the groups were homogeneous in terms of body weight, height, and BMI (Table 1). However, a significant difference was observed in relation to age, with the COPD group being composed of older individuals when compared to the control group. This finding is consistent with what is already discussed in the literature, where the disease is more prevalent in older individuals, having a higher frequency in people over 65 years of age [24].

The significantly higher tobacco load in the COPD group reinforces the influence of smoking on disease progression (Table 1). Continuous exposure to cigarette smoke triggers a persistent inflammatory process associated with oxidative stress in lung tissue, causing repeated cycles of injury and repair [25]. As a consequence, structural remodeling of the airways occurs, accompanied by stimulation of excessive mucus production, characteristic of chronic bronchitis, in addition to the progressive destruction of alveolar walls, contributing to the development of emphysema [25].

The increased respiratory resistance observed in the COPD group reflects the presence of airflow limitation characteristic of the disease [3] (Table 1). In individuals with COPD, the structural airway alterations already discussed contribute to increased airway resistance [3]. Thus, elevated resistance values obtained by oscillometry are consistent with the obstructive pattern evidenced by the spirometric parameters observed in this study.

With regard to spirometric parameters, the significant reduction in FVC, both in absolute values and as a percentage of predicted, suggests impaired pulmonary ventilation (Table 1). This alteration is mainly due to air trapping, which leads to an increase in residual volume (RV) relative to total lung capacity (TLC), configuring a common pathophysiological characteristic of COPD [26].

The reduction in FEV_1, in liters and as a percentage of predicted, confirms the presence of airflow obstruction (Table 1). This alteration may be mainly related to the impairment of the small airways, resulting from inflammation, excessive mucus production, and structural remodeling [27]. These processes promote narrowing of the bronchial lumen, causing a significant increase in airway resistance and limitation of expiratory airflow, which directly contributes to the decrease in FEV_1 observed in these individuals [27].

Furthermore, the significant reduction in the FEV_1/FVC ratio reinforces this obstructive pattern, being compatible with the diagnostic criteria used for the disease [3] (Table 1).

Intrabreath oscillometry allows continuous monitoring of lung mechanical properties during both inspiratory and expiratory phases, which are graphically represented as loops describing the respiratory cycle [12] (Fig. 1; Fig. 3; Fig. 5; Fig. 7).

Resistance primarily reflects viscous losses in the respiratory system [28], as well as representing opposition to airflow through the airways [29]. The absence of significant differences in both ARV and ARV′ between the control group and COPD patients suggests lower discriminatory performance of resistance-derived curve areas in the present sample (Fig. 2; Fig. 4).

A similar finding has been reported by Fu et al., who evaluated intrabreath oscillometry parameters in different clinical groups and analyzed resistance-derived loop areas, including ARV and ARV′. In their study, ARV did not differ significantly between groups, whereas ARV′ was significantly increased in patients with bronchiolitis obliterans syndrome compared to the other individuals [12].

In the study by Cousins et al., intrabreath oscillometry in school-aged children with prematurity-associated lung disease was investigated. These individuals underwent oscillometry at the beginning of the study, after the maximal cardiopulmonary exercise test, and after post-exercise bronchodilation. No significant differences were observed in either ARV or ARV′ between groups at baseline [13]. These findings are consistent with the results of the present study, in which no significant differences were observed for ARV and ARV′. However, their analysis was conducted in a pediatric population with distinct underlying pathophysiology related to prematurity, which differs from the adult COPD population evaluated in the present study.

As previously discussed, the relationships between Rrs and Xrs with V′ and V exhibit different loop patterns, which can be used to characterize pathological and physiological processes [11].

The reactance-based loop areas (AXV and AXV′) were significantly higher in patients with COPD, consistent with alterations in respiratory system mechanics (Fig. 6; Fig. 8). AXV has been associated with expiratory flow limitation [11], while AXV′ has been related to air trapping during tidal breathing [12]. These features are characteristic of COPD and may explain the significantly higher values observed in affected patients [3].

Similarly, Fu et al. reported that AXV was significantly increased in patients with bronchiolitis obliterans syndrome compared to other groups, while AXV′ values were significantly more negative in these patients [12].

Overall, these findings suggest that reactance-based loop parameters showed more pronounced differences in COPD

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

patients, particularly when compared to resistance-derived measures.

The correlation analysis demonstrated that reactance-derived parameters, particularly AXV, showed moderate to strong correlations with spirometric variables, whereas resistance-derived parameters did not show significant associations (Table 2).

The negative correlations observed between AXV and AXV′ and spirometric parameters suggest that greater alterations in reactance are associated with worse lung function. This finding is particularly relevant in COPD, where airflow limitation and small airway involvement play an important role in the pathophysiology of the disease [3].

Additionally, AXV′ showed significant correlations with most spirometric variables, although with lower magnitude compared to AXV. This finding suggests that volume-based loops may be more closely associated with the functional alterations captured by spirometry in this sample, whereas flow-based loops may be influenced by additional factors related to the breathing pattern.

In contrast, the absence of significant correlations for ARV and ARV′ may suggest a limited ability of resistance-derived parameters to reflect functional impairment. This may be explained by the fact that resistance primarily represents opposition to airflow [29], whereas reactance is related to the elastic and inertial properties of the respiratory system and has been associated with peripheral airway function and dynamic changes throughout the respiratory cycle [27].

The diagnostic performance observed for impedance area loops in the present study suggests that reactance-derived measures showed higher discriminatory performance in COPD when compared to resistance-derived parameters. AXV and AXV′ demonstrated moderate diagnostic accuracy, with higher sensitivity and specificity, indicating their potential to capture disease-related changes in respiratory mechanics (Table 3).

These findings are consistent with the correlation analysis (Table 2), in which reactance-based parameters, particularly AXV, showed significant associations with spirometric variables, suggesting that these measures may reflect functional impairment. In contrast, resistance-derived parameters showed both lower diagnostic accuracy and absence of significant correlations with spirometry, reinforcing their limited discriminatory capacity in this population.

The lower performance of ARV mean and ARV′ mean may be partly related to the physiological characteristics of resistance, which mainly represents opposition to airflow [29], and may be less sensitive to more subtle changes, especially those related to peripheral airways. Conversely, as previously discussed, reactance reflects the elastic and inertial properties of the respiratory system and has been linked to alterations in the peripheral airways, which play a key role in the pathophysiology of COPD [27].

Taken together, these results suggest that reactance-derived loop parameters may provide complementary information regarding functional impairment in COPD, while resistance-derived measures showed lower discriminatory performance.

The present study presents several limitations. First, the small sample size; consequently, the cutoff values derived from the ROC curve should be considered exploratory and require validation in independent samples or through internal resampling. Studies involving larger cohorts and adequate statistical power are needed to confirm these findings, evaluate these parameters longitudinally, and investigate their applicability across different stages of COPD, based on GOLD classification, and analysis in other respiratory diseases. Integrating parameters derived from the loops with machine learning techniques could also enhance their discriminatory and clinical potential.

V. Conclusions

The results of the present study demonstrated that reactance-derived parameters, specifically AXV and AXV′, showed stronger associations with functional impairment and moderate discriminatory performance in the present sample compared to resistance-derived parameters.

These findings suggest that reactance-based parameters may reflect aspects of the functional alterations associated with COPD, particularly those related to airflow limitation and small airway involvement. Although spirometry remains the gold standard for the diagnosis of the disease, the analysis of oscillometry-derived loops, especially those based on reactance, may provide relevant complementary information for the assessment of pulmonary function.

Therefore, the use of these parameters may represent a promising tool for the detection and characterization of respiratory alterations in COPD, contributing to a more comprehensive evaluation of respiratory mechanics.

***Abstract*— Photoplethysmography-based wearable devices enable the acquisition of multiple physiological measurements, but their performance may vary across physiological metrics and can be influenced by the optical properties of the skin. This study evaluated the performance of physiological measurements obtained with the Samsung Galaxy Watch4 and investigated the magnitude of measurement errors across different skin phototypes. A total of 114 participants classified as Fitzpatrick skin phototypes I–IV were evaluated. Systolic blood pressure (SBP), diastolic blood pressure (DBP), and heart rate (HR) measurements obtained with the smartwatch were compared with those obtained using a sphygmomanometer, whereas peripheral oxygen saturation (SpO2) and HR were compared with measurements obtained using a fingertip pulse oximeter. Associations were assessed using Pearson or Spearman correlation coefficients, agreement was evaluated using Bland–Altman analysis, and absolute errors across phototypes were compared using the Kruskal–Wallis test. SBP and DBP showed strong correlations with the comparison device (r = 0.974 and r = 0.980, respectively), small mean biases (+1.39 and +0.39 mmHg), and no significant proportional bias. HR showed strong associations with both comparison devices, whereas SpO2 showed a weak association (Spearman correlation coefficient = 0.192) and significant proportional bias. No statistically significant differences in absolute errors were detected across phototypes I–IV for any of the evaluated metrics (p > 0.05), and no systematic gradient of increasing error was observed across phototypes. Under the conditions evaluated, differences in smartwatch performance were more evident across physiological metrics than across the skin phototypes represented in the sample.**

***Keywords*- photoplethysmography, wearable devices, smartwatch, skin phototype, blood pressure, heart rate, peripheral oxygen saturation.**

I. INTRODUCTION

Wearable devices have become increasingly important tools for the continuous monitoring of physiological parameters, extending health-related data collections beyond traditional clinical settings. The integration of miniaturized sensors with signal-processing algorithms enables the noninvasive, real-time measurement of a range of physiological metrics, supporting applications in remote monitoring, longitudinal assessment, and digital health. As these technologies become increasingly integrated into health monitoring, understanding the factors that may affect measurement performance across populations with diverse individual characteristics becomes equally important [1], [2], [3].

Among the sensing technologies used in wearable devices, photoplethysmography (PPG) plays a prominent role. PPG is an optical technique based on the emission of light into tissue and the detection of signal changes associated with pulsatile variations in peripheral blood volume. This principle enables the derivation of heart rate (HR) and peripheral oxygen saturation (SpO_2) and provides signals that can be incorporated into computational models to estimate other cardiovascular parameters, including systolic blood pressure (SBP) and diastolic blood pressure (DBP). Although multiple physiological metrics may be derived from PPG signals, their estimation relies on distinct physiological principles, optical configurations, and signal-processing steps. Therefore, the performance observed for one metric should not be assumed to apply to others [2], [3], [4].

PPG signal quality depends on the interaction between the light emitted by the sensor, biological tissues, and the pulsatile blood component. This interaction can be influenced by factors such as motion, peripheral perfusion, temperature, contact pressure, sensor positioning, anatomical characteristics, and skin properties. In this context, skin pigmentation has received increasing attention because melanin contributes to light absorption and may alter the amount of optical energy that reaches the underlying tissues and returns to the photodetector. Changes in light absorption and scattering may affect the signal-to-noise ratio and, consequently, the quality of the optical signal processed by device algorithms [2], [4], [5].

This issue has been particularly evident in pulse oximetry. Previous studies have reported differences in pulse oximeter performance among individuals with different levels of skin pigmentation, particularly under conditions of low oxygen saturation. However, the influence of skin characteristics on optical devices should not be assumed to be uniform across physiological metrics. Heart rate, SpO_2, and blood pressure estimates rely on different signal features and processing stages and may therefore respond differently to variations in PPG signal quality [2], [3], [4], [5], [6], [7].

Skin phototype diversity is an important consideration when evaluating PPG-based technologies, as light–tissue interactions may vary among individuals. In this context, the Fitzpatrick scale is a widely used clinical approach for classifying skin phototypes, allowing participants to be stratified according to their skin response to sun exposure. Its application in studies of optical devices makes it possible to investigate whether measurement performance differs across phototypes, thereby contributing to the evaluation of these technologies in more diverse populations. In the present study, the Fitzpatrick scale was used to classify participants into skin phototype groups [8], [9], [10].

Despite the growing body of research on the influence of skin characteristics on optical technologies, studies evaluating multiple physiological metrics within the same population, using the same wearable device, across participants with different skin phototypes remain limited. This approach is particularly relevant because potential differences between phototype groups may not be consistent across the physiological metrics provided by the device.

To address this gap, we hypothesized that the association, agreement, and magnitude of differences between measurements obtained with the smartwatch and the comparison devices would vary across physiological metrics and skin phototypes.

This research was supported by the São Paulo Research Foundation (FAPESP), Brazil, Grant No. 21/14221-0. Kelly C. Baioco da Silva was supported by the Coordination for the Improvement of Higher Education Personnel (CAPES), Brazil, Grant No. 88887.941749/2024-00.

II. OBJECTIVE

The aim of this study was to evaluate the performance of physiological measurements obtained with a photoplethysmography-based smartwatch by comparing systolic blood pressure (SBP), diastolic blood pressure (DBP), and heart rate (HR) measurements with those obtained using a sphygmomanometer, and peripheral oxygen saturation (SpO_2) and HR measurements with those obtained using a fingertip pulse oximeter. In addition, the performance of these measurements was investigated across different skin phototypes classified according to the Fitzpatrick scale.

III. MATERIALS AND METHODS

A. Sample

The study included 114 adult participants of both sexes, recruited through direct invitations and referrals. Eligible participants were clinically healthy, had no known comorbidities that could interfere with the physiological measurements under investigation, and were able to understand and provide written informed consent. The sample had a mean age of 28.1 ± 9.1 years (range, 22–61 years) and comprised 71 women (62.3%) and 43 men (37.7%). All eligible participants with available data for the planned analyses were retained, with no participants excluded for the purpose of numerically balancing the skin phototype groups.

Participants were classified using a Skin Phototype Classification Questionnaire based on the Fitzpatrick scale and administered electronically. The analysis included participants classified as phototype I (n = 6), II (n = 48), III (n = 42), and IV (n = 18). Sample distribution and demographic characteristics according to skin phototype are presented in Table I.

Data were collected at the Polyclinic of the University of Mogi das Cruzes (UMC). The study was approved by the Research Ethics Committee of the University of Mogi das Cruzes under CAAE 64561022.7.0000.5497. All participants were informed about the study objectives and procedures and provided written informed consent before data collection.

TABLE I.
DEMOGRAPHIC CHARACTERISTICS OF THE SAMPLE ACCORDING TO SKIN PHOTOTYPE

Variable	*I (n=6)*	*II (n=48)*	*III (n=42)*	*IV (n=18)*	*Total (n=114)*
Age, years	23.5 ± 2.3	29.0 ± 10.1	28.5 ± 8.4	26.2 ± 9.0	28.1 ± 9.1
Age range, years	22–27	22–61	22–54	22–51	22–61
Female, n (%)	5 (83.3)	32 (66.7)	27 (64.3)	7 (38.9)	71 (62.3)
Male, n (%)	1 (16.7)	16 (33.3)	15 (35.7)	11 (61.1)	43 (37.7)

Note: Age is presented as mean ± standard deviation and range; sex is presented as n (%).

B. Protocol

Data collection was conducted in a controlled environment using a standardized protocol for all participants. Initially, each participant remained seated in a comfortable position while the study procedures and the informed consent form were explained. This period also provided an opportunity for participants to rest before the measurements. After receiving all relevant information, participants who agreed to take part provided written informed consent, and the experimental procedure was initiated.

During the measurements, participants remained seated with their backs supported against the chair, feet flat on the floor, and legs uncrossed. The Samsung Galaxy Watch4 BT was positioned on the left wrist, ensuring adequate contact between the sensor and the skin, while the cuff of the OMRON HEM-7320-BR automatic sphygmomanometer was placed on the right upper arm. The device uses an Intelli Wrap cuff (HEM-FL31), specified by the manufacturer for arm circumferences ranging from 22 to 42 cm. Throughout the data-collection period, the smartwatch software was checked approximately every 10 days and updated whenever an update was available. Consequently, a single firmware version was not maintained throughout the study.

For systolic blood pressure (SBP), diastolic blood pressure (DBP), and heart rate (HR) measurements, the smartwatch was individually calibrated for each participant, as required for a new user. During calibration, three consecutive measurements were obtained with the sphygmomanometer, with simultaneous smartwatch acquisition during each measurement. The blood pressure values obtained with the sphygmomanometer were entered into the device calibration procedure. Once the three measurements and calibration procedure were completed, the smartwatch performed a subsequent measurement independently, without concurrent cuff measurement. After automatic processing, the final SBP, DBP, and HR values displayed by the smartwatch were recorded in the study database. For the comparative analysis, the arithmetic mean of the three sphygmomanometer measurements was calculated separately for SBP, DBP, and HR, and these mean values were compared with the corresponding final values obtained from

the smartwatch.

After completion of the SBP, DBP, and HR measurements, the sphygmomanometer cuff was removed while the smartwatch remained on the left wrist. For peripheral oxygen saturation (SpO_2) and HR measurements, a Multilaser HC261 fingertip pulse oximeter was placed on the right index finger. During smartwatch acquisition, the left upper limb was maintained at an approximately 45° angle, with the device positioned at heart level. SpO_2 and HR were measured simultaneously by the smartwatch and fingertip pulse oximeter, and the readings were allowed to stabilize before the values displayed by both devices were recorded.

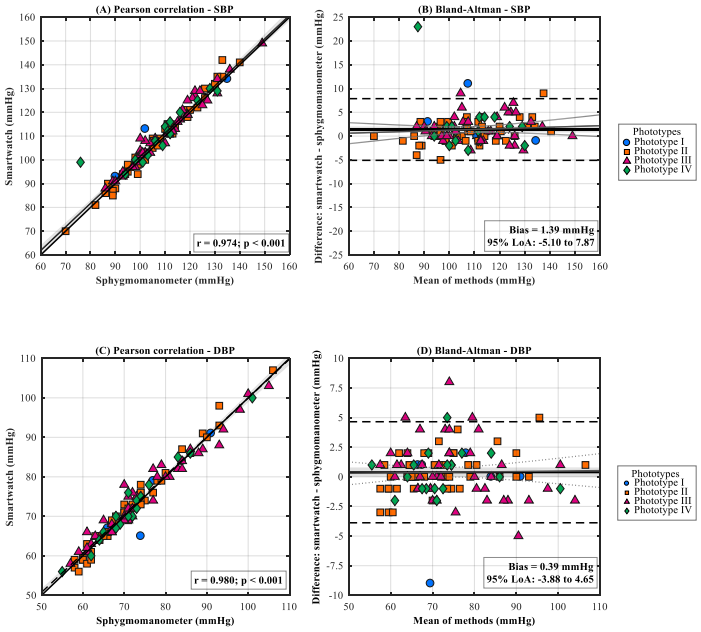
Throughout all measurements, participants were instructed to remain still and refrain from speaking to minimize interference caused by motion or sensor displacement. If motion or improper sensor positioning prevented a valid reading from being obtained, the measurement was restarted.

C. *Statistical Analysis*

Data were organized in an electronic spreadsheet and analyzed using MATLAB® R2017a. Associations between measurements obtained with the smartwatch and the comparison devices were assessed using Pearson's (r) and Spearman's (ρ) correlation coefficients. Pearson's correlation was used for SBP, DBP, and HR comparisons between the smartwatch and the sphygmomanometer, whereas Spearman's correlation was used for SpO_2 and HR comparisons between the smartwatch and the fingertip pulse oximeter. Correlation coefficients are reported with their respective 95% confidence intervals (95% CIs) and p values. Agreement between measurements was assessed using the Bland–Altman method, with differences calculated as smartwatch minus comparison device. Mean bias and 95% limits of agreement (LoA), defined as bias ± 1.96 standard deviations of the differences, were calculated together with their respective 95% CIs. Proportional bias was assessed by linear regression of the differences against the mean of the paired measurements, with the slope coefficient, its 95% CI, and the corresponding p value reported [11].

To investigate differences in error magnitude across skin phototypes, the absolute error between each smartwatch measurement and the corresponding measurement obtained with the comparison device was calculated. Absolute-error distributions across phototypes I, II, III, and IV were compared using the Kruskal–Wallis test and are summarized as median and interquartile range (IQR). Effect size was estimated using epsilon-squared (ε^2), together with its 95% CI. Statistical significance was set at 5% ($p < 0.05$).

In addition, a Monte Carlo simulation-based sensitivity analysis was performed using the Kruskal–Wallis test while preserving the observed sample sizes of the four phototype groups (n = 6, 48, 42, and 18). The simulation considered an ordered location-shift model in which observations for each group were generated according to



$$Xj \sim N\ [\ (j-1)\ \ \delta,1\ ],\quad j= 1, 2, 3, 4 \qquad (1)$$

where j denotes the phototype group (I–IV) and δ represents the standardized location shift between consecutive groups. Assuming continuous normal distributions with a common variance, a 5% significance level, and a target power of 80%, the minimum detectable standardized shift was defined as the smallest value of δ associated with approximately 80% power. The final power estimate was validated using 100,000 independent simulations.

IV. RESULTS

Blood pressure measurements obtained with the smartwatch showed strong positive linear associations with those recorded by the sphygmomanometer (Fig. 1A–D). For both SBP and DBP, values were closely distributed around the line of identity across the pressure range evaluated, with high correlation coefficients (SBP: r = 0.974; DBP: r = 0.980; both $p < 0.001$). Bland–Altman analysis showed differences predominantly centered around zero, with small positive mean biases of +1.39 mmHg for SBP and +0.39 mmHg for DBP, indicating slight average overestimation by the smartwatch. The 95% limits of agreement ranged from −5.10 to 7.87 mmHg for SBP and from −3.88 to 4.65 mmHg for DBP. Differences remained relatively stable across the observed blood pressure range, with no evidence of proportional bias for either SBP ($p = 0.470$) or DBP ($p = 0.836$).

HR showed a similarly strong positive association between the smartwatch and the sphygmomanometer ($r = 0.939$; $p < 0.001$), although with greater dispersion than observed for blood pressure measurements (Fig. 1E–F). Mean bias was small and positive (+1.45 bpm), while the 95% limits of agreement ranged from −6.79 to 9.69 bpm, indicating greater variability in individual differences. Although regression of the differences showed a positive slope with increasing mean HR, no statistically significant proportional bias was detected ($p = 0.087$).

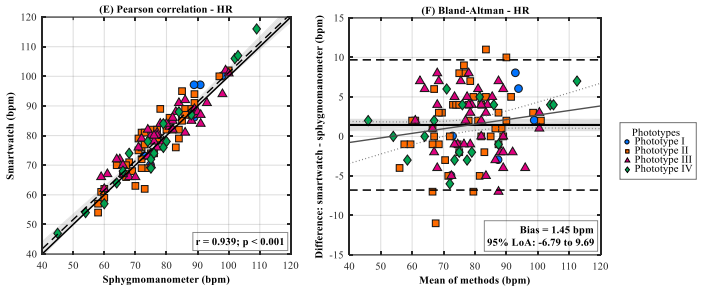


Fig. 1. Association and agreement between smartwatch and sphygmomanometer measurements of SBP (A–B), DBP (C–D), and HR (E–F), stratified by skin phototype. Pearson correlation (A, C, E) and Bland–Altman analysis (B, D, F).

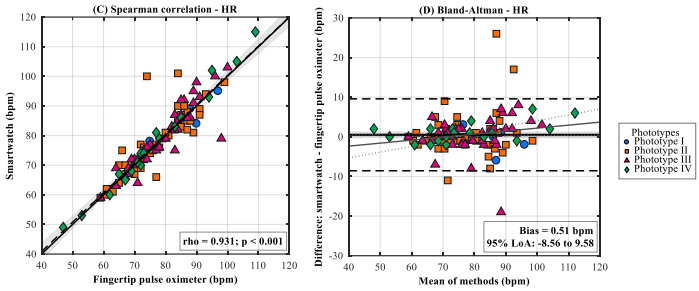

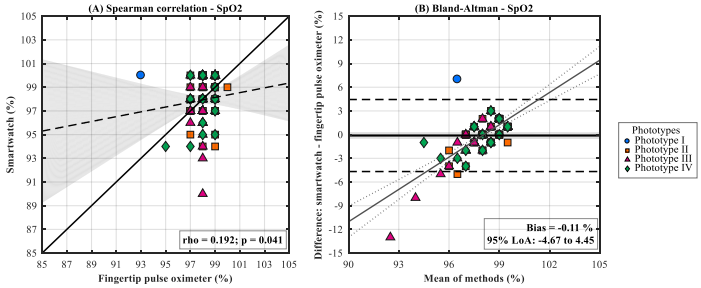

Fig. 2. Association and agreement between smartwatch and fingertip pulse oximeter measurements of SpO_2 (A–B) and HR (C–D), stratified by skin phototype. Spearman correlation (A, C) and Bland–Altman analysis (B, D).

In comparisons with the fingertip pulse oximeter, SpO_2 showed a markedly different pattern from the other physiological metrics (Fig. 2A–B). The association between devices was weak and positive (ρ = 0.192; 95% CI: 0.008–0.363; p = 0.041), with greater dispersion around the line of identity. Although mean bias was close to zero (−0.11%), the 95% limits of agreement ranged from −4.67% to 4.45%. A significant positive proportional bias was also identified (slope = 1.364; 95% CI: 1.119–1.609; p < 0.001), indicating that differences between the smartwatch and the pulse oximeter were not constant across the observed SpO_2 range but varied systematically with measurement magnitude.

In contrast to SpO_2, HR measured by the smartwatch maintained a strong positive association with HR measured by the fingertip pulse oximeter (ρ = 0.931; 95% CI: 0.902–0.952; p < 0.001) (Fig. 2C–D). Mean bias was small (+0.51 bpm); however, the 95% limits of agreement ranged from −8.56 to 9.58 bpm, indicating greater variability in individual differences despite the strong association between devices. Regression of the differences showed a positive slope, with a borderline result for proportional bias (slope = 0.076; 95% CI: 0.000–0.151; p = 0.050). Association and agreement results for all physiological measurements are summarized in Table II.

Stratified analysis of absolute errors showed substantial overlap in the distributions across phototypes I–IV for all evaluated metrics (Fig. 3A–E). No statistically significant differences among phototypes were detected for SBP (H = 1.36; p = 0.715), DBP (H = 4.49; p = 0.213), HR compared with the sphygmomanometer (H = 1.05; p = 0.788), SpO_2 (H = 2.67; p = 0.446), or HR compared with the fingertip pulse oximeter (H = 0.74; p = 0.865). None of the five metrics showed a progressive increase in absolute error across the evaluated phototypes, and effect-size estimates were null or small. Taken together, the error distributions, between-group comparisons, and effect-size estimates provided no evidence that larger errors were systematically concentrated within a specific phototype. Median and interquartile ranges of absolute errors by phototype, together with ε^2 estimates and their respective 95% CIs, are presented in Table III. In the Monte Carlo simulation-based sensitivity analysis, under the specified ordered location-shift model, the minimum detectable standardized shift was 0.405 standard deviations between consecutive groups, corresponding to a confirmed power of 80.7% (Monte Carlo 95% CI: 80.4%–80.9%).

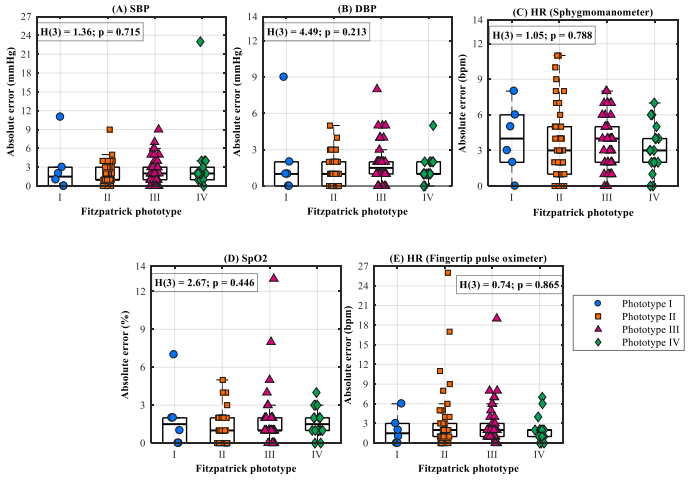

Fig. 3. Absolute errors across skin phototypes for SBP (A), DBP (B), HR compared with the sphygmomanometer (C), SpO_2 (D), and HR compared with the fingertip pulse oximeter (E). Kruskal–Wallis test.

TABLE II:

ASSOCIATION AND AGREEMENT BETWEEN SMARTWATCH MEASUREMENTS AND COMPARISON DEVICES

Metric	Association (95% CI)	P	Mean bias (95% CI)	Lower LoA (95% CI)	Upper LoA (95% CI)	Slope (95% CI)	Slope p
SBP	r = 0.974	<0.001	+1.39	−5.10	7.87	0.016	0.470

Note: r, Pearson correlation coefficient; ρ, Spearman correlation coefficient; 95% CI, 95% confidence interval; LoA, 95% limits of agreement; SBP, systolic blood pressure; DBP, diastolic blood pressure; HR, heart rate; SpO_2, peripheral oxygen saturation. Bias was calculated as smartwatch − comparison device. The slope corresponds to the linear regression of the differences against the mean of paired measurements and was used to assess proportional bias.

TABLE III:
ABSOLUTE ERRORS OF SMARTWATCH MEASUREMENTS ACCORDING TO SKIN PHOTOTYPE

Metric	Phototype I (n=6)	Phototype II (n=48)	Phototype III (n=42)	Phototype IV (n=18)	H(3)	p	ε^2 (95% CI)
SBP (mmHg)	1.50 [0.25–2.75]	1.00 [1.00–3.00]	2.00 [1.00–3.00]	2.00 [1.00–2.75]	1.36	0.715	0.000 (0–0.088)
DBP (mmHg)	1.00 [0.25–1.75]	1.00 [0–2.00]	1.50 [1.00–2.00]	1.00 [1.00–2.00]	4.49	0.213	0.014 (0–0.142)
HR – sphyg. (bpm)	4.00 [2.25–5.75]	3.00 [1.00–5.00]	4.00 [2.00–5.00]	3.00 [2.00–4.00]	1.05	0.788	0.000 (0–0.081)
SpO_2 (%)	1.50 [0.25–2.00]	1.00 [0–2.00]	1.00 [1.00–2.00]	1.50 [1.00–2.00]	2.67	0.446	0.000 (0–0.114)
HR – fingertip pulse oximeter (bpm)	1.50 [0.25–2.75]	2.00 [1.00–3.00]	2.00 [1.00–3.00]	2.00 [1.00–2.00]	0.74	0.865	0.000 (0–0.074)

Note: Absolute errors are presented as median [interquartile range]. Absolute error was defined as |smartwatch − comparison device|. H, Kruskal–Wallis test statistic; ε^2, epsilon-squared; 95% CI, 95% confidence interval; SBP, systolic blood pressure; DBP, diastolic blood pressure; HR, heart rate; SpO_2, peripheral oxygen saturation.

V. DISCUSSION

The present study showed that the performance of physiological measurements obtained with the Galaxy Watch4 varied more across the physiological metrics evaluated than across the skin phototypes represented in the sample. SBP, DBP, and HR showed strong associations with their respective comparison devices and small mean biases, whereas SpO_2 exhibited a distinct pattern characterized by a weak association and significant proportional bias. In parallel, analysis of absolute errors identified no statistically significant differences among phototypes I–IV for any of the five comparisons and no systematic gradient of increasing error toward numerically higher phototypes. Taken together, these findings suggest that the performance of a PPG-based wearable device should not be regarded as a single property of the sensor, but rather as the result of interactions among the physiological metric being estimated, optical signal characteristics, and the processing methods used to derive each measurement [1], [2], [4], [12], [13].

This interpretation is consistent with the fundamental principles of photoplethysmography. PPG signals are shaped by light–tissue interactions and the pulsatile component of blood flow and are influenced by optical, physiological, mechanical, and algorithmic factors. Wavelength, light intensity, peripheral perfusion, motion, contact pressure, and sensor geometry can affect signal quality and, consequently, have different effects on the physiological metrics derived from these signals. Previous PPG research has identified hardware characteristics, measurement site, physiological conditions, and signal processing as important determinants of system performance. Accordingly, the strong associations observed for some variables and the less consistent behavior of SpO_2 support the view that physiological metrics obtained with the same device do not necessarily share the same performance profile [2], [4], [14].

Blood pressure measurements showed the most consistent performance among the metrics evaluated. SBP and DBP showed high correlations (r = 0.974 and r = 0.980, respectively), small mean biases (+1.39 and +0.39 mmHg), and no evidence of proportional bias. The limits of agreement were also narrower than those observed for HR, indicating lower dispersion of the differences across the blood pressure range studied. These findings, however, should be interpreted in the context of the measurement approach used by the Galaxy Watch4. Blood pressure estimation requires individual cuff-based calibration, and in the present protocol, the three sphygmomanometer measurements used for calibration also provided, through their arithmetic mean, the comparison value for the final smartwatch measurement. Therefore, the findings characterize device performance after individual calibration and under the experimental conditions employed; they do not constitute an independent evaluation of the calibration procedure itself. This distinction is particularly important when interpreting wearable technologies designed to estimate blood pressure [2], [3], [4], [15].

HR also showed strong associations with both comparison devices, although with greater individual variability. Correlation coefficients remained high relative to both the sphygmomanometer (r = 0.939) and the fingertip pulse oximeter (ρ = 0.931), whereas the limits of agreement were wider than those observed for SBP and DBP. These findings highlight an important methodological distinction: a strong association between two measurement methods does not necessarily imply small differences at the individual level. This consideration is particularly relevant when evaluating PPG-based devices, as the quality of the pulsatile waveform may vary even under resting conditions because of physiological characteristics and the sensor–skin interface. Validation studies and reviews of wearable devices have reported heterogeneous performance across devices and acquisition conditions, reinforcing the importance of interpreting measures of association alongside the distribution of paired differences [12], [14], [16].

SpO_2 showed the greatest divergence between the two measurement methods. Although mean bias was close to zero (−0.11%), the 95% limits of agreement ranged from −4.67% to 4.45%, the association was weak (ρ = 0.192), and Bland–Altman regression showed significant proportional bias. Thus, the near-zero overall mean bias masked a magnitude-dependent pattern, indicating that a small mean bias alone does not imply stable differences between devices. The concentration of observations within a high saturation range limited SpO_2

variability in the sample and may have contributed to the weak correlation despite relatively small absolute differences. Previous studies have shown that pulse oximetry performance may vary according to skin pigmentation, device characteristics, and the saturation range evaluated, with particular concern at lower oxygen saturation levels [2], [4], [6], [7], [13], [14], [17].

Interpretation of the SpO_2 findings should also consider the nature of the comparison device. Both the Galaxy Watch4 and the fingertip pulse oximeter rely on optical principles to estimate peripheral oxygen saturation, whereas studies assessing pulse oximetry accuracy commonly use arterial oxygen saturation determined by CO-oximetry as the reference. Therefore, the differences observed in the present study reflect the relative performance of two optical measurement systems rather than the error of the smartwatch relative to arterial oxygen saturation. This distinction is particularly relevant given the evidence that pulse oximetry performance may vary according to skin pigmentation characteristics [13], [17].

The phototype-stratified analysis provides an additional perspective on these findings. Despite the optical basis for a potential effect of pigmentation on PPG signals, no progressive increase in absolute error was observed across phototypes I–IV. The five comparisons showed substantial overlap in their distributions, all Kruskal–Wallis tests were nonsignificant, and effect-size estimates were null or small. Across SBP, DBP, HR compared with the sphygmomanometer, SpO_2, and HR compared with the fingertip pulse oximeter, ε^2 values ranged from 0 to 0.014, with no evidence that larger errors were systematically concentrated within a single phototype. These results do not demonstrate equivalence among groups, nor do they indicate that pigmentation is irrelevant to optical measurement. Rather, they show that, in this sample and with this device, a potential effect of pigmentation did not translate into a detectable gradient of increasing physiological measurement error across phototypes I–IV [5], [7], [13].

This finding is consistent with the complex relationship between pigmentation and optical technologies described in the literature. Melanin absorption is only one of several factors that determine PPG signal quality, and changes in the raw optical signal do not necessarily produce changes of the same magnitude in the physiological measurement reported by the device. Emitter and photodetector characteristics, wavelength, optical power, sensor geometry, and signal processing may all modify the relationship between skin properties and device output. Available evidence also does not suggest a uniform effect of pigmentation across physiological metrics: recent studies have reported pigmentation-related differences in SpO_2 measurements, whereas systematic or clinically relevant pigmentation-associated bias has not been consistently identified for pulse rate measurements obtained from wearable devices. Therefore, the absence of a common gradient across the five metrics in the present study, together with the differences observed among them, reinforces the need to evaluate performance at the level of individual metrics and devices rather than assuming a uniform effect across PPG-based technologies [2], [4], [6], [13], [18].

Interpretation of the phototype-stratified findings should also account for the classification method used. The Fitzpatrick scale was developed on the basis of skin response to sun exposure and provides a clinical classification of skin phototype rather than a direct quantitative measure of melanin concentration or the optical properties of the skin. Consequently, individuals within the same phototype category may differ in pigmentation characteristics, and biologically relevant differences may not be fully captured by this ordinal classification. Future studies combining phototype classification with instrumental measurements, such as melanin index or spectrophotometry, may provide a more precise characterization of the relationship between skin optical properties and sensor performance. This distinction is important because skin phototype and pigmentation should not be regarded as equivalent concepts [8], [18].

Several characteristics of the sample and study design should be considered when interpreting these findings. Although all eligible participants were retained in the analyses, the distribution across phototypes was unequal, with only six participants classified as phototype I, and phototypes V and VI were not represented. The sensitivity analysis provides further context for this limitation: under the progressive-shift scenario defined for the observed sample sizes, approximately 80% power was achieved to detect a standardized shift of 0.405 standard deviations between consecutive groups; therefore, smaller effects remain compatible with the data and cannot be excluded solely on the basis of statistical nonsignificance. In addition, the study evaluated a single smartwatch model in clinically healthy adults under controlled resting conditions, limiting extrapolation to other devices, clinical populations, and physiological conditions. The smartwatch was not maintained on a single firmware version throughout data collection, which should also be considered when interpreting the findings. Despite these limitations, the study design allowed five physiological comparisons to be evaluated within the same population and under a standardized protocol, combining measures of association, agreement, proportional bias, and absolute errors across phototypes. Under the conditions evaluated, SBP and DBP showed the most consistent performance after individual calibration, HR maintained strong associations despite greater individual variability, and SpO_2 showed magnitude-dependent differences, while absolute errors showed no systematic gradient across phototypes I–IV. Taken together, these findings highlight the importance of evaluating PPG-based wearable technologies at the level of individual physiological metrics rather than assuming a generalized effect of skin phototype on device performance.

VI. CONCLUSION

The results of this study showed that the performance of physiological measurements obtained with the smartwatch varied across the physiological metrics evaluated. SBP and DBP showed strong associations, small mean biases, and no significant proportional bias, whereas HR maintained strong associations with the comparison devices, although with greater individual variability. SpO_2 showed a distinct pattern, with a weak association and significant proportional bias, indicating systematic variation in between-device differences according to measurement magnitude.

Across skin phototypes I–IV, no statistically significant differences in the magnitude of absolute errors were detected for any of the evaluated metrics, and no systematic gradient of increasing error was observed across groups. These findings indicate that, under the conditions evaluated and for the Galaxy Watch4, differences in performance were more evident across physiological metrics than across the skin phototypes represented in this sample. The results underscore the importance of evaluating each physiological metric individually when assessing PPG-based wearable technologies and contribute to a better understanding of their performance across populations with different skin phototypes.

***Abstract* — This study evaluated the effects of different levels of Mission-Oriented Protective Posture (MOPP) on physiological and perceptual responses in military personnel during simulated Chemical, Biological, Radiological, and Nuclear (CBRN) physical tasks. A quantitative, experimental, within-subjects, repeated-measures design was adopted, with 26 military personnel exposed to MOPP 0, MOPP 2, and MOPP 4 conditions. The protocol included a 4-km march, a 400-m high-intensity sprint, and simulated casualty transport. Heart rate, forehead infrared temperature, hydration-corrected percentage body mass loss, and rating of perceived exertion were analyzed, with emphasis on changes between the pre-exertion and post-physical-task assessments. Depending on data distribution, repeated-measures ANOVA or the Friedman test was applied. Increasing levels of protection produced greater physiological and perceptual strain, with large effect sizes for the change in heart rate and percentage body mass loss, a medium effect for the change in rating of perceived exertion, and a small effect for the change in forehead infrared temperature. Rating of perceived exertion was also significantly higher under MOPP 4 at the pre-exertion assessment. These findings indicate that equivalent physical tasks impose greater physiological and perceptual demands when performed under higher MOPP levels, suggesting that the level of protection should be considered when planning workload, recovery periods, and sustained personnel employment during CBRN operations.**

Keywords—MOPP, heat stress, physiological monitoring, military personnel, protective clothing, thermoregulation, CBRN operations, heart rate, rating of perceived exertion.

I. INTRODUCTION

The use of Personal Protective Equipment (PPE) in Chemical, Biological, Radiological, and Nuclear (CBRN) defense operations is essential for the safety and survival of military personnel on the modern battlefield [1]. However, the use of this equipment, which includes the Permeable Protective Combat Garment (PPCG) and the gas mask, imposes substantial physiological constraints on the operator [2]. The physical barrier required to filter hazardous agents also limits heat exchange with the environment and sweat evaporation, thereby increasing body heat storage and cardiovascular demand during exertion [3].

Body temperature regulation depends on the continuous balance between metabolic heat production and heat dissipation to the external environment [4]. Most of the energy generated by muscular metabolism is converted into heat, which must be dissipated through conduction, convection, radiation, and sweat evaporation. When these mechanisms become insufficient, physiological changes may occur, including increased heart rate, elevated body temperature, and dehydration [2], [4].

In CBRN scenarios, protective clothing adversely affects this balance because of the high thermal insulation and evaporative resistance of the textile materials employed [3], [5]. Military protective garments equipped with activated-carbon filtering layers, although permeable to some degree of gas exchange, substantially restrict sweat dissipation, an effect further aggravated by the use of fully impermeable rubber overboots and gas masks. This process creates a hot and humid microclimate within the protective ensemble, accelerating thermal and cardiovascular fatigue in the operator [2], [6].

The transition from a state of thermal compensation toward exhaustion requires continuous assessment of robust physiological markers. Heart rate (HR) serves as a key indicator of cardiovascular strain, reflecting the increased cardiac effort required to maintain blood flow to the periphery for heat dissipation. At the same time, changes in body mass provide an objective indication of acute fluid loss associated with high sweating rates [7]. In parallel, recent studies, together with advances in measurement technology, have established infrared measurement of surface temperature as a noninvasive and safe method for assessing peripheral thermal responses without significantly interfering with military personnel mobility [8]. In addition to objective parameters, the Rating of Perceived Exertion (RPE) has become a valuable and practical self-assessment tool for identifying increasing levels of discomfort and exertional strain [9].

To manage the balance between protection and thermal risk, military doctrine regulates the use of PPE through Mission-Oriented Protective Posture (MOPP), which organizes protective equipment into progressively higher levels, typically ranging from MOPP 1 to MOPP 4 [1], [10]. Progression to MOPP 4 increases the physiological and perceptual burden imposed on the operator because it combines the highest level of cutaneous and respiratory protection, thereby increasing strain during physical activity and thermal exposure [6].

The literature indicates that the operational safety margin is reduced under these conditions, making environmental and individual monitoring important for preventing heat-related casualties [7]. In this context, the present study aimed to investigate the effects of different levels of protection (MOPP 2 and MOPP 4), compared with a condition without protective measures (MOPP 0), on heart rate (HR), forehead infrared temperature (TIR), percentage body mass loss (ΔMC%), and Rating of Perceived Exertion (RPE), with particular emphasis

Escola de Aperfeiçoamento de Oficiais – Exército Brasileiro.

on changes between the pre-exertion and post-physical-task assessments. The analysis focuses on thermophysiological strain during the active phase of the mission, providing auditable evidence to support operational planning, heat-stress management, and the doctrinal application of protective measures during CBRN operations.

II. Methodology

A. Sample and Experimental Design

The study was characterized as quantitative, experimental, and applied research, using a within-subjects repeated-measures design with a 3 × 2 matrix, since the effects of three MOPP levels were evaluated at two different assessment moments, before and after the physical exercises. This design was adopted to reduce individual variability and allow direct comparison of the physiological responses produced by the different protection levels. The study protocol was approved by a Research Ethics Committee, and followed the Declaration of Helsinki.

Initially, the non-probabilistic purposive sampling design planned for the participation of 30 male military personnel from the 1st Chemical, Biological, Radiological, and Nuclear Defense Battalion (1st CBRN Def Bn). The selection sought to approximately reflect the actual distribution of ranks within the battalion, including officers, sergeants, corporals, and privates, with the aim of ensuring the functional representativeness of a typical Army unit engaged in CBRN operations.

Considering the repeated-measures design, a statistical power analysis was performed using a significance level of 5%, statistical power of 80%, and an expected medium-to-large effect size (d = 0.59), resulting in a minimum estimated sample of 25 participants [11]. The final sample consisted of 26 military personnel, therefore exceeding the minimum estimated sample size.

Participants were physically fit, medically cleared, free from musculoskeletal restrictions or a recent history of heat-related illness, and technically familiar with the PPE evaluated. The loss of four participants resulted from operational factors related to military routine and the application of exclusion criteria, including clinical indisposition, absence from any experimental session, failure to complete the full protocol, or noncompliance with prior instructions regarding hydration, rest, abstinence from alcohol, and avoidance of intense physical exercise during the preceding 24 h.

B. Procedures

The military personnel performed the tests under the three protection conditions on separate days, with the conditions balanced among participants to minimize learning effects or accumulated fatigue. Thus, on each day, one-third of the participants wore each of the three MOPP levels, randomly assigned, so that by the end of the study each participant had completed the experiment three times, once under each MOPP level.

The experimental conditions were defined so that participants were informed of the protective condition assigned to them only at the beginning of each experimental day, before exercise, as follows:

1) MOPP 0: standard military physical training uniform, consisting of a sleeveless shirt, shorts, and athletic shoes, without CBRN protective equipment.
2) MOPP 2: Permeable Protective Combat Garment (PPCG), consisting of a jacket and trousers with an activated-carbon inner layer, without hood or gloves, but with rubber overboots.
3) MOPP 4: complete protective ensemble consisting of a gas mask, PPCG, gloves, and overboots [1].

It is important to emphasize that MOPP 0 does not constitute an operational posture used in contaminated environments and was employed exclusively as the minimum experimental reference condition for quantifying the additional strain imposed by the protective levels. The MOPP levels adopted in the experiment are illustrated in Fig. 1.

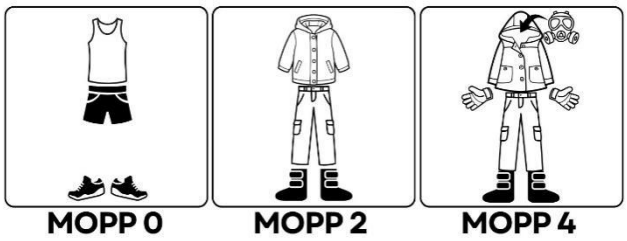

Fig. 1. MOPP levels adopted in the experiment.

C. Data Collection Instruments

For physiological and perceptual monitoring, pre-exertion and post-physical-task assessment points were established, in addition to the initial and final body-mass measurements used to determine percentage body mass loss. The instruments used comprised:

1) Kestrel 3000 portable digital weather station, used for environmental characterization of the experimental sessions, operating over an air-temperature range of −29.0°C to +70.0°C with an accuracy of ±1.0°C through a precision thermistor-based sensor, and over a relative-humidity range of 5% to 95%, with an accuracy of ±3.0% RH using a silicon-polymer capacitive sensor.
2) Digital scale, with a capacity of up to 180 kg and an accuracy of 100 g, used to record initial and final body mass and determine total fluid loss.
3) G-Tech Easy Sensor infrared thermometer, configured in body mode and used to measure forehead infrared temperature (TIR), positioned approximately 15 cm from the central point of the forehead along the midline between the eyebrows. The measurement distance and anatomical location were maintained across all sessions to standardize the procedure.
4) Digital fingertip pulse oximeter, based on Beer–Lambert law spectrophotometry, used to measure heart rate (HR) over a range of 30 to 235 bpm, with an accuracy of ±2% of the measured bpm.
5) Visual analog scale for perceived exertion, based on the Borg scale [9], consisting of a progressive 1-to-7 scale with emojis and descriptors ranging from *Almost Imperceptible* to *Extremely Hard*, as shown in Fig. 2.

Fig. 2. Borg scale adapted with emojis.

D. Physical Exertion Protocol

The simulated workload was divided into three practical tasks performed sequentially to generate aerobic and anaerobic demands under thermal strain. The following steps were performed each day:

1) Recording of environmental conditions.

2) Initial physiological assessment: initial body-mass measurement.

3) Donning of equipment according to the experimental condition assigned for the day.

4) Pre-exertion physiological assessment: measurement of HR, RPE, and forehead infrared temperature (TIR).

5) Task A (March): 4-km movement over flat terrain at a speed of 5 km/h, simulating controlled progression toward a contaminated area and emphasizing aerobic endurance.

6) Task B (Sprint): 400-m sprint at maximum speed and intensity, engaging the lactic anaerobic system and simulating tactical evasion or assault movements.

7) Task C (Casualty Evacuation): tactical evacuation performed in pairs over 200 m while carrying a litter loaded with 60 kg of weight plates placed in military backpacks, requiring submaximal strength and substantial involvement of the upper-body and trunk musculature, thereby simulating casualty evacuation from a contaminated area.

8) Post-physical-task physiological assessment: measurement of HR, RPE, and forehead infrared temperature (TIR).

9) Controlled removal of the protective equipment.

10) Final physiological assessment: final body-mass measurement.

Body-mass measurements were performed with participants wearing only shorts, preventing sweat retained in the protective clothing from being included in the measurement.

Fig. 3 provides a visual representation of the experimental procedures for improved understanding.

E. Investigated Variables

The *independent variables* were MOPP level (MOPP 0, MOPP 2, and MOPP 4) and assessment time (pre-exertion and post-physical-task). MOPP level constituted the main experimental factor, whereas assessment time represented the temporal factor used to quantify the physiological and perceptual changes produced by the physical exertion protocol, which consisted of marching, sprinting, and simulated casualty transport.

Air temperature and relative humidity were recorded as *control variables* and used to obtain a simplified estimate of the Wet Bulb Globe Temperature (WBGT) and characterize the thermal conditions of each experimental session. Because black-globe temperature was not measured, this index was used exclusively for environmental comparison among collection days and was not considered equivalent to the standardized measurement specified by ISO 7243. The starting time of exercise (09:00 h), the 4-km march route and pace (approximately 5 km/h), task sequence, 400-m sprint duration (between 90 and 100 s), and 200-m casualty transport with a 60-kg load were also standardized. Participants received standardized instructions regarding their usual diet, prior hydration, and abstinence from alcohol and intense physical exercise during the preceding 24 h. The balanced distribution of MOPP conditions across collection days was used to reduce the influence of environmental variation on within-subject comparisons.

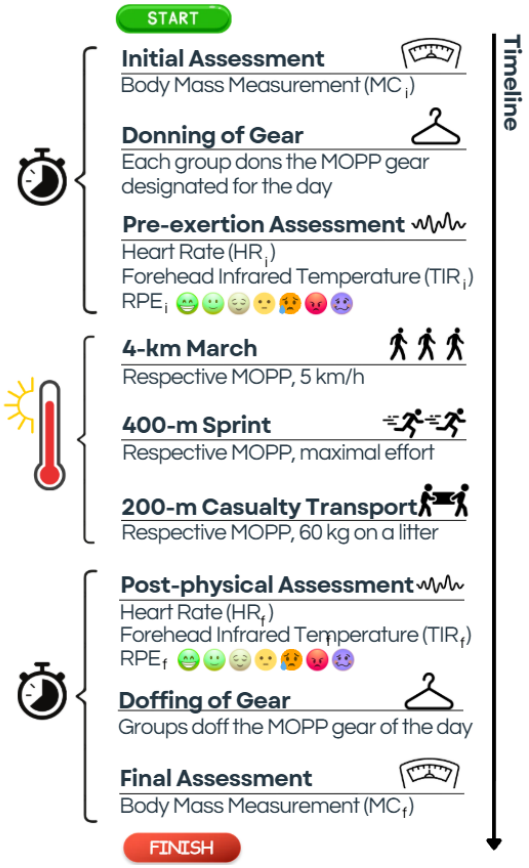

Fig. 3. Experimental and data collection protocol for the Physiological Evaluation of Heat Stress Associated with Mission-Oriented Protective Posture (MOPP) in Brazilian Army Personnel (Rio de Janeiro, 2025).

The *dependent variables* analyzed were:

1) Heart Rate (HR): measured in beats per minute (bpm) using a digital fingertip pulse oximeter at the pre-exertion and post-physical-task assessment points. HR was calculated as the mean of the values recorded during the third and fourth minutes of measurement and was used as an indicator of cardiovascular strain associated with physical exertion and the level of protection.

2) Forehead Infrared Temperature (TIR): measured noninvasively using a G-Tech Easy Sensor infrared thermometer positioned approximately 15 cm in front of the central point of the forehead. The difference between the post-physical-task and pre-exertion assessments (ΔTIR) was used as an indicator of the superficial thermal response associated with the protocol and the different MOPP levels.

3) Percentage Body Mass Loss (ΔMC%): used as an estimate of cumulative fluid loss during the protocol and calculated from initial and final body mass, corrected for the 500 mL of water ingested during the session. Body-mass measurements were performed while participants wore only standardized shorts, thereby reducing the influence of sweat retained in the clothing. The following expression was used:

$$\Delta MC\ (\%) = \frac{M_i - M_f + H}{M_i} \times 100 \quad (1)$$

where M_i represents initial body mass, M_f represents final body mass, and H represents the mass equivalent of the volume of water ingested during the session.

4) Rating of Perceived Exertion (RPE): assessed at the pre-exertion and post-physical-task assessment points using the adapted 1-to-7 visual analog scale based on the Borg scale [9]. The difference between the post-physical-task and pre-exertion assessments (ΔRPE) was used as an indicator of the perceptual response associated with the physical exertion protocol and the different MOPP levels. Higher scores indicated greater perceived exertion.

F. Statistical Analysis

Statistical analyses were performed using the *Statistical Analysis Software for Comparison of Measures Between Groups*, version 1.02, developed in Python [12]. Descriptive analyses were initially performed using means and standard deviations, with 95% confidence intervals when applicable. Distribution normality was assessed using the Shapiro–Wilk and Kolmogorov–Smirnov tests.

Considering the within-subjects design, changes between the post-physical-task and pre-exertion assessments were compared across MOPP 0, MOPP 2, and MOPP 4 using repeated-measures ANOVA followed by pairwise comparisons with Bonferroni adjustment when parametric assumptions were met. For non-normally distributed variables, the Friedman test followed by the Nemenyi post-hoc test was used. When necessary, the Greenhouse–Geisser correction was applied for violations of sphericity.

Effect magnitude was expressed using generalized eta squared ($\eta^2 g$) for parametric analyses and Kendall's W for Friedman analyses. The significance level was set at 5% ($p < 0.05$).

III. Results

The period between the first daily assessment and completion of the physical phase averaged 1 h 22 min. Environmental conditions are summarized in Table I. Day 1 showed the highest simplified WBGT estimate, whereas Days 2 and 3 were lower, with MOPP levels balanced across participants on all collection days.

TABLE I. Atmospheric Conditions of the Experimental and Data Collection Protocol for the Physiological Evaluation of Heat Stress Associated with Mission-Oriented Protective Posture (MOPP) in Brazilian Army Personnel (Rio de Janeiro, 2025).

Day	*Temperature (°C)*	*Relative Humidity*	*Estimated WBGT (°C)*
Day 1	26	81%	24.2
Day 2	24	72%	21.4
Day 3	25	64%	21.6

Table II presents the descriptive statistics for the physiological and perceptual variables at the pre-exertion and post-physical-task assessments across the three experimental conditions. Descriptively, post-physical-task heart rate and rating of perceived exertion values increased with increasing protection level. Forehead infrared temperature values showed a less uniform pattern across conditions.

TABLE II. Pre-Exertion and Post-Physical-Task Physiological Assessments for the Physiological Evaluation of Heat Stress Associated with Mission-Oriented Protective Posture (MOPP) in Brazilian Army Personnel (Rio de Janeiro, 2025)

Measurement	*Operational Condition*		
	MOPP 0	*MOPP 2*	*MOPP 4*
Pre-Exertion Heart Rate $[Avg \pm SD]$[a] (bpm)	79.62 ± 12.04	76.85 ± 14.96	76.73 ± 10.97
Post-Physical-Task Heart Rate $[Avg \pm SD]$[a] (bpm)	100.00 ± 11.08	108.19 ± 10.69	116.23 ± 13.72
Pre-Exertion TIR $[Avg \pm SD]$[a] (°C)	35.78 ± 0.32	35.66 ± 0.54	35.70 ± 0.40
Post-Physical-Task TIR $[Avg \pm SD]$[a] (°C)	35.41 ± 0.78	35.40 ± 0.52	35.75 ± 0.42
Pre-Exertion Rating of Perceived Exertion $[Avg \pm SD]$[a]	1.00 ± 0.00	1.08 ± 0.27	1.85 ± 0.61
Post-Physical-Task Rating of Perceived Exertion $[Avg \pm SD]$[a]	2.46 ± 1.03	3.50 ± 1.14	4.08 ± 0.89

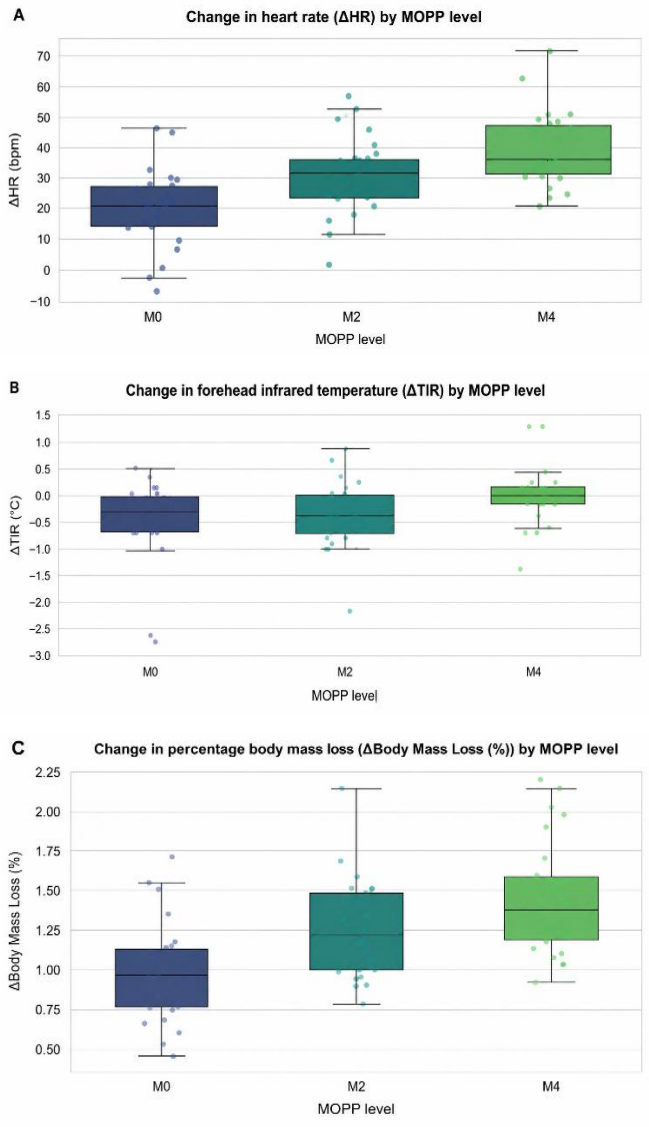
[a.] TIR = forehead infrared temperature; Avg = average; SD = standard deviation.

To assess the comparability of conditions before execution of the physical tasks, measurements obtained at the pre-exertion assessment under MOPP were analyzed, as shown in Table III. No significant differences among conditions were identified for heart rate or TIR. RPE showed a distinct pattern, with higher values under MOPP 4 than under MOPP 0 and MOPP 2, whereas MOPP 0 and MOPP 2 did not differ. It should be noted that this assessment was performed after donning the protective ensemble and therefore represents the pre-exertion condition under MOPP, rather than a baseline measure free from the influence of the equipment.

TABLE III. Statistical Comparison of Pre-Exertion Measurements for the Physiological Evaluation of Heat Stress Associated with Mission-Oriented Protective Posture (MOPP) in Brazilian Army Personnel (Rio de Janeiro, 2025)

Measurement	*Result [$\chi^2(2)$; p-value]*	*Effect Size (Kendall's W)*	*Difference between MOPP (p-value)*
Heart Rate (HR)[b]	1.000; p = 0.607	0.019 (Small)	-
TIR[b]	1.482; p = 0.477	0.029 (Small)	-
Rating of Perceived Exertion (RPE)[bc]	34.421; p < 0.001	0.662 (Large)	MOPP 0-4 (p < 0.001) MOPP 0-2 (p = 0.472) MOPP 2-4 (p < 0.001)

[b.] The global Friedman test was applied to all variables because normality was rejected ($p < 0.05$) by the Shapiro-Wilk and Kolmogorov-Smirnov tests.



[c.] For pairwise RPE comparisons, the Nemenyi post-hoc test was used.

The response to the physical phase was evaluated primarily using differences between the post-physical-task and pre-exertion assessments. The increase in heart rate was greater under MOPP 2 and MOPP 4 than under MOPP 0, with

no significant difference between MOPP 2 and MOPP 4. The change in TIR also differed among conditions, with MOPP 4 showing a distinct pattern from MOPP 0 and MOPP 2, whereas these two conditions did not differ from each other. For hydration-corrected percentage body mass loss, a progressive increase was observed from MOPP 0 to MOPP 2 to MOPP 4, with differences among all three conditions. The change in RPE was greater under MOPP 2 and MOPP 4 than under MOPP 0, with no difference between the two protected levels.

Although absolute post-physical-task RPE values increased progressively from MOPP 0 to MOPP 2 to MOPP 4, the change relative to pre-exertion did not show the same ordering because pre-exertion RPE was already higher under MOPP 4. This pattern should be considered when interpreting the pre-exertion values together with their respective changes.

Overall, the four indicators differed across protection levels, with distinct magnitudes: a large effect for ΔHR and percentage body mass loss, a medium effect for ΔRPE, and a small effect for ΔTIR. The distributions and physiological and perceptual changes are shown in Fig. 4, while the inferential results and comparisons among MOPP levels are summarized in Table IV.

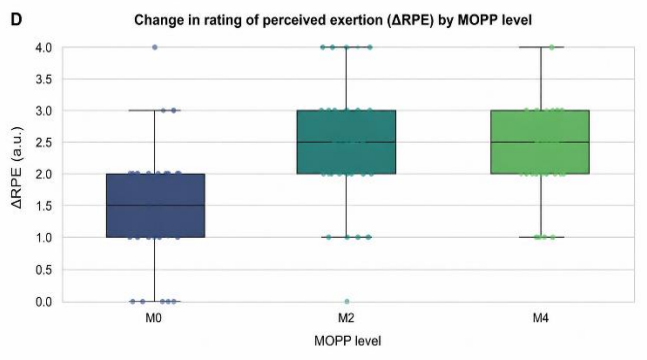


Fig. 4. Thermophysiological and perceptual changes in the sample before and after the physical exertion protocol under the different operational conditions: (A) change in heart rate (ΔHR); (B) change in forehead infrared temperature (ΔTIR); (C) change in percentage body mass loss (ΔMC%); (D) change in rating of perceived exertion (ΔRPE).

TABLE IV. STATISTICAL COMPARISON OF WITHIN-SUBJECT CHANGE (POST-PHYSICAL-TASK − PRE-EXERTION) ASSOCIATED WITH MISSION-ORIENTED PROTECTIVE POSTURE (MOPP) IN BRAZILIAN ARMY PERSONNEL (RIO DE JANEIRO, 2025)

Measurement (Δ)	*Result [Statistic; p-value]*	*Effect Size*	*Difference between MOPP (p-value)*
ΔHR[de]	F(1.537, 38.432) = 15.012 p < 0.001	η^2g = 0.295 (Large)	MOPP 0-2 (p = 0.022) MOPP 0-4 (p < 0.001) MOPP 2-4 (p = 0.174)
ΔTIR[df]	$\chi^2(2)$ = 10.950 p = 0.004	W = 0.211 (Small)	MOPP 0-2 (p = 0.936) MOPP 0-4 (p = 0.008) MOPP 2-4 (p = 0.023)
ΔMC%[de]	F(2,50) = 18.924 p < 0.001	η^2g = 0.260 (Large)	MOPP 0-2 (p = 0.005) MOPP 0-4 (p < 0.001) MOPP 2-4 (p = 0.039)
ΔRPE[df]	$\chi^2(2)$ = 17.167 p < 0.001	W = 0.330 (Medium)	MOPP 0-2 (p = 0.004) MOPP 0-4 (p = 0.003) MOPP 2-4 (p = 0.997)

[d.] ΔHR = post-physical-task minus pre-exertion change in heart rate; ΔTIR = post-physical-task minus pre-exertion change in forehead infrared temperature; ΔMC% = percentage body mass loss; ΔRPE = post-physical-task minus pre-exertion change in rating of perceived exertion.

[e.] For heart rate and percentage body mass loss, which met the parametric assumptions, repeated-measures ANOVA was applied with Bonferroni-adjusted pairwise comparisons and calculation of generalized eta squared (η^2g).

[f.] For TIR and RPE, the nonparametric Friedman test (χ^2) was used with the Nemenyi post-hoc test and Kendall's W for effect size. The significance level was $p < 0.05$.

IV. DISCUSSION

The results show that progression through MOPP levels increases the physiological and perceptual cost required to perform the same sequence of physical tasks. This pattern was not limited to a single marker: heart rate, percentage body mass loss, and rating of perceived exertion showed responses consistent with greater strain under protected conditions, although with different magnitudes. Heart rate and percentage body mass loss showed large effects, whereas the change in RPE showed a medium effect and forehead infrared temperature (TIR) a small effect. This difference in effect sizes reinforces that the assessed indicators represent distinct, although related, components of the response to exertion

under protection and should not be interpreted as interchangeable measures of heat stress [2], [7].

A particularly relevant finding was observed as early as the pre-exertion assessment. While heart rate and TIR showed similar initial conditions across protection levels, RPE was significantly higher under MOPP 4, with a large effect. Because this assessment was performed after donning the protective ensemble, the finding indicates that full protection already alters perceived exertion before physical activity begins. The gas mask, perceived breathing restriction, increased mass and bulk of the equipment, sensory limitation, and the sensation of confinement are components capable of increasing the discomfort associated with PPE use [13], [14]. However, this result does not allow the response to be attributed exclusively to an anticipatory psychological mechanism, since physical, respiratory, and perceptual factors are simultaneously present. Thus, MOPP 4 appears to impose a less favorable perceptual starting condition even before engagement in the tasks.

The cardiovascular response was one of the most consistent manifestations of the strain produced by MOPP. The increase in heart rate was substantially greater under MOPP 2 and MOPP 4 than under MOPP 0, with a large effect size. During exercise, the cardiovascular system must simultaneously meet the metabolic demands of the active muscles and redistribute blood flow to the periphery to facilitate heat dissipation. As protective clothing increases insulation and restricts heat exchange, maintaining this balance becomes progressively more demanding [2], [15]. Sweating and the reduction in circulating volume may further increase cardiovascular demand, favoring a compensatory rise in heart rate [2], [7]. In this sense, the greater ΔHR observed under protection represents not only a statistical difference, but also a relevant increase in the cardiovascular cost required to perform equivalent physical tasks. This pattern is supported by studies showing that heated environments alter cardiovascular responses during prolonged exercise [16] and that skin temperature is related to heart rate during exercise and recovery [17].

TIR showed a different pattern from the other indicators. While MOPP 0 and MOPP 2 showed a mean reduction in forehead temperature after the physical phase, temperature remained approximately stable under MOPP 4, producing a significant difference among conditions but with a small effect size. This result should be interpreted with caution. Surface temperature responses may also vary according to exercise characteristics, as demonstrated in a protocol using different resistance-training volumes [18]. Skin surface temperature is influenced by cutaneous blood flow, sweat evaporation, and environmental conditions and does not directly correspond to core temperature or total body heat storage [8], [19]. Accordingly, the smaller reduction in TIR under MOPP 4 is compatible with an altered peripheral thermal response under greater protection, particularly because of the use of the gas mask over the facial region where the measurement was obtained, but it does not, by itself, allow inference of an equivalent increase in core temperature. The main advantage of this indicator in the present protocol was its rapid and noninvasive measurement, a relevant characteristic in operational settings, although its smaller effect magnitude indicates that it should be interpreted together with other physiological markers [3], [8].

Percentage body mass loss showed a progressive response across MOPP 0, MOPP 2, and MOPP 4, with a large effect size. This pattern is consistent with the increased thermoregulatory demand imposed by protective clothing. In the presence of increased metabolic heat production, sweating is an important heat-dissipation mechanism; however, its effectiveness depends on sweat evaporation rather than on sweat production alone [20]. The increased insulation and evaporative resistance provided by the layers of protective clothing reduce the efficiency of this exchange, such that greater sweat production may coexist with lower cooling efficiency [3]. Therefore, the progressive increase in relative body mass loss observed across MOPP levels complements the cardiovascular findings by showing that maintaining activity under higher levels of protection requires greater mobilization of the physiological mechanisms involved in thermoregulation.

The perceptual response partially followed the objective indicators. After the physical phase, absolute RPE values increased progressively from MOPP 0 to MOPP 2 and MOPP 4. However, when specifically considering the post-physical-task minus pre-exertion difference, MOPP 2 and MOPP 4 showed greater increases than MOPP 0, with no difference between them. This apparent divergence results from the fact that MOPP 4 already showed significantly elevated RPE before the tasks began. Therefore, the absence of a linear progression in ΔRPE does not indicate less discomfort under MOPP 4; rather, it demonstrates the importance of considering both the absolute value and the pre-exertion condition. Taken together, the results suggest that full protection imposes part of its perceptual burden before movement begins and maintains the highest absolute levels of perceived exertion after the activity.

From an operational perspective, these findings indicate that physically equivalent tasks do not impose the same cost on military personnel when performed under different MOPP levels. Large effects on heart rate and percentage body mass loss, together with increased perceived exertion, suggest a reduction in the physiological reserve available for continued activity as the level of protection increases. This finding is particularly relevant for prolonged missions or missions composed of successive tasks, in which accumulated strain may influence the ability to sustain subsequent efforts [2], [6], [7]. Thus, MOPP level should be incorporated into the planning of work and recovery cycles together with task intensity, duration, environmental conditions, hydration availability, and the need for personnel rotation [19]. However, the results of this study were not designed to establish new prescriptive work-rest values; rather, they demonstrate that the level of protection is a variable that should be considered when applying such protocols.

Environmental differences among collection days should also be considered when interpreting the results. Although temperature and humidity varied among sessions, each day included participants under all three MOPP conditions, distributed in a balanced manner, reducing the likelihood that a particular protection condition was systematically associated with the hottest or most humid day. Nevertheless, collection day was not included as a specific factor in the statistical analysis, and therefore the residual influence of environmental conditions on the observed responses cannot be completely excluded. In addition, the WBGT used represented a simplified estimate for comparative characterization of the

sessions because black-globe temperature was not measured. These characteristics warrant caution when extrapolating the observed values to thermal environments different from those encountered during the experiment.

Finally, several limitations define the scope of these findings. Although the sample of 26 participants exceeded the minimum number previously estimated for the study design, it consisted of physically fit military personnel familiar with PPE and assigned to a specialized CBRN unit, limiting direct generalization to untrained individuals, other military populations, or different operational conditions. TIR is a superficial and indirect measure and should not be interpreted as equivalent to core temperature [8]. In addition, post-physical-task heart rate corresponded to the mean obtained during the third and fourth minutes of measurement and therefore represents a standardized measure of early cardiovascular recovery rather than the peak immediately after exertion. These limitations do not invalidate the differences observed among MOPP levels, but they define the context in which the findings should be interpreted and reinforce the need to consider multiple indicators jointly when assessing thermophysiological strain.

V. Conclusion

The results demonstrate that the use of progressively higher MOPP levels during operational physical tasks produces relevant physiological and perceptual changes in military personnel. Compared with the MOPP 0 experimental reference condition, MOPP 2 and MOPP 4 produced greater increases in heart rate, with a large effect size, while percentage body mass loss increased progressively from MOPP 0 to MOPP 2 to MOPP 4, also with a large effect. Rating of perceived exertion showed a medium effect for the post-physical-task minus pre-exertion comparison, in addition to higher pre-exertion values under MOPP 4, indicating that full protection already imposes a perceptual burden before physical activity begins. Change in forehead infrared temperature also differed among protection levels, although with a smaller effect magnitude.

These findings show that increasing individual protection is associated with greater cardiovascular demand, greater relative body mass loss, and greater perceived exertion during the evaluated tasks. Therefore, MOPP level should be considered together with activity intensity and duration and environmental conditions when planning workload, recovery periods, and sustained personnel employment during CBRN operations. The results do not independently establish new work-rest limits, but they provide experimental evidence that progression through protective measures reduces the physiological reserve available for continued exertion.

Acknowledgment

The authors thank the 1st Chemical, Biological, Radiological, and Nuclear Defense Battalion for its operational support and for the voluntary participation of the military personnel who composed the experimental sample of this study. The authors also thank the Specialized Instruction School for the technical collaboration of its military personnel, who served as evaluators during the execution and monitoring of the experimental activities.

Abstract

Blood-component irradiation prevents transfusion-associated graft-versus-host disease by inhibiting the proliferation of viable donor lymphocytes. Independent dosimetric verification is required to confirm that the prescribed dose is delivered throughout the irradiated volume. This study reports an ongoing, preliminary characterization of an RS 3400 X-ray blood irradiator using 50 lithium-fluoride thermoluminescent dosimeters doped with magnesium and titanium. The experimental program included background evaluation, reader- and crystal-sensitivity sets, preliminary response measurements in a hemodynamic X-ray system, a dose-response experiment using cone-beam computed tomography, and nominal-setting measurements in the RS 3400 from 5 to 25 Gy. Background readings showed a mean of 2370.9 counts and a coefficient of variation (CV) of 3.24%. In the hemodynamic system, mean net response increased from 6132.4 to 21353.0 counts for reference values from 0.9789 to 3.0277 Gy, with $R^2 = 0.9949$. The cone-beam experiment produced a slope of 4186.2 counts/Gy from 2.298 to 22.813 Gy. For the RS 3400, mean net response increased from 19150.5 counts at 5 Gy to 119456.6 counts at 25 Gy, with $R^2 = 0.9984$. However, each nominal level used a different ten-detector group, and the detectors were not completely rotated among all phantom positions. Position-dependent CVs of 18.58–22.75% and relative responses of approximately 72–130% therefore combine detector, position, and possible dose-response effects. The results are reported as relative thermoluminescent response, not as absorbed-dose validation. Replicated irradiations at each level, a balanced detector-rotation design, individual sensitivity correction in a uniform field, and comparison with an independently calibrated reference dosimeter are required before the absorbed-dose distribution can be validated.

Index Terms—blood irradiation, dosimetry, quality assurance, thermoluminescent dosimeter, LiF:Mg,Ti, X-ray irradiator.

I. Introduction

Transfusion of cellular blood components is essential in several clinical settings. In susceptible recipients, however, viable donor T lymphocytes may engraft, proliferate, and attack host tissues, causing transfusion-associated graft-versus-host disease (TA-GVHD). Although uncommon, TA-GVHD is associated with high mortality and limited therapeutic response after clinical manifestation [1].

Irradiation of blood components reduces this risk by inducing irreparable damage to the genetic material of donor lymphocytes, thereby preventing cellular division while preserving the intended therapeutic function of the blood component [1]. The effectiveness of the procedure depends on delivery of an adequate dose throughout the irradiated volume. Insufficient doses may fail to inactivate lymphocytes, whereas excessive doses may impair blood-component quality.

Brazilian regulations establish 25 Gy at the midplane of the irradiated unit, with no point receiving less than 15 Gy or more than 50 Gy [4]. The current Brazilian radiation-safety standard also requires equipment control, dosimetry, and quality assurance for blood and blood-component irradiators [5]. Commissioning and routine quality assurance must therefore verify both dose magnitude and dose distribution.

Blood irradiation has traditionally been performed using self-shielded devices containing cesium-137 or cobalt-60. X-ray tube-based systems constitute an alternative that eliminates radioactive-source replacement, transportation, security, and end-of-life management requirements [6, 7]. However, the output and spatial distribution of kilovoltage irradiators depend on tube voltage, filtration, anode geometry, irradiation distance, sample attenuation, and container motion [8, 9]. Consequently, the absence of a radioactive source does not eliminate the need for independent dosimetric characterization.

The RS 3400 blood irradiator is a self-shielded X-ray device equipped with a cylindrical X-ray emitter and a rotating carousel and canister system intended to improve dose uniformity [10]. The unit installed at Hospital Araújo Jorge operates nominally at 155 kV and 11 mA and delivers a nominal central dose of approximately 25 Gy during a standard irradiation cycle.

Dose mapping is required to identify the minimum, maximum, and central doses within the irradiation container. Previous studies using ionization chambers, alanine, thermoluminescent dosimeters, radiochromic films, and blood-equivalent phantoms have demonstrated that sample geometry and attenuation can produce clinically relevant spatial variations [2, 3, 9, 11].

Radiation dosimetry is the quantitative determination of energy imparted by ionizing radiation to matter [12]. Quantities such as air kerma and absorbed dose have distinct definitions and should not be used interchangeably without an appropriate conversion formalism and clearly specified reference conditions [12, 13]. This distinction is especially important when

measurements from diagnostic-radiology instruments are used to establish a calibration in absorbed dose.

Thermoluminescent dosimeters (TLDs) are suitable for measurements in confined and nonuniform geometries because of their small dimensions, reusability, and ability to integrate dose [12, 14]. In LiF:Mg,Ti, ionizing radiation produces charge carriers that become trapped at metastable defects within the crystalline lattice. Controlled heating releases these carriers, producing a light signal related to the energy absorbed by the material [12].

The response of a thermoluminescent system may vary with individual detector sensitivity, dose, beam quality, thermal history, fading interval, reader stability, and heating profile [15]. LiF:Mg,Ti may also exhibit supralinear response in the high-dose region, requiring calibration over the actual dose interval of interest [16].

This study characterizes the response of a LiF:Mg,Ti system for application to the RS 3400. The current stage evaluates background stability, preliminary linearity, dose-response behavior, and position-dependent thermoluminescent response. The final objective is to validate the delivered absorbed dose and support a routine quality-assurance protocol. That validation remains in progress.

II. Materials and Methods

A. Dosimetric System and Irradiation Equipment

The dosimetric system comprised 50 individually identified LiF:Mg,Ti TLDs, a TLD Cube reader, a TLD Heat furnace, and the TL Studio and Thermosoft software packages. TL Studio was used to configure the reader, define the heating profile and integration region, manage calibration sets, acquire thermoluminescent signals, and export results. Thermosoft controlled the furnace temperature profiles.

Measurements associated with the blood irradiator were performed using an RS 3400 installed in the Blood Bank of Hospital Araújo Jorge. The dosimeters were positioned in a cylindrical solid-water phantom using a dedicated polylactic-acid holder containing ten locations, labeled *a* to *j*. The arrangement sampled central, intermediate, and peripheral regions of the phantom (Fig. 1).

Preliminary response measurements were performed using a Philips Azurion hemodynamic X-ray system installed at Hospital das Clínicas of the Federal University of Goiás. Exposure conditions were independently evaluated using an RTI Piranha multipurpose X-ray quality-assurance meter.

A second dose-response experiment was performed using the cone-beam computed-tomography system coupled to a Varian TrueBeam linear accelerator at Cebrom. All irradiation and measurement systems were included in institutional quality-assurance programs during data acquisition.

B. Thermal Treatment and Readout

Before each irradiation, the dosimeters were annealed in the TLD Heat furnace at $400\,^{\circ}\mathrm{C}$ for 1 h, followed by 2 h at $100\,^{\circ}\mathrm{C}$. The dosimeters were then cooled and stored in a light-protected container until irradiation.

After irradiation, a pre-readout treatment was performed at $100\,^{\circ}\mathrm{C}$ for 15 min. This step reduces the contribution of unstable low-temperature trapping states and the initial fading component. The dosimeters were subsequently read in the TLD Cube using a fixed heating profile (Fig. 2).

The calibration region of the glow curve was selected to exclude unstable fading peaks, following the TLD Cube calibration procedure recommended by the manufacturer [17]. After initiation of the calibration workflow, the heating profile, reader gain, and integration region were maintained unchanged. Detector identification, processing order, heating conditions, and the approximate interval between irradiation and readout were preserved throughout the experiments.

The net response of dosimeter i was calculated as

$$C_{\mathrm{net},i} = C_{\mathrm{raw},i} - C_{0,i}, \tag{1}$$

where $C_{\mathrm{raw},i}$ is the irradiated reading and $C_{0,i}$ is the individual background reading obtained in the zero-count set.

C. Preliminary Response Measurements

Three groups of ten TLDs were exposed in the hemodynamic system to reference values of 0.9789 ± 0.0489, 1.5015 ± 0.0751, and 3.0277 ± 0.1514 Gy. The dosimeters were positioned under reproducible geometric conditions. Tube voltage, tube loading, number of exposures, field size, filtration, and measurement distance were recorded. The Piranha system was placed at the reference measurement location to verify exposure conditions.

The quantity reported by the Piranha must be confirmed as air kerma, absorbed dose, or another application-specific quantity before this experiment can be interpreted as an absorbed-dose calibration. The present analysis therefore treats the Piranha measurements as reference values for a preliminary response evaluation, following the formalism recommended for diagnostic X-ray systems [13, 18].

An exploratory experiment was also performed at Cebrom using tube voltages from 40 to 120 kV. Because tube voltage, tube loading, dose, and beam quality changed simultaneously, those measurements were not used to establish an independent dose-response curve.

A second Cebrom experiment used a fixed nominal condition of 140 kV, 100 mA, and 65 ms. Repeated cone-beam CT acquisitions generated accumulated reference values from 2.298 to 22.813 Gy. Different dosimeters represented the dose levels; thus, dose dependence and detector-to-detector sensitivity were not separated. A common exposure of six dosimeters was also performed to evaluate short-term consistency under an identical acquisition condition.

D. RS 3400 Calibration Sets

The TL Studio workflow comprised four sets: zero counts, device sensitivity, crystal sensitivity, and system/dose calibration, following the manufacturer instructions [17].

The zero-count set was obtained after annealing all 50 non-irradiated TLDs. The device-sensitivity set was acquired after a nominal 25 Gy irradiation cycle in the RS 3400. The crystal-sensitivity set was obtained after exposing the TLDs to nominally equivalent irradiation conditions. The individual response was compared with the group mean to estimate an element correction factor:

$$\mathrm{ECF}_i = \frac{\overline{C}_{\mathrm{net}}}{C_{\mathrm{net},i}}, \tag{2}$$

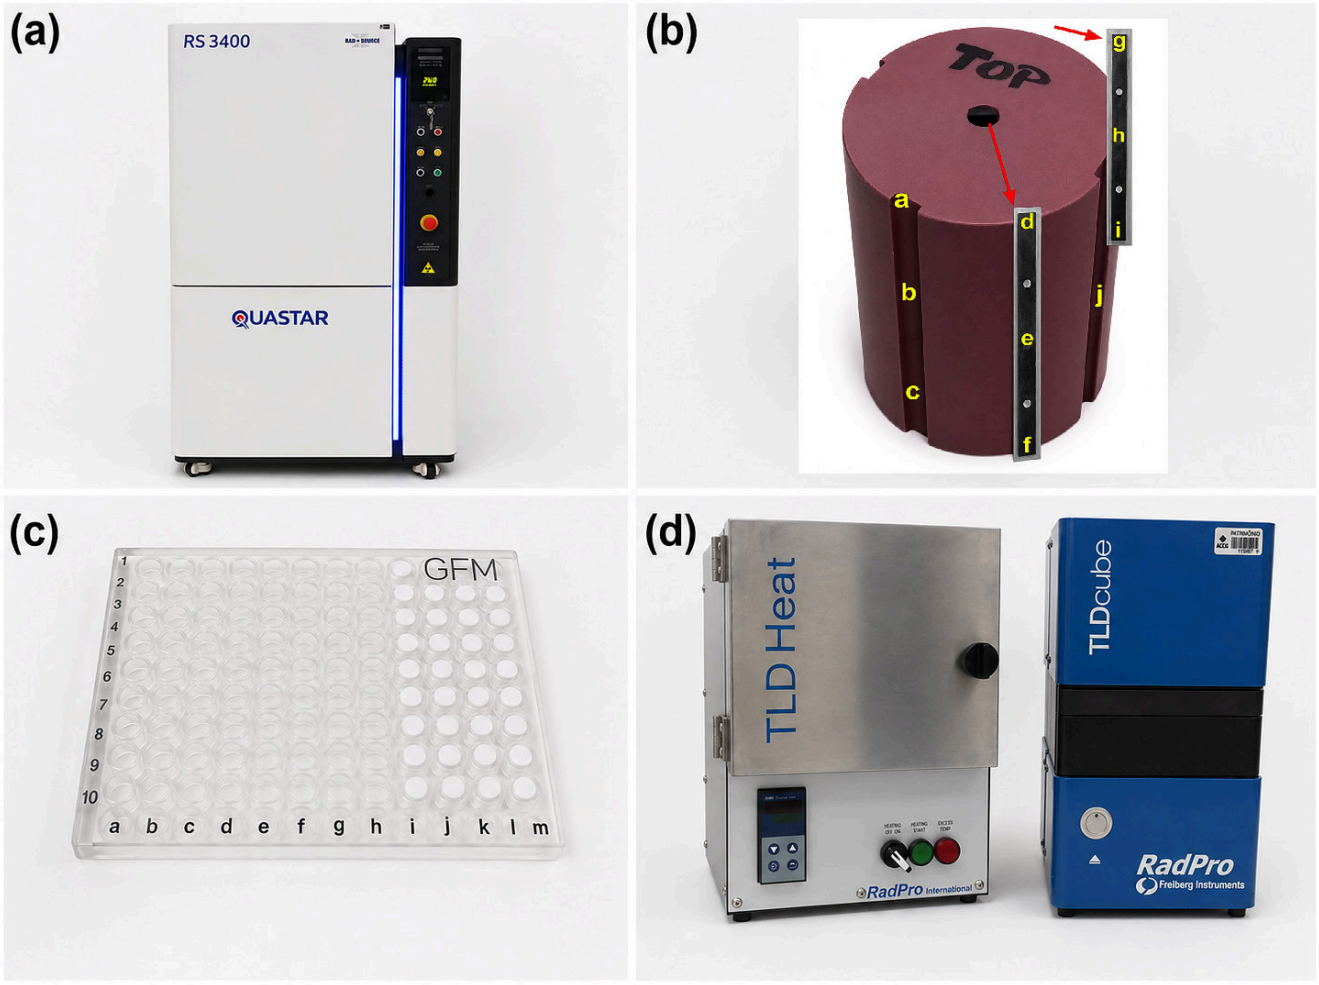

Figure 1. Experimental system used in the study: (a) RS 3400 blood irradiator; (b) cylindrical phantom and dosimeter positions; (c) LiF:Mg,Ti dosimeters; and (d) thermal-treatment and readout equipment.

and the corrected response would be

$$C_{\mathrm{corr},i} = \mathrm{ECF}_i C_{\mathrm{net},i}. \tag{3}$$

Because the TLDs occupied different phantom positions during these sets, the calculated factors may contain both individual-sensitivity and spatial-irradiation components. They were therefore not treated as definitive element correction factors in the present analysis.

For system/dose calibration, the 50 TLDs were distributed into five groups of ten. The groups were irradiated with programmed nominal settings of 5, 10, 15, 20, and 25 Gy by varying irradiation time according to the nominal delivery rate of the RS 3400. Each group occupied the same ten phantom positions. This first-pass design did not rotate each detector through all ten positions and did not include independent replicate irradiation cycles at each nominal level. Consequently, detector, position, and dose-level effects cannot be estimated separately from these data.

For dose level j, mean apparent sensitivity was calculated as

$$S_j = \frac{\overline{C}_{\mathrm{net},j}}{D_j}, \tag{4}$$

where D_j is the programmed nominal setting. A linear model was fitted according to

$$C_{\mathrm{net}} = aD + b. \tag{5}$$

To compare phantom positions across dose groups, each response was normalized to the mean of its respective group:

$$R_{i,j} = \frac{C_{\mathrm{net},i,j}}{\overline{C}_{\mathrm{net},j}} \times 100\%. \tag{6}$$

The resulting quantity was interpreted as relative thermoluminescent response, not as relative absorbed dose.

E. Beam Quality and Final Validation Strategy

A complete characterization of an X-ray field includes tube potential, filtration, half-value layer, homogeneity coefficient, output, spatial uniformity, and measurement uncertainty [13, 18, 19]. The beam-quality stage of the RS 3400 characterization remains in progress.

The final validation protocol will include first and second half-value layers, the homogeneity coefficient, replicated dose-response measurements at every nominal level, individual sen-

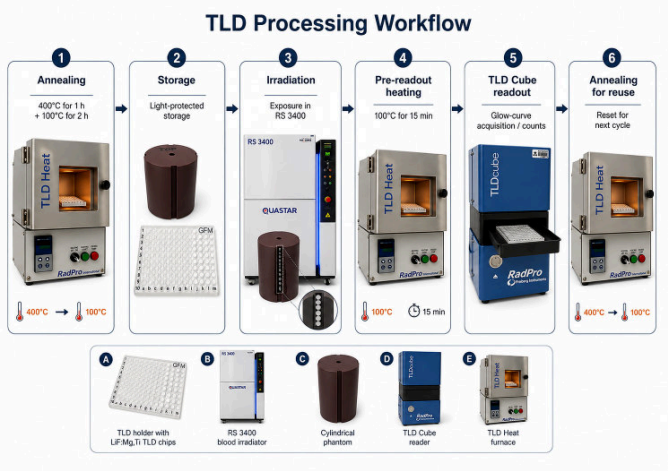

Figure 2. Thermal processing and readout workflow applied to the LiF:Mg,Ti dosimeters.

sitivity correction in a uniform field, and a balanced complete-block rotation in which detectors occupy all phantom positions across repeated cycles. A fixed-dose control group will monitor between-session stability. An independently calibrated reference dosimeter will be used to establish traceability and to compare the central reference value with the TLD-derived result. Only after these steps will corrected responses be converted into absorbed dose and used to determine central, minimum, and maximum values.

F. Statistical Analysis and Scope

For each experimental condition, the mean, sample standard deviation, CV, minimum, and maximum were calculated. Least-squares regression and the coefficient of determination, R^2, were used to evaluate dose-response behavior. Potential outliers were investigated at a significance level of 5% and were not excluded solely by visual inspection. When a potentially discrepant reading was identified, the analysis was performed with and without that result to evaluate its influence.

Because no complete rotation, replicated cycle at each RS 3400 setting, or independent absorbed-dose reference was available, the primary outcome of the present analysis is detector response in counts. No claim of regulatory conformity, dose-uniformity ratio, or validated absorbed-dose distribution is made from this preliminary dataset.

III. Results and Discussion

A. Background and Initial Calibration Sets

The zero-count set presented a mean of 2370.9 counts, an SD of 76.7 counts, and a CV of 3.24%, with values ranging from 2261 to 2511 counts (Table 1). The limited dispersion indicates satisfactory overall background stability; however, a systematic decrease was observed along detector identification and readout sequence. Since identification approximately followed acquisition order, this behavior may reflect reader stabilization, temporal photomultiplier variation, thermal-history effects, or another order-dependent component. Individual background subtraction was therefore preferred to correction by a single batch mean.

The device-sensitivity set presented a mean of 130045.5 counts and a CV of 19.14%. Crystal-sensitivity readings averaged 123166.1 counts, with a CV of 24.73%. One crystal-sensitivity result, 251944 counts for TLD 41, was markedly greater than the remaining readings. Omitting this value only for sensitivity analysis reduced the mean to 120538.0 counts and the CV to 20.23%. The result was not definitively excluded because it has not been repeated under an independently uniform radiation field.

Table 1. Summary of the Initial RS 3400 Calibration Sets

Set	Mean	SD	CV (%)	Range
Zero counts	2370.9	76.7	3.24	2261–2511
Device sensitivity	130045.5	24894.5	19.14	78634–173824
Crystal sensitivity	123166.1	30459.7	24.73	75581–251944
Crystal, TLD 41 omitted	120538.0	24384.0	20.23	75581–165274

Table 2. TLD Response in the Hemodynamic X-Ray System

Reference (Gy)	Mean net counts	SD counts	CV (%)	Sensitivity (counts/Gy)
0.9789	6132.4	231.0	3.77	6264.6
1.5015	8977.0	587.2	6.54	5978.8
3.0277	21353.0	883.4	4.14	7052.6

Excluding the provisional TLD 41 result, the correlation between device- and crystal-sensitivity readings was $r = 0.915$. The response pattern was not purely random; however, the dosimeters occupied different phantom positions during both sets. The correlation therefore includes both intrinsic detector sensitivity and spatial variation. Element correction factors should be determined under uniform and reproducible irradiation conditions [12, 15, 17].

B. Hemodynamic-System Response

Table 2 presents net responses obtained using the hemodynamic system. Within-group CV values ranged from 3.77% to 6.54%, indicating satisfactory repeatability under each condition.

The regression of the three mean responses was

$$C_{\text{net}} = 7582.3D - 1767.0, \tag{7}$$

with $R^2 = 0.9949$. When all 30 individual measurements were included, R^2 remained approximately 0.987. Apparent sensitivity varied from 5978.8 to 7052.6 counts/Gy. Since different dosimeters were used at each reference level and the precise Piranha quantity remains to be documented, these results confirm a consistent response at doses on the order of gray but do not establish a traceable counts-to-absorbed-dose conversion.

C. Cone-Beam Dose-Response Experiment

In the first Cebrom experiment, tube potential, tube loading, reference value, and beam quality changed simultaneously. Although net counts increased with the recorded value, the experiment could not distinguish dose dependence from energy dependence and was therefore treated as exploratory.

Under the fixed nominal condition of 140 kV, 100 mA, and 65 ms, net response ranged from 5509 to 90786 counts for reference values from 2.298 to 22.813 Gy. The linear fit was

$$C_{\text{net}} = 4186.2D - 3943.2, \tag{8}$$

with $R^2 = 0.9996$. The fitted slope differed by approximately 1.8% from the mean manufacturer-derived sensitivity of 4113.4 counts/Gy and was nearly equal to the slope of 4186.1 counts/Gy

Table 3. RS 3400 Response as a Function of Programmed Nominal Setting

Nominal setting (Gy)	Mean net counts	SD counts	CV (%)	Apparent sensitivity
5	19150.5	3591.8	18.76	3830.1
10	42224.1	8958.7	21.22	4222.4
15	65478.8	13437.7	20.52	4365.3
20	92720.1	17225.6	18.58	4636.0
25	119456.6	27178.3	22.75	4778.3

obtained by fitting the manufacturer data through the origin. This agreement supports the order of magnitude of the measured response.

The negative intercept has no direct physical interpretation at zero dose. Apparent sensitivity increased from 2397.3 counts/Gy at 2.298 Gy to approximately 3998.4 counts/Gy at 14.596 Gy and remained close to 3980 counts/Gy at 22.813 Gy. A high R^2 does not demonstrate strict proportionality; the trend may reflect background influence at the lowest levels, detector-to-detector sensitivity, uncertainty in the reference quantity, or supralinearity of LiF:Mg,Ti [12, 15, 16].

A common exposure of six TLDs yielded a mean recorded value of 2.381 Gy with a CV of 0.99% and mean raw counts of 8296.3 with a CV of 1.20%. These results indicate good short-term consistency under a fixed acquisition condition. However, mean net sensitivity was approximately 2436 counts/Gy, lower than the complete-curve slope. An interrupted initial acquisition also produced a different exposure history for TLDs 8 and 9. The curve must therefore be repeated using several TLDs per level and an identical acquisition sequence.

D. RS 3400 Response as a Function of Nominal Setting

Table 3 summarizes the first-pass system/dose calibration after individual background subtraction. Mean net response increased from 19150.5 counts at 5 Gy to 119456.6 counts at 25 Gy. The linear fit shown in Fig. 3 was

$$C_{\mathrm{net}} = 5022.2D - 7526.4, \tag{9}$$

with $R^2 = 0.9984$. A quadratic model increased R^2 to approximately 0.9998, indicating slight upward curvature. However, only five nominal levels were available, and each was represented by a different ten-detector group occupying the ten phantom positions. The present data cannot distinguish supralinearity from detector and position effects.

Mean apparent sensitivity across the five levels was 4366.4 counts/Gy, approximately 6.1% greater than the mean manufacturer-derived value, and increased by 24.8% between 5 and 25 Gy. This 24.8% change cannot be attributed to supralinearity because detector assignment and position changed with dose level. It is therefore described only as a change in apparent sensitivity in this preliminary design.

Mean background represented approximately 11.5% of raw response at 5 Gy and 1.9% at 25 Gy, demonstrating that individualized background correction is particularly relevant at the lower end of the investigated interval.

The programmed levels were derived from RS 3400 irradiation time and were not independently established using a traceable absorbed-dose standard. The fitted curve characterizes thermoluminescent response as a function of programmed nominal setting; it is not an absolute absorbed-dose calibration.

Table 4. Mean Relative Response at the Phantom Positions

Position	Mean (%)	SD (%)	Position	Mean (%)	SD (%)
a	86.1	12.5	f	73.4	4.0
b	119.3	6.9	g	102.9	4.9
c	95.4	4.4	h	129.6	4.7
d	71.7	3.4	i	97.9	4.0
e	101.5	2.1	j	122.2	4.3

E. Position Dependence of the Response

Within-level CV values from 18.58% to 22.75% were substantially greater than the dispersion observed within the hemodynamic groups. Normalization by the mean of each nominal group revealed a recurring position-dependent response pattern (Table 4 and Fig. 4).

Positions *d* and *f* presented the lowest relative responses, 71.7% and 73.4%, respectively. Positions *h*, *j*, and *b* presented the highest responses, 129.6%, 122.2%, and 119.3%. The central position *e* presented 101.5%, close to the group mean. The difference between the lowest and highest position means was approximately 58 percentage points.

Position-specific regressions produced R^2 values from 0.981 to 0.998, while their slopes varied by more than a factor of two. Within the five nominal-setting groups, the normalized means of paired positions *d*/*f* and *c*/*i* differed by 1.7 and 2.5 percentage points, whereas *b*/*h* and *a*/*g* differed by 10.3 and 16.8 percentage points. In the pooled 25 Gy device/crystal sets, relative pair differences for *b*/*h*, *d*/*f*, *a*/*g*, and *c*/*i* were approximately 0.2%, 3.8%, 5.3%, and 6.0%, respectively. Thus, geometric symmetry was only partial and cannot by itself establish irradiator uniformity.

The recurring pattern is compatible with a contribution from irradiation geometry, target orientation, attenuation, and the anode heel effect [8]. Dose distribution also depends on sample composition, container geometry, irradiation motion, and attenuation within the load [3, 9, 11]. Rotation and opposing irradiation directions can reduce, but do not necessarily eliminate, differences between minimum and maximum dose.

Nevertheless, the present result is a spatial variation of thermoluminescent response, not a definitive absorbed-dose map. The same detectors were not systematically rotated through all positions, and the individual correction factors were not determined in an independently uniform field. The observed response combines local dose, individual sensitivity, thermal processing, readout variability, and possible energy dependence. Attribution of the complete variation to irradiator nonuniformity is not justified at this stage.

F. Comparison with Previous Studies

Grasso *et al.* characterized an X-ray blood irradiator using ionization chamber, alanine, and TLD-100 dosimetry and reported a small TLD dose overestimation together with a dose-uniformity ratio consistent with the manufacturer specification [3]. Their use of multiple dosimetric systems illustrates the importance of independent cross-validation.

Lopes *et al.* described physical measurements required for routine quality control of blood irradiation, including absorbed-dose verification, radiation surveys, and documentation of equipment performance [2]. Fazad *et al.* used Gafchromic EBT-XD film and a blood-equivalent phantom to map central, minimum,

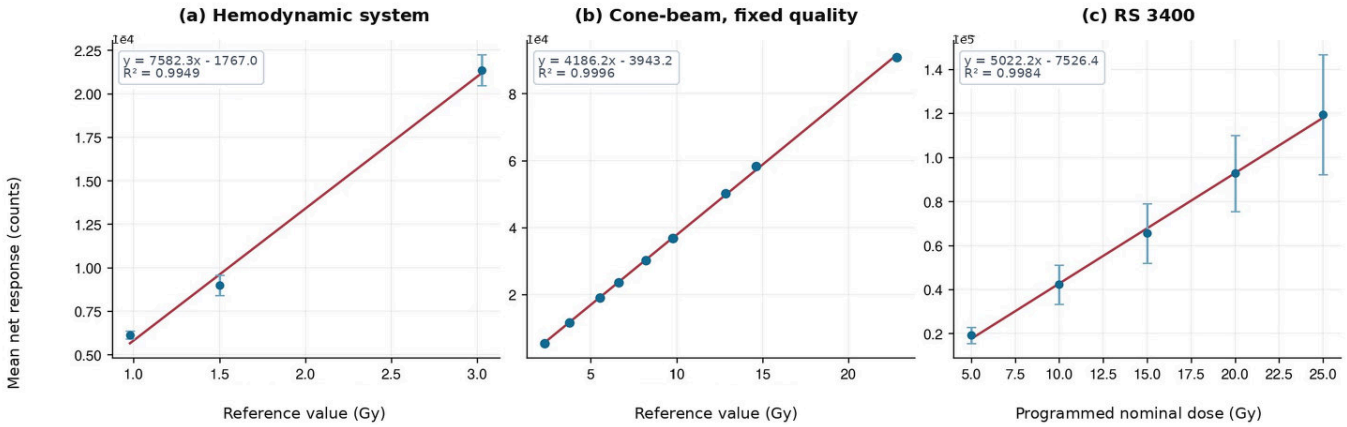

Figure 3. Dose-response results obtained in (a) the hemodynamic X-ray system, (b) the Cebrom cone-beam system under fixed nominal quality, and (c) the RS 3400. Axes, regression notation, decimal format, and equation placement were standardized. Error bars represent one SD where replicate measurements were available. The abscissas in (a) and (b) are reported as reference values because the associated quantity has not yet been confirmed as absorbed dose.

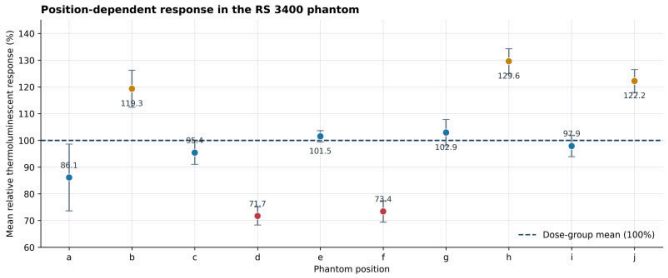

Figure 4. Mean thermoluminescent response at the ten phantom positions, normalized to the mean response of each nominal-setting group. Error bars represent the SD among the five groups. These values combine detector and position effects and must not be interpreted as a definitive absorbed-dose map.

and maximum doses in a cesium-137 irradiator [11]. Gómez-Simuta *et al.* demonstrated that dose mapping can identify reproducible minimum- and maximum-dose regions in an X-ray blood irradiator and emphasized routine dosimetry at a defined reference location [9]. Wagner *et al.* likewise showed that a cylindrical-anode Rad Source irradiator presents position-dependent output and requires experimental characterization of beam quality and dose rate [8].

These studies support the overall methodology but demonstrate that a high R^2 in a dose-response curve is insufficient for validation. Traceability, energy dependence, individual sensitivity, spatial mapping, reproducibility, and uncertainty must be considered jointly.

G. Limitations and Ongoing Work

This study reports an intermediate stage of dosimetric characterization. Its principal limitation is the absence of a complete independent and traceable calibration over the operating range of the RS 3400.

In the Cebrom experiment, each dose level was represented by one TLD, making detector-to-detector sensitivity inseparable from dose dependence. In the RS 3400 experiment, each programmed setting was represented by a different detector group, without independent replicate cycles at each level. The device- and crystal-sensitivity sets were obtained with TLDs distributed among positions that presented substantial response differences. The resulting correction factors may therefore contain both individual detector sensitivity and spatial irradiation effects.

Session-to-session normalization was not performed using a fixed-dose control group in every experiment. Changes in reader gain, thermal processing, fading interval, or irradiation output may contribute to comparisons among measurements performed on different dates and equipment. The precise reference quantities supplied by the Piranha and cone-beam systems must also be documented; air kerma, absorbed dose, and CT-related quantities are not equivalent and may only be converted under defined reference conditions [12, 13].

Beam-quality measurements, including first and second half-value layers and the homogeneity coefficient, have not yet been completed. The analysis also lacks a complete measurement-uncertainty budget. Future work will include contributions from the reference instrument, irradiation reproducibility, reader stability, annealing and pre-readout treatments, positioning, fading, background correction, individual sensitivity, regression coefficients, and beam-quality dependence.

The anomalous reading of 251944 counts for TLD 41 must be repeated before definitive exclusion. A statistical outlier test should be accompanied by investigation of experimental causes, including detector identification, positioning, incomplete annealing, and reader malfunction.

The next experimental stage will use several TLDs and independent irradiation cycles at every nominal setting, with a fixed-dose control group in each session. A balanced rotation will move the same detectors through all ten phantom positions, allowing detector and position effects to be estimated separately. Element correction factors will be established in a uniform reference field. Standard RS 3400 cycles will then be repeated and compared with an independently calibrated, traceable reference dosimeter. Only after completion of these stages will central, minimum, and maximum absorbed doses be compared with the regulatory interval and manufacturer uniformity specification.

IV. Conclusion

The LiF:Mg,Ti system exhibited stable overall background and an increasing response with exposure in three X-ray systems. Hemodynamic-system measurements showed satisfactory within-condition repeatability, and the fixed-quality cone-beam

experiment produced a dose-response slope consistent with the order of magnitude of manufacturer-derived reference data.

In the RS 3400, mean thermoluminescent response was strongly associated with the programmed nominal setting from 5 to 25 Gy. However, apparent sensitivity increased with setting, and each level presented substantial spatial dispersion. A recurring position-dependent pattern was observed, with relative responses from approximately 72% to 130% of the group mean, but geometric symmetry was only partial.

Because dose level, detector group, and position were not independently resolved, this variation cannot be assigned exclusively to irradiator nonuniformity or to LiF:Mg,Ti supralinearity. The results support the feasibility of thermoluminescent dosimetry for characterization and quality assurance of the RS 3400, but they do not constitute absorbed-dose validation or demonstrate regulatory conformity.

Definitive conclusions regarding dose accuracy, distribution, uniformity, and reproducibility require replicated measurements at each level, individual sensitivity correction, complete detector rotation, beam-quality characterization, uncertainty analysis, and independent reference dosimetry.

Acknowledgment

The authors thank the Blood Bank and Radiation Therapy Department of Hospital Araújo Jorge, Hospital das Clínicas of the Federal University of Goiás, and Cebrom for providing access to the irradiation and dosimetric systems used in this study.

***Resumo*—A transformação digital tem promovido mudanças estruturais nos sistemas de saúde contemporâneos, especialmente na organização do acesso assistencial. No Sistema Único de Saúde (SUS), a regulação assistencial constitui instrumento estratégico para garantir equidade, integralidade e eficiência na distribuição de recursos públicos. Este estudo analisa os impactos da saúde digital na regulação assistencial brasileira, considerando a Estratégia de Saúde Digital para o Brasil 2020–2028, a Rede Nacional de Dados em Saúde (RNDS) e experiências práticas como o ecossistema RegulaRN. Trata-se de estudo qualitativo, exploratório e descritivo, desenvolvido por revisão narrativa da literatura científica e documental. Os resultados demonstram que a adoção de interoperabilidade clínica, monitoramento em tempo real, algoritmos de priorização e integração de sistemas contribui para reduzir assimetrias informacionais, qualificar decisões regulatórias e ampliar a transparência institucional. Persistem, entretanto, desafios relacionados à infraestrutura digital, capacitação profissional, proteção de dados e desigualdades regionais. Conclui-se que a saúde digital representa elemento estruturante para modernização da regulação assistencial do SUS, com relevante interface com a Engenharia Biomédica.**

***Palavras-chave*—Saúde Digital, SUS, Regulação Assistencial, Interoperabilidade, Engenharia Biomédica, RNDS.**

I. Introdução

O Sistema Único de Saúde (SUS) configura uma das maiores redes públicas universais de saúde do mundo, sendo responsável pela assistência de milhões de brasileiros em diferentes níveis de complexidade [1]. Sua magnitude organizacional exige instrumentos capazes de ordenar fluxos, priorizar demandas e otimizar o uso de recursos assistenciais. Nesse contexto, a regulação assistencial tornou-se componente essencial da governança sanitária, sendo formalmente fortalecida pela Política Nacional de Regulação, instituída pela Portaria nº 1.559/2008 [3]. Tal política busca organizar o acesso a consultas especializadas, exames, internações e leitos críticos, promovendo maior racionalidade distributiva. Historicamente, entretanto, os processos regulatórios brasileiros enfrentaram limitações relacionadas à fragmentação dos sistemas de informação, filas descentralizadas, baixa integração entre níveis assistenciais e dependência de processos administrativos manuais [4]. Essas barreiras impactam diretamente a eficiência operacional e a justiça no acesso.

A saúde digital emerge como eixo estratégico de superação dessas limitações, ao incorporar tecnologias da informação, telessaúde, interoperabilidade clínica, análise de dados e apoio computacional à decisão [5], [6]. No campo regulatório, tais soluções ampliam a rastreabilidade, transparência e capacidade preditiva.

Além disso, a Engenharia Biomédica possui papel central nesse processo, ao integrar conhecimentos de tecnologia, gestão e sistemas clínicos aplicados à saúde pública. Diante disso, este artigo objetiva analisar o impacto da saúde digital na regulação assistencial do Sistema Único de Saúde (SUS), enfatizando aspectos relacionados à arquitetura tecnológica, à interoperabilidade e à gestão estratégica. Como contribuição, o estudo busca sistematizar e discutir os principais elementos tecnológicos e organizacionais que permeiam a transformação digital da regulação assistencial, evidenciando os avanços,

desafios e perspectivas para a construção de sistemas mais integrados, eficientes e orientados às necessidades dos usuários. Dessa forma, pretende-se contribuir para o debate sobre a aplicação estratégica das tecnologias digitais no SUS e para o fortalecimento de processos regulatórios mais qualificados, interoperáveis e equitativos.

II. Metodologia

Trata-se de um estudo qualitativo, descritivo e exploratório, desenvolvido por meio de revisão narrativa da literatura científica e documental. Optou-se pela revisão narrativa por possibilitar uma análise ampla e integrativa da produção científica acerca da saúde digital aplicada à regulação assistencial do SUS, permitindo reunir evidências provenientes de diferentes tipos de estudos, documentos técnicos e normativos.

A busca bibliográfica foi realizada entre março e abril de 2026 nas bases PubMed, Scopus, SciELO e Google Scholar, complementada pela consulta a documentos oficiais do Ministério da Saúde, da Estratégia de Saúde Digital para o Brasil 2020–2028 e da Rede Nacional de Dados em Saúde (RNDS). Os descritores foram combinados por operadores booleanos (AND e OR), utilizando termos em português e inglês relacionados à saúde digital, interoperabilidade, regulação assistencial, RNDS e HL7 FHIR.

Após a leitura dos estudos selecionados por meio dos critérios exibidos na tabela I, realizou-se análise qualitativa do conteúdo, agrupando as evidências conforme similaridade temática. Os achados foram organizados em três eixos analíticos: (i) arquitetura digital e interoperabilidade; (ii) impactos operacionais na regulação assistencial; e (iii) desafios, bioética e perspectivas futuras. Por fim, como complemento à revisão bibliográfica, foi incorporado um estudo de caso descritivo do ecossistema RegulaRN, escolhido por representar uma experiência consolidada de aplicação da saúde digital na regulação assistencial do SUS.

Tabela I
Critérios de inclusão e exclusão utilizados na seleção dos estudos

Critérios de inclusão	**Critérios de exclusão**
Estudos publicados entre 2020 e 2026	Trabalhos duplicados
Artigos completos	resumos sem texto completo disponível
Estudos em português, inglês e espanhol	Estudos sem relação com a regulação assistencial
Saúde digital aplicada ao SUS	publicações opinativas sem base técnica
Documentos normativos oficiais	trabalhos anteriores a 2020 sem relevância histórica central

III. Saúde Digital e Regulação Assistencial

A. Transformação digital no sistema único de saúde

A transformação digital tem promovido mudanças significativas na organização dos sistemas de saúde, possibilitando maior integração entre serviços, otimização dos processos assistenciais e qualificação da tomada de decisão. No Sistema Único de Saúde (SUS), esse processo representa importante estratégia para enfrentar desafios históricos relacionados à fragmentação das informações, à baixa integração entre os níveis de atenção e à elevada demanda por serviços especializados [2], [5], [6].

Nesse contexto, a incorporação de tecnologias digitais favorece a construção de um modelo assistencial baseado no compartilhamento de informações, no monitoramento em tempo real e no uso de dados para subsidiar decisões clínicas e gerenciais. Além de ampliar a eficiência operacional, essas ferramentas contribuem para maior transparência, rastreabilidade dos processos regulatórios e utilização mais racional dos recursos públicos [4], [6].

B. Estratégia de Saúde Digital para o Brasil

A Estratégia de Saúde Digital para o Brasil 2020–2028 estabelece diretrizes nacionais voltadas à transformação digital do setor saúde, promovendo ações relacionadas à integração dos sistemas de informação, fortalecimento da governança digital, ampliação da conectividade e desenvolvimento de serviços centrados no cidadão [2].

No âmbito da regulação assistencial, essa estratégia possibilita que as decisões regulatórias sejam fundamentadas em informações clínicas atualizadas, completas e interoperáveis. Dessa forma, torna-se possível reduzir assimetrias informacionais entre os diferentes pontos da Rede de Atenção à Saúde, minimizar retrabalhos administrativos e aprimorar os mecanismos de priorização do acesso aos serviços especializados [2], [6]. Além disso, o uso de indicadores assistenciais em tempo real favorece o monitoramento da oferta de serviços, permitindo aos gestores identificar gargalos assistenciais, redistribuir recursos e aperfeiçoar continuamente os fluxos regulatórios [6].

C. Rede Nacional de Dados em Saúde (RNDS)

A Rede Nacional de Dados em Saúde (RNDS) constitui a principal infraestrutura nacional para o compartilhamento seguro e padronizado de informações clínicas entre estabelecimentos públicos e privados de saúde [2], [5]. Sua implementação possibilita a interoperabilidade entre diferentes sistemas por meio da adoção de padrões tecnológicos e semânticos, permitindo que dados produzidos em unidades básicas de saúde, hospitais, laboratórios e serviços especializados sejam compartilhados de maneira segura e tempestiva [5], [7], [13].

Essa integração favorece a continuidade do cuidado, reduz a duplicidade de exames, melhora a qualidade das informações disponíveis aos profissionais de saúde e fortalece a capacidade das centrais reguladoras em realizar encaminhamentos baseados em evidências clínicas [5], [7]. Sob a perspectiva da regulação assistencial, a disponibilidade de informações clínicas consolidadas reduz incertezas durante o processo de classificação de pacientes, favorecendo maior equidade na distribuição de consultas, exames e leitos hospitalares [4], [7].

D. Interface com a Engenharia Biomédica

A implementação das tecnologias de saúde digital demanda conhecimentos multidisciplinares relacionados à arquitetura de sistemas, interoperabilidade, integração de dispositivos médicos, segurança cibernética, análise de dados clínicos e desenvolvimento de soluções computacionais para apoio à decisão [5], [7], [13]. Nesse cenário, a Engenharia Biomédica desempenha papel estratégico ao integrar competências tecnológicas e assistenciais voltadas ao desenvolvimento de ecossistemas digitais capazes de melhorar a eficiência da gestão em saúde. O desenvolvimento de arquiteturas interoperáveis, a validação de softwares médicos, a integração entre equipamentos biomédicos e sistemas hospitalares e a aplicação de inteligência artificial representam áreas diretamente relacionadas à modernização da regulação assistencial do SUS [7], [13], [14].

IV. Arquitetura Tecnológica e Interoperabilidade

A consolidação da Saúde Digital no Sistema Único de Saúde (SUS) depende da implementação de arquiteturas tecnológicas capazes de integrar os diferentes níveis da Rede de Atenção à Saúde, promovendo o compartilhamento seguro e oportuno das informações clínicas. A coordenação eficiente dos fluxos assistenciais exige que unidades básicas de saúde, hospitais, laboratórios, serviços especializados e centrais reguladoras atuem de forma integrada, favorecendo a continuidade do cuidado e a qualificação dos processos regulatórios [15].

Nesse contexto, a modernização da regulação assistencial requer arquiteturas escaláveis, seguras e adaptáveis às diferentes realidades regionais. Estudos recentes propõem modelos multicamadas fundamentados na integração de sistemas heterogêneos por meio de interfaces de programação de aplicações (APIs), microsserviços e padrões internacionais de interoperabilidade, possibilitando maior flexibilidade, disponibilidade e compartilhamento de informações entre diferentes plataformas de saúde [7].

Entre os principais padrões tecnológicos utilizados destaca-se o Health Level Seven Fast Healthcare Interoperability Resources (HL7 FHIR), reconhecido internacionalmente por sua arquitetura baseada em recursos (resources) e APIs RESTful. Essa abordagem permite que diferentes sistemas de informação em saúde troquem dados clínicos de forma padronizada, reduzindo barreiras técnicas e facilitando a integração entre prontuários eletrônicos, sistemas laboratoriais, plataformas de telemedicina e infraestruturas nacionais como a Rede Nacional de Dados em Saúde (RNDS) [13].

Além da interoperabilidade técnica, a qualidade do intercâmbio de informações depende da interoperabilidade semântica, responsável por assegurar que os dados compartilhados possuam o mesmo significado clínico independentemente do sistema utilizado. Para isso, empregam-se terminologias e classificações padronizadas, como SNOMED CT, LOINC, Classificação Internacional de Doenças (CID) e Classificação Internacional de Atenção Primária (CIAP), que favorecem a padronização dos registros clínicos, reduzem ambiguidades e ampliam a consistência das informações utilizadas na assistência e na gestão em saúde [12].

Nesse sentido da regulação assistencial, a integração entre arquiteturas interoperáveis e terminologias padronizadas possibilita maior rastreabilidade dos processos, atualização em tempo real das informações assistenciais e suporte mais qualificado à tomada de decisão pelos gestores. Dessa forma, torna-se possível reduzir retrabalhos, minimizar inconsistências cadastrais, otimizar a ocupação de leitos e aprimorar os mecanismos de priorização clínica, contribuindo para uma gestão mais eficiente, transparente e equitativa dos recursos disponíveis [7], [13].

O desenvolvimento dessas arquiteturas representa um campo estratégico de atuação, envolvendo modelagem de sistemas, integração de dispositivos médicos, desenvolvimento de softwares em saúde, segurança cibernética e governança de dados clínicos. A combinação entre interoperabilidade, infraestrutura tecnológica e análise inteligente de dados constitui um dos principais pilares para a transformação digital da regulação assistencial e para o fortalecimento da gestão pública em saúde [5], [7], [13].

A arquitetura de informação proposta para a regulação assistencial no SUS é apresentada na Figura 1, destacando o fluxo de dados desde o paciente e os estabelecimentos de saúde até a tomada de decisão, com integração entre os diferentes níveis do sistema.

Figura I. Fluxograma da arquitetura de informação para regulação assistencial no sus.

V. Estudo de caso: Ecossistema Regula RN

Como exemplo da aplicação prática dos princípios da Saúde Digital na regulação assistencial, destaca-se o ecossistema

RegulaRN, desenvolvido durante a pandemia da COVID-19 pelo Laboratório de Inovação Tecnológica em Saúde (LAIS/UFRN), em parceria com a Secretaria de Estado da Saúde Pública do Rio Grande do Norte (SESAP/RN). O sistema foi concebido para apoiar a gestão regulatória dos leitos hospitalares, promovendo maior integração entre os estabelecimentos de saúde e fornecendo informações em tempo real para subsidiar a tomada de decisão dos gestores públicos [8].

O desenvolvimento do RegulaRN ocorreu em resposta ao rápido aumento da demanda por leitos de internação, especialmente de terapia intensiva, cenário que evidenciou a necessidade de ferramentas capazes de integrar informações clínicas, reduzir o tempo de resposta das centrais reguladoras e ampliar a transparência dos processos de regulação. Nesse contexto, a plataforma consolidou informações provenientes de diferentes unidades assistenciais, permitindo o acompanhamento contínuo da disponibilidade de leitos e do perfil clínico dos pacientes [8]. Do ponto de vista arquitetural, o ecossistema RegulaRN fundamenta-se na integração entre sistemas de informação em saúde, utilização de bases de dados compartilhadas e disponibilização de painéis gerenciais (dashboards) destinados ao monitoramento da ocupação hospitalar e dos indicadores assistenciais. Essa arquitetura favorece a interoperabilidade entre diferentes serviços de saúde, alinhando-se aos princípios da Estratégia de Saúde Digital para o Brasil e às diretrizes de integração da Rede Nacional de Dados em Saúde (RNDS), discutidas nos capítulos anteriores [2], [7], [13].

Um dos principais diferenciais do sistema foi a implementação do Escore Unificado de Priorização (EUP), desenvolvido para apoiar tecnicamente a classificação de pacientes que necessitavam de internação em leitos críticos. O escore utiliza critérios clínicos padronizados para estabelecer prioridades de atendimento, reduzindo a subjetividade das decisões regulatórias e promovendo maior equidade na alocação dos recursos disponíveis [9].

Segundo Veras [9], a utilização do EUP contribuiu para padronizar os processos de priorização clínica, oferecendo maior segurança aos profissionais responsáveis pela regulação e permitindo decisões fundamentadas em parâmetros objetivos. Essa abordagem favoreceu maior rastreabilidade das decisões e fortaleceu a transparência institucional durante um período de elevada pressão sobre o sistema de saúde. Além da priorização clínica, o RegulaRN proporcionou benefícios relacionados à gestão da informação, ao monitoramento em tempo real da ocupação dos leitos e ao suporte à tomada de decisão pelos gestores estaduais. A consolidação de informações provenientes de diferentes hospitais permitiu maior visibilidade situacional da rede assistencial, contribuindo para otimizar a distribuição dos recursos hospitalares e reduzir o tempo necessário para análise das solicitações de internação [8], [9].

O ecossistema do RegulaRN demonstra como a integração entre arquitetura computacional, interoperabilidade, análise de dados e desenvolvimento de sistemas de apoio à decisão pode contribuir para a modernização da gestão pública em saúde. A experiência evidencia que soluções digitais desenvolvidas com base em princípios de interoperabilidade, governança de dados e inteligência computacional possuem potencial para fortalecer os processos regulatórios, ampliar a eficiência operacional e promover maior equidade no acesso aos serviços especializados do SUS [5], [7], [8].

Embora desenvolvido em um contexto emergencial, o RegulaRN consolidou-se como uma experiência nacional de inovação em saúde digital, demonstrando que ecossistemas tecnológicos integrados podem fortalecer a regulação assistencial e ampliar a eficiência da gestão pública em saúde [2], [6], [8]. Entretanto, a expansão de iniciativas semelhantes para outras regiões do país ainda enfrenta desafios relacionados à infraestrutura tecnológica. A aplicação e os impactos das funcionalidades do RegulaRN podem ser analisados a partir de diferentes aspectos relacionados à gestão, priorização, monitoramento e integração das informações, conforme apresentado na Tabela II.

Tabela II
ASPECTOS AVALIADOS, APLICAÇÃO E IMPACTOS NO REGULARN

Aspecto Avaliado	**Aplicação no RegulaRN**	**Impacto Observado**
Gestão de leitos	Monitoramento em tempo real	Maior visibilidade da ocupação hospitalar
Escore Unificado de Priorização (EUP)	Classificação clínica padronizada	Redução da subjetividade na regulação
Dashboards gerenciais	Acompanhamento de indicadores	Apoio à tomada de decisão
Compartilhamento de informações	Integração entre unidades assistenciais	Maior coordenação da rede
Governança digital	Rastreabilidade das decisões	Transparência institucional

VI. DESAFIOS, BIOÉTICA E PERSPECTIVAS FUTURAS

Ainda que a incorporação de tecnologias digitais tenha promovido avanços significativos na organização da regulação assistencial do Sistema Único de Saúde (SUS), a consolidação desse processo ainda enfrenta desafios de natureza tecnológica, organizacional, ética e regulatória. A superação dessas limitações é fundamental para garantir que os benefícios da transformação digital sejam distribuídos de forma equitativa entre as diferentes regiões do país e contribuam para o fortalecimento da gestão pública em saúde [2], [6]. Um dos principais obstáculos à implementação da Saúde Digital no SUS refere-se às desigualdades estruturais existentes entre as regiões brasileiras. Diferenças relacionadas à infraestrutura tecnológica, disponibilidade de conectividade, informatização dos serviços e acesso à internet comprometem a integração dos sistemas de informação e dificultam a adoção homogênea de soluções digitais em todo o território nacional [10]. Tais limitações podem repercutir diretamente nos processos regulatórios, uma vez que a indisponibilidade ou instabilidade de recursos tecnológicos compromete o registro, o compartilhamento e o acesso oportuno às informações necessárias

à gestão das filas e à tomada de decisão. Dessa forma, os investimentos em infraestrutura devem considerar as particularidades e desigualdades regionais, de modo a evitar que a transformação digital amplie disparidades já existentes no acesso aos serviços de saúde. Além da infraestrutura física, a heterogeneidade na maturidade digital das instituições de saúde também influencia diretamente a capacidade de implementação de arquiteturas interoperáveis e de utilização da Rede Nacional de Dados em Saúde (RNDS), ampliando as disparidades entre diferentes redes assistenciais [2], [10]. A interoperabilidade, nesse contexto, representa um desafio que ultrapassa a simples conexão entre plataformas, envolvendo a adoção de padrões comuns, a padronização das informações e a capacidade dos diferentes sistemas de trocar e interpretar dados de maneira consistente.

A transformação digital exige que gestores, profissionais de saúde e equipes técnicas desenvolvam competências relacionadas ao uso de sistemas de informação, análise de dados, interoperabilidade e governança digital. A incorporação de novas tecnologias sem investimento contínuo em qualificação profissional pode comprometer a efetividade das soluções implementadas e limitar seu potencial de impacto na assistência [6], [11].Ademais, a ausência de capacitação adequada pode contribuir para a subutilização das ferramentas disponíveis, para inconsistências no registro das informações e para dificuldades na adaptação dos processos de trabalho às novas tecnologias. Portanto, programas permanentes de educação e capacitação tornam-se fundamentais para fortalecer a cultura digital nas instituições de saúde, favorecendo a utilização adequada das ferramentas tecnológicas e estimulando processos decisórios fundamentados em evidências científicas [6].

O compartilhamento de informações clínicas em ambientes interoperáveis amplia a necessidade de mecanismos robustos de segurança da informação e proteção da privacidade dos pacientes. A Lei Geral de Proteção de Dados (LGPD) estabelece princípios e diretrizes para o tratamento de dados pessoais sensíveis, exigindo que instituições públicas e privadas adotem práticas voltadas à confidencialidade, integridade, disponibilidade e rastreabilidade das informações em saúde [14]. Além do cumprimento dos requisitos legais, a implementação de políticas de governança de dados, mecanismos de autenticação, criptografia e controle de acesso representa elemento essencial para garantir a confiança dos usuários e assegurar a utilização ética das tecnologias digitais no contexto assistencial [14]. Entretanto, a conformidade com a legislação representa um desafio contínuo, especialmente em ecossistemas caracterizados pelo compartilhamento de informações entre múltiplas instituições, sistemas e profissionais. Nesse cenário, torna-se necessário estabelecer critérios claros para o tratamento, o acesso, o compartilhamento e a responsabilização pelo uso dos dados, conciliando a circulação das informações necessária à continuidade do cuidado com a proteção dos direitos dos usuários.

O avanço das aplicações de Inteligência Artificial (IA) na saúde amplia as possibilidades de apoio à regulação assistencial, especialmente na classificação de pacientes, análise de prioridades, previsão de demanda e otimização da utilização dos recursos disponíveis. Entretanto, a adoção dessas tecnologias deve ser acompanhada por princípios de transparência algorítmica, explicabilidade, supervisão humana e equidade, reduzindo riscos relacionados a vieses computacionais e decisões automatizadas inadequadas [11], [14]. Nesse contexto, torna-se fundamental desenvolver sistemas inteligentes que conciliem elevado desempenho computacional com requisitos éticos, legais e clínicos, garantindo que a inovação tecnológica permaneça centrada nas necessidades dos pacientes e dos profissionais de saúde.

Como perspectivas futuras, a tendência é que a evolução da Saúde Digital no SUS seja impulsionada pela expansão da interoperabilidade nacional, pelo fortalecimento da Rede Nacional de Dados em Saúde (RNDS), pela consolidação de arquiteturas baseadas em padrões internacionais, como o HL7 FHIR, e pela incorporação progressiva de soluções baseadas em Inteligência Artificial para apoio à tomada de decisão [2], [7], [13].

VII. Conclusão

A transformação digital tem redefinido a organização da regulação assistencial no Sistema Único de Saúde (SUS), promovendo avanços na integração das informações, na otimização dos fluxos assistenciais e no apoio à tomada de decisão baseada em evidências. A partir da revisão narrativa realizada, verificou-se que iniciativas como a Estratégia de Saúde Digital para o Brasil 2020–2028, a Rede Nacional de Dados em Saúde (RNDS) e a adoção de padrões de interoperabilidade, como o HL7 FHIR, constituem elementos fundamentais para a construção de um ecossistema de saúde mais integrado, eficiente e centrado no cidadão [2], [5], [7], [13].

O estudo de caso do ecossistema RegulaRN evidenciou que a aplicação de arquiteturas interoperáveis, associadas ao uso de sistemas de apoio à decisão, dashboards gerenciais e critérios padronizados de priorização clínica, pode contribuir significativamente para a qualificação dos processos regulatórios, ampliando a transparência, a rastreabilidade e a eficiência da gestão pública em saúde [8], [9]. Esses resultados demonstram o potencial da transformação digital para fortalecer a coordenação das Redes de Atenção à Saúde e otimizar a utilização dos recursos assistenciais disponíveis [15]. Entretanto, a consolidação dessas iniciativas ainda depende da superação de desafios relacionados à infraestrutura tecnológica, à interoperabilidade entre sistemas, à capacitação dos profissionais, à governança dos dados e à observância dos princípios éticos e legais estabelecidos pela Lei Geral de Proteção de Dados (LGPD). Além disso, a incorporação crescente de soluções baseadas em Inteligência Artificial exige mecanismos de transparência, supervisão humana e avaliação contínua, de forma a garantir decisões seguras, equitativas e alinhadas às necessidades da população [6], [10], [11], [14].

Portanto, a Engenharia Biomédica desempenha papel estratégico ao integrar conhecimentos de engenharia, computação e saúde para o desenvolvimento de arquiteturas

tecnológicas interoperáveis, sistemas inteligentes e soluções inovadoras voltadas à gestão do cuidado. Espera-se que a continuidade dos investimentos em infraestrutura digital, padronização tecnológica e inovação contribua para o fortalecimento da regulação assistencial, promovendo maior eficiência, equidade e sustentabilidade do SUS, além de incentivar novas pesquisas voltadas à avaliação do impacto dessas tecnologias na qualidade da assistência e na gestão dos serviços de saúde [1], [2], [6], [7], [16].

Resumo— A hospitalização infantil é um processo estressante que afeta o bem-estar biopsicossocial da criança. Nesse cenário, jogos sérios e tecnologias assistivas emergem como estratégias valiosas, pois tornam a reabilitação um processo mais lúdico, motivador e menos focado na carga terapêutica. Este estudo teve como objetivo desenvolver um sistema integrado de jogo sério, composto por hardware dedicado, software de interação e plataforma de monitoramento, para estimular a movimentação de crianças hospitalizadas durante sessões de fisioterapia, bem como avaliar sua aplicabilidade clínica inicial em ambiente hospitalar. O sistema "Rocket Motion" foi criado utilizando um controlador inercial (baseado em ESP32-C3 e MPU-6050) e uma *game engine* (Godot). O processo abrangeu o desenvolvimento paralelo de hardware e software, testes de calibração e uma validação clínica preliminar com uma paciente pediátrica. Foi desenvolvida uma ferramenta que combina gamificação com a aquisição objetiva de dados cinéticos. Diferentemente da avaliação visual tradicional, o sistema permite quantificar a qualidade do movimento e armazenar métricas para acompanhamento clínico. A validação indicou alta aceitação e engajamento da paciente, confirmando a viabilidade técnica da solução como suporte à tomada de decisão clínica na reabilitação pediátrica.

Abstract - Child hospitalization is a stressful process that affects a child's biopsychosocial well-being. In this scenario, serious games and assistive technologies emerge as valuable strategies, as they make rehabilitation a more playful, motivating process, less focused on the therapeutic burden. This study aimed to develop an integrated serious game system, composed of dedicated hardware, interaction software, and a monitoring platform, to stimulate the movement of hospitalized children during physical therapy sessions, as well as to evaluate its initial clinical applicability in a hospital environment. The "Rocket Motion" system was created using an inertial controller (based on ESP32-C3 and MPU-6050) and a game engine (Godot). The process encompassed the parallel development of hardware and software, calibration tests, and a preliminary clinical validation with a pediatric patient. A tool was developed that combines gamification with the objective acquisition of kinetic data. Unlike traditional visual assessment, the system allows for quantifying movement quality and storing metrics for clinical monitoring. Validation indicated high acceptance and patient engagement, confirming the technical feasibility of the solution as a support for clinical decision-making in pediatric rehabilitation.

Palavras-chave— Jogos sérios; tecnologia assistiva; reabilitação; hospitalização.

I. Introdução

A hospitalização é um processo crítico, com grandes repercussões para o binômio família/criança. Em decorrência

da internação, a criança é retirada de seu núcleo familiar e social e inserida em um ambiente desconhecido, no qual passa por procedimentos técnicos, muitas vezes invasivos, que podem causar incômodo físico e psicológico. Como reflexo desse cenário, é comum observar, nesses pacientes, manifestações como ansiedade, perda de peso, alterações de humor, declínio cognitivo, baixa autoestima e desenvolvimento de fobias, além de inseguranças e dificuldades de adaptação psicossocial [1].

Em um ambiente inerentemente estressante, repleto de estímulos potencialmente dolorosos e de procedimentos invasivos, garantir a continuidade do desenvolvimento e da qualidade de vida torna-se um desafio crucial para a equipe de saúde. Com isso, ao compreender o brincar como um direito da criança, as Tecnologias Assistivas (TA) apresentam-se como uma estratégia de acessibilidade, uma vez que permitem que as crianças façam parte do seu processo de vida, criando repertório, vínculos, relações e possibilidades de ser e estar, a partir de soluções específicas para crianças em diferentes contextos [2].

Nesse cenário, tecnologias emergentes consolidam-se como recursos valiosos para o desenvolvimento de intervenções digitais lúdicas voltadas ao público infantojuvenil. A implementação de jogos digitais em ambiente hospitalar não apenas proporciona distração durante procedimentos dolorosos, mas também atua como um potente mecanismo para aumentar a motivação dos pacientes e fomentar a interação social entre a criança e a equipe de saúde. Com o avanço tecnológico, surge uma ampla gama de ferramentas que viabilizam a criação de jogos centrados no paciente. Ao utilizar tecnologias avançadas, esses jogos permitem o monitoramento da movimentação em tempo real e o fornecimento de feedback personalizado, tornando a reabilitação um processo mais eficaz e envolvente [3] [4] [5].

O desenvolvimento de jogos sérios (JS) voltados à reabilitação permite a personalização dos níveis de intensidade, bem como o ajuste e o fornecimento de feedback, adaptando-se às necessidades individuais e aos diferentes níveis de comprometimento dos pacientes [6] [7] .

A gamificação, ao integrar elementos como cenários virtuais e atividades lúdicas que exigem movimentação corporal, introduz um componente motivacional à terapia. Isso transforma a sessão de reabilitação em um espaço de descontração e superação pessoal, tornando o processo mais prazeroso e menos focado na carga terapêutica. É importante ressaltar que a criação de tecnologias demanda colaboração interdisciplinar, unindo os conhecimentos de profissionais da saúde e da tecnologia para garantir o sucesso das ferramentas e sua viabilidade na prática clínica [6] [8].

Com isso, partiu-se da hipótese de que a utilização de um jogo sério associado a um controlador inercial personalizado seria capaz de tornar os exercícios fisioterapêuticos mais atrativos, permitindo, simultaneamente, o registro objetivo de parâmetros de desempenho motor durante a execução das atividades.

Portanto, o presente estudo teve como objetivo desenvolver um sistema integrado de jogo sério, composto por hardware dedicado, software de interação e plataforma de monitoramento, para estimular a movimentação de crianças hospitalizadas durante sessões de fisioterapia, bem como avaliar sua aplicabilidade clínica inicial em ambiente hospitalar.

II. Metodologia

O sistema foi concebido como uma arquitetura integrada composta por três subsistemas principais: (i) hardware responsável pela aquisição dos movimentos do paciente; (ii) software de interação baseado em jogo sério; e (iii) módulo de aquisição, armazenamento e visualização de dados clínicos. O desenvolvimento desses subsistemas ocorreu de forma paralela e integrada, garantindo compatibilidade funcional entre todos os componentes. Componentes e a aplicabilidade clínica. Partindo de uma decisão em equipe, foi definido que o jogo precisaria atender às seguintes diretrizes:

- Estimular por meio de recompensa (pontos, estímulo visual e sonoro) exercícios específicos para recuperação e reabilitação dos pacientes;
- Receber os comandos do jogador, por meio de um dispositivo (controle) sem fio;
- Gerar dados para avaliação posterior à sessão de jogo (evolução do quadro clínico);

Esses requisitos foram definidos para contemplar simultaneamente objetivos terapêuticos, aspectos motivacionais e necessidades de monitoramento clínico, permitindo que o sistema funcionasse tanto como recurso de reabilitação quanto como ferramenta de acompanhamento da evolução dos pacientes.

Antes de iniciar o processo de desenvolvimento, realizou-se um levantamento dos softwares e recursos necessários para atender às diretrizes estabelecidas. Por se tratar de um projeto sem fins lucrativos, foram adotados softwares classificados como *"Open Source"*. Dentre os principais softwares, destacam-se o Blender, para modelagem 3D, e o Godot, uma engine de jogos na qual seria desenvolvida a lógica de programação do jogo, bem como a exportação do jogo (aplicativo) para execução. Para o desenvolvimento do hardware (controle), foi adotado o sistema embarcado "ESP32-C3 Super Mini", capaz de ler diversos sensores, em particular, o acelerômetro "MPU-6050".

Quanto ao desenvolvimento do controle, foi dividido em três etapas: programação, construção do protótipo e, por fim, testes e ajustes do controle.

Primeiramente, o desenvolvimento do código precisava garantir que o sistema embarcado executasse as seguintes funções:

1. Inicializar o sistema, definindo terminais e protocolos de comunicação;

2. Verificar a comunicação com o acelerômetro;
3. Verificar a comunicação Bluetooth;
4. Esperar solicitação de conexão Bluetooth;
5. Fazer a leitura do acelerômetro;
6. Calcular o ângulo de inclinação do sensor;
7. Enviar o valor do ângulo para o dispositivo;

Este estudo foi aprovado pelo comitê de ética em pesquisa sob o parecer CAAE: 94597525.5.0000.0237

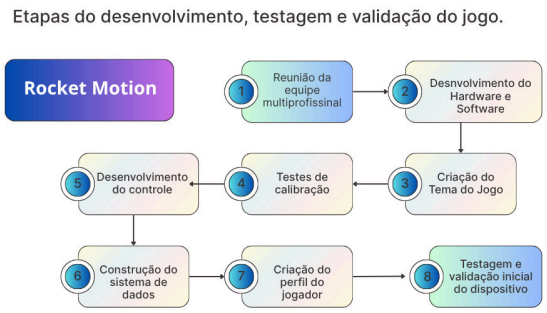

Figura 1: Etapas de desenvolvimento, testagem e validação do jogo.

III. Resultados

O principal resultado deste estudo foi o desenvolvimento de uma plataforma integrada de reabilitação motora, composta por um controlador inercial personalizado, um jogo sério e um sistema automatizado de aquisição de dados. Diferentemente de jogos digitais convencionais, utilizados apenas como recurso motivacional, o sistema desenvolvido incorpora mecanismos objetivos de monitoramento do desempenho motor, permitindo seu uso simultâneo como ferramenta terapêutica e como instrumento de acompanhamento clínico.

Após testes de comunicação e de calibração do acelerômetro, garantindo que toda a parte de programação estava finalizada, iniciou-se a construção do hardware. Nesta etapa, foram estabelecidas características como: tamanho e capacidade de carga da bateria, forma de carregamento da bateria, orientação do acelerômetro, botão de acionamento (liga/desliga), peso máximo e forma de prender o dispositivo ao corpo. A bateria escolhida apresentava tensão nominal de 3,6 volts e capacidade de carga de 450 mAh (miliampères-hora).

O acelerômetro foi posicionado acima do sistema embarcado, o que resultou no conjunto mais compacto possível. Por fim, o conjunto foi acomodado em uma "*case*" feita de PET-G (Polietileno Tereftalato Glicol), impressa em impressora 3D. O material da "*case*" foi escolhido por sua boa resistência mecânica e pela facilidade de higienização.

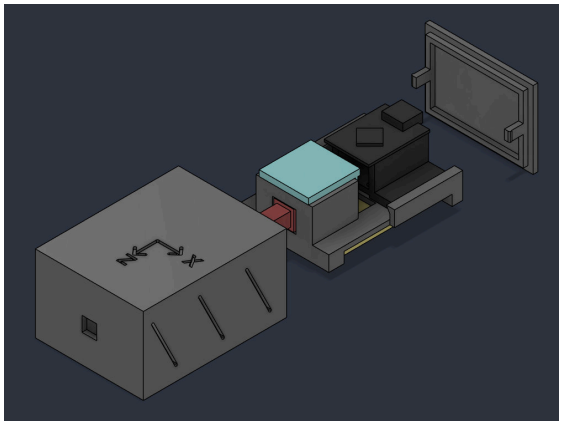

Figura 2: Modelo virtual da montagem do controle.

A última etapa do desenvolvimento do controle foi realizada simultaneamente ao início do desenvolvimento do jogo. Foram feitos pequenos ajustes, tais como a adição de detalhes na tampa da "*case*" para indicar a orientação do sensor, a modificação da taxa de envio e do formato das informações enviadas pelo controle.

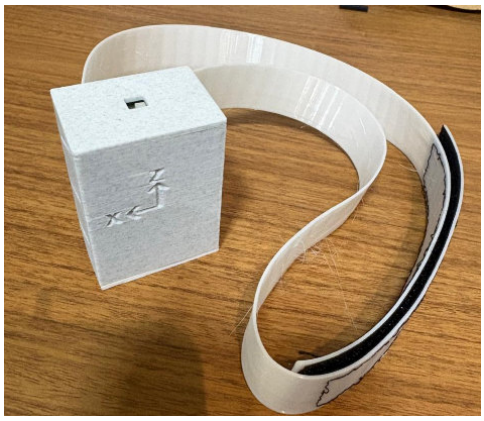

Figura 3: Controle finalizado.

Para iniciar o desenvolvimento do jogo, foi desenvolvido um protótipo no qual o jogador era representado por um bloco, inicialmente localizado no centro da tela, e, conforme o controle era inclinado, o bloco se movia. Essa etapa fez parte do que é conhecido como "blocagem", na qual todos os elementos do jogo são representados da forma mais simples possível. Com o fim desta etapa, foi concluído o desenvolvimento do controle e deu-se início à implementação das mecânicas de jogo.

A escolha da temática espacial teve como objetivo reduzir associações diretas a procedimentos hospitalares, criando um ambiente virtual lúdico capaz de estimular a curiosidade, a exploração e a sensação de progressão durante a execução dos exercícios fisioterapêuticos. Desta forma, foram escolhidos elementos que estimulariam o jogador a agir no jogo: estrelas e

asteroides. Dentro dessa temática, o jogador passa a ser representado por um foguete cujo objetivo é coletar o maior número possível de estrelas, desviando de asteroides.

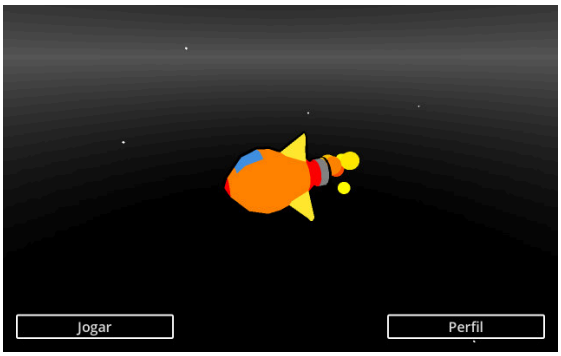

Figura 4: Tela inicial do jogo “Rocket Motion”.

As estrelas são itens coletáveis no jogo que aumentam a pontuação e acionam efeitos visuais e sonoros. Em termos de jogabilidade, é conhecido como “*feedback positivo*” quando uma ação do jogador é recompensada. A pontuação é um fator relevante para aumentar o engajamento do jogador. Se ele apresenta pontuação elevada, o jogador está buscando realizar o exercício proposto; do contrário, o engajamento é baixo e o exercício não está sendo cumprido.

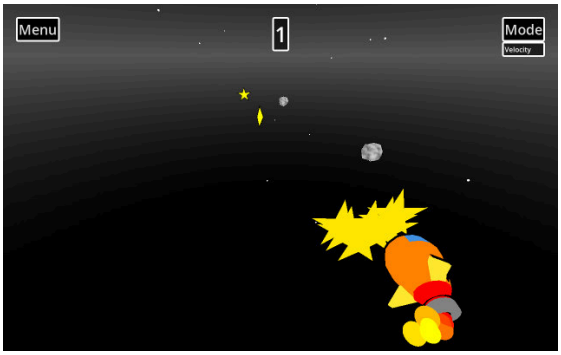

Figura 5: Foguete coletando uma estrela.

Os asteroides funcionam de forma semelhante às estrelas, porém, quando o jogador colide com um asteroide, a pontuação é subtraída e um ruído desagradável é emitido. Trata-se, portanto, de um “*feedback negativo*”. Esse elemento é um estímulo de reforço à ação do jogador, impactando o engajamento dele no jogo.

Depois de implementadas as mecânicas básicas do jogo, passou-se à construção do sistema de dados para análise. O sistema é baseado na criação de um “Perfil” para cada paciente, que contém as seguintes informações: nome, código do paciente e espaço para comentários e observações. O processo de criação do “Perfil” gera uma pasta no dispositivo em que o jogo é executado, na qual são armazenadas as informações de cada exercício.

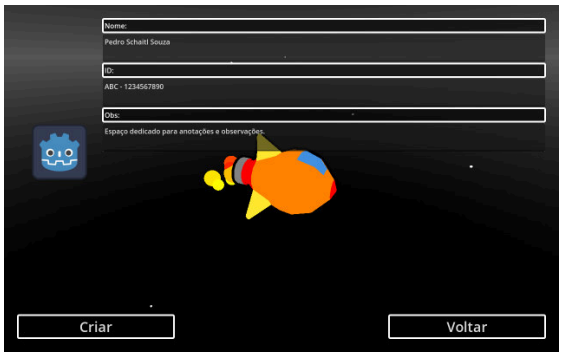

Figura 6: Tela de criação de perfil.

As informações coletadas são utilizadas para analisar o comportamento do paciente durante a execução do exercício, gerando dados sobre o tempo e a intensidade do movimento. Além dos dados numéricos, é gerado um gráfico com três linhas: a branca indica a posição do foguete na tela, a vermelha a inclinação do dispositivo e a amarela a pontuação durante a partida. As linhas pontilhadas são referências fixas para comparação entre os gráficos gerados.

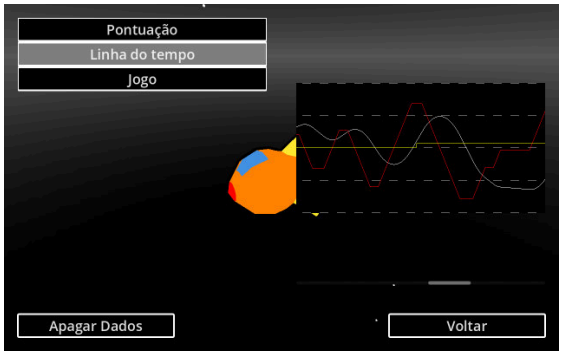

Figura 7: Tela de análise de dados.

A representação gráfica simultânea do movimento executado, da resposta do personagem e da evolução da pontuação fornece ao fisioterapeuta uma visualização integrada do desempenho do paciente, permitindo identificar padrões motores, oscilações de desempenho e possíveis dificuldades durante a execução do exercício.

Desenho experimental, testagem e validação do dispositivo

Foi selecionada uma paciente com diagnóstico de osteomielite, com média de internação superior a 20 dias e que necessitava de descarga de peso do membro inferior. A criança foi convidada a participar da pesquisa juntamente com seu responsável e após o esclarecimento sobre a pesquisa e o objetivo do jogo, foram assinados o termo de consentimento

livre e esclarecido e o termo de assentimento livre e esclarecido.

A criança foi avaliada, antes de iniciar o jogo, quanto à saturação e à frequência cardíaca e, após a sessão, foi aplicada a Escala de Percepção de Esforço da Criança (EPEC). O jogo foi utilizado para trabalhar, de forma lúdica, a movimentação e a descarga de peso bilaterais.

IV. Discussão

A interação no jogo ocorre por meio de enredos lúdicos, como o de guiar um foguete no espaço, no qual a criança o move tanto para coletar estrelas quanto para fugir de asteroides. O cenário interativo ajuda a aumentar a motivação, desvia o foco da dor e da repetição extenuante em um ambiente hospitalar [4].

O principal diferencial do sistema desenvolvido não reside apenas na utilização de elementos de gamificação durante a fisioterapia, mas também na integração entre um controlador inercial personalizado, um ambiente virtual interativo e um módulo automatizado de aquisição de dados clínicos. Corroborando com o estudo de um jogo sério de realidade aumentada desenvolvido para a reabilitação de ombro, que integra métricas específicas para monitorar o desempenho e o progresso do usuário durante as sessões de reabilitação. Os dados coletados são armazenados automaticamente em um banco de dados para permitir a análise clínica e o acompanhamento da evolução ao longo do tempo [9].

Outro fator relevante é o ajuste de velocidade e de dificuldade, o que permite adaptar o desafio ao paciente (jogador) e, consequentemente, mantê-lo engajado no jogo. Para garantir que o paciente se mantenha engajado, os jogos utilizam o Ajuste Dinâmico de Dificuldade (DDA). Esse sistema altera a complexidade do jogo em tempo real com base no desempenho do usuário (ou até mesmo em respostas fisiológicas), garantindo que o desafio não seja tão fácil a ponto de causar tédio, nem tão difícil a ponto de gerar frustração [10] [6].

Essa integração permite que o mesmo sistema utilizado para aumentar o engajamento do paciente também atue como ferramenta objetiva para monitorar a execução dos exercícios e a evolução funcional ao longo do tratamento. Diferentemente da avaliação visual tradicional do terapeuta, o sistema registra métricas precisas que permitem quantificar a qualidade do movimento. Sendo assim, a interação entre dispositivos eletrônicos, jogos digitais e a experiência de análise e compreensão de sistemas biológicos (jogador) propõe um sistema capaz de fornecer dados para o dia a dia dos profissionais da reabilitação, permitindo acompanhar a evolução e regular o processo de reabilitação [11] [12].

A representação gráfica do jogo Rocket Motion permite identificar padrões motores, oscilações de desempenho e possíveis dificuldades na execução do exercício. Isso viabiliza que o profissional modifique, personalize e programe a dificuldade e os parâmetros das futuras sessões (como a velocidade dos alvos ou a tolerância a erros), auxiliando na reabilitação e na tomada de decisão clínica [13].

Na validação, a criança demonstrou fácil compreensão do movimento a ser realizado. Além disso, com o componente de diversão e interação, a criança conseguiu realizar o movimento de inclinação para ambos os lados, com descarga de peso para o lado esquerdo (lado da lesão no joelho). Ao promoverem a motivação intrínseca e a diversão, esses jogos combatem o comportamento sedentário excessivo durante as internações, além de aliviar a ansiedade e a dor [4].

Desse modo, o jogo foi desenvolvido e adaptado para crianças no ambiente hospitalar e, por isso, apresenta menos recursos de interface e sistemas de feedback mais simples. Portanto, reduzir a complexidade, diminuir o número de recursos da interface e incorporar sistemas de recompensa são estratégias recomendadas para minimizar o esforço cognitivo exigido da criança, aumentando as chances de que ela consiga e queira jogar, mesmo estando cansada [3].

V. Conclusão

O presente estudo viabilizou o desenvolvimento e a validação inicial do sistema “Rocket Motion”, um jogo sério integrado a um controlador inercial personalizado, projetado especificamente para a reabilitação motora de crianças hospitalizadas. Ao unir elementos de gamificação,como estímulos lúdicos, recompensas e cenários virtuais, a um sistema de monitoramento de dados cinéticos, a ferramenta demonstrou ser uma alternativa promissora para tornar o processo terapêutico mais atrativo, motivador e menos focado na carga exaustiva do tratamento.

Os resultados obtidos na validação clínica inicial indicaram que a interface simplificada e o feedback em tempo real facilitaram a compreensão e a execução dos movimentos terapêuticos pela paciente, promovendo maior engajamento e auxiliando na descarga de peso. Além do componente lúdico, o sistema mostrou-se uma ferramenta valiosa para o fisioterapeuta, ao fornecer métricas objetivas que permitem quantificar o desempenho, identificar padrões motores e personalizar as intervenções com precisão, superando as limitações da avaliação visual tradicional.

Embora o sistema apresente potencial promissor como recurso assistivo no ambiente hospitalar, este estudo reconhece como limitação a realização de uma única validação preliminar. Dessa forma, pesquisas futuras devem contemplar a

aplicação do “Rocket Motion” em uma amostra maior de pacientes, com diferentes quadros clínicos, bem como a incorporação de instrumentos validados para avaliar a experiência do usuário (usabilidade e aceitação) sob a perspectiva da criança. Mais do que desenvolver um jogo sério, este estudo demonstra a viabilidade técnica de uma plataforma integrada de reabilitação digital capaz de unir gamificação, aquisição objetiva de dados motores e monitoramento clínico em um único sistema. Essa abordagem amplia o potencial dos jogos sérios como ferramentas de apoio à tomada de decisão clínica, além de favorecer sua incorporação em programas de reabilitação pediátrica.

***Abstract*—A qualidade dos registros no pré-natal tem impacto direto na promoção da saúde da gestante e do recém-nascido. Diante desse cenário, o registro e o acesso aos dados gerados durante a gestação devem ser realizados de forma consistente para permitir o sucesso do cuidado. Contudo, é possível identificar diversas deficiências associadas ao uso da Caderneta da Gestante que levam à incompletude e à ilegibilidade dos dados. Com o objetivo de superar esses gargalos operacionais, este trabalho desenvolveu e validou a usabilidade de um sistema web capaz de apoiar o acompanhamento pré-natal de baixo risco. O estudo definiu uma metodologia de desenvolvimento voltada ao domínio e centrada no usuário, utilizando *Domain-Driven Design* e Arquitetura Hexagonal. A validação da proposta evidenciou-se na avaliação da usabilidade da ferramenta, que demonstrou alta aceitação por parte dos profissionais de saúde, atingindo nota 77.5 na *System Usability Scale*.**

***Index Terms*—Usabilidade, Engenharia de Software, Desenvolvimento Orientado ao Domínio, Saúde Digital, Saúde da gestante.**

I. Introdução

No Brasil, o acompanhamento pré-natal é uma política pública que engloba iniciativas de promoção de saúde para as gestantes e os recém-nascidos. Para que esta política resulte em ações efetivas, é necessário que os dados clínicos gerados sejam sólidos e rastreáveis [1]. Atualmente, a Caderneta da Gestante atua como instrumento de registro e acompanhamento. Contudo, o modelo impresso apresenta limitações que tornam o processo suscetível a erros de preenchimento, extravio ou deterioração, prejudicando a atuação profissional e a qualidade do cuidado [2].

A associação entre a qualidade dos indicadores de assistência pré-natal e desfechos neonatais ruins é evidenciada na literatura, relacionando a morbimortalidade infantil à descontinuidade da assistência [3]. Em resposta a essa lacuna, o setor da saúde tem intensificado o desenvolvimento de softwares voltados para o apoio à atuação do profissional de saúde.

Com o objetivo de promover a qualificação dos registros, este trabalho desenvolveu um sistema voltado à digitalização da Caderneta por meio da informatização dos fluxos de cadastro e exibição de dados clínicos. O escopo da pesquisa concentra-se no acompanhamento de gestações de baixo risco, situando-se na interseção entre a Engenharia de Software e a Saúde Pública. Para validar a eficácia da ferramenta, foram conduzidos testes de usabilidade com profissionais da área.

II. Fundamentação teórica

A. Desafios no Registro Pré-natal

A Caderneta da Gestante é o principal documento de integração da rede de atenção à saúde [1], [2]. No entanto, a natureza física do documento impõe barreiras à continuidade da informação, como a ilegibilidade e a fragmentação dos dados em prontuários de papel. A digitalização deste processo exige, portanto, não apenas a transposição de formulários, mas uma reengenharia dos fluxos de informação para garantir a integridade dos dados clínicos em um domínio complexo.

B. Saúde Digital no Brasil

A transição para o registro eletrônico de saúde no Brasil é orientada pela Estratégia de Saúde Digital (ESD) 2020-2028. Segundo o 4º Relatório de Monitoramento da ESD, a interoperabilidade e a disponibilidade de dados estruturados são pilares para a continuidade do cuidado na Atenção Primária à Saúde (APS) [13]. O desenvolvimento de soluções que digitalizam a Caderneta da Gestante alinha-se a essa visão, buscando reduzir a fragmentação da informação clínica entre diferentes níveis de atenção.

C. Modelagem e Arquitetura do Sistema

O projeto utilizou *Domain-Driven Design* (DDD), um conjunto de princípios que orientam a modelagem de um domínio de negócio [4] e a sua subsequente transcrição para software. Juntamente, adotou-se a Arquitetura Hexagonal, que visa isolar o núcleo da aplicação de tecnologias externas, como interfaces de usuário e bancos de dados [5].

A escolha pelo DDD se justifica pela complexidade inerente ao domínio obstétrico, onde regras de negócio, como cálculo de idade gestacional, devem ser desacopladas da infraestrutura tecnológica. A Arquitetura Hexagonal complementa essa abordagem ao permitir que as regras de negócio permaneçam agnósticas quanto à detalhes de implementação e tecnologia, facilitando a testabilidade automatizada e a manutenção evolutiva do software.

A Fig. 1 ilustra essa estrutura, evidenciando como as regras de negócio estão protegidas no núcleo, dependendo apenas de interfaces para se comunicar com o mundo externo.

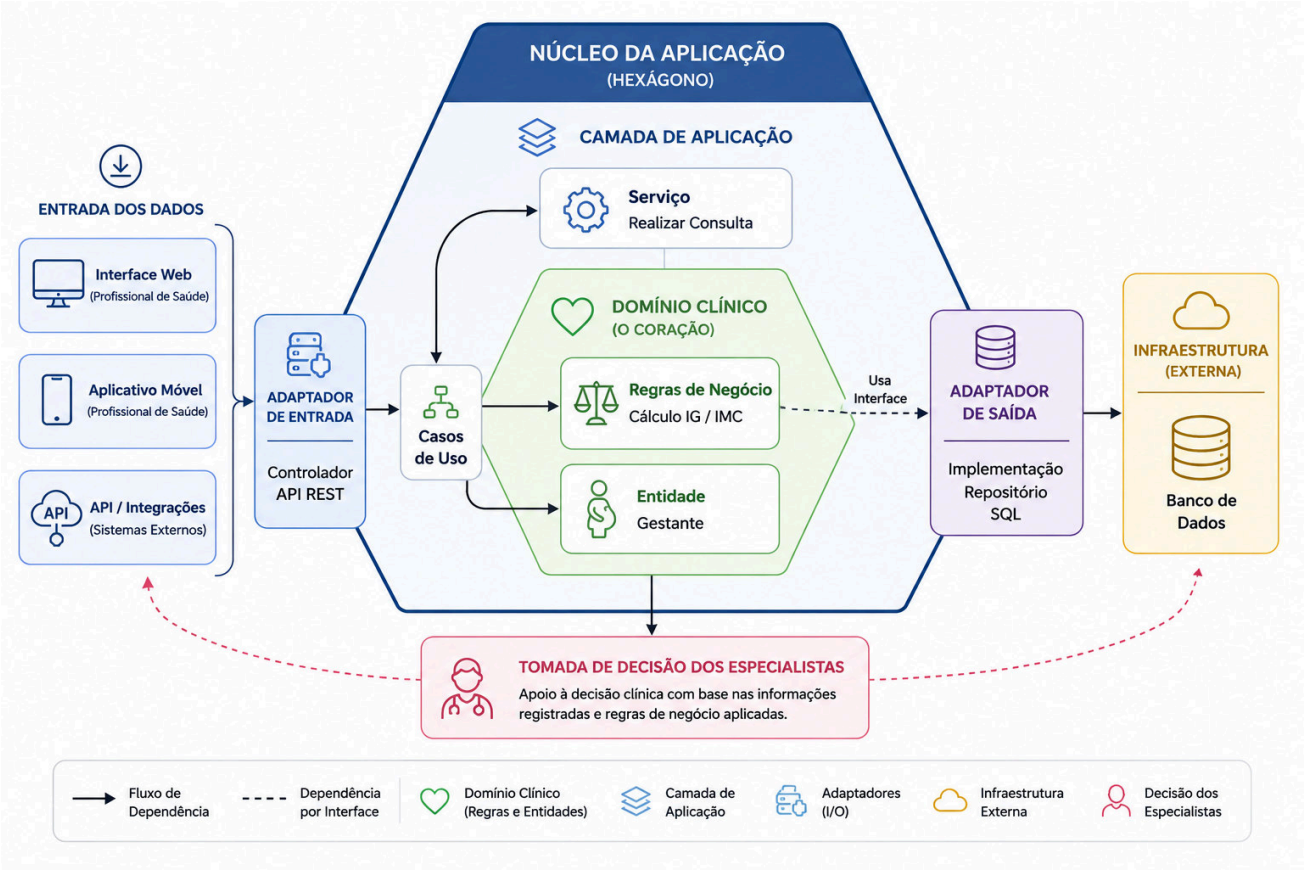

Fig. 1. Modelo arquitetural baseado em Domain-Driven Design e Arquitetura Hexagonal para o sistema proposto de acompanhamento pré-natal.

D. Usabilidade e SUS

A usabilidade é compreendida como o grau em que um sistema pode ser utilizado para alcançar objetivos com efetividade, eficiência e satisfação [7]. Para a avaliação quantitativa, adotou-se a *System Usability Scale* (SUS), um questionário padronizado composto por 10 afirmações mistas (positivas e negativas) avaliadas em uma escala Likert de 5 pontos, variando de ”Discordo Totalmente” (1) a ”Concordo Totalmente” (5) [6].

O cálculo do *score* final do SUS, que varia de 0 a 100, é obtido através de uma normalização das respostas. Para os itens ímpares (positivos), subtrai-se 1 da resposta do usuário ($R - 1$). Para os itens pares (negativos), subtrai-se a resposta de 5 ($5 - R$). A soma resultante é multiplicada por 2,5 para obter a pontuação final, conforme expresso em (1):

$$SUS_{Score} = 2.5 \times \left[\sum_{i=1}^{5} (R_{2i-1} - 1) + \sum_{i=1}^{5} (5 - R_{2i}) \right] \quad (1)$$

Essa metodologia permite mitigar o viés de resposta automática e fornece um indicador único de aceitação do sistema.

III. Metodologia

A. Elicitação de Requisitos e Linguagem Ubíqua

O processo de definição do sistema seguiu uma abordagem centrada no usuário, pautada na técnica de *co-design*. Esta colaboração envolveu sessões de entrevistas e prototipação conjunta com um enfermeiro obstetra especialista na atenção básica. O objetivo central foi o estabelecimento de uma Linguagem Ubíqua, termo do DDD que designa um vocabulário comum compartilhado entre desenvolvedores e especialistas do domínio [4].

Através dessa colaboração, mapeou-se que termos como “Acolhimento”, “Apresentação Fetal” e “Idade Gestacional” deveriam ser refletidos não apenas na interface, mas como entidades centrais no código-fonte. A técnica de *co-design* permitiu validar a sequência lógica de preenchimento dos dados em baixa fidelidade antes da implementação, garantindo que o *software* espelhasse a rotina real de um consultório e reduzisse o hiato entre os requisitos de negócio e o produto final [9].

B. Desenvolvimento da Solução

A arquitetura do servidor fundamenta-se no padrão de Portas e Adaptadores, conhecido como Arquitetura Hexagonal, visando o isolamento rigoroso da lógica de negócio obstétrica frente às tecnologias de infraestrutura [5]. O núcleo da aplicação (*Domain*) centraliza as regras de maior valor da solução, como os cálculos de Idade Gestacional (IG), Data Provável do Parto (DPP) e as validações clínicas essenciais para a integridade dos dados. Operando sob o modelo cliente-servidor, o *backend* expõe esses serviços através de uma API

RESTful, o que assegura que as regras de negócio permaneçam agnósticas à implementação do *frontend*.

Para viabilizar a comunicação desacoplada entre o domínio e o ambiente externo, implementaram-se dois componentes fundamentais:

- Portas (Ports): Interfaces definidas no núcleo que estabelecem o contrato de interação com atores externos, tais como repositórios de dados ou serviços de mensageria.
- Adaptadores (Adapters): Implementações que materializam a comunicação de entrada e saída, subdividindo-se em:
  - *Driving Adapters* (Entrada): Implementados via *Controllers* em Express.js, que traduzem requisições HTTP em comandos para os casos de uso do domínio.
  - *Driven Adapters* (Saída): Artefatos que convertem modelos de domínio em esquemas tecnológicos específicos de forma transparente. Como exemplo, o uso do Prisma ORM para a persistência em banco de dados PostgreSQL foi implementado de modo a permitir que a aplicação gerencie os dados sem acoplamento direto com a tecnologia de armazenamento [8].

Essa estrutura garante que evoluções tecnológicas, como a substituição do banco de dados ou a migração para microsserviços, ocorram sem a necessidade de reescrever o núcleo clínico, elevando a testabilidade e a manutenibilidade da solução.

O desacoplamento proporcionado pela arquitetura facilitou a concepção do sistema sob os princípios do DDD, assegurando que a implementação técnica fosse um reflexo direto das necessidades operacionais dos profissionais de saúde [4].

No nível tático, a consistência dos dados clínicos foi garantida pela implementação de Objetos de Valor (*Value Objects*). Diferente de entidades comuns, esses objetos encapsulam regras de negócio específicas que podem ser reaproveitadas em diversas partes do código, visto que são definidos por seus atributos e não possuem identidade própria. Por exemplo, o objeto de valor responsável pela idade gestacional não apenas armazena o dado, mas valida a cronologia das informações, formata resultados e impede que estados inconsistentes sejam persistidos no núcleo da aplicação, independentemente do contexto ou da função em que é instanciado.

Essa abordagem permitiu que a complexidade dos cálculos obstétricos e das regras de acompanhamento longitudinal fosse isolada em modelos ricos, facilitando a manutenibilidade e garantindo que o sistema atue como uma extensão confiável do raciocínio clínico. A partir desses artefatos, a solução foi organizada em dois contextos delimitados (*Bounded Contexts*) principais:

- Módulo de Consulta: Responsável pela captura estruturada de dados e pela manutenção das invariantes de negócio durante o ato médico. Este módulo centraliza a lógica de validação de parâmetros fisiológicos e automatiza cálculos complexos, como a IG e o IMC, eliminando erros de transcrição e garantindo a integridade imediata do registro clínico. Adicionalmente, o módulo propõe um fluxo estruturado para o atendimento, orientando as etapas necessárias para a realização plena de uma consulta pré-natal. Essa abordagem reduz a carga cognitiva do profissional, permitindo maior foco na interação clínica e nas necessidades da paciente.
- Módulo de Acompanhamento: Voltado à síntese e interpretação do histórico clínico, transformando dados fragmentados em informações estratégicas. Através da agregação de registros longitudinais, o módulo processa a evolução da gestação para gerar projeções visuais de tendência, como curvas de altura uterina e ganho de peso, fundamentais para a detecção precoce de desvios e suporte à decisão clínica baseada em evidências.

C. Stack Tecnológica e Implementação

A materialização dos conceitos arquiteturais utilizou uma pilha tecnológica moderna focada em escalabilidade e robustez. O *frontend* foi desenvolvido com a biblioteca React e o framework Next.js, aproveitando o roteamento baseado em arquivos e a renderização otimizada. Para a gestão de estados de servidor e sincronização de dados, utilizou-se a TanStack Query, garantindo uma interface responsiva mesmo sob condições de rede instáveis.

A camada de persistência foi implementada com o banco de dados relacional PostgreSQL, gerenciado através do Prisma ORM. Esta escolha permitiu o uso de um esquema de dados tipado e migrações estruturadas, refletindo o modelo de agregados definido no DDD. Para garantir a integridade dos dados na entrada, a biblioteca Zod foi aplicada na definição de esquemas de validação tanto no cliente quanto no servidor, assegurando que apenas informações consistentes com o domínio clínico sejam persistidas.

D. Regras de Negócio e Protocolos Clínicos

O sistema foi parametrizado conforme as diretrizes do Ministério da Saúde e as recomendações da Agência Nacional de Saúde Suplementar (ANS), que estabelece a realização mínima de seis consultas durante o período gestacional [14].

O fluxo de dados foi organizado para refletir a jornada da paciente:

- Acolhimento: Registro inicial focado no Cartão Nacional de Saúde (CNS) e na Data da Última Menstruação (DUM), servindo como âncora para os cálculos de IG e DPP.
- Exame Físico Geral e Específico: Interface estruturada para coleta de dados biométricos (peso, altura, IMC) e obstétricos (altura uterina, batimentos cardíacos fetais), onde o sistema aplica validações em tempo real para evitar a incompletude histórica do modelo em papel.

E. Procedimento de Teste

O protocolo de validação seguiu um roteiro estruturado de tarefas que simulavam a rotina real de um consultório. As tarefas foram divididas em três fluxos principais:

1) *Realização de Consulta:* O participante deveria iniciar um atendimento, navegar entre as abas de exame físico e obstétrico e registrar dados clínicos simulados. O sistema deveria validar automaticamente os campos obrigatórios antes de permitir a conclusão.
2) *Gestão de Exames:* Inserção de resultados de exames trimestrais e ultrassonografias, verificando a resposta do sistema quanto à visualização imediata dos dados salvos.
3) *Monitoramento Longitudinal:* Acesso ao histórico da paciente para análise da curva uterina e ganho de peso.

Durante a execução, utilizou-se a técnica *Think Aloud*, onde os participantes verbalizavam suas ações e dificuldades em tempo real. Ao final, aplicou-se o questionário SUS e a entrevista estruturada para quantificar a percepção de usabilidade e obter a percepção dos participantes a respeito do uso da aplicação no contexto de trabalho do profissional de saúde.

Os testes de usabilidade foram validados por profissionais especialistas na atenção primária à saúde vinculados ao contexto do Sistema Único de Saúde (SUS), incluindo enfermeiros e profissionais com experiência em acompanhamento pré-natal de baixo risco. Os participantes possuíam familiaridade prévia com fluxos clínicos obstétricos e com o uso de prontuários eletrônicos em diferentes níveis de maturidade tecnológica. A seleção buscou contemplar profissionais envolvidos na rotina assistencial do pré-natal, garantindo maior aderência entre os cenários simulados e o contexto real de utilização da ferramenta.

IV. Resultados e discussões

A. Resultados Quantitativos

O sistema obteve uma pontuação média de 77.5 na escala SUS (Desvio Padrão = 4.68), como destacado na Tabela **??**, superando o limiar de 68 pontos considerado como média da indústria. Na escala de aceitabilidade, a nota posiciona o sistema na categoria ”Bom” a ”Excelente”.

B. Resultados Qualitativos

Os participantes destacaram a agilidade e a organização das informações. A centralização dos dados na seção de acompanhamento foi citada como uma contribuição significativa para a continuidade do cuidado. Um participante relatou: ”Senti que pude me concentrar mais na paciente e menos em escrever no computador”. Entretanto, foram identificados pontos de melhoria relacionados à curva de aprendizado inicial, refletidos nas notas menores nos quesitos de ”Facilidade de Aprendizagem”.

TABLE I
Pontuação média por componente de usabilidade

Componente Avaliado	Média	Desvio Padrão
Facilidade de Aprendizado	3,8/5,0	0,72
Eficiência de Uso	4,2/5,0	0,65
Consistência do Sistema	4,5/5,0	0,50
Satisfação Geral	4,0/5,0	0,81
Score SUS Total	**77,5**	**4,68**

C. Análise de Usabilidade

A avaliação do protótipo por meio da *System Usability Scale* (SUS) resultou em um escore médio de 77,5 pontos, situando a ferramenta na categoria “B” (Excelente) de acordo com a escala de adjetivos de Bangor [10]. Este índice supera o limiar de mercado de 68 pontos e valida a eficácia da interface na redução de erros de registro clínico.

Os itens com médias mais elevadas estiveram associados à percepção de integridade dos dados e à confiança nos cálculos obstétricos automáticos. Em contrapartida, observou-se uma curva de aprendizado inicial mais acentuada, refletida em escores moderados nos quesitos de facilidade de aprendizado e memorização. A relevância deste escore torna-se evidente ao contrastá-lo com sistemas da APS no Brasil: o aplicativo e-SUS Território apresenta um escore SUS médio de apenas 55,3 [11], enquanto o Prontuário Eletrônico do Cidadão (PEC) atingiu 60,1 [12]. Esta disparidade quantitativa posiciona o protótipo como uma solução superior em aceitação técnica frente aos sistemas governamentais vigentes.

D. Análise Crítica e Sugestões dos Usuários

Durante os testes de usabilidade, a técnica *Think Aloud* revelou que a percepção de utilidade do sistema está diretamente ligada à automação de cálculos repetitivos. Profissionais relataram que a visualização automática da curva de ganho de peso e altura uterina facilita a identificação imediata de desvios de crescimento fetal, algo que na caderneta física exige consulta a gráficos anexos e cálculos manuais.

Contudo, as sugestões coletadas apontam para a necessidade de um módulo de exportação em PDF dos registros digitais. Essa demanda reflete o cenário de transição, onde o registro digital precisa coexistir com a necessidade de a paciente portar um documento físico em casos de emergência hospitalar fora da rede integrada.

V. Discussão

Os resultados indicam que a superioridade nos índices de usabilidade não é acidental, mas sim uma consequência direta da rigidez arquitetural imposta pelo DDD e pela Arquitetura Hexagonal. Ao isolar o domínio, o sistema garantiu que o fluxo de trabalho refletisse a realidade clínica em vez de moldar o médico a uma restrição tecnológica.

Entretanto, a tensão observada entre a ”excelência global” e a ”curva de aprendizado” revela um *trade-off* de design: a aplicação rigorosa de invariantes de negócio e validações cronológicas impede a entrada de dados inconsistentes, mas exige maior esforço cognitivo inicial do usuário. Diferente do e-SUS e do PEC, que apresentam aceitação marginal devido a fluxos genéricos, este protótipo prioriza a segurança do dado sobre a simplicidade trivial, o que justifica a percepção de valor superior relatada pelos profissionais.

Sob o prisma estratégico, a Arquitetura Hexagonal resolve o problema da obsolescência tecnológica na saúde pública. A capacidade de manter o núcleo de regras obstétricas agnóstico permite que futuras integrações com a Rede Nacional de Dados em Saúde (RNDS) ou a substituição de interfaces

web por aplicações móveis ocorram sem reescrever a lógica de cuidado. Por outro lado, a dependência de infraestrutura (internet) e o escopo restrito ao ”Baixo Risco” são riscos críticos que podem limitar a adoção em larga escala em cenários de alta complexidade ou precariedade tecnológica.

Sob a perspectiva de interoperabilidade, a separação entre área clínica e infraestrutura tecnológica favorece a adoção de padrões utilizados na saúde digital, como HL7 FHIR e APIs interoperáveis compatíveis com a RNDS. Essa característica possibilita que o sistema evolua para cenários de compartilhamento de dados clínicos entre diferentes níveis assistenciais do SUS, reduzindo redundâncias de registro e dando continuidade ao cuidado materno-infantil.

Adicionalmente, a arquitetura desacoplada da solução cria condições favoráveis para integração futura com dispositivos de Internet das Coisas (IoT) voltados ao monitoramento materno-fetal. Sensores biomédicos para acompanhamento de frequência cardíaca fetal, pressão arterial materna e glicemia poderiam ser incorporados por meio de adaptadores específicos, sem necessidade de reestruturação do núcleo clínico da aplicação. Essa possibilidade torna a ferramenta proposta promissora para contextos de telemonitoramento e assistência remota em saúde digital.

Diferentemente de abordagens centradas exclusivamente na digitalização de formulários, a proposta apresentada estrutura o domínio clínico como núcleo estratégico da aplicação. Essa característica favorece sustentabilidade tecnológica de longo prazo, reduz dependências de infraestrutura específica e facilita manutenção evolutiva em ambientes públicos de saúde, tradicionalmente impactados por heterogeneidade tecnológica e descontinuidade de sistemas.

VI. Conclusão

Este trabalho apresentou o desenvolvimento e a validação de um protótipo para a digitalização da Caderneta da Gestante, abordando lacunas críticas na continuidade do cuidado pré-natal. A aplicação dos princípios da arquitetura hexagonal e DDD resultou em um artefato de software que não apenas atende aos requisitos funcionais, mas que demonstra alta manutenibilidade e extensibilidade técnica.

Conclui-se que a ferramenta possui potencial significativo para reduzir a carga cognitiva dos profissionais de saúde, automatizando cálculos e centralizando informações vitais que anteriormente estavam dispersas ou ilegíveis.

Além das vantagens operacionais observadas durante a validação de usabilidade, o sistema proposto apresenta alinhamento estratégico com as diretrizes da Estratégia de Saúde Digital para o Brasil, especialmente no que se refere à interoperabilidade, rastreabilidade de dados clínicos e continuidade assistencial. A modularidade arquitetural proposta favorece a integração futura com ecossistemas nacionais de saúde digital, como a RNDS, contribuindo para políticas públicas voltadas à qualificação da atenção pré-natal no SUS.

É importante destacar que a arquitetura proposta permite evolução incremental para cenários mais complexos, incluindo suporte *offline* em regiões com baixa conectividade e expansão do domínio clínico para acompanhamento de gestação de alto risco. Essas possibilidades reforçam a capacidade da solução de adaptação a diferentes realidades assistenciais e tecnológicas do contexto brasileiro.

Para trabalhos futuros, sugere-se:

- A implementação de estratégias *offline* com sincronização através de aplicações *mobile* ou *desktop* para garantir a operação em áreas remotas;
- A expansão do domínio para contemplar protocolos de Gestação de Alto Risco;
- A integração com a RNDS para interoperabilidade com outros sistemas do SUS.

***Abstract*—Access to microbiologically safe water may be compromised in humanitarian emergencies. This work presents SolTerm, a solar thermal system concept that may be applied to water pasteurization and that may integrate a parabolic concentrator, a copper receiver, a hydraulic circuit, control, and telemetry. The experimental stage, carried out on June 27, 2026, in Santa Rita do Sapucaí (MG), was limited to the heating of a copper absorber plate coated with graphite paint and enamel, positioned at the focal point of a 500 mm parabolic concentrator, without water circulation through a coil. The plate reached 100 °C in 10 s and 307 °C in 300 s. These values suggest preliminary heating capacity of the optical–absorber assembly, but do not represent the water temperature and do not allow validation of flow rate, residence time, valves, automatic control, or microbiological inactivation. In a separate exploratory trial, condensate formation was observed after 5 min of solar exposure; the sample was inoculated on Brain-Heart Infusion (BHI) agar and evaluated only by visual inspection, a procedure that will not demonstrate microbiological efficacy or potability. The intended future flow rate of 10 L/h remains a nominal target for a future 2 m model and will be verified experimentally. Future validation of SolTerm will take as reference Ordinance No. 888/2021 of the Cabinet of the Minister of Health (GM/MS) and must cover thermal, hydraulic, microbiological, and physicochemical aspects.**

***Index Terms*—solar pasteurization, parabolic concentrator, water treatment, humanitarian emergencies, experimental validation, public health**

I. Introduction

Access to microbiologically safe water may be compromised in humanitarian emergencies associated with floods, droughts, and other extreme events. Damage to infrastructure, interruptions in treatment and distribution, contamination of sources, and unavailability of power may increase the population's exposure to waterborne agents. Vulnerability will likely be more significant in small, decentralized, or temporary systems, in which recovery of conventional supply may require more time [1]. In this context, technologies that use solar energy may contribute to local and emergency treatment strategies, provided that their performance is demonstrated under real operating conditions.

Solar water treatment will not be considered, in this work, as a single technology. Solar water disinfection (SODIS) may jointly exploit ultraviolet radiation and the heating of water exposed to sunlight. Solar pasteurization (SOPAS) will depend predominantly on maintenance of the water at a validated combination of temperature and time. In turn, distillation and certain solar desalination processes will involve evaporation, condensation, or salt separation and will constitute routes distinct from pasteurization. Because these processes will present different mechanisms, operational variables, and performance criteria, results obtained in one of these configurations must not be used in isolation to validate another [2], [3]. Consequently, the observation of condensate in an assembly similar to a distiller will not demonstrate the pasteurization of the water that will circulate through SolTerm in the future.

Recent reviews may expand the state of the art applied to the development of the system. Chaúque, Brandão, and Rott systematized applications of SODIS, SOPAS, and hybrid systems and noted that scale-up will likely depend on collector geometry, flow regime, and water characteristics [2]. Jeon *et al.* compared different point-of-use solar technologies and indicated that target pathogen, water quality, materials, irradiance, location, and season may substantially alter performance [3]. These contributions will suggest that the maximum temperature of an absorber surface will not be sufficient to estimate, by itself, the microbiological quality or the productivity of a treatment system.

Pilot-scale studies may also guide future validation. Chaúque *et al.* evaluated continuous-flow systems that combined heating and ultraviolet radiation for the inactivation of bacteria, *Acanthamoeba* cysts, and spores [4], [5]. These results may demonstrate the potential of hybrid arrangements, but will not allow inactivation to be attributed exclusively to heating. In a predominantly thermal approach, Koninck *et al.* characterized, in an indoor environment, a passive continuous-flow pasteurization process and subsequently carried out outdoor experiments with river water [6], [7]. The use of heat recovery, gravity flow, a thermostatic valve, and thermal-

hydraulic modeling in these studies may serve as a reference for the measurement of flow rate, temperature, and residence time in SolTerm, without direct transfer of their results to the geometry proposed here.

The choice of concentrator and receiver must also be grounded in current research. The review by Paliyal and Mondal may support the use of parabolic concentrators in pathogen inactivation, desalination, and contaminant removal processes, in addition to noting future possibilities for automation, tracking, and improvement of absorber materials [8]. Sizirici, Rachid, and Eniola evaluated a passive system with copper tubes and indicated that temperature, thermosiphon circulation, contact time, and a possible germicidal effect of copper may act jointly [9]. Therefore, the presence of copper in SolTerm must not be treated as a guarantee of inactivation, and its contribution can only be analyzed through controls and quantitative microbiological comparison.

Integrated configurations may also combine complementary mechanisms. Pretorius *et al.* studied a system that brought together pasteurization, solar disinfection, and photosensitization, and considered seasonal variations in irradiance, temperature, and flow rate [10]. In the Brazilian context, Araújo *et al.* carried out field tests with a solar pasteurizer equipped with automated flow control and reported operational limitations associated with valve actuation [11]. These works may help in the specification of SolTerm's control system, but the combination of mechanisms or the use of different geometries will prevent their results from being considered a validation of the present system.

Recent literature will thus indicate that performance will likely depend on the interaction between collection area, solar concentration, heat transfer, flow rate, residence-time distribution, temperature history, initial water quality, and the organism evaluated. A distinction between absorber-surface temperature and the temperature actually experienced by each volume of water will also be necessary. A future microbiological evaluation must compare samples before and after treatment, employ replicates and controls, investigate indicators such as *Escherichia coli* and coliforms, and produce quantitative results through colony-forming units (CFU) and/or most-probable-number (MPN) counts. Visual inspection of growth on non-selective medium will be considered exploratory only and will not allow demonstration of logarithmic reduction, potability, or sanitary compliance.

Given this scenario, SolTerm will be conceived as a proposal for a decentralized solar thermal system that may integrate a parabolic concentrator, a copper receiver or coil, a hydraulic circuit, valves, sensors, microprocessor-based control, and telemetry. The objective of this work will be to present its proposed architecture, record the preliminary thermal characterization of the optical–absorber assembly, and delimit the trials that will still be necessary. The experimental stage already carried out was restricted to the heating, without hydraulic load, of a copper plate positioned at the focal point of a 500 mm concentrator; there was no circulation through the coil, flow control, valve actuation, or microbiological comparison before and after treatment. The measured results will be interpreted exclusively as preliminary evidence of plate heating, while the future effectiveness of SolTerm will depend on the thermal, hydraulic, microbiological, and physicochemical validation of the complete system.

A. Biological and Regulatory Foundations of Water Potability

1) Time–temperature relationship: Thermal inactivation may vary according to the target organism, the matrix, the temperature, the thermal history, and the intended logarithmic reduction. Da Silva, Tiba, and Calazans evaluated five time and temperature conditions for total coliforms and *Escherichia coli*, reproduced in Table I [12]. These conditions belong to the system and protocol of that study; in SolTerm, they will be treated only as a preliminary reference until a specific thermal criterion is validated.

TABLE I
TIME AND TEMPERATURE CONDITIONS EVALUATED IN THE LITERATURE. SOURCE: PREPARED BY THE AUTHORS BASED ON DA SILVA, TIBA, AND CALAZANS [12].

Temperature (°C)	Time (s)	Time (min)
55	3600	60
60	2700	45
65	1800	30
75	900	15
85	15	0.25

2) Regulatory reference: GM/MS Ordinance No. 888/2021 amends Annex XX of GM/MS Consolidation Ordinance No. 5/2017 and establishes the control and surveillance procedures and the potability standard [13]. In the future evaluation, the requirements applicable to the supply form studied will be considered, including absence of *Escherichia coli* in 100 mL, criteria for total coliforms, and relevant physicochemical parameters. Thus, visual inspection, temperature, or a single microbiological result will not be treated as a demonstration of full compliance.

The parameters of the Ordinance will be used as a reference for the validation plan. Any eventual demonstration of compliance will depend on physicochemical and microbiological tests of the complete system and on analysis of the requirements applicable to the supply and distribution strategy adopted.

II. MATERIALS AND METHODS

A. Optical subsystem

In the preliminary trial, a 500 mm parabolic antenna coated with mirror fragments of approximately $5\ \mathrm{cm} \times 5\ \mathrm{cm}$ was used. In a later stage, a 2 m model may be built to expand the collection area. The productivity of the future model must be determined experimentally and cannot be inferred directly from results obtained with other geometries or in other locations [8].

B. Thermal subsystem

In a separate thermal trial, carried out on June 27, 2026, between solar noon and 1 p.m., in Santa Rita do Sapucaí (MG), a thin copper plate coated with graphite paint and enamel was positioned at the focal point of the 500 mm parabolic concentrator. The plate temperature was recorded with a thermocouple as a function of exposure time. The initial temperature recorded was 27 °C, and the plate reached 100 °C in 10 s and 307 °C in 300 s.

This trial was carried out without water, without a coil installed, and without hydraulic load. Therefore, the recorded values correspond exclusively to the temperature of the absorber plate and do not represent the temperature of the water, the vapor, or the condensate. They also do not allow the useful power transferable to the water or the thermal efficiency of the system to be determined in isolation.

The future assembly may employ a 1/2-inch copper coil, with 22 turns and approximately 30 cm in height, combined with thermal insulation. These dimensions will remain preliminary specifications and may be changed after the hydraulic and thermal trials with circulating water.

C. Hydraulic subsystem, sensors, and control

The complete hydraulic system must include a feed reservoir, a coil, piping, flow measurement, temperature sensors at the inlet and outlet, and normally closed solenoid valves. The flow rate of 10 L/h will remain a future design target and must be verified by calibrated measurement during the trials under hydraulic load. The residence-time distribution and the period during which the water remains above the thermal criterion must also be determined experimentally [6], [7].

These components did not take part in the thermal and exploratory condensation trials described here. Consequently, water circulation through the coil, actual flow rate, inlet and outlet temperatures, and integrated valve actuation have not yet been evaluated.

D. Automation, sensing, and control

The control logic will be designed to consider temperature history and residence time, and not only an instantaneous thermal threshold, since irradiance may vary during treatment. The algorithm must stop the count when temperature falls below the defined criterion, block the outlet in the event of sensor or power failure, and record temperature, flow rate, treatment duration, and valve state.

Telemetry based on the Internet of Things (IoT) may assist operational traceability, but will not replace water-quality analysis or sanitary compliance evaluation. Automation, sensors, valves, and control logic must be tested jointly in the complete system. Recent continuous-flow and automated-control systems may guide this stage, without constituting validation of SolTerm [6], [7], [10], [11].

The preliminary parameters that will guide the development are summarized in Table II. The values classified as future targets must still be submitted to experimental validation.

TABLE II
TECHNICAL PARAMETERS AND THEIR CLASSIFICATION. SOURCE: AUTHORS (2026).

Parameter	Value/classification
Application	Solar water pasteurization: design objective
Regime	Batch or controlled flow: will be defined after trials
Prototype tested	500 mm concentrator
Future model	2 m concentrator: may be built
Intended future flow rate	10 L/h: target to be validated
Thermal range	65–70 °C: reference to be reassessed
Proposed receiver	1/2-in. copper, 22 turns, 30 cm
Future control	Arduino platform or ESP32 microcontroller, sensors, and normally closed (NC) valves
Reference standard	GM/MS Ordinance No. 888/2021; compliance to be evaluated

E. Culture Medium Preparation

Brain-Heart Infusion (BHI) agar was used as the culture medium. Petri dishes were prepared in triplicate for the experimental condition. Dehydrated BHI agar was weighed according to the manufacturer's recommendations, dispersed in distilled water, and heated under constant stirring until fully homogenized.

The culture medium and the Petri dishes, previously wrapped in surgical-grade paper envelopes, were autoclaved at 121 °C for 15 min. After sterilization, the medium was allowed to cool inside a previously sterilized laminar flow cabinet until it reached a temperature between 45 and 50 °C. Finally, the medium was poured into sterile Petri dishes and allowed to solidify, forming a uniform agar layer.

F. Sample Collection

A 10 mL volume of contaminated water was transferred to a previously cleaned porcelain crucible positioned at the focal point of the parabolic antenna. The crucible was covered with the lid of a previously sterilized Petri dish, which served as the collection surface for the condensate.

The experimental setup, using the antenna coated with mirror fragments, was subjected to solar heating for 5 min to induce water evaporation and the subsequent condensation of the resulting vapor on the inner surface of the Petri dish lid. The temperature of the water, vapor, and condensate was not measured during this experiment. The value of 307 °C at 300 s refers exclusively to the separate dry-plate thermal experiment described in Subsection B and must not be reported as the condensation or sample temperature.

After the exposure period, the condensate formed on the inner surface of the lid was collected using sterile swabs; these were rubbed across the entire surface containing the condensate for microbiological evaluation purposes. Subsequently, the swabs were used to inoculate plates containing BHI agar using the spread-plate technique. The plates were incubated in a bacteriological incubator at 35 °C for 48 h. Following the incubation period, the plates underwent microbiological

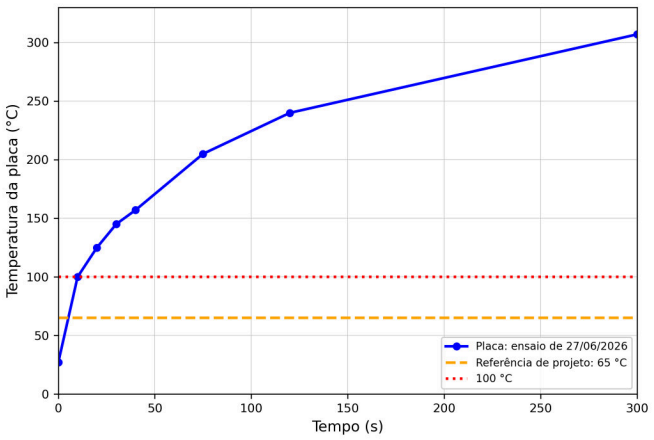

Fig. 1. Experimental temperature curve of the absorber plate. The values do not represent the water temperature. Source: authors (2026).

evaluation based on a visual analysis of the presence or absence of microbial growth.

This procedure was exploratory: no colony-forming-unit (UFC) or most-probable-number (NMP) counts, identification of *E. coli* or coliforms, before-and-after comparison, or positive and negative controls were performed. Therefore, the observation must not be interpreted as evidence of microbial reduction, potability, or validation of the SolTerm system.

III. Results

A. Experimental data

The time and temperature values recorded in the trial are presented in Table III.

The evolution of plate temperature throughout the trial is represented in Figure **??**.

The plate reached 100 °C in 10 s and 307 °C in 300 s. These values suggest that the concentrator–plate assembly may provide relevant heating, but do not represent a water temperature. Without an energy balance and a trial under load, it will not be possible to estimate the useful power transferred to the water, the thermal efficiency, the treatable flow rate, or the residence time.

The apparent average rate was higher at the start and decreased throughout the trial. This behavior may be related to the increase in thermal losses at higher temperatures. However, since there was no measurement of irradiance, repetitions, instrumental uncertainty estimation, or loss balance, no quantitative model will be fitted from this isolated series.

TABLE III
Absorber plate temperature versus exposure time. Source: authors (2026).

Time (s)	Temperature (°C)	Measured quantity
0	27	Absorber plate
10	100	Absorber plate
20	125	Absorber plate
30	145	Absorber plate
40	157	Absorber plate
75	205	Absorber plate
120	240	Absorber plate
300	307	Absorber plate

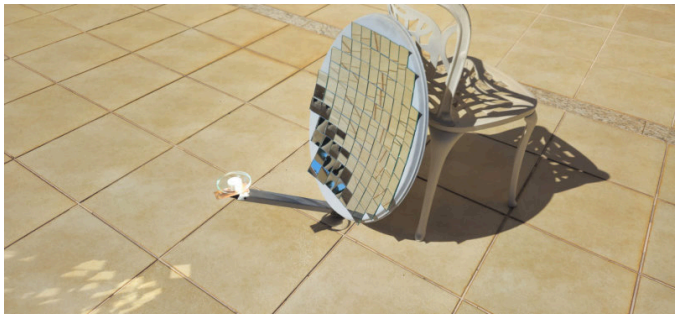

Fig. 2. Assembly of the exploratory condensation trial, with the 500 mm parabolic concentrator and the collection set positioned in the focal region. Source: authors (2026).

B. Exploratory observation of condensate

In the exploratory trial described in Subsection II-F, condensate formation was observed after 5 min of solar concentration. The temperature of the water, the vapor, and the condensate was not measured. The value of 307 °C at 300 s belongs to the separate, water-free trial of the copper plate. The assembly and the sample obtained are presented, respectively, in Figures **??** and **??**. Only visual inspection was performed, without CFU or MPN counts, without identification of *E. coli*/coliforms, without before/after comparison, and without positive and negative controls.

In the visual inspection of the plates prepared in triplicate, no macroscopic changes were observed. This observation will not be treated as a microbiological result: it does not demonstrate logarithmic reduction, does not evaluate water that has passed through the SolTerm coil, and will not support any conclusion about potability or regulatory compliance.

C. Discussion

1) Measured results and projected performance: Only the exposure time and the temperature of the copper plate at the focal point of the 500 mm concentrator were measured. The heating observed suggests that the optical–absorber arrangement may reach elevated temperatures, but will not allow prediction of behavior under hydraulic load. The observation of condensate will be considered only an exploratory record of an assembly similar to a distiller, and not a trial of the SolTerm system.

The intended future flow rate of 10 L/h, the 65–70 °C range, the coil geometry, valve control, and telemetry will remain design parameters or functions. In systems distinct from SolTerm, Koninck *et al.* evaluated thermal characterization and bacterial inactivation in continuous flow, in an indoor environment, and subsequently carried out outdoor trials with river water [6], [7]. Chaúque *et al.* also studied hybrid continuous systems, in which heating and ultraviolet

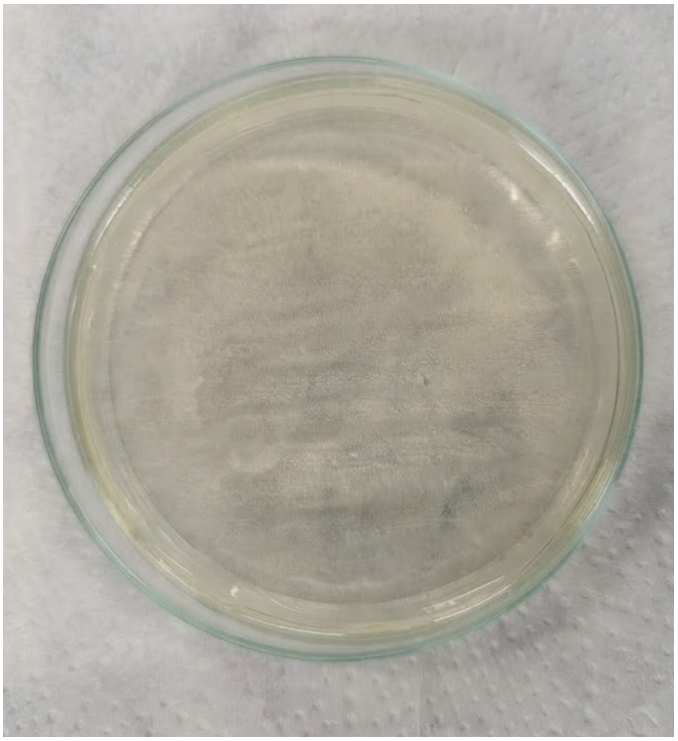

Fig. 3. Condensate sample after 48 h of incubation at 35 °C. Visual inspection does not constitute quantitative microbiological analysis. Source: authors (2026).

radiation acted jointly [4], [5]. Consequently, the productivity and effectiveness of SolTerm must be measured with water and will not be inferred from the no-load plate temperature nor transferred directly from other geometries.

2) Limitations of the study: The current experimental stage did not evaluate: water circulation; actual flow rate; inlet and outlet temperatures; residence-time distribution; period above the thermal criterion; joint valve actuation; performance under hydraulic load; useful thermal efficiency; capacity to reach the future target of 10 L/h; quantitative microbiological reduction; physicochemical parameters; repeatability; measurement uncertainty; or variability with irradiance, wind, and cloud cover.

IV. Conclusion

The preliminary trial was limited to the heating, without hydraulic load, of a copper absorber plate coated with graphite and enamel at the focal point of the 500 mm parabolic concentrator. The plate started at 27 °C, reached 100 °C in 10 s, and reached 307 °C in 300 s. These data may suggest thermal potential for the continuity of development, but must not be interpreted as validation of water pasteurization.

With the current trial, it will not be possible to conclude what temperature the water will reach, what flow rate can be treated, what the residence time will be, how the valves will act, or what microbiological reduction will be obtained. These conclusions will depend on future thermal, hydraulic, and microbiological trials of the complete system.

V. Future Work

Validation of the complete system will be carried out with water, since the current results describe only the heating of the copper plate: 100 °C in 10 s and 307 °C in 300 s, without water circulation through the coil, without valve control, and without evaluation of actual residence time. The next stage must include:

1) the coil, valves, sensors, and control logic will be installed and characterized;
2) the proposed flow rates, including the future target of 10 L/h, will be tested, with calibrated measurement of actual flow rate and of inlet and outlet temperatures;
3) residence time and the period during which each volume of water will remain above the thermal threshold to be validated will be determined;
4) different flow rates will be compared, with repetitions, irradiance measurement, and uncertainty estimation;
5) the preliminary condensate trial will be replaced by microbiological analysis before and after treatment in the complete system, with raw water and water treated by SolTerm;
6) *E. coli* and coliforms will be evaluated by CFU and/or MPN, according to the method selected, with positive controls, negative controls, and replicates; and
7) the applicable physicochemical parameters and the risk of recontamination after treatment will be evaluated.

Acknowledgments

The authors thank the National Institute of Telecommunications (Inatel), the 45th Inatel Technology Fair (FETIN), and Technician Luiz Fernando (Technician in Electrical and Industrial Automation) for the review of the control architecture and for the identification of the limitations of programmable logic controllers (PLCs) and human-machine interfaces (HMIs) in outdoor environments.

***Abstract*—Myocardial revascularization (MR) is the main revascularization strategy for patients with advanced coronary artery disease, and medium-term survival analysis is essential to assess the clinical impact of the procedure. This study aimed to evaluate overall survival for up to one year and identify independent predictors of mortality in patients undergoing MR with and without cardiopulmonary bypass (CPB). This is a single-center retrospective cohort of 104 patients operated on at Hospital Santa Casa de Misericórdia de Curitiba, with data obtained from electronic medical records. Survival was estimated using the Kaplan-Meier method (Log-rank test), and independent predictors were identified using a parsimonious Cox proportional hazards model restricted to three clinical covariates (smoking, systemic arterial hypertension, and type of surgery) with Ridge regularization (penalty factor = 0.025) to mitigate the risk of overfitting resulting from the low number of events (20 deaths). Indication bias between the surgical techniques was controlled using the Inverse Probability of Treatment Weighting (IPTW) method. Smoking was the main independent predictor (HR = 2.320; 95% CI: 1.009–5.338; p = 0.048). Systemic arterial hypertension (HR = 2.155; 95% CI: 0.394–11.781; p = 0.376) and type of surgery (without CPB vs. with CPB: HR = 0.431; 95% CI: 0.125–1.493; p = 0.184) did not show a statistically significant association in the multivariable model. The model showed an apparent C-index of 0.652, which increased to 0.796 when corrected by internal bootstrap (200 iterations), with an AIC of 180.40 and an IBS of 0.2113. These findings indicate that smoking is an independent predictor of mortality in this cohort, whereas the use of CPB did not demonstrate a statistically significant impact on survival within the observed follow-up period of approximately one year, reinforcing the central role of patient risk factors in prognostic stratification.**

***Index Terms*—Myocardial revascularization; Survival analysis; Cox proportional hazards model; Smoking; Cardiopulmonary bypass.**

I. Introduction

Cardiovascular diseases continue to be the leading cause of morbidity and mortality worldwide and in Brazil, with coronary artery disease (CAD) occupying a prominent position in this epidemiological scenario [1], [2]. Population aging and the high prevalence of modifiable risk factors smoking, systemic arterial hypertension, diabetes, and dyslipidemia sustain the high incidence of CAD and its complications, making myocardial revascularization a procedure of major clinical and public health relevance [1], [3].

Myocardial revascularization surgery (MR) is indicated for patients with significant coronary obstruction, with the aim of restoring myocardial perfusion, reducing ischemic events, and prolonging survival. The procedure may be performed with cardiopulmonary bypass (CPB) or without CPB (off-pump), and the comparison between these techniques regarding medium-term outcomes is a subject of intense debate in the literature [6], [7]. Meta-analyses and follow-up studies, including elderly and higher-risk populations, have demonstrated comparable survival between both approaches, suggesting that prognosis is predominantly determined by the patient's risk profile [8]–[12].

The assessment of survival after MR, however, requires methodological rigor. Survival analysis using the Kaplan-Meier estimator and Cox proportional hazards modeling [5] makes it possible to quantify not only the probability of survival over time, but also the independent effect of clinical, demographic, and surgical covariates on the risk of death. Predictive models for post-MR mortality have been proposed in different contexts, incorporating variables such as age, ventricular function, and comorbidities [4], [13]–[15], and factors such as cardiorespiratory fitness and sex have also been associated with medium-term outcomes [16]–[18].

Despite these advances, important gaps remain, particularly the scarcity of data representative of the Brazilian population, whose epidemiological profile and access to health services differ substantially from those of the countries from which most of the evidence originates [3]. In this context, the application of computational tools dedicated to survival analysis [20] to a local cohort contributes to characterizing the prognosis of these patients and identifying modifiable targets for intervention.

Additionally, the scientific novelty of this work lies in

the application of a robust survival analysis study (incorporating IPTW weighting to control indication bias, Ridge regularization to control overfitting due to the low number of events, and rigorous internal validation by bootstrap) in a local Brazilian cohort from the public health system, demonstrating the methodological feasibility of this approach in secondary hospital databases with restricted sample size and number of events. In view of the above, this study aimed to evaluate the impact of clinical, demographic, and surgical factors on the overall survival of patients undergoing myocardial revascularization, identifying independent risk predictors through Cox regression modeling.

II. Methods

A. Study Design, Setting, and Population

This is a retrospective cohort study with a quantitative approach, conducted with data from adult patients (age $\geq$ 18 years) who underwent myocardial revascularization surgery at Hospital Santa Casa de Misericórdia de Curitiba (PR), Brazil. The sample comprised 104 patients with complete electronic medical records containing the clinical information necessary for survival analysis. Patients undergoing elective, urgent, or emergency procedures were included regardless of sex or the presence of comorbidities; those whose medical records did not allow reliable retrieval of the variables of interest or follow-up time were excluded.

The study protocol was approved by the Research Ethics Committee (REC), opinion no. 8.649.194/CAAE: 97691226.5.0000.0177, in accordance with Resolution no. 466/2012 of the National Health Council and the Declaration of Helsinki. As this study involved the analysis of secondary data, the REC waived the requirement for a free and informed consent form, ensuring strict confidentiality, patient anonymization, and data protection in accordance with the General Data Protection Law (LGPD - Law no. 13.709/2018).

Patients who underwent myocardial revascularization surgery during the period from 05/2025 to 05/2026 were evaluated. The data were analyzed according to the following variables: whether the patient was a smoker or not, whether the patient had been diagnosed with SAH, and which type of surgery was performed.

B. Data Collection, Variables, and Outcome

Clinical, demographic, and surgical data were collected retrospectively from the institutional electronic medical record system (TASY) in anonymized form. The covariates initially considered in the univariable modeling were: age (continuous), sex, smoking status, alcohol use, systemic arterial hypertension (SAH), number of affected coronary vessels, preoperative left ventricular ejection fraction (preoperative LVEF %), and type of surgery according to the use of cardiopulmonary bypass (with or without CPB). The outcome of interest was death from any cause, and survival time was defined as the interval, in days, between the date of surgery and the occurrence of the event or the last available follow-up information (censored observations), covering the observed follow-up period of the cohort.

C. Statistical Analysis

Continuous variables were described using measures of central tendency and dispersion, while categorical variables were expressed as absolute frequencies and percentages. The crude comparison of overall survival rates between groups was performed using the Kaplan-Meier estimator, and statistical differences between the curves were assessed using the Log-rank test.

To assess the independent effect of covariates on survival, the Cox proportional hazards model was used. In order to ensure the mathematical stability of the model given the number of available outcomes (20 events) and to respect the principle of parsimony, the final multivariable model was restricted to three clinically relevant covariates (Smoking, Systemic Arterial Hypertension, and Type of Surgery). This selection resulted in an Events per Variable (EPV) ratio of 6.67. As the EPV was slightly below the traditional threshold of 10, Ridge regularization was adopted as a strategy to mitigate the risk of overfitting. The penalty (with a penalizer factor of 0.025) was applied to promote coefficient shrinkage, ensuring greater stability and precision in the estimates of Hazard Ratios (HR - Hazard Ratios).

Considering the observational nature of the study and the possible baseline differences between the compared groups (with and without cardiopulmonary bypass), a causal inference approach using Inverse Probability of Treatment Weighting (IPTW - Inverse Probability of Treatment Weighting) was implemented. Covariate balance between treatment and control groups was assessed using the Standardized Mean Difference (SMD), and was considered adequate after weighting. The final IPTW-adjusted Cox model reported Hazard Ratios using robust standard errors to correct the variance introduced by the weights.

Due to the absence of an external validation cohort and the impossibility of calculating pre-existing clinical scores (such as EuroSCORE II and STS Score) because of limitations in the original database, the generalizability of the model was rigorously subjected to internal validation techniques. Discriminatory power was quantified by the concordance index (C-index). To correct for the optimism inherent in apparent performance in the training sample, internal Bootstrap resampling (200 iterations) was applied, obtaining the corrected C-index (Harrell method), which provided a more realistic estimate of the predictive ability of the model. Additionally, k-fold cross-validation (with 5 partitions) was performed and the overall accuracy of the model was measured using the Integrated Brier Score (IBS).

The proportional hazards assumption intrinsic to the Cox model was statistically verified through the analysis of Schoenfeld residuals, confirming fulfillment of the assumption for all included covariates ($p < 0.05$). The absence of severe multicollinearity was attested by the Variance Inflation Factor ($<$VIF), with all values remaining below 2. This verification

ensured that variance was not inflated, also respecting the stability thresholds of the adjusted GVIF (Adjusted Generalized Variance-Inflation Factor), which is the most robust metric for avoiding overestimation of penalties in strictly categorical variables. Finally, an exploratory subgroup analysis was performed to assess whether the prognostic impact remained consistent across different clinical profiles (SAH and Surgery strata). Effect modification was formally tested by the statistical significance (p-interaction) of the interaction terms between the main exposure and baseline characteristics.

All analyses were performed using the Statistical Software for Survival Analysis (Version 1.0) [20]. Statistical tests were two-tailed, with a significance level of $\alpha = 0.05$ for inferential conclusions.

III. Results

The general clinical and epidemiological profile of the 104 patients evaluated is detailed in Table I. The sample had a mean age of 63.9 $\pm$ 8.5 years, with a predominance of males (71.2%). Regarding baseline comorbidities and lifestyle habits, systemic arterial hypertension was the most prevalent risk factor (90.4%), followed by smoking (35.6%) and alcohol use (12.5%). From an anatomical and functional perspective, coronary involvement was predominantly multivessel, with a mean of 2.8 $\pm$ 0.6 diseased vessels (median 3.0), associated with a mean preoperative left ventricular ejection fraction (LVEF) of 49.4 $\pm$ 17.0%. Regarding the procedure, 79.8% of the interventions were MR with CPB (conventional myocardial revascularization with cardiopulmonary bypass), whereas 20.2% were without CPB (off-pump). During a mean follow-up of 382.7 $\pm$ 173.8 days, a mortality rate of 19.2% was recorded in the sample.

The initial comparison of survival time suggested a statistically significant difference between the crude survival curves of the groups analyzed (p = 0.0432 in the Log-rank test). In practical terms, this indicates that, even before considering other clinical factors, the time to the occurrence of the outcome differed clearly and non-randomly among the patients in the study.

The Kaplan-Meier curve (Figure 1.) was strictly stratified by smoking status (smokers vs. non-smokers), and the significant difference observed (p = 0.0432) refers to this behavioral stratification, and not to the surgical technique.

To understand how multiple clinical variables jointly influence prognosis, a Cox proportional hazards model containing three main covariates was structured: Smoking, Systemic Arterial Hypertension (SAH), and type of Surgery. The model maintained an acceptable ratio of 6.67 events per variable and employed a Ridge regularization technique (penalizer = 0.025) to avoid overfitting, ensuring greater reliability of the findings.

The multivariable analysis (Table II) revealed that Smoking is an independent risk predictor (Hazard Ratio [HR] = 2.320; 95% CI: 1.009–5.338; p = 0.048). From a clinical perspective, a Hazard Ratio (HR) greater than 1 means an increased risk. In this case, individuals with a history of smoking had more than twice the risk of experiencing the event over the period studied, compared with non-smokers, while the other factors remained unchanged.

Table I
Clinical and Demographic Characteristics and Outcomes of Patients Undergoing Myocardial Revascularization Surgery (N = 104), Curitiba, 2025.

Variable	Category / Measure	Result
Age (years)	Mean $\pm$ SD	63.9 $\pm$ 8.5
	Median (IQR)	64.0 (58.8–70.0)
No. of diseased vessels	Mean $\pm$ SD	2.8 $\pm$ 0.6
	Median (IQR)	3.0 (3.0–3.0)
Pre-op. LVEF (%)	Mean $\pm$ SD	49.4 $\pm$ 17.0
	Median (IQR)	54.5 (42.4–61.1)
Follow-up (days)	Mean $\pm$ SD	382.7 $\pm$ 173.8
	Median (IQR)	436.5 (384.2–491.8)
Sex	Male	74 (71.2%)
	Female	30 (28.8%)
SAH	No	10 (9.6%)
	Yes	94 (90.4%)
Smoking	No	67 (64.4%)
	Yes	37 (35.6%)
Alcohol use	No	91 (87.5%)
	Yes	13 (12.5%)
Type of surgery	MR with CPB	83 (79.8%)
	MR without CPB	21 (20.2%)
Death	No	84 (80.8%)
	Yes	20 (19.2%)

SD: standard deviation; IQR: interquartile range (25–75%); LVEF: left ventricular ejection fraction; SAH: systemic arterial hypertension; MR: myocardial revascularization; CPB: cardiopulmonary bypass.

Table II
Univariable and Multivariable Hazard Ratios (HR) by the Cox Model of Patients Undergoing Myocardial Revascularization (N = 104), CURITIBA, 2025.

		Univariable		Multivariable	
Variable	**Cat.**	**HR (95% CI)**	**p**	**HR (95% CI)**	**p**

Note: Multivariable model adjusted with Ridge regularization (penalizer = 0.025). EPV: 6.67. SAH: Systemic Arterial Hypertension

As shown in Table I, among the surgeries evaluated, 79.8% were performed with cardiopulmonary bypass (with CPB) and 20.2% occurred without it (without CPB). This distribution is highly consistent with the national literature; for example, a broad review conducted by Ortolan et al. [21], encompassing data from more than 2.1 million procedures in Brazil, indicated that approximately 73.3% of myocardial revascularization surgeries are performed with CPB support, whereas 26.7% use the technique without CPB. Therefore, although there is a sample imbalance that imposes statistical limitations regarding

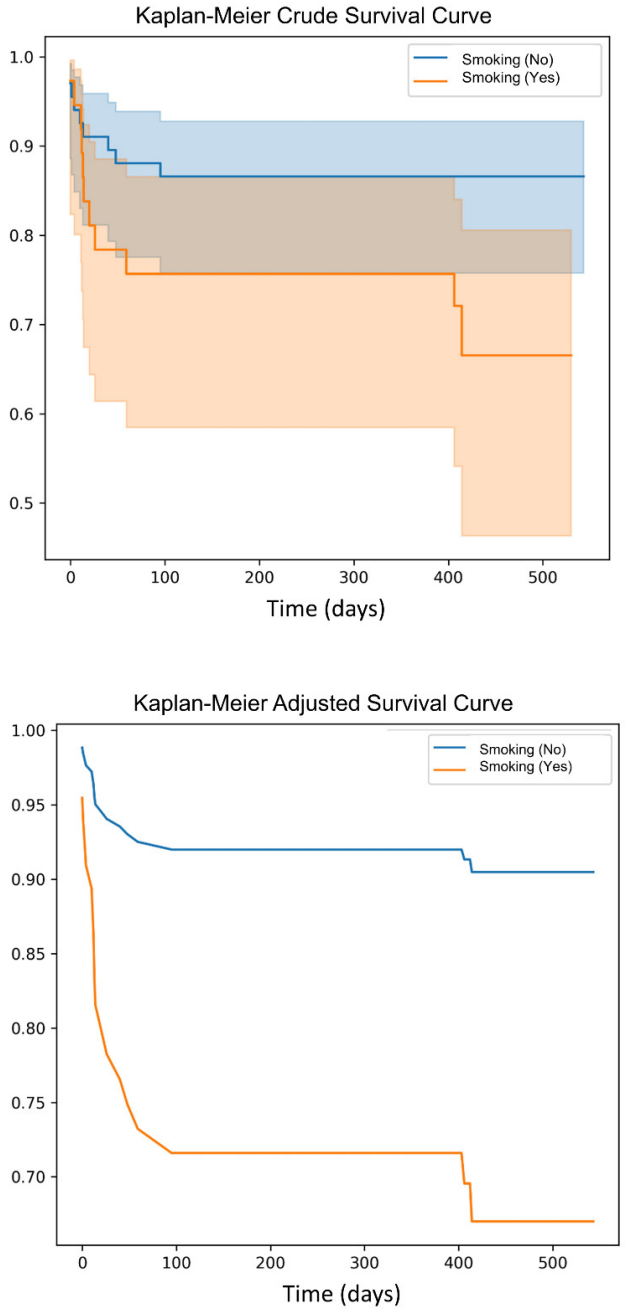

Figure 1. Overall survival curves estimated using the Kaplan-Meier method (Crude and Adjusted), stratified by smoking status (Log-rank test: p = 0.0432).

direct comparisons between the surgical methods, the analysis performed robustly supports future studies in the Brazilian context.

Due to the nature of the study and the possible prior differences between patients operated on with and without cardiopulmonary bypass, Inverse Probability of Treatment Weighting (IPTW) was applied. This technique works as a mathematical 'balance' that corrects imbalances in the groups, simulating a scenario similar to a randomized clinical trial. Covariate balancing was successful, reducing the Standardized Mean Difference (SMD) to values close to zero (SAH from -0.062 to 0.004; Surgery from 0.158 to -0.002). After this rigorous bias correction, the negative impact of smoking remained robust and significant, with an adjusted HR of 2.330 (95% CI: 1.058 – 5.131; p = 0.036). This confirms that the effect found is not caused by baseline differences between the groups.

Seeking to verify whether the risk associated with smoking varied depending on the patient's profile, a subgroup analysis was conducted. In the subgroup of patients with SAH (n=94), the risk remained high and significant (HR = 2.809; 95% CI: 1.126–7.006; p = 0.027). The statistical interaction did not demonstrate significant effect modification between the SAH strata (p-interaction = 0.317) and Surgery (p-interaction = 0.550), suggesting that smoking acts as a consistent risk factor regardless of the clinical profile evaluated.

The mathematical stability of the analysis was confirmed by the absence of multicollinearity (all variance inflation factors [VIF] < 1.65) and by fulfillment of the Schoenfeld proportional hazards assumption ($p > 0.05$ for all variables). The predictive capacity of the model was assessed using the Concordance Index (C-index), which functions in a manner similar to accuracy. After rigorous internal resampling (Bootstrap with 200 repetitions), which corrects the initial 'optimism' of the model, the C-index corrected by the Harrell method reached 0.796. This value suggests that the model has a good ability to discriminate which patients will experience the event first, strengthening the generalizability of the results obtained. The overall accuracy of the model, assessed by the Integrated Brier Score (IBS), ended with a rate of 0.2113.

IV. Discussion

The present study provided an overview of the medium-term postoperative period of patients undergoing Myocardial Revascularization because it was conducted in a cardiology referral hospital in the city of Curitiba. The high prevalence of cardiovascular risk factors in the present sample, with 90.4% systemic arterial hypertension (SAH) and 35.6% smoking, accurately reflects the epidemiological profile of surgical patients in Brazil. This scenario is corroborated by the study by Wagner et al. [22] in a philanthropic cardiology hospital, where an almost identical rate of 91.89% SAH and 37.84% smoking was observed among those undergoing myocardial revascularization, consolidating the national representativeness of our local cohort.

In this retrospective cohort of patients undergoing MR, smoking emerged as the most robust independent predictor of mortality. The multivariable analysis (Table II) revealed that Smoking is an independent risk predictor (Hazard Ratio [HR] = 2.320; 95% CI: 1.009–5.338; p = 0.048). When using SMD, it was also observed that this predictor has a negative impact, with an adjusted HR of 2.330 (95% CI: 1.058 - 5.131; p = 0.036). Thus, using two hazard ratio analysis models, it was observed that the values were close, demonstrating that smoking is an independent risk factor even after adjustment for other relevant clinical variables.

The identification of smoking as the main independent predictor of medium-term mortality (HR = 2.320) finds strong clinical support in the findings of Pietrobon and Barbisan [23]. The authors emphasize that patients who continue smoking in the peri- and postoperative period have significantly higher rates of death and new acute coronary events than those who stop the habit, which justifies the magnitude of the risk observed in our Ridge-stabilized model. This finding is consistent with the central role of smoking as a modifiable cardiovascular risk factor [1], [2] and with the literature identifying smoking among the determinants of mortality after MR. Chua et al. [4] demonstrated, in a medium-term follow-up study after isolated MR, that smoking remains among the main independent predictors of mortality, with a magnitude comparable to the results found in this cohort. The clinical relevance is direct: it reinforces smoking cessation as a priority therapeutic target in perioperative management and in the medium-term follow-up of these patients.

In the univariable analysis, the age variable did not show a statistically significant association with the outcome (HR = 1.041; p = 0.149). Aiming to build a more parsimonious and statistically stable final model, it was decided to limit the multivariable adjustment to only three predictor variables. This restriction was essential to mitigate the risk of overfitting.

A particularly relevant result was the absence of an independent association between the type of surgery (with or without CPB) and survival. This finding aligns with a consistent body of evidence that does not demonstrate superiority of one technique over the other in terms of medium-term survival: the ten-year follow-up of MASS III found no difference between with and without CPB [6]; similar results were observed in left main coronary artery disease [7], in meta-analyses of elderly patients [8], [10], in patients with COPD [11], and in propensity score-matched comparisons with total arterial revascularization [12]. Taken together, these data support the notion that the decision to use CPB should be guided by technical characteristics and the patient's profile, and not by the expectation of a survival benefit.

The implementation of IPTW weighting techniques made it possible to control indication confounding in this retrospective observational sample, balancing the groups with and without CPB (SMD close to zero). The fact that the prognostic impact of smoking remained significant in the weighted model (HR = 2.330, p = 0.036) strengthens the internal validity of the study. In addition, internal validation using 200 Bootstrap iterations (corrected C-index of 0.796) provides a reliable and realistic estimate of the discriminatory power of the local model, surpassing the simplified assessment by the apparent C-index.

It should also be noted that validated clinical scores, such as EuroSCORE II or the STS Score, could not be calculated for comparison due to the scarcity of specific parameters during the collection of data available in the medical records (for example, serum creatinine, NYHA functional class, and history of previous surgeries). This may help justify the need to develop simplified prognostic models focused on the local reality, especially given the absence of complex variables for calculating the aforementioned scores, as supported by the classic epidemiological study by Almeida et al. [24], in which the authors highlight that predictors of mortality in Brazilian cohorts treated by the Unified Health System (SUS) depend on very particular baseline and structural characteristics, reinforcing the incremental value and practical utility of our localized statistical framework, which achieved excellent discriminatory capacity (corrected C-index of 0.796).

This study has limitations related to the assessment of medication, postoperative complications, and socioeconomic data. The retrospective design and the small absolute number of all-cause events (20 deaths) limit the precision of the estimates, as evidenced by the wider confidence intervals. In addition, the marked sample imbalance between the surgical groups (83 vs. 21) reduces statistical power to detect small differences between the revascularization techniques, recommending caution when interpreting the absence of statistical significance as definitive equivalence. In the future, analyses considering these data will be performed and a multicenter study may be conducted with an expanded sample and evaluation of survival time.

V. Conclusion

The present study demonstrated that the medium-term prognosis after myocardial revascularization surgery (MR), in this specific cohort of patients treated at a referral hospital for cardiology care, is predominantly governed by the individual's behavioral risk profile (smoking status) rather than by the surgical technique adopted (with or without cardiopulmonary bypass). Cox proportional hazards modeling with Ridge regularization identified active smoking or recent cessation as the only significant independent predictor of mortality during approximately one year of follow-up, being associated with a significantly elevated risk of death. Internally validated by bootstrap resampling (C-index of 0.796), this framework demonstrates that the absence of cardiopulmonary bypass does not compromise medium-term survival, so technical selection should be individualized based on coronary anatomy. Additionally, this work mitigates the scarcity of representative data in the Brazilian cardiac surgery literature and establishes a robust methodological reference for the analysis of localized hospital databases.

As a suggestion for future studies, increasing the sample size through prospective and multicenter validation of the proposed model is recommended, which will also allow the temporal horizon of survival follow-up to be extended. Second, the inclusion of other predictor variables in the model is suggested, incorporating clinical data of major prognostic relevance that were not available in this secondary cohort. This expansion should encompass the post-discharge therapeutic profile, specific perioperative complications (such as stroke and acute kidney injury), specific causes of death, socioeconomic data, and the incremental role of contemporary cardiac biomarkers, optimizing clinical decision-making algorithms in the national setting.

ACKNOWLEDGMENTS

The authors express their gratitude to Hospital Santa Casa de Curitiba, particularly the Cardiac Surgery team and the institution's research center, for their collaboration and support throughout this study.

Abstract: This article presents the development and application of a structured form for the technical evaluation of samples in public procurement processes for medical devices, using as a case study the evaluation of a portable fundus camera within a tender process conducted by the Brazilian Agency for Support to the Management of the Unified Health System (AgSUS). The instrument was drawn up on the basis of the technical requirements set out in the Terms of Reference and structured into eliminatory criteria, linked to the mandatory requirements of the contract, and informative criteria intended for recording the operational aspects observed during the practical demonstration. The application of the form made it possible to document non-conformities related to the connectivity requirements set out in the tender documents, as well as to record complementary information on usability, image capture and the operational performance of the equipment evaluated. The analysis highlighted the importance of complementary mechanisms of practical verification for assessing characteristics that cannot always be fully ascertained solely by means of the documentation submitted by suppliers. The results indicate that the instrument contributed to organizing the record of the evidence produced during the demonstration, favouring the traceability of the evaluation process and the substantiation of the technical decision. The experience described suggests that structured approaches of this nature may support health technology assessment processes that require practical analysis complementary to documentary evaluation.

Keywords: HTA; Medical Devices; Technical conformity analysis; Portable fundus camera; Public procurement..

I. INTRODUCTION

The incorporation of medical equipment into the health system requires evaluation processes capable of ensuring that the equipment acquired presents performance compatible with its clinical purpose, operational safety and conformity with the technical requirements established in the tender documents [1], [2]. Especially in the evaluation of equipment that incorporates digital resources, such as diagnostic systems, embedded software and data transmission functionalities, exclusively documentary analysis proves insufficient. In order to ensure the adequate functional validation of the technology offered, the adoption of practical evaluation mechanisms, such as proofs of concept and sample approval procedures, is recommended [3].

In Brazil, the public procurement of medical and hospital equipment traditionally takes into consideration the technical specifications declared by the manufacturers, the regulatory documentation and the sanitary registration issued by the National Health Surveillance Agency. However, part of this information is self-declared in nature, which may limit the capacity for objective analysis of the performance of the equipment under real conditions of use. Although certification carried out by metrological bodies ensures conformity with specific regulatory requirements, it does not necessarily cover in full the operational, clinical and functional aspects that are relevant to the reality of the end user [1], [2], [3].

In addition, it is observed that health technology procurement processes, especially those involving medical and hospital equipment, do not always benefit from the direct participation of professionals with specialized technical knowledge in clinical engineering and/or biomedical engineering [4], [5], [6]. The absence of such technical support may hinder the critical analysis of the specifications presented by manufacturers, increasing dependence on documentation and the risk of incorporating technologies that, although formally compliant, present operational limitations not identified during the judgement phase [3], [7], [8].

In this scenario, the practical evaluation of samples emerges as a tool complementary to documentary analysis, making it possible to observe functional, operational and usability characteristics under conditions of use that cannot

always be fully verified by means of the documentation submitted by the manufacturers. Aspects such as ease of operation, suitability to the workflow, operational stability and performance observed during the use of the equipment may provide additional information to support the technical analysis of health technologies [9], [10], [11].

The present work presents the development of a structured form for technical analysis and the methodology employed for the practical on-site evaluation of equipment submitted to a public procurement process, using as a case study the acquisition of portable fundus cameras. The objective is to describe the structure of the instrument, its application in the evaluation of the sample and its use in systematizing the evidence that supported the technical analysis carried out by the evaluation committee, contributing to greater organization, traceability and transparency of the evaluation process.

II. CASE STUDY

A. Context

The case study presented in this work was developed within the scope of Public Notice No. 5/2026, Electronic Reverse Auction (Price Registration System) No. 5/2026, Process No. AGSUS.001686/2026-01, intended for the price registration for the future and eventual acquisition of portable fundus cameras, expanding Telehealth actions for the Primary Health Care Network, conducted by the Brazilian Agency for Support to the Management of the SUS (UASG: 932133).

Telehealth has been highlighted as a strategic tool for the consolidation of the SUS. Through the use of Digital Information and Communication Technologies (DICT) to expand access to medical care and decentralize health services, Telehealth has managed to connect remote regions to information and support networks, thereby optimizing the efficiency of public care by reducing unnecessary travel and the waiting time of SUS patients and users [12].

The technical evaluation of the sample involved professionals affiliated with AgSUS, the Ministry of Health and the Federal University of Goiás, working in the technical, clinical and information technology areas. This composition was used to record different aspects of the practical demonstration and to support the preparation of the opinion of the Joint Technical Committee.

The tender documents of the said procedure provided for the possibility of submitting samples for technical analysis during the judgement of the bids, expressly establishing the possibility of a practical evaluation of the equipment offered. In accordance with the judgement rules of the procedure, the sample analysis stage is carried out only for the bid summoned during the regular evaluation flow. Accordingly, the present study focused on the analysis of the solution actually submitted to practical demonstration, with no comparative evaluation between different pieces of equipment.

The provision for sample analysis in the tender documents constitutes a relevant complementary mechanism for the technical validation of medical devices, especially in procurement processes for technologies whose verification cannot be fully ascertained solely by means of the technical documentation submitted by the suppliers.

However, it was observed that, although the tender documents provided for the possibility of evaluating samples, there was no prior definition of a structured form or standardized methodology to guide the technical analysis of the equipment submitted for evaluation.

The criteria capable of producing effects on the approval or rejection of the sample were limited to the requirements previously established in Public Notice No. 5/2026 and in the respective Terms of Reference. The process was conducted in accordance with the AgSUS Procurement and Contracting Regulations and with the other rules expressly set out in the tender documents.

Although the process analysed was conducted within the scope of the institutional regulations of AgSUS, the literature on public procurement has emphasized the importance of mechanisms capable of complementing documentary analysis in the evaluation of goods and technologies, especially when certain characteristics of the object cannot be fully verified solely on the basis of the documentation submitted by the suppliers [3].

In this context, the evaluation of the sample constituted a complementary mechanism for verifying the adherence of the solution offered to the technical requirements established for the contract. In the case analysed, its use made it possible to complement the documentary analysis through practical observation of the functional, operational and connectivity characteristics of the equipment, contributing to the technical substantiation of the decision adopted in the evaluation process.

B. Motivation for developing the protocol

In the process analysed, the judgement criterion adopted was the lowest price, conditional upon compliance with the technical specifications and the other requirements established in the tender documents. Under this model, the technical evaluation aimed to verify the conformity of the product offered with the previously defined requirements, rather than to compare or assign relative scores to different technological solutions.

During the initial phase of the analysis of the bids, it was found that the technical documentation submitted by the ranked supplier formally met all the technical specifications required in the tender documents, including the functional characteristics of the equipment, the regulatory documentation and the sanitary registration issued by the National Health Surveillance Agency. From an exclusively documentary perspective, no nonconformities were identified that would justify the technical disqualification of the bid.

However, the technical analysis carried out by the joint technical committee identified the need for complementary validation of the device, considering that the equipment evaluated was a technology recently introduced into the Brazilian market, still without a consolidated history of use in care settings.

In addition, it was found that the equipment did not yet present consolidated evidence of operational validation in telehealth environments, particularly with regard to the transmission of information to the systems of the National Telehealth Network for tele-diagnosis based on the examinations performed. This condition introduces a level of technical uncertainty regarding the functional performance of the device under real conditions of use.

Because of this, the joint technical committee decided to trigger the sample analysis stage provided for in the tender documents, understanding that documentary conformity, although necessary, would not be sufficient to ensure full compliance with the established technical requirements.

In this context, it became necessary to build a structured technical evaluation protocol aimed at the practical on-site verification of the performance of the medical device,

covering aspects related to functional performance, quality of image acquisition, usability, interoperability, operational reliability and full adherence to the previously defined technical specifications.

The instrument was designed to meet the needs of the sample evaluation in the process analysed. Its structure may serve as a reference for adaptations in future evaluations, provided that the criteria are defined in accordance with the object and with the requirements previously established in the respective tender documents. Although it was developed for a specific situation, the form was structured so as to favour its adaptation to similar evaluation processes, and it may be improved and applied in different contexts of health technology acquisition.

III. METHODOLOGY

A. Elaboration of the evaluation instrument

A structured form was developed for the practical evaluation of samples of portable fundus cameras, intended to provide technical support for the process of acquiring medical equipment for use in Primary Health Care, within the context of Telehealth actions.

The eliminatory requirements of the form were derived from the technical specifications and the conditions for the presentation of the sample set out in Public Notice No. 5/2026 and in the Terms of Reference. Informative fields were also included, relating to usability, observed clinical performance, operational stability, connectivity, battery autonomy, biosafety, patient comfort, learning curve, productivity, alerts and additional features. These informative fields were used to record the demonstration and did not, in isolation, constitute grounds for rejecting the sample.

The construction of the instrument involved organizing the requirements of the Terms of Reference and including fields for recording technical, clinical and operational observations. Professionals from AgSUS, the Ministry of Health and the Federal University of Goiás (UFG) took part in monitoring the evaluation, including professionals working in the areas of engineering, information technology and ophthalmology. The preparation of the instrument relied on the participation of professionals from the areas involved in the evaluation, but did not include a formal stage of content validation according to specific methodologies for instrument development.

The instrument was designed to organize the recording of the requirements assessed, the observations made and the evidence produced during the demonstration. In accordance with the rules of the procedure, the practical demonstration was carried out only for the solution summoned to the sample analysis stage, following the regular flow of bid judgement. Accordingly, the instrument was applied to the only sample actually submitted to practical evaluation in the process analysed, without simultaneous comparison between different pieces of equipment.

B. Structure of the evaluation instrument

The instrument was organized into 14 thematic blocks, structured so as to allow the systematic verification of the technical requirements set out in the Terms of Reference, as well as the recording of operational aspects observed during the practical demonstration. It should be noted that each item of the form was associated with the respective regulatory or technical source used in its preparation, ensuring traceability between the evaluative criteria and the requirements of the procurement process. Table 1 details the structure of this instrument and the origin of the evaluation criteria.

TABLE I. TABLE 1 – STRUCTURE OF THE INSTRUMENT AND ORIGIN OF THE EVALUATION CRITERIA

Evaluation block	Item in the form	Purpose	Main source	Nature
Technical and regulatory conformity	5.1, requirements 13 and 14; and 5.6	Verify the mandatory synchronization and protocol requirements set out in the Terms of Reference and record complementary observations on export and integration	Terms of Reference	Eliminatory only for the requirements expressly set out in the Terms of Reference; the other records are informative
Maintenance and support	5.2	Verify the mandatory warranty and support requirements	Terms of Reference	Eliminatory
Usability	5.3	Assess the user's interaction with the equipment	Clinical Engineering	Informative
Clinical performance	5.4	Assess the practical quality of the examinations	Ophthalmology and Clinical Engineering	Informative
Operational Stability	5.5	Assess functioning during real use of the equipment	Clinical Engineering	Informative
Connectivity and interoperability	5.6	Verify communication with external systems	Terms of Reference, Clinical Engineering and Telehealth integration requirements	Eliminatory when provided for in the Terms of Reference
Battery autonomy	5.7	Assess the operating time of the equipment	Clinical Engineering	Eliminatory when provided for in the Terms of Reference
Biosafety	5.8	Assess safety and hygiene aspects	Good practices	Informative, unless specifically provided for in the Terms of Reference
Patient Comfort	5.9	Assess the experience during the performance of the examination	Practical evaluation	Informative
Learning Curve	5.10	Assess the ease of training and operation	Practical evaluation	Informative
Productivity	5.11	Assess performance in real use	Practical evaluation	Informative
Alerts and error systems	5.12	Assess the capacity to identify and signal errors or abnormal conditions	Practical evaluation	Informative

Evaluation block	Item in the form	Purpose	Main source	Nature
Additional features/AI	5.13	Record complementary functionalities	Practical evaluation	Informative
Types of examination	6.0	Assess the performance of the equipment in carrying out the different types of examination, considering image quality, ease of capture, stability, clinical adequacy and the need for repetition	Practical evaluation	Informative, unless specifically provided for in the Terms of Reference

An anonymized version of the form used in the evaluation is provided as supplementary material, preserving the structure of the blocks, the response options, the decision rules and the linkage of the mandatory requirements to the Terms of Reference. Personal data, company identification, contacts, serial numbers, signatures, images of participants and other identifiable information are not available. The provision of the instrument is intended for methodological transparency and does not represent formal validation of its reproducibility.

The Terms of Reference required the equipment to be capable of synchronizing examinations in DICOM format with remote servers using FTP, SFTP, SMB and DICOMweb. These requirements were incorporated into item 5.1 of the form, specifically requirements 13 and 14. Item 5.6 was used to record complementary information on transmission, export, connection, integration and traceability of the examinations. During the demonstration, it was recorded that the equipment provided local export in DICOM, PDF and JPEG, but did not support the mandatory remote transmission protocols. Owing to the absence of these functionalities, no tests of transmission, failure rate, traceability or integration with an external system were carried out. Therefore, the evaluation demonstrated noncompliance with the connectivity requirements set out in the Terms of Reference, but did not constitute a formal conformity test with the DICOM standard, nor a validation of interoperability in a reference environment.

HL7 FHIR and IHE profiles are not included as requirements in the Terms of Reference, in the form or in the final opinion. Consequently, they were not assessed and must not be presented in this article as standards tested or demonstrated. Likewise, no reference server, endpoint, PACS, protocol version or conformity testing tool was documented.

TABLE II. TABLE 2 – MAPPING OF THE CONNECTIVITY AND INTEROPERABILITY CRITERIA

Requirement or functionality	Source	Nature	What was verified	Documented result
Synchronization of examinations in DICOM with remote servers	Terms of Reference; form 5.1, item 13	Eliminatory	Declared/ observed functional availability	The form records the item as met, but without a description of a test with a remote server
Support for FTP, SFTP, SMB and DICOMweb	Terms of Reference; form 5.1, item 14	Eliminatory	Availability of the required tools	Not met; the equipment provided only local DICOM
Export in DICOM, PDF and JPEG	Form 5.6, item 2	Informative	Local file export	Recorded as available
Wi-Fi or wired connection	Form 5.6, item 3	Informative	Network Connectivity	Not assessed
Transmission failures and time	Form 5.6	Informative	Transmission performance	Not assessed
Integration with a real system	Form 5.6, item 5	Informative, unless linked to a mandatory requirement	External functional integration	Not carried out
Traceability of the transmitted examination	Form 5.6, item 6	Informative	Retrieval and identification of the examinations	Not assessed

[a.] Note: "local DICOM" or the export of a DICOM file is not equivalent to a demonstration of full conformity with the DICOM standard, nor does it prove interoperability with external systems.

For the purposes of interpreting the results, the records were organized into four analytical categories:

1. Mandatory requirement of the tender documents: a requirement expressly provided for in the Public Notice or in the Terms of Reference, non-compliance with which could substantiate the rejection of the sample;

2. Observed technical or clinical quality: a result obtained during the demonstration, such as image quality, ease of capture and the need for repetition, recorded in order to characterize performance in the case studied;

3. Preference or functional characteristic: a potentially useful attribute, but one not defined as a mandatory requirement of the contract;

4. Complementary information or item not assessed: data recorded without any effect on the decision, or whose verification was not carried out.

For the administrative decision, only the first category had an eliminatory character. The remaining categories could not, in isolation, substantiate the rejection of the sample. This classification sought to ensure adherence to the principles of binding to the tender documents, objective judgement and equal treatment of bidders, while at the same time allowing the documentation of information relevant to future technology assessments.

In addition, any requirement whose absence would imply noncompliance with the mandatory specifications of the Terms of Reference, or would render unfeasible functionalities considered essential to the purpose of the solution evaluated, was regarded as an eliminatory criterion. The informative criteria were used exclusively to document the performance observed during the practical demonstration and could not, in isolation, justify the rejection of the sample.

In addition to the classification of the criteria, the instrument incorporated formal requirements of technical traceability. The decisions of the evaluation committee were to be supported by objective evidence, associated with the respective requirements of the Terms of Reference, so as to allow the auditing and reconstitution of the decision-making process.

The eliminatory requirements were linked to the requirements of the Terms of Reference, and the non-

conformities were recorded with an indication of the respective evidence. This structure favoured the documentary traceability of the decision in the process analysed. Although the structure of the instrument was designed to favour its application by other teams, the present study did not include a formal assessment of reproducibility or of inter-rater agreement. Furthermore, the requirements assessed were derived from the technical specifications previously defined for the technological solution, and no new criteria were introduced during the practical demonstration phase.

The specifications used in the preparation of the instrument were derived from the technical requirements previously established for the contract and subsequently incorporated into the Terms of Reference, preserving the correspondence between the requirements of the procurement process and the items actually assessed during the practical demonstration.

C. Application of the instrument

The evaluation of the sample was carried out in a real clinical environment, on the premises of UFG, during a practical demonstration conducted by a multiprofessional technical committee composed of specialists from the fields of ophthalmology, nursing, clinical engineering and information technology.

During the practical demonstration, the fundus photography modalities provided for in the Terms of Reference were performed, including colour, red-free, infrared and stereo optic disc images. The tests were conducted on different patients, allowing the observation of the performance of the equipment under distinct conditions of use. Aspects related to image capture, quality for clinical interpretation, operational stability, usability, connectivity, data transmission, availability of the functionalities provided for and other parameters covered by the evaluation instrument were observed.

The entire evaluation process was documented by means of photographic and video records, reports issued on the basis of the examinations performed, and the completion of the evaluation form by the technical team taking part in the demonstration. The evidence produced supported the preparation of the technical opinion of the joint committee, contributing to the traceability, transparency and substantiation of the decision regarding the approval or rejection of the sample.

The evaluation form was completed collectively by the technical team taking part in the demonstration, involving the joint consolidation of the evidence observed during the execution of the tests and of the technical discussions held throughout the evaluation.

The multiprofessional committee acted in accordance with its respective areas of competence, with the criteria of the instrument previously organized into eliminatory and informative categories, together with specific guidance for recording evidence and applying the decision rule. Before the practical demonstration, the participants were briefed on the classification of the criteria, the definition of the eliminatory and informative requirements and the procedures for recording evidence, with a view to promoting greater consistency in the evaluation process.

Before the practical demonstration, the participants received guidance on the classification of the criteria, the definition of the eliminatory and informative requirements, the procedures for recording evidence and the rules for conducting the evaluation. The role of the participants present was also clarified, namely that of observers only, including the representatives of the companies, who could not interfere in the execution of the tests or in the conduct of the evaluations, with a view to promoting greater consistency and impartiality in the evaluation process.

Once the practical demonstration had been concluded, the records of the form and the evidence collected were analysed internally by the evaluation committee. Any divergences of interpretation were discussed until a technical understanding was consolidated, and the final opinion was issued by the Joint Technical Committee by consensus, on the basis of the objective criteria provided for in the evaluation instrument and in the Terms of Reference.

The final result of the evaluation was based exclusively on the eliminatory criteria linked to the requirements of the Public Notice and the Terms of Reference. The informative criteria were used only to record the practical, operational and clinical performance of the equipment and could not, in isolation, justify the rejection of the sample. Accordingly, limitations related to usability, productivity or clinical quality supported the general technical analysis, while the administrative decision to reject the sample remained linked to non-compliance with the previously established mandatory requirements.

IV. RESULTS AND DISCUSSION

The application of the structured form made it possible to systematically assess technical, regulatory, functional and operational aspects of the portable fundus camera submitted to practical demonstration, extending the analysis beyond the mere documentary verification of the specifications set out in the tender documents [1], [2], [10], [11].

The organization of the instrument into eliminatory and informative criteria proved appropriate for distinguishing requirements that are indispensable to compliance with the demands of the tender process from those related to the operational performance of the technology. This structure made it possible to base the decision of the joint committee on objective, previously defined criteria, preserving the principles of binding to the tender documents, equal treatment and objective judgement, while at the same time recording information relevant to supporting future technology incorporations [3], [13], [14].

Among the eliminatory criteria, a non-conformity was identified in relation to support for the connectivity protocols required in the Terms of Reference. The document required the synchronization of examinations in DICOM format with remote servers using FTP, SFTP, SMB and DICOMweb. During the evaluation, it was recorded that the equipment provided only local DICOM functionality and did not offer the required protocols. For this reason, it was not possible to execute the remote transmission flows envisaged for the solution. Documentary omissions were also recorded at the time of the evaluation, including the technical manual and other documents indicated in the form and in the opinion. The rejection was based on non-compliance with these mandatory requirements, and not on the informative criteria of usability or clinical quality.

In addition to the eliminatory criteria, the form made it possible to record operational aspects which, although they did not determine the rejection of the sample, had a potential impact on the use of the equipment in a care environment. A frequent need for focus and positioning adjustments during

image capture was observed, along with a high rate of examination repetition and dependence on the operator for obtaining images of diagnostic quality. Of the seven examinations performed during the evaluation, four (57.1%) were considered adequate for clinical interpretation, while three (42.9%) presented insufficient quality for diagnostic purposes.

The findings indicate that the form was able to record, in the case studied, aspects of usability and image quality that were not sufficiently characterized in the documentary analysis. Although the observations made are restricted to the specific context of the evaluation, they made it possible to document operational characteristics relevant to understanding the performance of the equipment under conditions of use. In technologies intended for Primary Health Care and Telehealth, factors such as ease of operation, learning curve and stability during image acquisition become particularly relevant, since the equipment is often used by professionals with different levels of experience [9], [10].

Another relevant aspect identified during the evaluation was the difficulty of validating the interoperability of the equipment in a telehealth environment. In the case analysed, the unavailability of FTP, SFTP, SMB and DICOMweb prevented the execution of the envisaged remote flows. No formal conformity tests with interoperability standards or with specific reference environments were carried out. Accordingly, the evaluation focused on verifying the connectivity requirements set out in the Terms of Reference and on their practical demonstration during the evaluation process.

Although the equipment presented functionalities related to the storage and export of examinations, the impossibility of fully demonstrating communication using the protocols established in the tender documents highlighted the importance of including practical connectivity tests during sample evaluation processes [15]. Documentary verification alone proved insufficient to ensure that the integration requirements were effectively met under real conditions of use, since many devices declared to be compatible with the DICOM standard or with PACS systems frequently fail to provide full functional conformity when inserted into the institution's network, requiring the execution of practical proofs of concept in order to mitigate the risk of acquiring inoperable platforms [3], [13], [15].

During the practical demonstration, it was found that some functionalities described in the technical documentation submitted by the manufacturer could not be reproduced or demonstrated under the real conditions of use adopted during the evaluation, especially with regard to interoperability and examination transmission tests. This result shows that exclusively documentary analysis may not be sufficient to fully verify the expected functional performance of medical equipment, reinforcing the importance of carrying out practical evaluations, such as proofs of concept and clinical validation, as complementary stages of public procurement and Health Technology Assessment processes [3], [11], [13].

As a positive aspect, the equipment presented additional technological resources, including embedded artificial intelligence to support image analysis, autofocus functionalities and export of examinations in multiple formats. Although these resources add potential value to clinical practice, their presence does not replace compliance with the essential technical requirements established in the procurement process, reinforcing the need for structured evaluations that simultaneously consider regulatory, functional and operational aspects.

The results obtained indicate that the form contributed to organizing the record of the evidence produced during the practical demonstration, favouring the documentation of the findings observed by the evaluation committee and increasing the traceability of the technical analysis process. The distinction between eliminatory and informative criteria proved particularly relevant in making explicit the grounds for the decision adopted in the evaluation process, allowing the operational aspects observed during the demonstration to be recorded without compromising the binding of the decision to the mandatory requirements set out in the Public Notice and in the Terms of Reference.

Finally, the experience described in this study indicates that the adoption of structured evaluation instruments may contribute to qualifying the processes of incorporation and acquisition of health technologies within the Brazilian Unified Health System, favouring evaluation processes that are more transparent, better documented and more closely aligned with care needs.

A. Limitation of the study

The present study has limitations that should be taken into account when interpreting the results. It is a case study based on a single tender process and on the practical evaluation of a single technological solution submitted to the sample demonstration stage, in accordance with the judgement rules applicable to the procedure analysed. Accordingly, the results should not be generalized to all categories of medical devices.

In addition, the evaluation was conducted in a single institutional environment and did not include multicentre validation. The evaluation covered only the solution summoned to the sample analysis stage, owing to the judgement system adopted in the procedure, and it was therefore not possible to make comparisons between different pieces of equipment, suppliers or competing technologies. Formal measures of interrater reliability, internal consistency of the instrument and quantitative indicators capable of measuring impact on the efficiency of the procurement process, economic outcomes or clinical results were also not assessed. The evaluation process was conducted collectively, with the consolidation of the evidence by the technical team and by the Joint Technical Committee; no independent application of the instrument by different teams and no formal assessment of agreement between evaluators were carried out. Thus, the results obtained should be interpreted as evidence of the applicability of the methodology in the context studied, and not as definitive validation of the instrument for different scenarios of use.

V. CONCLUSION

The development and application of a structured form for the evaluation of samples demonstrated the feasibility of using a systematized approach to support the technical analysis of medical equipment in public procurement processes.

In the analysed case, the instrument contributed to organizing the record of the requirements assessed, of the evidence produced during the practical demonstration and of the elements considered in substantiating the technical decision.

The practical application showed that documentary analysis, although indispensable, may not be sufficient to fully verify certain functional and operational characteristics of health technologies. The practical demonstration made it

possible to identify limitations related to connectivity, image quality and the operational performance of the equipment evaluated, highlighting the relevance of complementary verification mechanisms when critical aspects cannot be fully ascertained solely by means of the documentation submitted by suppliers.

The organization of the criteria into eliminatory and informative categories proved appropriate for reconciling the objectivity required in tender processes with a more comprehensive evaluation of the performance of the technology. This structure made it possible to make explicit that the administrative decision was based exclusively on noncompliance with previously established mandatory requirements, while the other findings were recorded as complementary information characterizing the performance observed during the demonstration.

The experience described in this study indicates that structured evaluation instruments may contribute to making technical analysis processes more transparent, better documented and more traceable, especially in situations that require practical verification complementary to documentary analysis.

Finally, it should be stressed that the preparation and application of instruments of this nature require the participation of professionals with technical knowledge compatible with the technology being evaluated, since the definition of the criteria, the interpretation of the evidence and the conduct of the analysis depend on an adequate understanding of the regulatory, operational and clinical requirements involved. In this context, the experience reported reinforces the importance of the work of multiprofessional teams in the technical evaluation of health technologies.

VI. FUTURE PERSPECTIVES AND INSTRUMENT VALIDATION

Although it was developed to meet a specific need of the process analysed, the instrument has the potential to be adapted to similar evaluations of health technologies, provided that its criteria are defined in accordance with the characteristics of the object and with the requirements established for each contract.

Following the application described in this study, the methodology has come to be used as a reference for structuring instruments intended for the evaluation of other technologies, including portable ultrasound equipment assessed in a different institutional context. These experiences suggest the possibility of adapting the approach to different care and technological scenarios.

As indicated by the limitations of the present study, future applications may involve different evaluation teams, institutions and categories of medical devices, contributing to the methodological improvement of the instrument and to a more robust assessment of its reproducibility and applicability in different contexts.

In addition, future investigations may incorporate quantitative indicators aimed at assessing reliability, agreement between evaluators, reproducibility of results and the capacity of the instrument to identify relevant non-conformities during practical evaluation processes of health technologies.

TABLE III. TABLE 3 – INDICATORS PROPOSED FOR FUTURE STUDIES OF VALIDATION AND IMPROVEMENT OF THE INSTRUMENT

Dimension	Proposed Indicator	Form of future evaluation
Inter-rater agreement	Cohen's kappa, weighted kappa or Fleiss' kappa, according to the number of evaluators and the nature of the response	Independent application of the same instrument by two or more evaluators
Reproducibility between teams	Percentage of concordant decisions and chance-adjusted agreement	Re-evaluation of the same cases by independent teams
Decision traceability	Proportion of decisions with an explicit link between requirement, evidence and conclusion	Audit of the forms and opinions
Completeness of the instrument	Proportion of items completed, justified or classified as not assessed	Audit of the completion
Operational efficiency of the evaluation	Total application time, time per stage and number of complementary clarification requests	Prospective recording of times
Complementary detection capacity	Number and proportion of mandatory non-conformities identified in the demonstration and not identified in the documentary analysis	Prospective comparison between the documentary and practical stages
Internal consistency	Cronbach's alpha, only where there is a set of items measuring the same construct	Specific psychometric study
Content validity	Content validity index by a panel of specialists	Structured assessment of the items by specialists
External validity	Consistency of the results across different institutions, equipment and teams	Multicentre study
Quality of the decision	Previously defined indicators of completeness, adherence to the tender documents and support by evidence	Independent evaluation of the decision-making processes
Economic impact or risk reduction	Specific prospective indicators, with a comparison group or historical series	Not to be inferred from the present study

[b.] NOTE: The indicators above constitute a proposal for future studies and were not calculated in the present study. "Complementary detection of non-conformities" should not be presented as a synonym for proven risk reduction.

ACKNOWLEDGEMENTS

The authors thank the Federal University of Goiás (UFG) for providing the infrastructure and physical space required to conduct the practical demonstration and technical evaluation described in this study.

The authors further acknowledge the institutional partnership established with the Brazilian Ministry of Health, through the Secretariat of Primary Health Care (SAPS) and the General Coordination of Primary Health Care Programming and Financing (CGFAP), which contributed to enabling the activities related to the development of the project.

Finally, the authors thank the Brazilian Agency for Support to the Management of the Unified Health System (AgSUS) for its institutional partnership, support, and encouragement in carrying out this research.

***Abstract*—This work presents a comparative analysis of emerging technologies for monitoring patient positioning in medical imaging and radiotherapy, focusing on computer vision systems, laser-based optical sensors, and radar sensors. A literature review was conducted considering monitored-area coverage, detection accuracy, susceptibility to interference, and technological versatility. In addition, a computer-vision-based solution was developed for the automatic identification of patient body displacement. The Mask R-CNN and Keypoint R-CNN models were implemented in Python using Google Colab to extract spatial parameters, including centroid position, body area, and anatomical keypoints. The results demonstrated the feasibility of these techniques for monitoring patient positioning and supporting clinical decision-making. The comparative analysis also highlighted the promising potential of computer-vision-based systems compared with the other technologies evaluated.**

***Index Terms*—Computer Vision; Image-Guided Radiotherapy; Patient Monitoring; Mask R-CNN; Keypoint R-CNN.**

I. Introduction

Proper patient positioning is a critical factor for the quality and safety of medical procedures that depend on high spatial accuracy, such as radiotherapy, computed tomography, magnetic resonance imaging, and other imaging examinations. Positioning consists of accurately aligning the body with the equipment coordinate system so that the region of interest is correctly located within the image acquisition field or therapeutic procedure. This process involves not only the initial setup but also continuous tracking and maintenance of the position throughout the clinical procedure, preventing voluntary or physiological movements from compromising image quality or treatment accuracy [1].

In computed tomography examinations, misalignments of only a few centimeters relative to the equipment isocenter can significantly increase radiation dose and degrade image quality. Displacements of 2, 4, and 6 cm were associated with increases of up to 13.5%, 33.3%, and 51.1% in surface dose, respectively, in addition to an average increase of 23% in total dose and 7% in image noise [2]. In radiotherapy, even systematic errors of approximately 0.6 mm may cause variations of approximately 2% in the equivalent dose delivered to the target volume, emphasizing the high sensitivity of treatments to small geometric inaccuracies [3]. These findings demonstrate the importance of accurate patient-position monitoring.

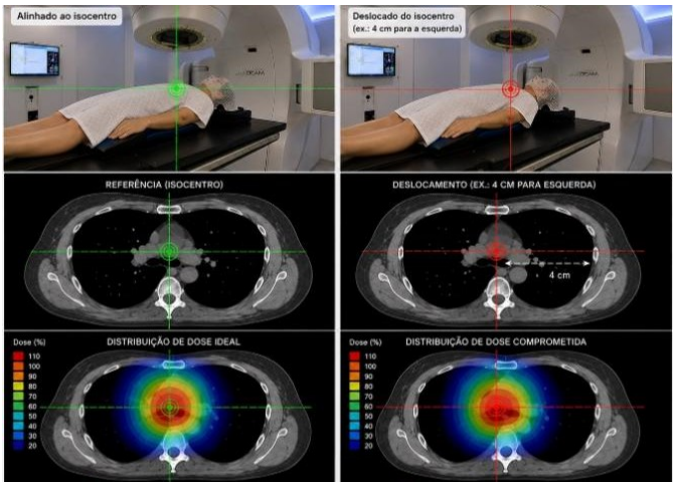

Fig. 1. Schematic representation of the effect of positioning deviations in radiotherapy. Correct alignment with the isocenter (left) is compared with a displaced condition (right).

To ensure appropriate patient alignment during radiotherapy treatments, different immobilization methods have been used, many of which are applied manually. These resources include

thermoplastic masks, used for head and neck tumors to immobilize the patient during treatment. In breast radiotherapy, a *breast board* is used to ensure proper alignment; this adjustable platform allows different inclinations and can be adapted to each patient [4]. Sedation has also become a common practice, particularly for pediatric patients, because movement during imaging procedures may compromise image quality [5].

To mitigate these challenges, technological advances in radiotherapy have enabled the development of systems for real-time monitoring and verification of patient positioning. One example is *ExacTrac Dynamic (BrainLab)*, which combines infrared cameras and X-ray images to ensure patient alignment during treatment. The system correlates external anatomical landmarks with internal structures visible in radiographic images, enabling automatic table adjustments and continuous position verification, thereby reducing deviations during the procedure [6].

Another example is *IDENTIFY (VARIAN)*, a *Surface Guided Radiation Therapy (SGRT)* system based on optical monitoring of the body surface. The system uses cameras to capture images and measure the distance to the patient's surface, reconstructing a three-dimensional body model in real time. It projects light patterns and analyzes their deformation to calculate surface geometry and continuously compare it with a previously acquired reference, allowing even small displacements to be identified [7].

Despite the effectiveness of systems currently used in clinical practice to monitor patients during radiotherapy and diagnostic imaging procedures, new technological approaches are being investigated to expand the availability of continuous and noninvasive methods. These technologies aim to reduce limitations associated with conventional techniques, such as the need for physical markers, implantable devices, or complex image acquisition systems.

Among the main current research areas are advances in computer-vision-based systems. Computer vision uses methods for image and video acquisition, processing, and interpretation to extract relevant information from the environment. Through cameras and algorithms such as three-dimensional reconstruction, image segmentation, and pattern tracking, these systems identify and monitor structures of interest noninvasively. In this context, SGRT has evolved through more robust algorithms for three-dimensional reconstruction of the patient's surface and real-time motion tracking, improving monitoring accuracy and reliability. Consequently, computer vision has enabled more accurate estimates of body position and markerless approaches to patient positioning [8].

Another promising approach involves millimeter-wave radar sensors for noninvasive monitoring of body position and movement during radiotherapy. These sensors emit and analyze signals in the 24 GHz range reflected by the body surface, enabling the detection of distance variations and micromovements associated, for example, with respiration or involuntary patient displacement.

Optical distance sensors have also been investigated for monitoring respiratory motion during medical examinations. In these systems, a laser sensor is directed toward the patient's chest or abdomen to measure distance variations caused by body expansion and contraction during breathing. Experimental studies have shown that this approach can accurately detect respiratory patterns during magnetic resonance imaging, with good agreement relative to conventional respiratory sensors used as references [9].

In this context, this study aims to comparatively evaluate emerging technologies for monitoring and positioning patients in medical equipment, particularly in applications requiring detection of physiological motion and small displacements, such as medical imaging and radiotherapy systems. The study also proposes a practical solution for monitoring patients positioned on imaging and radiotherapy tables, serving as a decision-support tool for identifying dynamic deviations from a reference position.

II. Methodology

A literature review was initially conducted to identify technologies used for monitoring and tracking patient positioning in clinical environments. The search was performed in *Google Scholar*, *PubMed*, and *IEEE Xplore*, considering publications from 2019 to 2026. Search terms related to sensors and software included "optical sensors," "radar sensors," and "computer vision," whereas clinical assessment terms included "electromagnetic interference," "interference in medical equipment," "advantages," and "disadvantages." Additional specific descriptors included "patient motion tracking," "motion monitoring in imaging examinations," "radiotherapy positioning," "surface-guided radiation therapy (SGRT)," and "motion correction in magnetic resonance imaging."

The selected studies addressed the following technological categories: first, computer-vision-based systems, particularly techniques used in SGRT, totaling two studies [8]; second, laser-based optical sensors for motion detection through reflection and the Doppler effect, comprising eight studies [10]–[14], [20]; and third, radar sensors used for vital-sign detection and contactless motion monitoring, totaling seven studies [15]–[18]. Studies related to electromagnetic interference and the compatibility of these technologies with clinical environments were also considered [13], [19]. Fig. 2 presents the classification of the main emerging technologies investigated in this study.

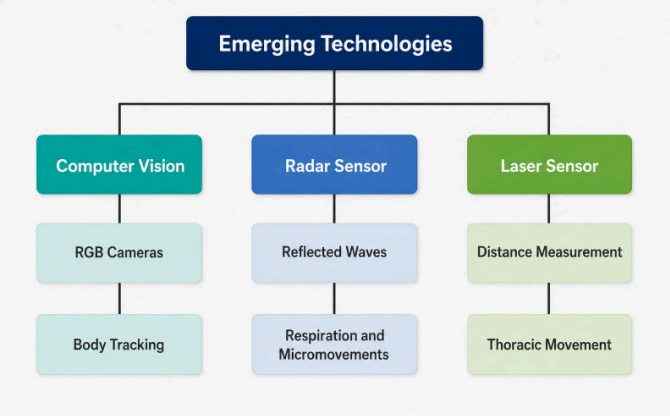

Fig. 2. Emerging technologies analyzed in this study for patient-position monitoring, including computer-vision-based systems, radar sensors, and laser sensors.

The technologies were compared according to the following parameters: monitored-region coverage, susceptibility to interference, technological versatility in examination environments, and motion-detection accuracy. A comparative table was then developed in which each technology was qualitatively classified as "poor," "fair," or "good," based on the synthesis of the literature findings and the parameters established for comparison.

A. Monitored-Region Coverage

Monitored-region coverage refers to the technology's ability to adequately cover the area of interest during an examination. This parameter was analyzed using different approaches from the literature, including laser tracking systems that depend on detector position [20] and body-surface monitoring through optical systems used in SGRT [8]. Studies on millimeter-wave motion tracking [15] and the operational parameters described in radar-sensor manuals [16] were also considered.

B. Susceptibility to Interference

Susceptibility to interference concerns the influence of external factors such as noise and data distortion. This parameter was analyzed from different perspectives reported in the selected studies. First, the influence of electromagnetic interference on image acquisition systems was investigated [19]. Interference associated with laser-based displacement measurements in civil structures [10] was then examined, along with a study assessing respiratory rate using a line laser and an RGB (*Red, Green and Blue*) camera [11]. Finally, radiofrequency-based systems were evaluated through a study on respiratory-motion monitoring using ultra-wideband radar [17].

C. Technological Versatility

Technological versatility in examination environments refers to the ability to adapt to different clinical contexts and operational configurations. This parameter was analyzed by considering operation in environments subject to electromagnetic interference and mitigation strategies such as filtering unwanted noise and signals [19]. Laser-based solutions were also investigated, including self-monitoring applications in breast-cancer radiotherapy [12], LiDAR (*Light Detection and Ranging*) technology for detecting individuals in indoor environments [20], its integration with detectors for displacement identification [8], and laser-tracking systems whose accuracy depends on detector position [20]. Applications of millimeter-wave sensors for identifying human activities in telemedicine were also analyzed [18].

D. Motion-Detection Accuracy

Motion-detection accuracy refers to the ability to correctly identify motion or physiological signals during monitoring. Different perspectives described in the literature were considered. First, accurate displacement tracking using optical systems in magnetic resonance imaging environments was analyzed [13]. Laser-based applications were then examined, including spectroscopy for respiratory-rate monitoring [11], [14], calibration and validation of prototypes for respiratory-motion detection using tracking techniques [14], and optical systems for measuring structural displacement in civil engineering [10]. Finally, millimeter-wave solutions were considered, including sensor-based applications [18] and investigations of motion tracking in radiotherapy using this frequency range [15].

E. Practical System for Preliminary Validation

For preliminary validation of the positioning-monitoring solution, four images were used to simulate different patient-positioning conditions. The images were produced with the assistance of the generative artificial intelligence tool *ChatGPT* (*Chat Generative Pre-trained Transformer*), using a reference scene representing a patient lying on a radiotherapy equipment table. Additional versions were subsequently generated with small changes in body position.

The solution was implemented in a cloud-computing environment using *Google Colab*, which enabled model execution with GPU support to accelerate image processing. The processing *pipeline* was developed in *Python* using libraries such as *Detectron2* for model detection and inference in segmentation and pose estimation, *OpenCV* for image reading and manipulation, *NumPy* for numerical operations and metric calculation, *Matplotlib* for graphical visualization of the results, and *Pandas* for tabular data organization. The source code was made publicly available in a *GitHub* repository at: https://github.com/fssmonique-debug/patient-position-monitoring.

Two approaches were tested and evaluated: instance segmentation using *Mask R-CNN*, which allowed the patient's silhouette to be extracted from each *frame*, and anatomical keypoint estimation using *Keypoint R-CNN*. Both models were pretrained on the COCO (*Common Objects in Context*) *dataset*. The parameters obtained from both models included detection *score*, centroid coordinates, segmented patient area, centroid displacement relative to the reference image, *bounding box* area, number of valid anatomical keypoints, and detected keypoint positions.

Parameters obtained in pixels, such as area and displacement, were converted into physical units in millimeters using a scale factor equivalent to the *Pixel Spacing* attribute in medical images. Based on the displacement values calculated in millimeters, tolerance thresholds were defined for automatic motion classification into three categories: mild, for displacements below 1 mm; moderate, for displacements between 1 and 2 mm; and critical, for displacements above 2 mm.

III. Results

A. Monitored-Region Coverage

Computer vision systems provide broad coverage of the body surface through three-dimensional reconstruction and continuous monitoring of extensive regions. This characteristic is observed both in SGRT systems using optical and infrared cameras [8] and in optical tracking systems applied to magnetic resonance imaging [13]. Radar sensors also provide broad coverage, determined by the sensor field of view and the spatial configuration of the system [15], [18]. The analyzed sensors have conical detection regions with range and angular aperture capable of covering extensive areas or the entire body surface [16]. Laser-based systems provide more localized coverage because measurement depends on beam incidence, detector position, and the selected region [11]. In LiDAR sensors, although the horizontal field of view is broad, the vertical field of view of approximately 33.2° may limit acquisition when the sensor is positioned near the patient, allowing only a body strip to be observed [20]. This characteristic reduces system flexibility in environments with positioning restrictions.

B. Susceptibility to Interference

In computer vision systems, the main sources of interference are associated with electromagnetic fields in magnetic resonance imaging environments, which may distort image-sensor data [19]. However, measures such as grounding, electromagnetic control [19], and the use of adapted optical systems [13] make this limitation less critical. Radar sensors are more sensitive to the physical conditions of the environment because they operate by transmitting and receiving electromagnetic waves. Metallic surfaces may produce multiple reflections, multipath propagation, and unwanted echoes [15], [16]. Manufacturers also report installation restrictions associated with metallic objects and moving elements [16]. In radiotherapy, gantry motion may significantly reduce the system signal-to-noise ratio and impair respiratory-motion detection [17]. In laser-based systems, interference is associated with obstacles in the beam path, sensor alignment, and the optical properties of the monitored surface. Rapid changes in patient position or orientation may require continuous updating of the spatial tracking model, increasing tracking complexity and potentially reducing measurement accuracy [11], [20].

C. Technological Versatility

Computer vision provides greater clinical versatility and has established applications in radiotherapy [8]. In magnetic resonance imaging, adaptations are required to ensure sensor electromagnetic compatibility [13], [19]. Even so, the technology can be used in different clinical environments when these requirements are met. Radar sensors provide lower versatility in clinical environments because of electromagnetic-wave emission and susceptibility to reflections and echoes in rooms containing shielding or metallic structures [15], [16]. These characteristics make installation more challenging in environments with electromagnetic and structural restrictions. Laser-based systems adapt well to the physical environment because they do not depend on broad electromagnetic emission [11], [20]. However, beam incidence must be controlled in sensitive regions such as the eyes, face, and areas of injured or fragile skin [11], [14]. Therefore, these systems provide good environmental versatility but require greater attention to potential patient risks.

D. Motion-Detection Accuracy

Computer vision systems provide high accuracy. In magnetic resonance imaging, reported accuracies were approximately 0.1 mm for translation and 0.15° for rotation [13]. In radiotherapy, these systems enable continuous monitoring of millimeter-scale deviations of the body surface [8]. Radar sensors can detect body-surface micromovements and respiratory motion in real time [15]–[17]. One study reported an accuracy of 94% even under the critical condition of apnea and in the presence of environmental interference [18], indicating high accuracy and robustness for respiratory monitoring. Laser-based systems provide high accuracy in the directly monitored region, particularly for respiratory tracking and displacement measurement [10], [11], [14]. However, movement outside the illuminated region may not be detected with the same efficiency [11], [20]. Accuracy also depends on the distance between the sensor and the target. Although some systems operate at distances of up to 150 m, the study in [20] used a distance of 8 m to increase the number of points projected onto the target and improve measurement reliability.

E. Comparative Summary

Computer vision provided the most balanced set of characteristics, including broad coverage, high accuracy, and greater clinical versatility. Despite the need for adaptations in magnetic resonance imaging environments, it was considered the most appropriate technology for the proposed application and was therefore selected for practical testing. Radar sensors also provided good coverage and accuracy but showed more relevant limitations related to environmental interference and adaptation to clinical rooms. Laser-based systems provided high accuracy for localized measurements but had more restricted spatial coverage and greater dependence on positioning, alignment, and system configuration. Based on these findings, Table I, proposed in the methodology, was completed.

Table I
COMPARISON OF THE TECHNOLOGIES ACCORDING TO THE ANALYZED PARAMETERS.

Parameter	Computer Vision	Laser	Radar
Monitored-region coverage	Good	Poor	Good
Susceptibility to interference	Fair	Fair	Poor
Technological versatility	Fair	Fair	Poor
Motion-detection accuracy	Good	Fair	Good

F. Preliminary Validation

After implementing the code in the *Google Colab* cloud-computing environment, the images were imported. A binary mask was generated for each image: pixels belonging to the patient were assigned a value of 1 and represented as the white region, whereas the remaining pixels were assigned a value of 0 and represented as the black background. This binary mask enabled identification of the area occupied by the patient and served as the basis for calculating spatial parameters.

The main patient spatial parameters were also calculated. The centroid was determined from the mean coordinates of the pixels belonging to the mask. Centroid coordinates were expressed as row (L) and column (C), corresponding to pixel positions in the image. The masks with centroid markings were displayed using the *Matplotlib* library. For the reference mask (a), the centroid was located at $L = 446$ and $C = 474.5$; for mask (b), it was located at $L = 568$ and $C = 494.1$; for mask (c), at $L = 560$ and $C = 495.7$; and for mask (d), at $L = 685.4$ and $C = 613.2$.

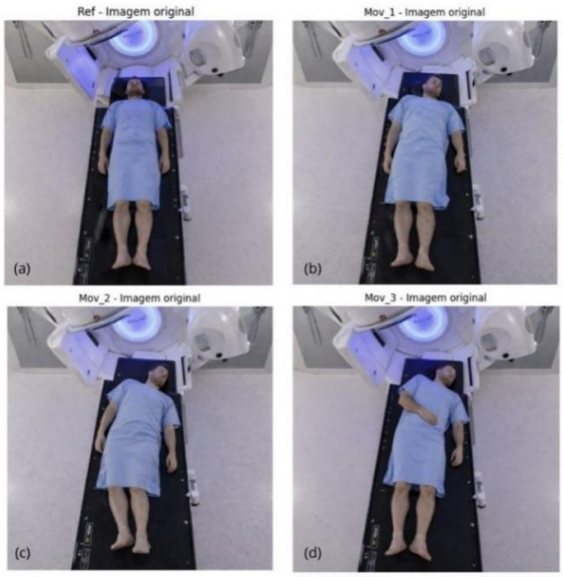

Fig. 3. Set of images used in the models: patient in the initial position (ref.), patient with a slight lateral displacement relative to the table axis (mov_1), patient with slight trunk rotation relative to the longitudinal table axis (mov_2), and patient with lateral displacement combined with slight upper-limb flexion (mov_3).

F.1 – Instance Segmentation (Mask R-CNN): After implementation in *Google Colab*, the images were imported and converted into binary masks. Pixels corresponding to the patient were assigned a value of 1 and represented by the white region, whereas the background was assigned a value of 0 and represented by the black region. These masks enabled identification of the area occupied by the patient and calculation of spatial parameters.

The centroid was calculated from the mean coordinates of the pixels belonging to the mask and represented by a red point in the images. Its coordinates were expressed as row (L) and column (C), in pixels. The masks were displayed using the *Matplotlib* library.

For the reference mask (a), the calculated centroid was $L = 446$ and $C = 474.5$. For the masks with displacement, the following values were obtained: (b) $L = 568$ and $C = 494.1$; (c) $L = 560$ and $C = 495.7$; and (d) $L = 685.4$ and $C = 613.2$.

For each image, the *Mask R-CNN* detection *score* was obtained, with values ranging from 0 to 1. Values closer to 1 indicate greater confidence in identifying the person class. Table II presents the main parameters obtained in pixels.

Table II
PARAMETERS OBTAINED, INCLUDING THE DETECTION *score* FROM THE *Mask R-CNN* MODEL IN THE *Detectron2* LIBRARY AND THE CENTROID ROW AND COLUMN COORDINATES.

Frame	Score	Centroid (row)	Centroid (column)
Ref.	0.997	446.01	474.45
Mov_1	0.997	567.96	494.11
Mov_2	0.998	565.96	495.67
Mov_3	0.996	685.37	613.19

The displacement values obtained for the motion images were expressed in pixels and subsequently converted into millimeters, as was the area. A scale factor of 0.1 mm was used to convert the measurements into physical units. This factor is equivalent to the *Pixel Spacing* commonly available in DICOM (*Digital Imaging and Communications in Medicine*) images. Table III was then constructed.

Table III
PARAMETERS OBTAINED, INCLUDING THE PATIENT AREA IN THE IMAGE FROM THE *Mask R-CNN* MODEL IN THE *Detectron2* LIBRARY AND CENTROID DISPLACEMENT ACROSS THE IMAGES IN PIXELS AND MILLIMETERS.

Frame	Area (px)	Area (mm^2)	Displacement (px)	Displacement (mm)
Ref.	86683	866.83	0.00	0.00
Mov_1	149656	1496.56	123.52	12.35
Mov_2	150761	1507.61	121.81	12.18
Mov_3	208186	2081.86	276.66	27.67

The displacement values in millimeters were classified according to tolerance thresholds used in high-precision radiotherapy positioning systems: mild for values below 1 mm, moderate for values between 1 and 2 mm, and critical for values above 2 mm. These thresholds were based on the

approximately 1–2 mm tolerances adopted in systems such as *ExacTrac Dynamic* [21]. Table IV presents the classification obtained for each image.

Table IV
CENTROID DISPLACEMENT IN MILLIMETERS, MOTION CLASSIFICATION, AND SIMULATED SYSTEM ACTION FOR DIFFERENT PATIENT POSITIONS RELATIVE TO THE REFERENCE IMAGE.

Frame	Displacement (mm)	Classification	System action
Ref.	0.00	Mild	Normal operation
Mov_1	12.35	Critical	Immediately interrupt acquisition / beam
Mov_2	12.18	Critical	Immediately interrupt acquisition / beam
Mov_3	27.67	Critical	Immediately interrupt acquisition / beam

F.2 – Keypoint Detection (Keypoint R-CNN): The same four images were imported for a different analysis approach using the *Keypoint R-CNN* model. Each image was processed individually to detect the person in the *frame* and extract anatomical body keypoints. First, an image containing the keypoints, centroid marker, and body *bounding box* was generated, as shown in Fig. 4. The keypoints were represented as green points at specific anatomical regions such as the shoulders, arms, hips, and legs. The *bounding box* was represented by a red outline delimiting the region occupied by the patient.

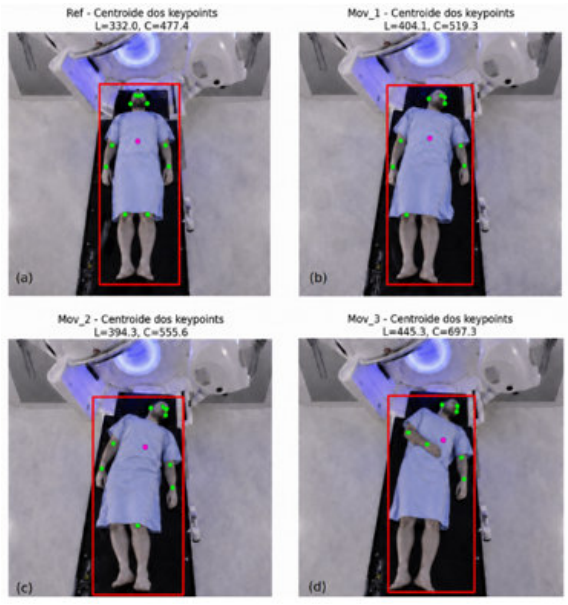

Fig. 4. *Keypoint R-CNN* detection results for the four analyzed images. Images (a), (b), (c), and (d) show the anatomical keypoints (green points), the *bounding box* (red rectangle), and the calculated body centroid (central pink point). Centroid coordinates are expressed as row and column.

Spatial parameters were calculated from the detected *keypoints*. The model used a confidence threshold of 0.7 for person-instance detection and an additional threshold of 0.5 for validating individual keypoints, and only anatomical points above this value were considered. The centroid was obtained from the mean coordinates of the valid points and expressed as row (L) and column (C). The number of valid keypoints and the main detection *score* were also recorded. The results are presented in Table V.

Table V
QUANTITATIVE PARAMETERS EXTRACTED BY THE *Keypoint R-CNN* MODEL FOR THE FOUR IMAGES, INCLUDING THE PERSON-INSTANCE DETECTION *score*, CENTROID COORDINATES IN PIXELS, AND THE NUMBER OF VALID DETECTED KEYPOINTS.

Frame	*Score*	Centroid (row)	Centroid (column)	No. of valid *keypoints*
Ref.	1.000	331.99	477.37	11
Mov_1	1.000	404.08	519.30	9
Mov_2	1.000	394.25	555.61	11
Mov_3	1.000	445.26	697.27	7

The area of the patient-associated *bounding box* was calculated from the dimensions of the delimited region. Patient displacement was calculated as the difference between the centroid of the anatomical keypoints in the current image and the centroid in the reference image. Displacement values were initially obtained in pixels and then converted into millimeters, considering that 1 pixel corresponds to 0.1 mm. Area values were converted in the same manner, enabling a physical interpretation closer to a real clinical scenario. Table VI was constructed from these parameters.

Table VI
PARAMETERS OBTAINED WITH THE *Keypoint R-CNN* MODEL, INCLUDING THE PATIENT-ASSOCIATED *bounding box* AREA AND DISPLACEMENT OF THE ANATOMICAL-KEYPOINT CENTROID ACROSS THE IMAGES, EXPRESSED IN PIXELS AND MILLIMETERS.

Frame	Box area (px^2)	Box area (mm^2)	Displacement (px)	Displacement (mm)
Ref.	142689.06	1426.89	0.00	0.00
Mov_1	243481.83	2434.82	83.40	8.34
Mov_2	251717.70	2517.18	99.99	10.00
Mov_3	363800.53	3638.01	247.36	24.74

The displacement values in millimeters were then classified as mild, moderate, or critical using the same tolerance thresholds adopted for the previous *Mask R-CNN* model. Table VII presents the results obtained from the image analysis.

Table VII
DISPLACEMENT OF THE KEYPOINT CENTROID IN MILLIMETERS, MOTION CLASSIFICATION, AND SIMULATED SYSTEM ACTION FOR DIFFERENT PATIENT POSITIONS.

Frame	Displacement (mm)	Classification	System action
Ref.	0.00	Mild	Normal operation
Mov_1	8.34	Critical	Immediately interrupt acquisition / beam
Mov_2	10.00	Critical	Immediately interrupt acquisition / beam
Mov_3	24.74	Critical	Immediately interrupt acquisition / beam

IV. Discussion

A. General Analysis

The comparative analysis showed that the technologies investigated in this study perform differently when applied to patient-motion monitoring in clinical environments according to the defined parameters. Overall, computer vision provided the most balanced set of characteristics among the evaluated approaches, particularly because of its broader monitored-region coverage, good motion-detection accuracy, and greater versatility across different clinical contexts.

B. Discussion of the Comparative Parameters

Coverage was analyzed according to the extent of the observed region and the ability to track movement along the patient's body. In this respect, computer vision and radar provided better performance, whereas laser-based systems offered more localized coverage [11], [20].

Susceptibility to interference was evaluated according to its impact on detection reliability in clinical environments with physical and electromagnetic restrictions, such as shielded diagnostic imaging and radiotherapy rooms. Under these conditions, radar sensors were more vulnerable to reflections, echoes, and environmental interference [15]–[17].

Versatility was assessed according to the ability of each technology to adapt to different rooms, equipment, and procedures without disrupting clinical workflow. Accuracy was interpreted together with the operating principle of each technology, distinguishing broad measurements from localized detection. Therefore, the most appropriate solution must be selected through an integrated analysis of the parameters, because good performance in an isolated criterion does not necessarily indicate the best clinical application.

C. Considerations Regarding the Selection of Computer Vision

Some factors that could initially be interpreted as limitations of computer vision were not sufficient to prevent its application. Low-light environments, for example, do not necessarily constitute a critical obstacle for optical systems because many clinical arrangements use infrared cameras or acquisition methods adapted to these conditions. Similarly, although magnetic resonance imaging environments impose additional electromagnetic-compatibility challenges, the analyzed studies describe adaptation and mitigation strategies for these scenarios [13], [19].

Among the evaluated technologies, computer vision therefore presented the most manageable limitations and the most favorable balance for monitoring patient positioning. The results reinforce the importance of this project by demonstrating the feasibility of investigating these technologies in clinical environments and by emphasizing the need for more specific and quantitative studies of their practical application. Such progress may support the development of systems capable of improving the safety, accuracy, and reliability of clinical procedures.

D. Proposed Practical Solution

The results demonstrated the feasibility of using computer vision to monitor patient positioning in simulated diagnostic imaging and radiotherapy scenarios. However, because suitable public clinical *datasets* were unavailable, artificial-intelligence-generated images were used to represent different positional changes. The sequence of these images simulated the basic behavior of a video composed of successive *frames*.

In the model comparison, *Mask R-CNN* provided greater stability in silhouette segmentation and body-area estimation. *Keypoint R-CNN* was more sensitive to postural changes because the calculated centroid directly depends on the positions of the detected anatomical points. Consequently, movements of the arms, legs, or head produced more significant variations in the calculated displacement.

Both models were pretrained on the COCO *dataset* and were not specifically developed for clinical applications, which contributed to the limitations observed in segmentation and anatomical-point detection.

This study reinforces the importance of research on patient positioning for improving procedural safety and reducing risks such as unnecessary radiation exposure to healthy tissues [2], [3]. It also demonstrates the potential to develop more accurate and accessible solutions for continuous monitoring without necessarily increasing operating costs [8], [9], [15].

V. Conclusion

The results demonstrated that computer vision, laser-based sensors, and radar sensors have potential for monitoring patient positioning and movement in imaging examinations and radiotherapy, although they provide different levels of suitability. Computer vision showed the most balanced set of characteristics, with broad coverage, good accuracy, and greater versatility, and was therefore considered the most promising approach. Radar provided good coverage and accuracy but was more susceptible to interference, whereas laser-based systems were suitable for localized measurements but offered more restricted coverage and greater dependence on system configuration. The practical stage confirmed the technical feasibility of using convolutional neural networks in simulated scenarios: *Mask R-CNN* was more stable in segmenting the body region, whereas *Keypoint R-CNN* was more sensitive to postural changes. Limitations associated with the scarcity of studies, public clinical data, and quantitative information on the effects of improper positioning were also identified. Although this study did not develop a system validated for hospital use, it demonstrated the computational feasibility of the proposal and established a basis for future research on patient monitoring, computer vision, and decision support in clinical procedures.

***Abstract*—Blood collection is an essential procedure for the diagnosis, monitoring, and therapeutic management of various clinical conditions. However, conventional venipuncture presents limitations regarding pain, discomfort, vascular access difficulties, and occupational risks. In this context, minimally invasive technologies have been developed to enhance safety, improve the patient experience, and increase the efficiency of diagnostic processes. This study conducted a Systematic Literature Review (SLR), following PRISMA 2020 guidelines, aiming to identify and analyze the main technologies employed in minimally invasive blood collection from the perspectives of Biomedical Engineering and Product Engineering. Searches were performed in the PubMed, Scopus, and Web of Science databases, covering studies published between 2015 and 2026. The selected works were grouped into technological categories, encompassing microneedle-based devices, capillary collection systems, blood microsampling technologies, and biosensors, as well as aspects related to usability and regulation. The results highlighted the advancement of these technologies, driven by developments in biomaterials, microfabrication techniques, and integration with smart systems. Despite the significant potential for pain reduction, improved sample quality, and expanded remote monitoring, challenges regarding clinical validation, industrial scalability, and regulatory compliance remain. It is concluded that Biomedical Engineering plays a fundamental role in developing innovative, safe, and user-centered solutions, contributing to the evolution of devices designed for minimally invasive blood collection.**

***Keywords*—Blood collection; Minimally invasive technologies; Biomedical engineering; Product engineering.**

I. Introduction

Blood collection is one of the most frequently performed procedures in clinical practice, essential for the diagnosis, therapeutic monitoring, and management of various diseases. Although conventional venipuncture remains the most widely used method, it is associated with pain, discomfort, vascular access difficulties in specific patient groups, and occupational risks arising from the use of sharp instruments.

Despite their widespread use, traditional collection methods still present significant limitations such as pain, discomfort, venipuncture failure, and variable sample quality which can compromise test results and necessitate repeat procedures in healthcare settings [1].

In recent years, the development of minimally invasive technologies has provided alternatives capable of mitigating these issues; notable examples include microneedle-based devices, microfluidic systems, needle-free technologies, wearable biosensors, and blood microsampling platforms.

Hoffmann, point out that the perception of pain is related not just to the method used, but also to the technique applied, the professional's experience, and the patient's venous conditions and the systems they use [6].

According to data from ANVISA, approximately 15,501 interruptions to blood collection procedures were recorded in Brazil (with 306 in Rio Grande do Norte), with venipuncture difficulty being one of the primary associated causes [3].

Despite the significant growth in scientific output in this field, challenges remain regarding clinical validation, standardization, regulation, and the integration of these technologies into healthcare services. Thus, it is relevant to gather and critically analyze available evidence, identifying technological trends and opportunities for the development of new biomedical devices.

The incorporation of advanced technologies in the healthcare sector has brought about profound transformations in how clinical processes are conceived, organized, and executed.

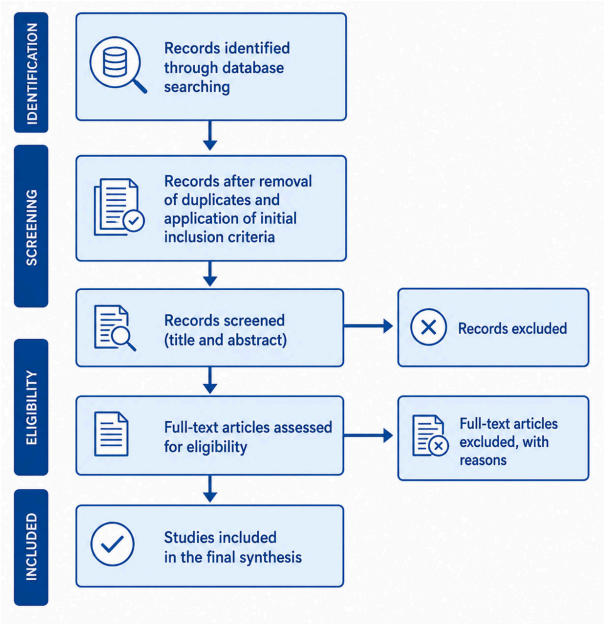

Fig. 1. Study search and selection strategy. Flowchart of the phases of the PRISMA method. Source: adapted from Moher et al. (2009)

These innovations not only expand diagnostic and therapeutic capabilities but also reshape the roles of patients and healthcare professionals in establishing a more integrated and personalized model of care [4].

Accordingly, this study aims to map and analyze minimally invasive blood collection technologies, identifying their technical characteristics and discussing how Product Engineering principles contribute to the development of devices that are safer, more ergonomic, reliable, and user-centered.

II. Materials and Methods

This study is a Systematic Literature Review (SLR) conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA 2020) guidelines. The objective was to identify, analyze, and synthesize scientific evidence regarding minimally invasive technologies used for blood collection, considering technological, clinical, and product development aspects.

A. Search strategy

The bibliographic search was conducted in the Scopus, PubMed, and Web of Science databases in 2026, covering publications from 2015 to 2026. The search strategy combined Medical Subject Headings (MeSH) and free-text terms using Boolean operators. The core search string employed was:

(”blood collection” OR ”blood sampling” OR ”capillary blood”) AND (”microneedle” OR ”microsampling” OR ”minimally invasive” OR ”microfluidic” OR ”biosensor”) AND (”product engineering” OR ”usability” OR ”ergonomics” OR ”device design” OR ”point-of-care”)

English descriptors combined with Boolean operators were used, including the terms blood collection, microneedles, microfluidics, capillary blood collection, minimally invasive, point-of-care, wearable biosensors, and product engineering. The searches covered publications from 2015 to 2026, a period characterized by the growth of research related to the development of minimally invasive biomedical devices.

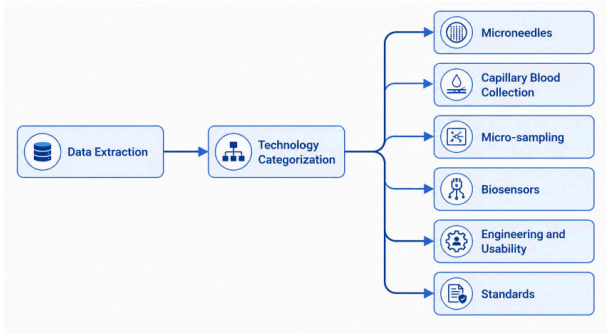

Fig. 2. Search and study selection strategy.Source: Author (2026)

B. Eligibility criteria

Original articles published in journals or scientific conference proceedings were included if they were available in full text, written in English or Portuguese, and related to the development, evaluation, or application of technologies for minimally invasive blood collection.

Duplicate studies, literature reviews, editorials, extended abstracts lacking full text, and works that did not directly address technologies for obtaining blood samples were excluded.

C. Selection of studies

The selection of studies was carried out in successive stages. Initially, duplicate records were removed. Subsequently, titles and abstracts were reviewed to assess their relevance to the topic. Potentially eligible articles underwent full-text evaluation, resulting in the final selection of studies included in the systematic review. The process of identification, screening, eligibility assessment, and inclusion was organized according to the PRISMA 2020 flow diagram.

D. Data extraction and analysis

Information from the selected studies was extracted in a standardized manner, covering authors, year of publication, technology employed, objective, methodology, main results, advantages, limitations, and clinical applications.

Subsequently, the articles were grouped into technological categories to facilitate comparative analysis:

- microneedle-based devices;
- minimally invasive capillary collection systems;
- blood microsampling technologies;
- biosensors and smart devices;
- product engineering and usability aspects;
- applicable standards and regulations.

The synthesis of the results was conducted qualitatively, identifying technological trends, development challenges, and

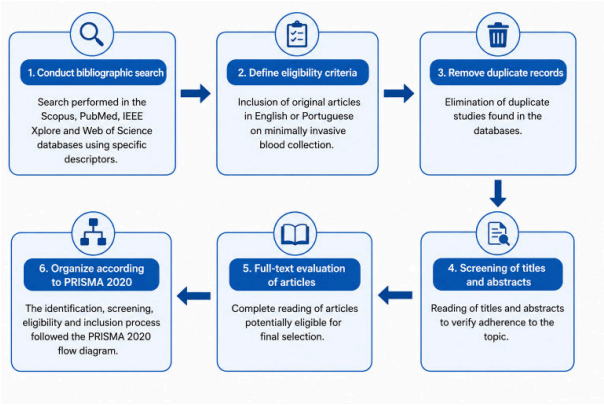

Fig. 3. Data Extraction and Analysis Process.Source: Author (2026)

opportunities for innovation in the field of Biomedical Product Engineering.

III. Results

The search strategy resulted in the identification of studies related to the development of devices for minimally invasive blood collection. After applying eligibility criteria and removing duplicate records, the studies considered most relevant were selected for inclusion in the systematic review.

The included studies demonstrated significant growth in research over the last decade, driven primarily by advances in microfabrication, biomaterials, microfluidics, and biosensors.

The analysis enabled the classification of the technologies into six main categories, presented in Table I.

TABLE I
Criteria used for the analysis of the selected studies

Criterion	Description
Technology	Type minimally invasive device used for blood collection.
Clinical application	Purpose of the technology (diagnosis, monitoring, or laboratory tests).
Degree and level	Invasiveness the procedure (minimal, low, or moderate).
Sample volume and amount	Blood required for collection (μL or mL).
Pain reduction	Evidence regarding the reduction pain or discomfort during collection.
Usability, ergonomics, ease	Use, comfort,interaction between user and device. Safety and aspects related to the risk of infection accidents, and to patient and professional protection.
Technological maturity	Technology development stage.
Limitations	Main technical, clinical, regulatory implementation restrictions identified in the studies.

Source: Author (2026)

A predominance of studies focused on the development of microneedle-based devices was observed, highlighting the technology's potential to reduce pain during collection, improve the patient experience, and enable integration with microfluidic platforms and diagnostic systems.

Studies related to capillary sampling demonstrated advances in obtaining samples with lower blood volumes, thereby reducing patient discomfort and facilitating applications in home monitoring, pediatrics, and chronic disease management. Research on blood microsampling highlighted the reduction in sample volume, simplified sample transport logistics, and the potential for remote monitoring, all of which contribute to the decentralization of laboratory services.

For the Quantitative data for the PRISMA Flowchart:

TABLE II
Quantitative data from the PRISMA flowchart.

PRISMA stage	n	Description
Identification	7.130	Records retrieved from the databases.
Duplicates removed	2.150	Duplicate records removed before screening.
Screening	4.980	Records screened by title and abstract.
Records excluded	4.100	Records excluded after title and abstract screening.
Eligibility assessment	880	Full-text articles assessed for eligibility.
Full-text articles excluded	760	Articles excluded due to ineligible study type ($n = 320$), insufficient data ($n = 260$), or out-of-scope content ($n = 180$).
Studies included	120	Articles included in the final qualitative synthesis.

Source: Author (2026)

The study selection process was conducted in successive stages. Initially, 7,130 records were retrieved from the selected databases, followed by the identification and removal of 2,150 duplicate records, resulting in 4,980 records for screening. Subsequently, the records were screened based on their titles and abstracts according to the predefined inclusion and exclusion criteria, and 4,100 records were excluded at this stage. The remaining 880 articles were assessed for eligibility through full-text reading. At this stage, 760 articles were excluded because they presented an ineligible study type (n = 320), insufficient information for analysis (n = 260), or content outside the scope of the research (n = 180). Finally, 120 studies that met all predefined eligibility criteria were included in the qualitative synthesis. To reduce subjectivity throughout the selection process, the eligibility criteria were established in advance and applied consistently to all retrieved records, considering the relevance of the study to minimally invasive technologies for blood collection and its alignment with the objectives of the research. Product Engineering also contributes to defining requirements for performance, reliability, manufacturability, and regulatory compliance factors

essential for the effective transfer of technologies developed in research settings to clinical practice and the industry.

IV. DISCUSSION

The search and selection process identified studies related to the development and evaluation of technologies for minimally invasive blood collection. After removal of duplicate records, titles and abstracts were screened according to the eligibility criteria. The potentially eligible studies were subsequently assessed in full text, resulting in the final set of studies included in the systematic review.

The characteristics of the included studies are presented in Table II, including the technological category, device characteristics, sample characteristics, blood volume, pain or discomfort outcomes, analytical performance, validation stage, and limitations. The included studies demonstrated continued development of minimally invasive blood collection technologies, particularly in the areas of microneedles, capillary sampling, blood microsampling, microfluidic systems, and biosensor-integrated platforms.

Of the 120 studies included in the systematic review,19 were highlighted for a more specific analysis of the main technological approaches identified. The selection of these studies aimed to demonstrate the diversity of solutions proposed for minimally invasive blood collection, encompassing different collection strategies, operating principles, and device configurations. Table III presents these studies and their respective technologies or approaches, allowing the recurring trends in the analyzed literature to be identified.

The process of identifying, screening, assessing eligibility, and including studies was carried out according to the recommendations of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA 2020).

Table III shows a slice of the 120 studies included in the systematic review, selected to illustrate the main technologies and approaches identified.

The analysis of the highlighted studies reveals the presence of different technological strategies aimed at reducing invasiveness, discomfort, and dependence on conventional venipuncture. Among the main patterns identified are microneedles, microsampling technologies, capillary blood collection devices, and microfluidic-based solutions.

Microneedles constitute one of the most recurrent approaches, being used to penetrate the skin superficially and enable the collection of small amounts of blood with reduced invasiveness. The studies analyzed present different configurations, including solid and hollow microneedles, as well as systems associated with patches and collection mechanisms.

Another identified pattern corresponds to microsampling technologies, which use small blood volumes and may facilitate simpler and more accessible collection strategies suitable for different use contexts. This approach is also associated with the possibility of performing blood collection outside conventional laboratory settings.

Capillary blood collection devices represent another relevant technological pathway. These solutions use blood obtained through superficial skin puncture and incorporate mechanisms designed to facilitate blood flow, sample capture, and storage. The strategies identified include self-collection devices, capillary-based systems, and auxiliary mechanisms for sample acquisition.

The integration of microfluidic systems is also noteworthy, particularly in solutions in which blood collection is associated with sample transport, processing, or analysis within miniaturized structures. This integration expands the potential of these devices by bringing the collection stage closer to subsequent sample processing and diagnostic steps.

Overall, the identified patterns indicate a development trend toward solutions that go beyond simply replacing the conventional needle. The technologies analyzed present different levels of integration among sample collection, transport, processing, and analysis, reflecting a product development perspective focused on reducing invasiveness, improving usability, and integrating different stages of the process. Thus, the selected studies contribute to understanding the main technological directions in minimally invasive blood collection and provide a basis for analysis from a Product Engineering perspective.

The reported technologies varied in their degree of invasiveness, sample volume, level of technological development, usability, and clinical validation. From a Product Engineering perspective, the studies were analyzed according to functionality, ergonomics, usability, materials, manufacturing, safety, reliability, sustainability, regulatory aspects, and industrialization potential.

Among the technologies identified, devices based on microneedles stand out as one of the main trends, presenting the potential to significantly reduce pain during collection, minimize tissue damage and allow obtaining samples suitable for clinical analysis. Furthermore, the integration of these structures with microfluidic systems and biosensors favors the development of portable platforms for diagnosis and continuous monitoring.

Regarding the analysis from a Product Engineering perspective, the devices identified in this review can be examined in terms of a development process spanning various design stages—from the definition of functional requirements to validation for production and integration into healthcare services. This approach reveals that innovation in minimally invasive devices depends not only on clinical efficacy but also on the integration of factors such as ergonomics, usability, material selection, manufacturing processes, safety, reliability, sustainability, and regulatory compliance.

In this context, microneedles stand out for meeting various design requirements, such as pain reduction, minimized tissue damage, ease of application, and the potential for integration with microfluidic systems and biosensors. From a Product Engineering standpoint, these characteristics reflect a user-centered development process that prioritizes comfort, safety, and functional performance.

Blood technologies demonstrate a significant contribution from Product Engineering by simplifying the collection process and sample transport logistics. These devices are designed to obtain low-volume capillary blood or interstitial fluid with minimal tissue trauma, avoiding deep venipuncture [5], [6]. From this perspective, these solutions are developed to meet functionality, usability, and operational efficiency requirements, reducing costs, favoring the decentralization of laboratory tests, and expanding the feasibility of self-collection [5].

These solutions reduce operational costs, facilitate the decentralization of laboratory testing, and expand the potential for self-collection—features that add value to the product and ease its integration into various care settings.

Thus, it is evident that Product Engineering serves not merely as support for technological development but as a strategic element in translating clinical requirements into innovative solutions, balancing technical performance, user experience, industrial feasibility, and regulatory compliance. This integration strengthens the innovation process and enhances the potential for these technologies to be adopted by healthcare systems.

To compare criteria related to Product Engineering, scores contributing to the classification were assigned in the table.

Note: A = High; M = Medium; L = Low. The qualitative classification was established based on a comparative analysis of the studies included in the Systematic Literature Review and was linked to product engineering criteria, such as functional requirements, ergonomics, usability, material selection, manufacturing processes, safety, reliability, sustainability, regulations, and industrialization potential. The technologies were qualitatively classified according to Product Engineering criteria, considering the evidence reported in the studies included in the systematic review. The following classification scale was adopted:

- **A – High:** the criterion was strongly addressed or demonstrated in the analyzed technology.
- **M – Medium:** the criterion was partially addressed or demonstrated, with moderate evidence.
- **B – Low:** the criterion was weakly addressed or demonstrated, with limited evidence.

Note: Technological categories are defined as follows:
T1: Microneedle-based collection systems;
T2: Minimally invasive capillary collection devices;
T3: Blood microsampling dried blood spot (DBS) technologies;
T4: Wearable biosensors and smart diagnostic platforms.
Scale: A = High (criterion strongly fulfilled/demonstrated); M = Medium (partially fulfilled/moderate evidence); B = Low (weakly addressed/limited evidence).

The criteria considered were functionality, ergonomics, usability, materials, manufacturing, safety, reliability, sustainability, regulatory aspects, and industrialization potential. The classification was based on a comparative analysis of the technological characteristics reported in the selected studies.

TABLE IV
COMPARISON OF TECHNOLOGIES BASED ON PRODUCT ENGINEERING CRITERIA

Criterion	T1	T2	T3	T4
Functionality	A	M	A	A
Ergonomics	A	M	A	A
Usability	A	A	A	M
Materials	A	M	M	A
Manufacturing	B	A	A	B
Safety	A	M	A	A
Reliability	A	A	M	M
Sustainability	M	M	A	M
Regulation	M	A	M	B
Industrialization	M	A	A	M

Note: A = High; M = Medium; B = Low.

Studies on blood microsampling have also shown promising results, particularly in applications requiring small blood volumes, such as remote monitoring, personalized medicine, and chronic disease management. These solutions reduce the need for complex laboratory infrastructure, fostering the decentralization of healthcare services and expanding access to diagnostics.

Microneedles (MNs) emerge as a promising alternative to transform this scenario; they are microscopic structures, typically less than 1 mm in length, capable of penetrating the skin's outermost layer the stratum corneum without reaching nerve endings or deep blood vessels. This allows for virtually painless application, with minimal risk of infection and rapid skin healing after use. The stratum corneum is the outermost layer of the skin, acting as a robust barrier against microorganisms, skin dehydration, and drug permeation [6].

From the perspective of Product Engineering, the development of these devices involves specification, design, manufacturing and validation stages, aiming to guarantee technical performance, usability and safety. Product engineering is responsible for activities ranging from project specification and details of its operations to the generation of the necessary documentation for its production [2].

From a product engineering perspective, it has been found that factors such as ergonomics, ease of use, safety, reliability, and user-centered design directly influence the clinical acceptance of these technologies. Consequently, device development must consider not only technical performance but also aspects related to the patient experience, usability by healthcare professionals, and the feasibility of large-scale manufacturing.

However, despite the advances observed, significant challenges remain regarding clinical validation, standardization of collection methods, industrial scalability, and compliance with national and international regulatory requirements. Overcoming these limitations will be crucial to expanding the incorporation of these technologies into clinical practice and strengthening their application in minimally invasive systems.

V. Final Remarks

This systematic review identified the key technologies employed in minimally invasive blood collection, highlighting the growth of research focused on the development of microneedle-based devices, microsampling systems, capillary collection, and platforms integrated with biosensors. The results demonstrate that these technologies hold significant potential to reduce pain, enhance procedural safety, improve sample quality, and expand the possibilities for remote monitoring and decentralized diagnostics.

From the perspectives of biomedical and product engineering, the integration of technological innovation, usability, and regulatory compliance is a key factor in developing more efficient, user-centered clinical devices.

Although challenges regarding clinical validation, large-scale production, and regulation persist, the evidence indicates a trend toward these technologies becoming established as promising alternatives to conventional blood collection methods. Thus, this study contributes to mapping the state of the art and provides a foundation for future research and the development of innovative solutions for healthcare diagnostic and monitoring systems.

***Abstract*—This ecological cross-sectional study evaluated the geographic distribution and administrative availability of eight telehealth-related equipment categories registered in the Brazilian National Registry of Health Establishments (CNES). Municipal- and state-level analyses combined population-adjusted indicators, global and local spatial autocorrelation, and municipal sensitivity models including connectivity, household income, and urbanization. Nationwide, 11,745 devices were identified, of which 11,285 were registered as "in use", corresponding to a national administrative in-use ratio (AIR) of 96.08%. Among 5,571 municipal territorial units, 4,138 had no equipment registered as in use. Municipal Global Moran's I for equipment registered as in use per 100,000 inhabitants was 0.193 (permutation $p = 0.0001$). At nominal $p < 0.05$, Local Moran analysis classified 352 municipalities as High–High, 51 as Low–High, and 42 as High–Low, with no Low–Low clusters. No municipality met the Benjamini–Hochberg or Bonferroni multiplicity criteria, whereas a permutation-based maxT familywise-error analysis retained four High–High local associations in Mato Grosso do Sul. In the fully adjusted municipal negative-binomial model, the IBC estimate included the null (IRR=1.039, 95% CI 0.957–1.127, $p = 0.361$). These findings support municipal-scale spatial structure but more limited municipality-specific localization, and indicate that the connectivity association is sensitive to socioeconomic adjustment. The CNES "in use" field was interpreted as administrative availability rather than direct evidence of clinical utilization, productivity, or uptime.**

***Index Terms*—Telehealth, CNES, Spatial Analysis, Clinical Engineering, Health Inequalities.**

I. Introduction

Telehealth has become an important strategy for mitigating geographical barriers and expanding access to specialized healthcare [1], [2]. Its effectiveness, however, depends on a chain of mutually dependent resources, including suitable medical devices, reliable connectivity, interoperable information systems, trained personnel, maintenance capacity, and integration with clinical workflows [2]–[4].

In Brazil, the Telessaúde Brasil Redes Program and other digital-health initiatives have contributed to the institutionalization of telehealth within the Unified Health System (SUS) [5]–[8]. Nevertheless, large territorial distances and persistent socioeconomic inequalities create substantial heterogeneity in technological capacity, with previous studies reporting regional concentration of telemedicine services and barriers related to connectivity, professional training, and organizational readiness [9], [10].

Absolute equipment counts alone are insufficient for evaluating equitable access. Highly populated territories are expected to contain larger equipment stocks even when population-adjusted availability is comparatively low. Likewise, the proportion of equipment registered as in use describes the administrative status of installed stock but does not measure clinical service use. These dimensions should therefore be analyzed separately.

Accordingly, this study characterizes the distribution of telehealth-related equipment at municipal and state levels, evaluates spatial autocorrelation in population-adjusted administrative availability, and examines the robustness of the association between connectivity and equipment availability after adjustment for selected municipal socioeconomic characteristics.

II. Methodology

A. Study Design and Data Sources

A quantitative, ecological, and cross-sectional design was adopted. Equipment data were extracted from the CNES physical-resources database maintained by DataSUS [11]. The SCNES filling guide defines "in use" as the number of registered units effectively being used at the establishment and instructs that equipment under maintenance be excluded from this quantity [34]. Because this is a registry field rather than a direct measurement of device activity, we use it as an indicator of administrative availability. The analytical dataset comprised eight telehealth-related equipment categories: facial-recognition cameras, dermatoscopes, portable fetal detectors, medical audiological diagnostic kits, digitizing tablets, portable multiparameter telehealth monitors, portable retinographs, and portable ultrasound systems. The equipment reference period was January 2026.

Population estimates with a reference date of July 1, 2025 were obtained from the Brazilian Institute of Geography

and Statistics (IBGE) [12]. Municipal household income was obtained from the 2022 Demographic Census income results (SIDRA Table 10295), while urban and rural population counts were obtained from the 2022 Census municipal tables and used to calculate the urbanization percentage [30], [31]. Connectivity was represented by the 2025 Brazilian Connectivity Index (IBC), developed by Anatel [13]. The 2025 IBGE Municipal Digital Mesh was used to define municipal and state boundaries for the spatial analysis [32].

The descriptive and spatial analysis comprised 5,571 municipal territorial units. The socioeconomic sensitivity models included 5,570 units with complete IBC, income, urbanization, population, and equipment information. Boa Esperança do Norte (MT), created after the 2022 Census reference structure, was present in the 2025 population/equipment database but had no 2022 socioeconomic covariates and was therefore excluded only from the adjusted municipal models. Complementary analyses were aggregated to the 27 Brazilian federative units.

B. Outcome Definitions

For each territorial unit, the existing quantity ($Q_{existing}$) and the quantity registered as in use (Q_{use}) were summed across the equipment set. The administrative in-use ratio (AIR) was defined as

$$AIR = \frac{Q_{use}}{Q_{existing}} \times 100\%, \tag{1}$$

provided that $Q_{existing} > 0$. Population-adjusted availability was defined as

$$D_{100k} = \frac{Q_{use}}{P} \times 100{,}000, \tag{2}$$

where P is the 2025 population estimate.

The CNES "in use" field was treated as an administrative availability indicator. Although CNES instructs establishments to classify as "in use" only equipment effectively being used and to exclude units under maintenance [34], the registry does not provide direct measurements of uptime, examination or consultation volume, clinical productivity, intensity of use, or integration into routine care. AIR and D_{100k} therefore characterize registered infrastructure rather than realized clinical service production.

C. Statistical and Spatial Analysis

Descriptive statistics were calculated for all indicators. At the municipal level, Spearman rank correlations were used to examine the bivariate associations of population-adjusted equipment availability with IBC, household income, urbanization, and population. Two-sided p-values were calculated and the Benjamini–Hochberg procedure was used to control the false discovery rate across these municipal correlation tests [14]. Because of the large municipal sample, interpretation emphasized both the magnitude of the correlation coefficient and statistical significance. State-level Spearman correlations were retained as a scale-comparison analysis and were likewise reported with Benjamini–Hochberg-adjusted q-values.

Global Moran's I was calculated for equipment registered as in use per 100,000 inhabitants using row-standardized Queen contiguity and 9,999 random permutations [28], [29]. Local Moran's I classified nominal High–High, Low–Low, Low–High, and High–Low patterns at $p < 0.05$ [29]. Two island units had no Queen neighbors, leaving 5,569 local tests. Municipality-specific inference was then re-evaluated using Benjamini–Hochberg FDR ($q < 0.05$) [14], Bonferroni ($\alpha = 0.05/5569$), and permutation maxT FWER control [35]. The upper-tail maxT distribution retained the maximum positive Local Moran statistic across municipalities within each common permutation and therefore targeted positive High–High/Low–Low cluster-type association; negative spatial outliers remained exploratory. The same Global Moran framework was applied at state level. Municipal boundaries came from the 2025 IBGE Digital Mesh [32]. A simulation sensitivity analysis used contiguous clusters of 10, 25, 50, or 100 municipalities, signals of 1–5 observed SD, and approximately 2,000 replicates per scenario to compare Global Moran detection with maxT localization and FWER.

D. Municipal Socioeconomic Modeling

The municipal adjusted analysis used the equipment count registered as "in use" as the dependent variable rather than the rate itself. The count exhibited marked overdispersion (mean $= 2.03$, variance $= 153.64$; variance-to-mean ratio $= 75.83$); therefore, negative-binomial regression with NB2 variance specification was selected instead of a Poisson model [33]. The 2025 municipal population was included as the exposure term, which is equivalent to including $\ln(\text{population})$ as an offset with its coefficient fixed at one.

Four nested sensitivity models were estimated: Model 1 included IBC alone; Model 2 included IBC and per-capita household income; Model 3 included IBC and urbanization; and Model 4 simultaneously included IBC, income, and urbanization. For interpretability, IBC was scaled per 10-point increase, income per R$1,000 increase, and urbanization per 10-percentage-point increase. Results are reported as incidence-rate ratios (IRRs), 95% confidence intervals, and two-sided p-values. In the fully adjusted model, variance-inflation factors were 2.02 for IBC, 1.56 for income, and 1.49 for urbanization, providing no indication of problematic multicollinearity. Because the municipal outcome showed significant spatial autocorrelation, these models were treated as sensitivity analyses. No spatial count regression was fitted; therefore, the regression coefficients were not interpreted as causal or spatially independent effects.

III. Results

A. National and Regional Distribution

Across Brazil, 11,745 telehealth-related equipment items were identified, of which 11,285 were registered as "in use" in CNES. The national administrative AIR was 96.08%, and the population-adjusted availability was 5.29 equipment items registered as in use per 100,000 inhabitants. Among the 5,571

municipal-level territorial units included in the spatial analysis, 4,138 (74.28%) had no equipment registered as in use.

Regional variation was observed in absolute stock, administrative AIR, and population-adjusted availability. The Northeast had 6,601 existing equipment items and 6,404 registered as in use, corresponding to 11.19 per 100,000 inhabitants. The Southeast had 2,517 existing items and 2,423 registered as in use, corresponding to 2.73 per 100,000 inhabitants, while the North had 561 existing items and 550 registered as in use, corresponding to 2.93 per 100,000 inhabitants. Administrative AIR ranged from 85.85% in the Central-West to 98.04% in the North, whereas population-adjusted availability ranged from 2.73 to 11.19 per 100,000 inhabitants. The two indicators are reported separately because they represent distinct features of the registered equipment infrastructure. Regional values are summarized in Table I.

TABLE I
DISTRIBUTION OF TELEHEALTH-RELATED EQUIPMENT BY BRAZILIAN MACRO-REGION.

Region	Existing	In use	Admin. AIR (%)	In use/100k
North	561	550	98.04	2.93
Northeast	6,601	6,404	97.02	11.19
Central-West	763	655	85.85	3.80
Southeast	2,517	2,423	96.27	2.73
South	1,303	1,253	96.16	4.00
Brazil	11,745	11,285	96.08	5.29

B. Equipment-Specific Distribution

The composition of the existing stock also varied across equipment categories. Facial-recognition cameras accounted for 8,132 units (69.24% of the national stock), followed by portable fetal detectors with 1,582 units (13.47%). Dermatoscopes accounted for 491 units (4.18%), digitizing tablets for 402 (3.42%), portable multiparameter telehealth monitors for 327 (2.78%), portable ultrasound systems for 295 (2.51%), portable retinographs for 277 (2.36%), and medical audiological diagnostic kits for 239 (2.03%). Table II presents the distribution across all eight categories.

TABLE II
EXISTING TELEHEALTH-RELATED EQUIPMENT STOCK BY EQUIPMENT CATEGORY.

Equipment category	Existing stock	Share (%)
Facial-recognition camera	8,132	69.24
Portable fetal detector	1,582	13.47
Dermatoscope	491	4.18
Digitizing tablet	402	3.42
Portable multiparameter telehealth monitor	327	2.78
Portable ultrasound system	295	2.51
Portable retinograph	277	2.36
Medical audiological diagnostic kit	239	2.03
Total	11,745	100.00

C. Municipal Spatial Autocorrelation

For equipment registered as in use per 100,000 inhabitants, municipal Global Moran's I was 0.193 (permutation $p = 0.0001$; Queen contiguity; 9,999 permutations), providing evidence of positive global spatial autocorrelation. Among the 5,569 non-isolated municipalities, nominal Local Moran inference identified 445 local associations: 352 High–High, 51 Low–High, and 42 High–Low; no Low–Low municipality met the nominal $p < 0.05$ criterion. The two Queen isolates, Fernando de Noronha (PE) and Ilhabela (SP), were not tested locally (Table III).

Multiplicity correction substantially restricted municipality-specific inference. No municipality satisfied BH-FDR at $q < 0.05$ (minimum $q = 0.0796$), and none satisfied Bonferroni correction. The Bonferroni threshold was 8.98×10^{-6}, below the minimum attainable permutation p-value of 0.0001 with 9,999 permutations; Bonferroni non-rejection therefore cannot be interpreted as evidence that local structure is absent. In contrast, the permutation maxT FWER procedure retained four High–High local associations, all in Mato Grosso do Sul: Pedro Gomes ($p_{FWER} = 0.0047$), Taquarussu ($p_{FWER} = 0.0141$), Jateí ($p_{FWER} = 0.0173$), and Alcinópolis ($p_{FWER} = 0.0400$).

TABLE III
MUNICIPAL LOCAL MORAN CLASSIFICATIONS BEFORE AND AFTER MULTIPLICITY CONTROL.

LISA class	Nominal	BH-FDR	Bonf.	maxT FWER
High–High	352	0	0	4
Low–Low	0	0	0	0
Low–High	51	0	0	0
High–Low	42	0	0	0
No local rejection	5,124	5,569	5,569	5,565
Not tested (isolate)	2	2	2	2
Total	5,571	5,571	5,571	5,571

Simulation confirmed substantially greater global than local detection power: a 25-municipality, 3-SD cluster yielded 78.2% Global Moran power but 2.3% probability of at least one true maxT localization. Global power reached approximately 100% in stronger scenarios, whereas maximum maxT localization power was 52.9%; the mean probability of any outside-cluster maxT detection was 4.84%, consistent with 5% FWER.

D. State-Level Scale Analysis

After aggregation to the 27 federative units, Global Moran's I was 0.166 with $pseudo\text{-}p = 0.0632$, which did not meet the prespecified 5% significance threshold. At this scale, IBC was positively correlated with equipment registered as in use per 100,000 inhabitants ($\rho = 0.589$, BH-adjusted $q = 0.0197$). This state-level association is reported as a scale-specific descriptive result and is interpreted alongside the municipal analysis below.

E. Municipal Associations and Socioeconomic Sensitivity Analysis

The municipal bivariate correlations with equipment registered as in use per 100,000 inhabitants were small in magnitude. The Spearman coefficients were $\rho = -0.060$ for IBC

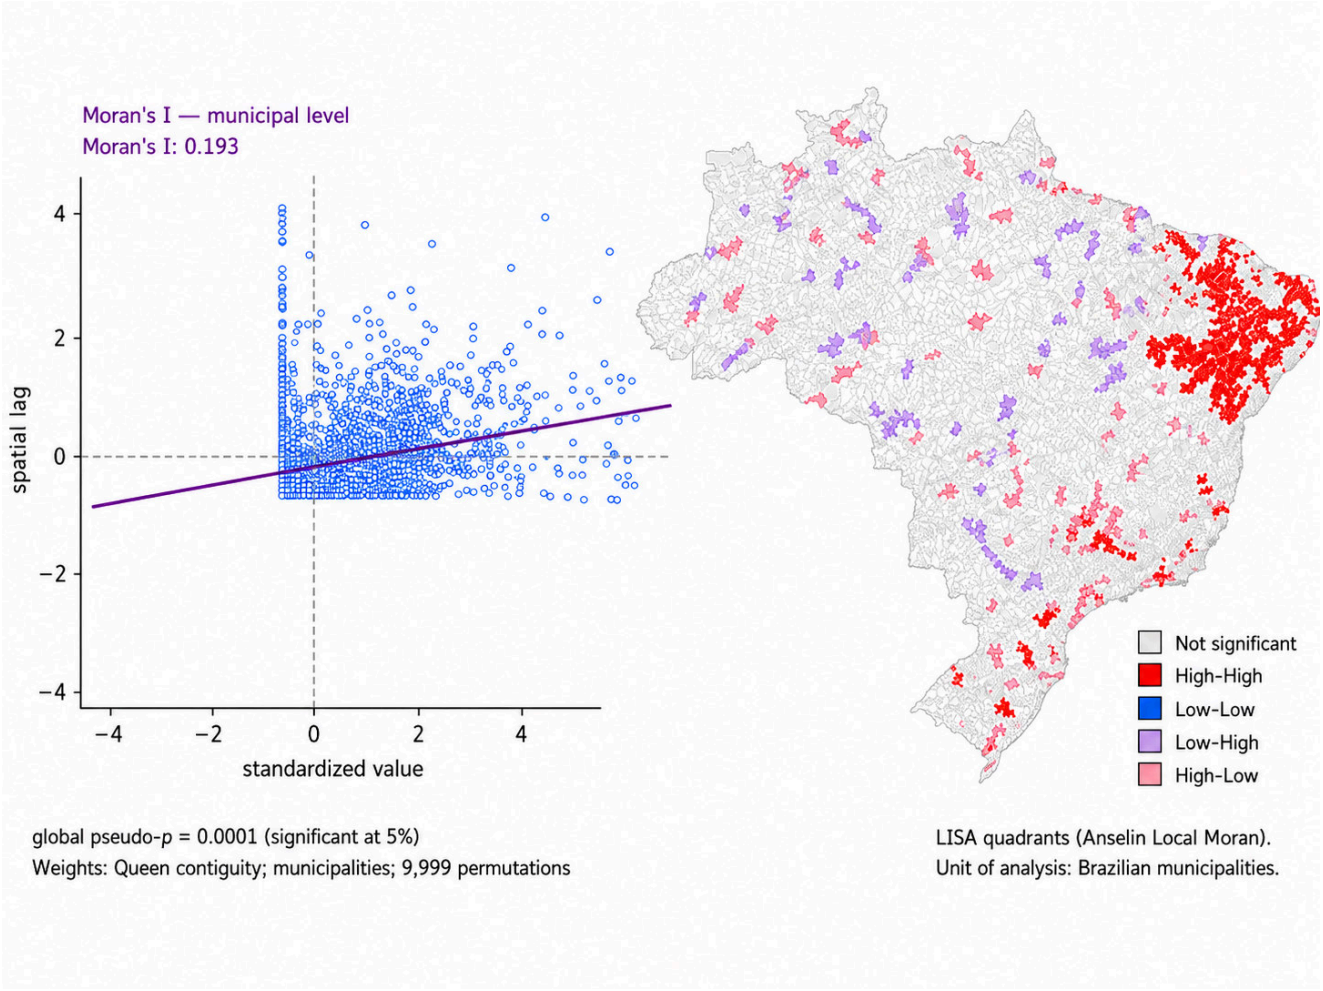

Fig. 1. Municipal spatial analysis of telehealth-related equipment registered as in use per 100,000 inhabitants. The left panel shows the Moran scatterplot and the right panel shows nominal Local Moran (LISA) quadrants at $p < 0.05$. Global Moran's $I = 0.193$ (permutation $p = 0.0001$), based on Queen contiguity and 9,999 permutations. Multiplicity-corrected local results are reported in Table III.

TABLE IV
COMPARISON OF GLOBAL SPATIAL AUTOCORRELATION AT MUNICIPAL AND STATE LEVELS.

Spatial scale	**N**	**Moran's I**	*pseudo-p*
Municipal	5,571	0.193	0.0001
State	27	0.166	0.0632

($q < 0.001$), $\rho = -0.138$ for household income ($q < 0.001$), $\rho = -0.060$ for urbanization ($q < 0.001$), and $\rho = 0.029$ for population 2025 ($q = 0.033$), after Benjamini–Hochberg adjustment across the four municipal correlation tests.

In the negative-binomial models, the IBC estimate differed across model specifications. In Model 1, the IRR for IBC was 0.806 (95% CI 0.759–0.856; $p < 0.001$). With household income included (Model 2), the IBC IRR was 0.943 (95% CI 0.876–1.016; $p = 0.122$). With urbanization included (Model 3), the IBC IRR was 0.886 (95% CI 0.826–0.950; $p < 0.001$). In the fully adjusted Model 4, the IBC IRR was 1.039 (95% CI 0.957–1.127; $p = 0.361$), while the IRRs for household income and urbanization were 0.506 (95% CI 0.420–0.611; $p < 0.001$) and 0.877 (95% CI 0.835–0.920; $p < 0.001$), respectively. AIC values were 13,960.7, 13,915.9, 13,935.5, and 13,889.3 for Models 1–4, respectively.

IV. DISCUSSION

The principal spatial finding is municipal-scale geographic structure rather than the nominal count of LISA locations. Global Moran's I was significant, whereas municipality-specific localization was far more restrictive: 445 local associations appeared nominally, but only four High–High municipalities in Mato Grosso do Sul survived maxT FWER control. These are best interpreted as high-confidence local association cores under the specified Queen weights, not as independent clusters or complete cluster boundaries. The simulations showed the same global/local asymmetry; therefore, failure to survive a local multiplicity criterion is not evidence that local spatial structure is absent. The BH and maxT rejection sets need not be nested because BH was applied to discrete local

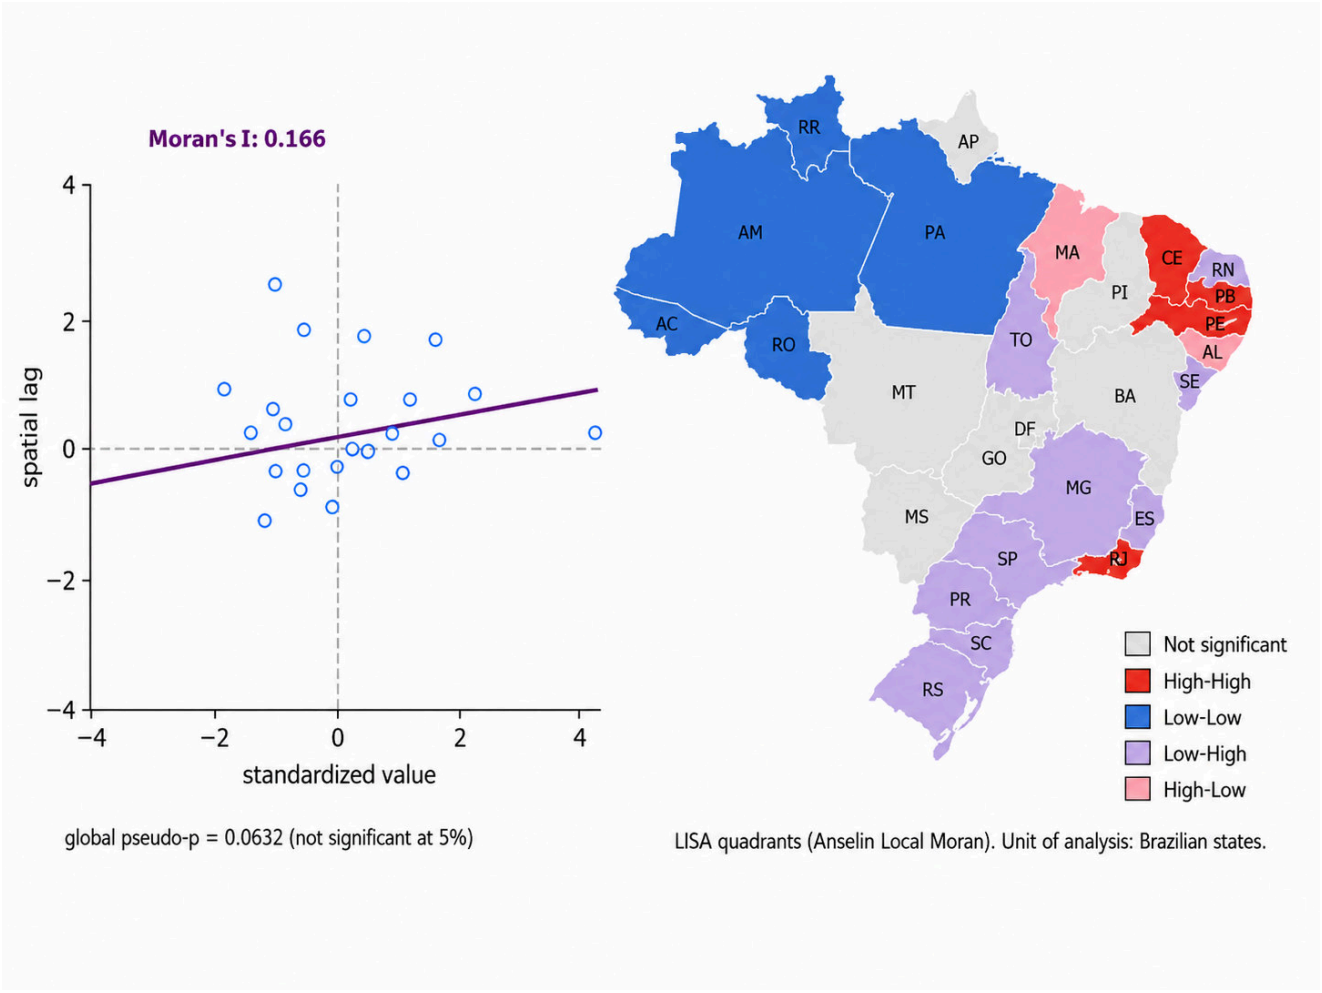

Fig. 2. State-level spatial analysis of telehealth-related equipment registered as in use per 100,000 inhabitants. Global Moran's $I = 0.166$ and $pseudo\text{-}p = 0.0632$. Because the state-level global test did not meet the 5% significance threshold, local state patterns are shown for descriptive and exploratory comparison only.

TABLE V
MUNICIPAL NEGATIVE-BINOMIAL SENSITIVITY MODELS FOR EQUIPMENT REGISTERED AS IN USE.

Model	**Predictor**	**IRR**	**95% CI**	***p*-value**
M1	IBC (per 10 points)	0.806	0.759–0.856	< 0.001
M2	IBC (per 10 points)	0.943	0.876–1.016	0.122
	Income (per R$1000)	0.507	0.419–0.613	< 0.001
M3	IBC (per 10 points)	0.886	0.826–0.950	< 0.001
	Urbanization (per 10 pp)	0.879	0.837–0.923	< 0.001
M4	IBC (per 10 points)	1.039	0.957–1.127	0.361
	Income (per R$1000)	0.506	0.420–0.611	< 0.001
	Urbanization (per 10 pp)	0.877	0.835–0.920	< 0.001

Outcome: count of equipment registered as "in use" in CNES. The 2025 municipal population was included as the exposure term. M1: IBC only; M2: IBC + income; M3: IBC + urbanization; M4: IBC + income + urbanization. The model sample contained 5,570 municipal units with complete covariate data. The models did not explicitly model spatial dependence and are therefore reported as sensitivity analyses rather than causal estimates.

permutation p-values, whereas maxT used the joint maximum-statistic permutation distribution.

The connectivity association was likewise sensitive to scale and adjustment. The positive state-level IBC correlation ($\rho = 0.589$, $q = 0.0197$) was not reproduced municipally, and the IBC coefficient included the null after adjustment for household income and urbanization. Connectivity was therefore not an independent determinant of equipment allocation in this municipal sample and is better interpreted as one dimension of a broader territorial context.

Municipal disaggregation also changes the interpretation of regional inequality. State averages can mask heterogeneity, particularly in extensive Northern states. Municipal analysis reduces this aggregation problem, although municipality-wide averages still conceal urban, rural, remote, and riverine within-municipality differences.

Equipment stocks may reflect historical investment, regional development, health-service density, management capacity, workforce, and private-sector participation [17], [22], [26], [27]. Income and urbanization captured only part of this context, and their inverse adjusted coefficients are treated as ecological associations, not evidence that either factor reduces equipment availability.

Training, organizational readiness, maintenance, consumables, and clinical-engineering support are plausible determinants described in the literature [16], [18], [20], [23], [24], but none was measured here and they are therefore hypotheses rather than study results. Likewise, CNES defines "in use" as equipment reported to be effectively used and not under maintenance [34], but the field does not quantify continuous uptime, clinical throughput, productivity, or realized patient use.

V. Limitations

CNES is an administrative registry; "in use" does not directly measure uptime, throughput, productivity, service use, or quality. The ecological, cross-sectional design does not support causality, and municipal averages may still mask intramunicipal inequality, especially in large Northern municipalities. Residual confounding by historical investment, health-system capacity, workforce, private-sector participation, maintenance, and clinical engineering remains possible. Local inference depends on the Queen weights; with 9,999 permutations the pseudo-p grid could not attain the Bonferroni threshold, and the simulations showed limited maxT localization power. Thus, absence of a corrected local rejection does not establish absence of local structure. The negative-binomial models did not explicitly model spatial dependence, and the municipal–state comparison is not a formal decomposition of the modifiable areal unit problem.

VI. Conclusion

Telehealth-related equipment registered as in use in CNES showed substantial municipal heterogeneity and significant positive global spatial autocorrelation. Formal local inference was more selective: four High–High municipalities in Mato Grosso do Sul remained significant under maxT FWER control, while the broader nominal LISA pattern should be interpreted exploratorily. The IBC association was strongly dependent on geographic scale and socioeconomic adjustment and included the null in the fully adjusted municipal model. The findings therefore support a spatially structured but multifactorial interpretation of equipment allocation, not a connectivity-only mechanism. Future studies should combine longitudinal infrastructure data with direct measures of service production, historical investment, health-system capacity, and spatial regression to clarify the mechanisms underlying these geographic inequalities.

Conflict of Interest

***Resumo*—A terapia fototérmica (PTT) assistida por nanopartículas plasmônicas constitui uma estratégia promissora para o tratamento localizado de tumores. Neste trabalho é apresentada uma metodologia integrada que combina simulações eletromagnéticas, modelagem térmica, estimativa de dano tecidual e validação experimental para o planejamento racional da PTT. Nanobastões e nanocascas de ouro foram avaliados por meio do método de elementos finitos visando identificar nanoaquecedores eficientes na região do infravermelho próximo. Os resultados mostram que a eficiência fototérmica depende não apenas da seção de choque de absorção, mas também do volume da nanopartícula, sendo o Número de Joule uma métrica adequada para sua seleção. A distribuição de temperatura em tecido biológico foi obtida utilizando a equação de bioaquecimento de Pennes, enquanto o dano térmico irreversível foi estimado pelo modelo de Arrhenius. As predições numéricas foram validadas experimentalmente em um modelo *in vivo* de sarcoma 180 implantado em camundongos, utilizando nanobastões de ouro irradiados com laser de 808 nm. A metodologia proposta fornece uma abordagem abrangente para otimização de terapias fototérmicas mediadas por nanoaquecedores plasmônicos.**

***Index Terms*—Óptica biomédica; Nanomateriais; Terapia óptica; Modelagem computacional.**

I. Introdução

A terapia fototérmica (PTT) tem se consolidado como uma abordagem minimamente invasiva para o tratamento localizado de tumores, explorando a conversão da energia luminosa em calor para induzir dano térmico seletivo em tecidos malignos [1], [2]. Essa estratégia apresenta elevada seletividade espacial, baixa toxicidade sistêmica e potencial para combinação com outras modalidades terapêuticas, como quimioterapia, radioterapia e imunoterapia [2]. A eficiência da PTT depende da interação entre o agente fototérmico, as propriedades ópticas do tecido biológico e os parâmetros de irradiação, como comprimento de onda, irradiância e tempo de exposição [3].

Nesse contexto, nanopartículas metálicas, particularmente as de ouro, têm despertado grande interesse como agente fototérmico devido à elevada estabilidade química, biocompatibilidade, facilidade de funcionalização superficial e intensa absorção óptica associada à ressonância localizada de plasmons de superfície (LSPR) [4], [5]. Além disso, a geometria dessas nanopartículas permite ajustar a posição da ressonância plasmônica para a janela biológica do infravermelho próximo (650–950 nm), região espectral em que os tecidos apresentam menor absorção e espalhamento óptico, favorecendo uma maior profundidade de penetração da luz [6]. Os primeiros estudos utilizando nanocascas de ouro demonstraram a viabilidade da destruição térmica de tumores sob irradiação no infravermelho próximo [1], [7]. Trabalhos posteriores consolidaram os nanobastões de ouro como agentes fototérmicos promissores para aplicações em PTT [8]. Mais recentemente, nanoaquecedores plasmônicos têm sido empregados em plataformas teranósticas multifuncionais e funcionalizados com ligantes específicos para aumentar a seletividade tumoral [9]–[11].

Em aplicações fototérmicas, a seleção de nanoaquecedores normalmente é baseada na magnitude da seção de choque de absorção (σ_{abs}). Entretanto, elevados valores de σ_{abs} não implicam necessariamente na maior eficiência de aquecimento, uma vez que a geração e a dissipação de calor também dependem do volume e da geometria da nanopartícula. Assim, foi demostrado que o Número de Joule (Jo), definido como a razão entre a seção de choque de absorção e o volume da nanopartícula, constitui uma métrica mais apropriada para avaliar a eficiência fototérmica de nanoestruturas plasmônicas [12].

A resposta óptica de nanopartículas com geometrias arbitrárias pode ser determinada por simulações eletro-

magnéticas baseadas no Método dos Elementos Finitos (MEF), que resolvem numericamente as equações de Maxwell [10]. Além da seleção do nanoaquecedor, o planejamento racional da terapia fototérmica requer a previsão da distribuição espacial da temperatura e do dano térmico produzido durante a irradiação. A distribuição de calor no tecido biológico pode ser obtida por meio da equação de bioaquecimento de Pennes, que considera os efeitos combinados da condução térmica, perfusão sanguínea, metabolismo e absorção óptica [13]. Finalmente, a extensão do dano térmico irreversível pode ser estimada pelo modelo cinético de Arrhenius, que relaciona a evolução temporal da temperatura aos processos de desnaturação proteica e morte celular [14], [15].

Embora avanços significativos tenham sido alcançados na terapia fototérmica assistida por nanopartículas plasmônicas, ainda permanecem desafios relacionados à seleção de nanoaquecedores mais eficientes, à definição dos parâmetros de irradiação e à previsão quantitativa do aquecimento e do dano térmico em tecidos biológicos. Nesse contexto, este trabalho propõe uma metodologia integrada para o planejamento racional da terapia fototérmica assistida por nanopartículas plasmônicas. A metodologia combina simulações eletromagnéticas para seleção de nanoaquecedores, modelagem térmica baseada na equação de Pennes, estimativa do dano térmico pelo modelo de Arrhenius e validação experimental em camundongos portadores de Sarcoma 180 tratados com nanobastões de ouro irradiados por laser de 808 nm.

II. Metodologia

Foram investigados nanobastões (NBs) e nanocascas (NCs) de ouro com ressonância plasmônica próxima de 800 nm, visando identificar nanoaquecedores com elevada eficiência fototérmica. As propriedades ópticas das nanopartículas foram obtidas por simulações tridimensionais utilizando o Método dos Elementos Finitos no software COMSOL Multiphysics, considerando uma nanopartícula imersa em água e excitada por uma onda plana linearmente polarizada. A permissividade dielétrica do ouro foi descrita pelo modelo de Drude modificado com correção para efeitos de tamanho [16], [17]. Na seleção do agente fotoaquecedor plasmônico, foram consideradas nanoestruturas cuja ressonância plasmônica ocorre em aproximadamente 800 nm. Para os nanobastões, diferentes orientações em relação ao campo elétrico incidente foram consideradas, permitindo calcular o valor médio angular da eficiência fototérmica.

A seleção dos nanoaquecedores foi realizada por meio do Número de Joule, definido como [18]:

$$Jo = \frac{\lambda_{ref}}{2\pi}\frac{\sigma_{abs}}{V_{np}}, \tag{1}$$

em que V_{np} representa o volume da nanopartícula e $\lambda_{ref} = 1240$ nm corresponde ao comprimento de onda associado à energia de 1 eV.

A distribuição espaço-temporal da temperatura foi obtida resolvendo numericamente a equação de bioaquecimento de Pennes [13], dada por:

$$\rho c_p \frac{\partial T}{\partial t} = \nabla \cdot (k\nabla T) + Q_r + Q_b + Q_m, \tag{2}$$

em que ρ, c_p e k correspondem, respectivamente, à densidade, ao calor específico e à condutividade térmica do tecido, enquanto Q_r, Q_b e Q_m representam as contribuições da absorção óptica, da perfusão sanguínea e do metabolismo. O termo fonte associado à absorção óptica (Q_r) foi obtido explorando simulações de transporte de fótons utilizando o método de Monte Carlo [19], [20]. O modelo numérico reproduziu um tumor de Sarcoma 180 implantado em camundongos, considerando as diferentes camadas do tecido biológico. Os parâmetros ópticos, térmicos e fisiológicos empregados nas simulações foram obtidos da literatura [21]–[26]. Foram avaliadas diferentes concentrações de nanopartículas e irradiâncias do laser.

O dano térmico irreversível foi estimado utilizando o modelo cinético de Arrhenius, dado por [14]:

$$\Omega(t) = \int_0^t A \exp\left[-\frac{E_a}{RT(\tau)}\right] d\tau, \tag{3}$$

em que A é o fator pré-exponencial, E_a a energia de ativação, R a constante universal dos gases e T a temperatura absoluta. Valores de $\Omega \geq 1$ foram considerados indicativos de dano térmico irreversível.

As predições numéricas foram validadas experimentalmente explorando camundongos Swiss portadores de Sarcoma 180. O manejo dos animais durante o experimento foi aprovado pelo Comitê de Ética em Experimentação Animal da Universidade Federal de Pernambuco (UFPE), sob o processo nº 0088/2023. Os animais receberam injeção intratumoral de nanobastões de ouro PEGilados (41 × 10 nm) na concentração de 100 μg/mL, correspondendo a uma concentração numérica de 1.4×10^{17} NP/m^3 no volume tumoral, seguida de irradiação com laser pulsado de 808 nm (140 fs, 80 MHz) e irradiância de 1 W/cm^2. A evolução da temperatura foi monitorada por câmera termográfica (FLIR E4) e comparada aos resultados das simulações.

III. Resultados e Discussão

A Figura 1 apresenta os valores calculados do Número de Joule para nanocascas de ouro com núcleo de sílica (indicado o diâmetro total da nanopartícula) e para nanobastões de ouro (indicado o comprimento do nanobastão), Em ambos os casos, as dimensões das nanoestruturas foram ajustadas de modo a posicionar a LSPR em aproximadamente 800 nm. A curva azul representa a média angular de Jo, considerando todas as possíveis orientações entre o vetor de onda da radiação incidente e o eixo longitudinal do nanobastão. Observa-se que o nanobastão otimizado para fotoaquecimento em 800 nm apresenta dimensões aproximadas de 41×10 nm, correspondendo ao maior valor médio de Jo (160,7). Diferentemente dos nanobastões, as nanocascas de ouro exibem resposta fototérmica independente da orientação da nanoestrutura. A curva vermelha apresenta os valores de Jo para diferentes diâmetros de nanocascas. Verifica-se que a nanocasca de ouro

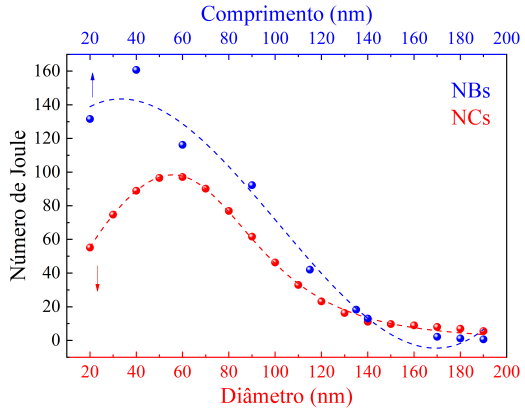

Fig. 1: Número de Joule em função do comprimento do nanobastão (curva azul) e diâmetro total da nanocasca (curva vemerlha).

com núcleo de diâmetro 53 nm e espessura de casca de $3,5$ nm apresenta o maior valor de Jo (97). Apesar do elevado valor de Jo obtido para as nanocascas, seu desempenho fototérmico ainda é inferior ao dos nanobastões. Isso ocorre porque, para uma dada concentração de nanopartículas e irradiância I, o termo de geração volumétrica de calor associado às nanopartículas é proporcional ao Número de Joule, de modo que $Q \propto JoI$. Assim, o maior valor de Jo do nanobastão de 41×10 nm implica maior geração de calor sob a mesma irradiância, justificando sua seleção como nanoaquecedor para as etapas subsequentes da análise térmica.

Com base na equação de bioaquecimento de Pennes, foram construídos mapas da distribuição de temperatura no tecido tumoral alvo. As Figuras 2(a) e 2(b) apresentam a distribuição térmica prevista para o tecido na ausência e na presença de nanobastões de ouro, respectivamente, considerando uma concentração de 1.4×10^{17} NP/m^3, intensidade luminosa incidente de 1 W/cm^2 e tempo de irradiação de $600s$. Observa-se que a elevação da temperatura do tecido depende diretamente da concentração de nanoaquecedores empregada. A Figura 2(c) mostra que a temperatura máxima no tecido aumenta monotonicamente com o aumento da concentração de nanopartículas. Entretanto, para concentrações mais elevadas, esse aumento torna-se menos pronunciado, indicando uma tendência à saturação.

A análise da dinâmica de aquecimento do tecido permite estimar, com base no modelo de Arrhenius, a extensão dos danos térmicos irreversíveis fotoinduzidos. A Figura 3 apresenta a evolução da área de dano irreversível após 600 s de irradiação laser para diferentes intensidades de iluminação e concentrações de nanobastões de ouro. Como esperado, a área normalizada de dano irreversível aumenta com a intensidade da irradiação laser e com a concentração de nanopartículas. Para uma mesma irradiância, concentrações mais elevadas de nanobastões promovem regiões mais extensas de dano térmico irreversível, em decorrência da maior deposição de energia óptica no interior do tumor. Esses resultados evidenciam a

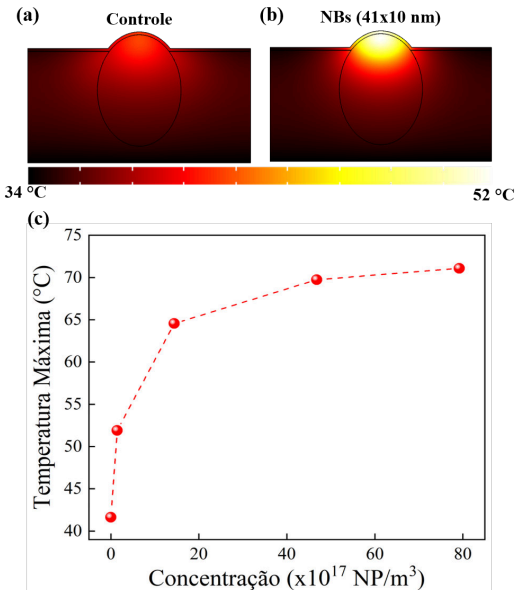

Fig. 2: Distribuição térmica prevista para o tecido (a) na ausência de NBs e (b) na presença de NBs de ouro de 41x10 nm. (c) Alcance térmico em função da concentração de NBs.

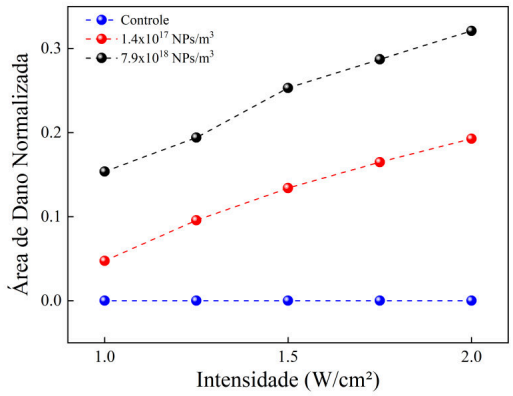

Fig. 3: Área do dano térmico irreversível normalizada na ausência de NBs (curva azul), contendo NBs de ouro de 41x10 nm com concentração de 1.4×10^{17} NP/m^3 (curva vermelha) e 7.9×10^{18} NP/m^3 (curva preta).

importância da otimização conjunta da intensidade do laser e da concentração de nanopartículas, de modo a maximizar a eficiência da ablação tumoral, evitando simultaneamente o emprego de doses excessivas de nanopartículas e exposições desnecessariamente elevadas à radiação laser.

A validação da metodologia foi realizada por meio da análise experimental da elevação de temperatura em camundongos submetidos ao fotoaquecimento com laser de intensidade 1 W/cm^2 durante 10 min. A Figura 4 apresenta a evolução da temperatura superficial da pele dos animais na ausência e na presença de nanopartículas, considerando uma concentração de 1.4×10^{18} NP/m^3. As linhas sólidas representam as predições do modelo teórico proposto, evidenciando

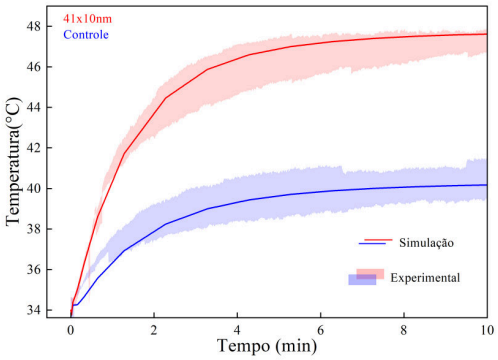

Fig. 4: Evolução temporal da temperatura na região tumoral obtida computacionalmente e experimentalmente.

a concordância com os resultados experimentais ao longo de todo o período de irradiação. O modelo apresentou um erro absoluto médio de 1,3 °C para a condição de controle e de 3,7 °C para a condição contendo nanopartículas.

IV. Conclusão

Foi apresentada uma metodologia integrada para o planejamento da terapia fototérmica assistida por nanopartículas plasmônicas, combinando simulações eletromagnéticas, modelagem térmica, estimativa do dano tecidual e validação experimental. Os resultados mostraram que o Número de Joule é uma métrica eficiente para a seleção de nanoaquecedores, identificando os nanobastões de ouro como a geometria de melhor desempenho para excitação em aproximadamente 800 nm. Além disso, verificou-se que a eficiência da terapia depende da otimização conjunta da concentração de nanopartículas e da irradiância do laser. A boa concordância entre as predições numéricas e os resultados experimentais demonstra o potencial da metodologia como ferramenta para o planejamento e a otimização de protocolos de terapia fototérmica assistida por nanoagentes fototérmicos.

Agradecimento

***Abstract*—Access to healthcare services in Brazilian Indigenous communities is often limited by geographic distance, a shortage of professionals, and the lack of measurement equipment at the point of care. This work presents VitaCheck, a low-cost, portable kit to potentially aid health triage, designed for use by health workers in primary care contexts with limited infrastructure. The device integrates an ESP32 microcontroller with sensors for heart rate and peripheral oxygen saturation (MAX30102), non-contact infrared body temperature (MLX90614), and contact temperature (DS18B20), as well as an LED-based colorimetric module for reading urine reagent strips, extending triage to parameters such as protein and glucose. A piezoelectric actuator signals alerts, and data are formatted into JSON and transmitted via Bluetooth to a mobile device, enabling record-keeping and care prioritization. The entire system is housed in a 3D-printed enclosure with a footprint equivalent to an A4 sheet. The prototype is currently under development, and the proposed experimental evaluation will investigate its accuracy, repeatability, and applicability as a triage support tool.**

***Index Terms*—health triage, indigenous health, telehealth, biomedical instrumentation, ESP32, pulse oximetry, colorimetric urinalysis, low-cost devices.**

I. Introduction

Ensuring equitable access to healthcare services is a persistent challenge for populations living in remote regions, among which Brazilian Indigenous communities stand out. Within the scope of the Unified Health System (SUS), the Indigenous Health Care Subsystem and the National Health Care Policy for Indigenous Peoples were created to ensure differentiated care for these peoples, considering their sociocultural, epidemiological, and logistical particularities [1]. Despite advances, major challenges persist, such as long distances to health units, care discontinuity, high turnover of healthcare professionals, and the lack of basic measurement equipment at the point of care [1]. Primary healthcare for Indigenous populations is operationalized by the Special Indigenous Sanitary Districts and executed at the local level by multidisciplinary teams that often work in villages far from reference health units [1]. In this context, simple instruments that assist health workers in the early identification of cases requiring referral can potentially contribute to comprehensive care and to the rational use of emergency transport and removal resources, which are historically costly [1].

In this scenario, triage — the process of prioritizing care based on objective clinical signs — plays a central role in the rational use of available resources and is aligned with the principles of primary healthcare [2]. Measuring vital signs such as heart rate, peripheral oxygen saturation (SpO_2), and body temperature provides relevant information for this classification. Urine analysis using reagent strips, in turn, is a rapid and low-cost test widely used for general health screening, aiding in the identification of alterations such as proteinuria and glucosuria, which may indicate kidney disease, diabetes, or other conditions [3], [4]. However, these tests often rely on multiple standalone, high-cost devices that are not always available in the field.

Furthermore, alongside all the difficulties in healthcare delivery, public investment in Indigenous health fluctuates depending on the governing administration, and mortality indicators for various diseases remain concerning. For instance, the risk of an Indigenous child dying prematurely is 2.44 times higher than in the non-Indigenous population, with neonatal and post-neonatal mortality remaining 55% above the national average [5], [6]. Thus, the need for alternative measures to access initial information is reinforced — information that is often obtained through advanced triage protocols in emergency

services. Studies indicate that triage can potentially reduce care time and costs [7], and a low-cost, portable triage support kit will likely assist the Special Secretariat of Indigenous Health (SESAI) workforce of 22,000 healthcare professionals — 52% of whom are Indigenous — in potentially serving more than 762,000 Indigenous people living in villages across Brazil [8].

The diffusion of affordable microcontrollers, integrated sensors, and wireless communication has enabled low-cost digital health solutions targeting resource-limited environments, where the point of care often coincides with the patient's home or village [9], [10]. Solutions of this type do not intend to replace clinical examination, but are expected to offer objective triage and data recording that enhance the quality of referral decisions. It is within this gap — the lack of a single, portable, and low-cost instrument that brings together objective measurements to support field triage — that this work is situated.

The main contributions of this work are: (i) the design and integration of a low-cost ESP32-based hardware platform for multiparametric acquisition of vital signs; (ii) the development of an LED-based colorimetric module for automated reading of urine reagent strips, aiming to reduce the subjectivity of visual inspection; (iii) the definition of a triage logic based on configurable rules, with audible alerts and JSON data structuring; and (iv) the proposal of a 3D-printed portable enclosure intended for field use.

This paper proposes VitaCheck, a portable triage kit that combines, into a single low-cost device, automated vital sign acquisition, colorimetric reading of urine reagent strips, a rule-based classification logic, and wireless data transmission to a mobile application. The objective of this study is to offer health workers an accessible, replicable, and easy-to-operate tool suited to the infrastructure constraints found when delivering care to Indigenous communities.

The remainder of this article is organized as follows. Section II discusses related work. Section III details the materials and methods, which will be discussed in Section IV. Section V presents the conclusions, and Section VI outlines future work.

II. Related Work

Recent literature describes several vital signs monitoring devices based on low-cost microcontrollers. Platforms such as the ESP32 are widely used due to their availability, low cost, processing capability, and native Wi-Fi and Bluetooth connectivity [9], [11]. The MAX30102 sensor, based on photoplethysmography (PPG), is broadly employed for measuring heart rate and SpO_2 in wearable and low-cost devices, which are frequently combined with temperature sensors and 3D-printed enclosures for use in resource-limited contexts [9], [12]. Such platforms typically integrate the vital signs sensor via the I^2C bus, a sound actuator for alarms, and a wireless communication interface, potentially offering a lower-cost alternative to commercial monitors that could be deployed in field scenarios.

In the field of urinalysis, reagent strips function as solid-phase colorimetric sensors, in which pads impregnated with reagents change color upon reacting with urinary analytes such as glucose, protein, and nitrite [4]. However, visual reading of these strips can be subject to errors resulting from illumination variations and color perception differences among observers [10]. To mitigate this issue, several studies propose optical readers: Yang et al [3] present a Point-of-Care Testing (POCT) device that illuminates the strip inside a dark chamber and analyzes color through color space conversion; Laucher et al [10] propose smartphone-based colorimetric analysis for home prenatal care; and Çelik et al [4] review point-of-care urinalysis approaches supported by smartphones and artificial intelligence that could shape the future of decentralized diagnostics.

Compared with existing solutions, the distinct advantage of VitaCheck lies in combining vital signs and colorimetric urinalysis with embedded triage logic within a single portable, low-cost device. This integrated architecture is expected to provide an explicit focus on the context of healthcare delivery to Indigenous populations in hard-to-reach regions, potentially improving healthcare coverage and significantly optimizing field decision-making in future deployments.

III. Materials and Methods

A. Design Requirements

The design of VitaCheck stemmed from a set of requirements derived from the usage context: (i) low cost, enabling replication; (ii) portability, for transport between villages; (iii) low power consumption and the option of battery operation, given the unavailability of a stable power grid; (iv) robustness for transport and adverse environmental conditions; (v) simple operation, allowing use by community health workers without specialized technical training; and (vi) data logging and communication for referrals. These requirements guided the selection of components and the architecture described below.

B. Selection of Triage Parameters

The adopted parameters were chosen for their triage value and the feasibility of measurement using low-cost sensors. SpO_2 and heart rate are objective indicators of cardiorespiratory status and routinely form part of risk classification protocols. Body temperature aids in identifying febrile states, which are frequently associated with infectious processes. Urinalysis using reagent strips adds a low-cost biochemical axis: the presence of protein may signal renal impairment, whereas the presence of glucose may indicate hyperglycemia; leukocytes and nitrite may suggest a urinary tract infection [3], [4]. Combining these two axes — physiological and biochemical — is expected to broaden the scope of triage without significantly increasing equipment costs.

C. System Overview and Architecture

VitaCheck comprises a central processing unit (ESP32 microcontroller), a sensing layer for vital signs, a colorimetric module for urinalysis, an audible actuator for alert signaling, and a wireless communication module. The ESP32 was chosen because it natively integrates Wi-Fi and Bluetooth

connectivity, possesses adequate processing capacity for the application, and is low-cost [11]. In terms of architecture, the ESP32 occupies the central position and concentrates the control of the entire system. Connected to its inputs are the vital signs sensors (MAX30102, MLX90614, and DS18B20) and the colorimetric urinalysis module (composed of LEDs and a photodetector); connected to its outputs are the piezoelectric actuator, responsible for audible alerts, and the wireless communication interface (Bluetooth), through which data will be sent to the mobile device. Sensors using the I^2C interface share the same bus, whereas the DS18B20 and the colorimetric module utilize dedicated input and output pins of the microcontroller.

The vital signs sensing layer integrates three sensors connected to the ESP32:

- **MAX30102** — an optical sensor that measures heart rate and SpO_2 via photoplethysmography by emitting red and infrared light and detecting variations in arterial blood volume; communicates via I^2C interface [12].
- **MLX90614** — an infrared thermometer allowing non-contact body temperature measurement, also via I^2C [13].
- **DS18B20** — a digital contact temperature sensor used as a reference/complement, with 1-Wire communication [14].

According to their respective datasheets, the MLX90614 presents a typical accuracy of ± 0.5 °C in the body temperature range, the DS18B20 an accuracy of ± 0.5 °C between -10 °C and $+85$ °C, and the MAX30102 adequate resolution for HR and SpO_2 measurement in wearable devices [12]–[14].

The MAX30102 estimates heart rate (HR) from the time interval Δt between successive peaks of the PPG signal, as:

$$HR = 60/\Delta t \tag{1}$$

with Δt in seconds and HR in beats per minute. Peripheral oxygen saturation is estimated by the ratio-of-ratios R between the alternating (AC) and direct (DC) components of red and infrared light:

$$R = (AC_{\text{red}}/DC_{\text{red}})/(AC_{\text{IR}}/DC_{\text{IR}}) \tag{2}$$

which is related to SpO_2 through an empirical calibration curve of the form $SpO_2 \approx a - b \cdot R$, whose coefficients a and b will be obtained through calibration [12]. Since the PPG signal is sensitive to noise and motion artifacts, filtering and averaging will be applied to the readings prior to calculation. The two I^2C sensors share the same bus, distinguished by their addresses, while the DS18B20 uses a dedicated 1-Wire bus.

D. Colorimetric Module for Urinalysis

To extend triage beyond vital signs, VitaCheck incorporates an optical reading module for urine reagent strips. The operating principle is based on reflectance: a set of LEDs illuminates each reagent pad on the strip, and a photodetector measures the reflected light, whose color

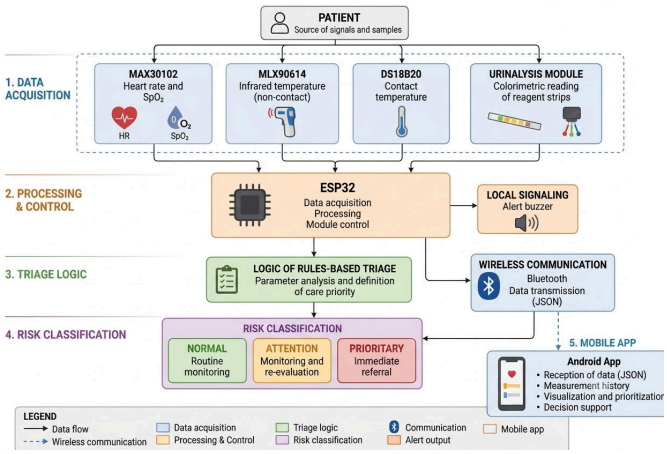

Figure 1. Assembly of the ESP32 with the MAX30102 sensor. Source: The authors (2026)

varies according to analyte concentration [3], [10]. The measured intensity/color is then converted into a concentration range using a calibration curve constructed from the manufacturer's reference color chart.

To reduce environmental light interference — one of the primary sources of error in colorimetric reading [10] — the reading was designed to take place inside a dark chamber with controlled internal illumination, a strategy also adopted in optical urine readers reported in the literature [3]. In this work, the TCS34725 RGB color sensor (I^2C interface, with an integrated white LED) is adopted to capture reflected light; alternatively, discrete LEDs in red (∼625 nm), green (∼525 nm), and blue (∼470 nm) associated with a photodiode could be employed. Reading each pad must be performed after the reaction time recommended by the strip manufacturer, typically between 30 and 60 s.

The reading is normalized against a white reference to mitigate variations in the light source. For each pad, relative reflectance is defined as:

$$R_\lambda = I_\lambda / I_{\lambda,\text{ref}} \tag{3}$$

where I_λ is the measured intensity in color channel λ and $I_{\lambda,\text{ref}}$ is the reference intensity. Channel reflectances will then be mapped to the analyte concentration range via a calibration curve combining red, green, and blue (RGB) channel reflectances, fitted based on the manufacturer's color chart levels. The measurement procedure consists of: (1) dipping the strip into the sample; (2) waiting for the reaction time specified by the manufacturer, a critical factor for result accuracy; (3) inserting the strip into the chamber; (4) reading and normalization; and (5) classification by range.

Multi-parameter reagent strips allow screening for several analytes. In this work, a commercially available multi-parameter reagent strip is used.

E. Triage Logic

Following acquisition, parameter values will be compared against configurable reference ranges, generating a priority classification (e.g., normal, caution, and priority). When at least one parameter exceeds the defined threshold, the piezoelectric actuator is triggered to emit an audible alert, and the priority level will be included in the output message. The decision flow follows four steps: (i) acquisition of sensor measurements; (ii) comparison of each measurement against configured reference ranges; (iii) classification of the priority level based on the worst condition found among the parameters; and (iv) triggering of the audible alert, when applicable, and transmission of the JSON message.

F. Firmware and Processing

The firmware embedded in the ESP32 is responsible for sensor initialization, periodic measurement acquisition, basic signal filtering (especially the PPG signal from the MAX30102), application of the triage logic, and data packetization and transmission. The firmware was developed in C/C++ using the Arduino IDE, employing the SparkFun MAX3010x (MAX30102), Adafruit MLX90614, OneWire, and DallasTemperature (DS18B20) libraries, along with BluetoothSerial for Bluetooth communication. To reduce PPG signal noise, moving averages and rejection of invalid readings are applied before calculating HR and SpO_2. The organization of the firmware into well-defined stages — initialization, acquisition, processing, classification, and transmission — is expected to facilitate maintenance and component swapping, enabling adjustments to parameters (such as averaging windows and triage thresholds) without altering the core program structure.

G. Communication and Data Structuring

Data from each measurement are structured into JSON format and transmitted via Bluetooth to a mobile device, potentially enabling visualization, record-keeping, and care prioritization. The use of JSON aims to facilitate interoperability with mobile applications and health information systems. An example message is shown below:

```
{ "hr": 78, "spo2": 97,
  "temp_ir": 36.5, "temp_contact": 36.7,
  "urine": { "protein": "negative",
             "glucose": "negative" },
  "priority": "normal" }
```

H. Mobile Application and Data Logging

On the paired mobile device, an application receives the JSON messages, displays measured values and priority classification, and maintains a measurement history. This record is expected to allow longitudinal patient monitoring and provide structured information for referral decisions by the healthcare team. Using a standardized, machine-readable format can support future integration with health information systems and organized data export. The application is developed for the Android platform and displays received values, priority classification, and measurement history, with local storage of records on the device. Figure 2 below shows the main application screen featuring the risk classification.

Figure 2. Main application screen displaying risk classification. Source: The authors (2026)

I. Enclosure (Kit)

The electronic assembly was housed in a 3D-printed enclosure with a base footprint equivalent to an A4 sheet, designed to protect components, organize wiring, accommodate the dark chamber for strip reading, and potentially facilitate field transport. The enclosure was printed in PLA, with approximate dimensions of 210 $\times$ 300 $\times$ 50 mm (footprint area equivalent to an A4 sheet) and a sliding drawer-style lid, which should allow access to components and proper positioning and fixing of sensors for measurement.

J. Field Workflow

The intended operation workflow will follow these steps: (1) the health worker turns on the device and pairs it with the mobile application via Bluetooth; (2) places the MAX30102 sensor on the patient's finger and measures HR and SpO_2; (3) performs temperature measurement

with the MLX90614 and/or DS18B20; (4) when indicated, inserts the urine reagent strip into the colorimetric module; (5) the device applies the triage logic, emits an audible alert if priority status is met, and sends the JSON message to the application; and (6) the result is logged to potentially support the referral decision. The process was designed to be completed in a few minutes with minimal training requirements.

Figure 3. Screen displaying patient registration. Source: The authors (2026)

K. Prototype Cost

A core requirement of the project is low cost. The total estimated cost of the components is approximately R$ 200; however, any Point-of-Care Testing (POCT) equipment properly regulated by ANVISA (RDC 302/2005; RDC 786/2023; RDC 978/2025) will ultimately have to comply with various requirements, even if these have been made more flexible in recent years.

L. Evaluation Procedure

The evaluation will consist of comparing VitaCheck measurements with calibrated commercial equipment used as references: a fingertip pulse oximeter for HR and SpO_2, and a clinical thermometer for temperature. For urinalysis, the colorimetric module's automated classification will be compared against visual inspection using the strip manufacturer's color chart. Measurements will be conducted on healthy volunteers under controlled environmental conditions, repeating each reading to verify measurement stability. For each parameter, mean error, standard deviation, and agreement relative to the reference will be calculated to rigorously assess overall accuracy.

IV. Discussion

The interpretation of the results must consider both the accuracy of each measurement and the usability of the overall assembly under real field conditions, including total care time and ease of operation for the health worker. Among the expected limitations are the accuracy of low-cost sensors, the sensitivity of the MAX30102 to motion and peripheral perfusion, the dependence of urinalysis on reaction time and controlled illumination [10], and the need for calibration and clinical validation prior to clinical deployment.

The context of use in Indigenous communities also imposes specific requirements, such as energy autonomy in locations without a stable power grid, transport robustness, simple maintenance, an adapted user interface, and respect for sociocultural diversity [1].

Integrating vital signs and urinalysis into a single device tends to reduce the amount of equipment to transport and maintain, which is desirable in the field; on the other hand, it increases the need for calibration and care with consumables (reagent strips), which have specific shelf lives and storage requirements.

The sustainability of the solution depends, therefore, not only on the cost of the hardware, but also on the supply chain for consumables and the training of health workers for operation and alert interpretation.

In relation to related work, devices based on ESP32 and MAX30102 have already demonstrated performance comparable to reference oximeters for SpO_2 and HR in resource-limited scenarios [9], [12], while optical urine strip readers report good agreement with clinical inspection when illumination is controlled [3], [10].

VitaCheck seeks to combine these two capabilities into a single field device; verifying that this integration preserves the accuracy of each isolated measurement is precisely the objective of the experimental evaluation presented in Section IV.

The potential consolidation of VitaCheck as a triage tool requires a staged validation roadmap: bench evaluation with reference measurements and solutions, comparison against calibrated commercial equipment, repeatability tests, and, subsequently, clinical environment studies with appropriate ethical approval. The scalability of the solution benefits from the low cost and replicability of the hardware, which allow the production of multiple units,

provided that the supply of consumables and training for healthcare teams are secured.

However, the durability of low-cost components, particularly sensors, may influence the overall product lifecycle. Thus, field tests are required to verify the resistance and durability of components in the specific forest environment, characterized by high humidity and heat.

It is worth highlighting ethical and regulatory considerations: devices intended to support health decisions require, for actual clinical use, clinical validation and compliance with applicable standards, such as ANVISA regulatory requirements for medical devices and Brazilian ethical standards for research involving human subjects (CNS Resolution No. 466/2012), as well as specific provisions for research involving Indigenous peoples.

VitaCheck, in its current stage, is a triage support prototype rather than a certified medical device, and it does not replace clinical evaluation.

V. Conclusion

This work presented VitaCheck, a low-cost, portable health triage kit designed for Indigenous communities, integrating multi-parametric acquisition of vital signs, colorimetric reading of urine reagent strips, rule-based classification logic, and wireless data transmission in JSON format.

The total of 22,000 healthcare professionals dedicated to servicing the Indigenous population highlights the economic potential for large-scale production of the equipment, underscoring its potential impact on the quality of life of a population of 762,000 Indigenous individuals through efficiency gains (time and cost) and improved satisfaction in advanced triage within emergency services. VitaCheck presents a promising architecture to support triage in limited-infrastructure settings. However, its accuracy, repeatability, and practical applicability still remain to be investigated through experimental evaluations and future testing.

VI. Future Work

We will conduct standard laboratory measurements, which limits confidence in its diagnostic precision. Additional studies involving representative patient populations, repeatability analyses, environmental robustness, battery autonomy, and usability evaluations under real field conditions will be performed to demonstrate its practical applicability.

We will discuss interoperability with electronic health record standards and data security during wireless transmission, aiming to strengthen the platform's translational perspective.

We will report ethical and consent criteria, reference device calibration, repeated measurements per individual, collection time, and individual paired errors.

We will validate heart rate, SpO2, and temperature across clinically relevant ranges and under adverse conditions

Figure 4. Screen displaying registered patients. Source: The authors (2026)

using agreement analysis. For colorimetry, all target analytes, strip lots, reaction times, illumination levels, camera variations, and interfering substances will be tested against an objective laboratory standard or a validated reader.

Community partnerships, cultural appropriateness, Indigenous data governance, maintenance, consumables, and connectivity will be incorporated. No actual field deployment should be inferred at this stage.

***Abstract*—Sustained attention is a crucial cognitive function for daily living activities, and its enhancement through neurofeedback or brain-computer interface interventions has gained great interest. This study presents the preliminary validation of an electroencephalography based brain-to-brain collaboration interface with a serious car-racing game for attention training. The system establishes an adaptive subject-specific collaborative neurofeedback model for two individuals jointly modulate their theta and beta cortical rhythms. We hypothesized that the participant with superior attentional skill may serve as a reference to dynamically guide the brain wave modulation of the other user. The collected brain signals during pilot test were processed, and preliminary results with two participants demonstrated high classification accuracy between 0.82 and 0.86 during the calibration phase. Throughout the 10-min collaborative training session, the participant with lower-performance successfully reduced the own theta/beta power ratio, stabilizing it closer to the reference participant's levels. Additionally, a significant negative correlation between the attention ratio and the game speed confirmed effective modulation. These findings suggest that collaborative brain-computer interfaces offer a promising and interactive approach to support sustained attention training.**

I. Introduction

Attention is a cognitive function very important in life living and in interaction day by day, allowing the communication between people, and is important to understanding and execution of professional, social and domestic activities that require alertness, perception, focus, selectivity, memorization, and learning. Furthermore, it is a fundamental mechanism to select relevant information in the brain, prioritizing pertinent stimuli while suppressing information considered irrelevant to cognitive processing.

The phenomenon of attention can be classified according to the way in which percepts are attended to. This research will analyze sustained attention, which consists of the voluntary maintenance of attention over time, while ignoring potential distractors and avoiding mind-wandering [1]. Sustained attention is composed of two fundamental aspects: (1) the duration for which performance is maintained and (2) the consistency of performance throughout that period. This attentional dimension is heavily dependent on inhibitory control and is therefore the most commonly impaired in individuals with attention deficits [2].

The neural architecture of attention comprises multiple large-scale networks that interact dynamically. This work primarily focus on the frontoparietal control network (FPN), comprising the lateral prefrontal cortex and inferior parietal lobule, supports working memory and flexible control of goal-directed behavior, along with the cingulo-opercular network, including the medial superior frontal cortex and anterior insula, sustaining stable task-set maintenance over longer periods [3], [4].

This work was partially supported by CNPq projects (Processes: 403247/2025-0, 445300/2024-8), Santos Dumont Institute, Brazilian Ministry of Education (MEC), Coordination for the Improvement of Higher Education Personnel (CAPES) and CNPq scholarships (Process: 313426/20252).

During specific activities involving cognition, motor function, or even resting states, neural oscillations are generated within functional networks, arising from the summation of excitatory and inhibitory postsynaptic activity in the brain. Theta oscillations (4-7 Hz) are associated with cognitive control and performance monitoring, signaling the need to increase attentional control when errors are detected or focus is lost. Beta oscillations (13-30 Hz) indicate an actively engaged and alert brain, with deficits in this frequency consistently associated with difficulty maintaining stable concentration [1], [5]. These cortical oscillations play distinct and fundamental roles in maintaining and regulating sustained attention. Consequently, any alteration in brain wave oscillations within neuronal networks, such as those cognitive performance, leading to effects ranging from memory impairment to significant behavioral impacts.

The neurofeedback and brain-computer interfaces (BCIs) have been successfully applied for attention training often using the ratio between theta (4-8 Hz) and beta (13-30 Hz) rhythms as an attentional biomarker [6]. It is worth noting that attention training using neurofeedback is expanding beyond clinical treatment; it is being applied to neurotypical individuals in various contexts to enhance cognitive performance in professional and sports activities that place high demands on attention [7]–[9]. These findings indicate that attention training interventions can serve not only as therapeutic tools but also as strategies for cognitive enhancement, offering alternatives to pharmacological treatments and their associated side effects [10].

More recently, brain-to-brain collaboration interfaces (BBCIs) have explored synchrony between two or more brains to potentialize performance in joint tasks, with applications ranging from collective decision making to the detection of affective states [11]–[13]. However, the application of BBCIs specifically directed at modulating brain rhythms in attentional cognitive networks in collaboration between individuals remains underexplored in the literature, which focuses mainly on motor and individual performance.

Additionally, integration of serious game into BCIs has proven to be an effective strategy to enhance user's engagement and adhesion during training [14]–[16], while there are emerging concerns regarding the security and integrity of transmitted brain data, since the wireless communication employed by these interfaces exposes them to risks of interception and tampering [17].

In this current work, we proposed to develop and validate an EEG-based brain-to-brain collaboration interface integrated into a serious game, aiming to teach two individuals to jointly modulate theta and beta rhythms in regions associated with the attention network, using performance of the participant with superior modulation as a reference and establishing an adaptive collaborative neurofeedback model between two users.

II. Materials and Methods

A. Overview of the brain-to-brain collaborative interface

EEG signals are acquired by two amplifiers V-Amp 16 (Brain Products), each connected to a cap with 16 positioned electrodes according to the international 10/20 system, covering: Fp1, Fp2, Fz, F3, F4, F7, F8, C3, Cz, C4, Pz, P3, P4, O1, Oz and O2. A desktop computer and a laptop run OpenViBE and Python scripts for the real-time acquisition, processing, classification and generation of the attentional biomarker. The serious game, developed in Unity, receives commands from both participants via MQTT protocol, which guarantee the continuous and secure transmission of attentional indices between the two processing environments.

The system operates in two sequential and uninterrupted stages. At the first moment, during 2 min, each participant controls a virtual car using only the computer keyboard, maintaining a base speed of 40 km/h. This period provides the calibration data for obtaining the attention-level classification models and the neurofeedback model-based in θ/β power ratio variations, usually represented by speed control. In the second stage, lasting 10 min, the car's both participants control their respective cars simultaneously, with speed modulated by both the keyboard and the attentional effort estimated from the θ/β biomarker, such that high sustained attention increases the vehicle's speed, while low attention reduces it. Furthermore, a trigger was implemented at the start and end of the game to temporally synchronize the EEG signals acquired by the two amplifiers, given the data acquisition had to begin before the game.

EEG data of 2 min in length are used to calibrate the classification system, dividing them into a set composed of adjacent 5s segments. This set is later randomly divided into a training (T) set (80% of trials) and testing (E) set (20% of trials) by a k-folds cross-trial validation ($k = 10$). A subset V from T is obtained for validation. Each segment is then divided into 1s windows with 50% overlap, which are pre-processed by a second order Butterworth band-pass filter between 0.1 and 50 Hz, followed by a Common Average Reference filter to remove physiological and non-physiological interferences.

The filtered windows are after transformed into the frequency domain using the Fast Fourier Transform, extracting feature vectors containing the normalized average powers for θ (4–7 Hz), α (8–12 Hz), low β (13–20 Hz), high β (20–30 Hz), and low γ (30–45 Hz) frequency bands from all electrodes.

A Linear Discriminant Analysis (LDA) classifier is then trained exclusively on T and validated on V across $k = 10$ cross-validation folds, retaining the model that yields the highest classification accuracy. For binary decision purposes, the moderate and high attention classes are combined into a single high-attention class.

In the game, the keyboard provides a constant base speed of 40 km/h, while θ/β modulation contributes an additional speed of up to 60 km/h, reaching a maximum of 100 km/h. Vectors classified as low attention force the additional speed contribution to 0 km/h.

Fig. 1. Experimental protocol used during the collaborative BCI session. (A) Participants performing the attention training task. (B) Timeline of the experimental session, including initial preparation (30 min), calibration phase (2 min), and neurofeedback training (10 min).

B. Experiment Protocol

This study was approved by the ethics committee (code number 85123524.6.0000.0129) of the Santos Dumont Institute. Pilot experiments were conducted with two healthy adult participants who were not taking psychiatric medications known to adversely affect cognitive function and had no history of depression, attention-deficit/hyperactivity disorder (ADHD), or other psychiatric or neurological disorders. Neither participant presented any motor impairment affecting the upper limbs. One participant had mild myopia and astigmatism; however, corrective eyeglasses were not worn during the experiment because they were incompatible with the EEG cap. They were recruited conveniently from the state of Rio Grande do Norte in Brazil. A male of 27 years old (Participant 1) and other female of 23 years old (Participant 2).

To acquire the brain signals and use the proposed system with serious game, the participant's scalp was cleaned with 70% alcohol, followed by the application of an abrasive paste all electrically conductive gel to ensure the skin-electrode impedance below 10 kΩ. This preparation stage delayed a total period of 30 min. Subjects comfortably seated in front of a computer screen displaying the serious game, and were instructed in a familiarization stage on the basic keyboard commands required to control their virtual car along the track. The first phase of the experiment EEG data to calibrate the brain-computer interface collected for a period of 2 min. During this stage, participants were oriented to focus their attention on the car while simultaneously controlling the virtual vehicle for a period of 2 min. Afterwards, the participants continued controlling their car for a period of 10 minutes.

C. Evaluation

The performance of the LDA classifier during the calibration phase was evaluated using standard machine learning metrics. Specifically, accuracy, precision, recall, and F1-score were calculated to assess model reliability. Furthermore, Cohen's Kappa coefficient was computed to measure the classification agreement beyond chance level, and confusion matrices were generated to visualize the correct predictions and misclassifications between the "LOW ATTENTION" and "HIGH ATTENTION" classes. During the 10-minute collaborative neurofeedback session, the temporal dynamics of the θ/β power ratio and the corresponding virtual car speeds were continuously recorded and analyzed for both participants. To evaluate the effectiveness of the neurofeedback control model in linking cognitive effort to game performance, a Pearson linear correlation was calculated between each participant's θ/β ratio and their respective vehicle speed. Finally, the spatiotemporal evolution of the attentional biomarker was visually assessed using topographic maps of the θ/β ratio. These maps were segmented into continuous 2-minute time windows to track dynamic changes in cortical engagement, particularly across frontopolar and central brain regions.

III. Results and Discussion

Figure 2 shows that both participants achieved metrics significantly above chance level (0.5), indicated by the red dashed line, in the calibration phase. The LDA classifier achieved mean accuracy of 0.86 (±0.075) and 0.82 (±0.079) for Participants 1 and 2, respectively, with F1-scores of 0.909 and 0.88, demonstrating reliable discrimination between low and high/moderate attention states. The Kappa coefficients of 0.64 and 0.54 indicate substantial and moderate agreement beyond chance, consistent with results reported in previous EEG-based attention classification studies [18]. Furthermore, the lower Kappa for Participant 2 and the larger deviations reflects the pilot nature of the study ($n = 2$, one calibration session), these values are expected to improve with additional data collection sessions and more calibration data.

The confusion matrix illustrates the actual correct predictions and errors between the "LOW ATTENTION" and "HIGH ATTENTION" (high/moderate attention) classes in the calibration phase. For Participant 1, the classifier correctly identified 100% of the LOW ATTENTION samples and 94% of the HIGH ATTENTION samples, with only 6% of the HIGH ATTENTION samples being misclassified as LOW. For participant 2, the classifier correctly identified 83% of the LOW ATTENTION samples and 94% of the HIGH ATTENTION samples. Misclassification consisted of 17% of the LOW ATTENTION samples being classified as HIGH ATTENTION and 6% of the HIGH ATTENTION samples being classified as LOW ATTENTION.

Figure 3 shows the performance of both participants driving the car using the calibrated system for a period of 10 min. Figure 3(a) shows that Participant 1 (winner) maintained a consistently low and stable θ/β power ratio (fluctuating between approximately 2 and 4) throughout the session. On the other hand, Participant 2 began the car control with θ/β power ratios reaching values up to 14 during the first 100s. Later, this participant managed reduced θ/β, stabilizing its

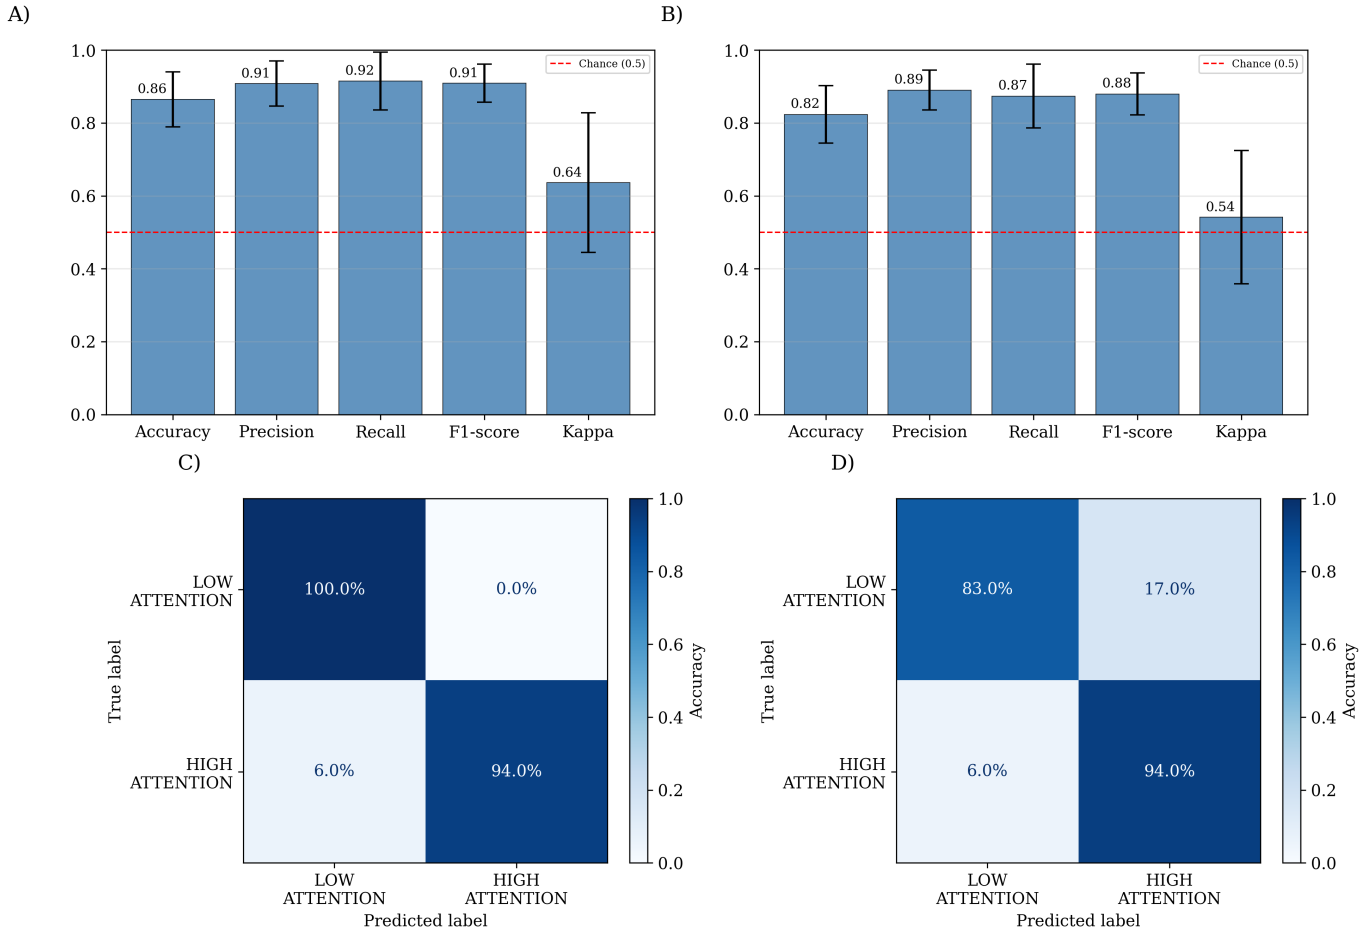

Fig. 2. The system performance during the calibration phase. A) and B) show the mean and standard deviation values for Participant 1 and Participant 2, respectively. C) and D) show confusion matrices corresponding to the best-performance for each Participant 1 and Participant 2, respectively

values much closer to those of the winner player during the last 5 min of the experiment.

Observing Figure 3(b), it is evident that the speed of both cars remained consistently above 40 km/h baseline default speed via keyboard, fluctuating around 60 km/h. The winner's average speed reached 63.2 km/h, while the follower's average speed was around 61.5 km/h. Furthermore, it can be noted that the follower's drops in attention at the start of the run resulted in speed drops, approaching 40 km/h, however the participant managed to recover their performance.

Figure 3(c) illustrates the relationship between the θ/β ratio and virtual car speed for both participants. Analyzing the results, Participant 2 showed a moderate negative correlation (r = -0.449, $p < 0.001$), indicating that lower θ/β ratios were associated with higher car speeds, consistent with the neurofeedback model design. Participant 1 (winner) presented a weak positive correlation (r = 0.208, $p < 0.001$), however, the winner's data were highly concentrated within a narrow θ/β range.

The asymmetric correlation observed among the participants reflects their distinct roles within the collaborative paradigm. The fact that Participant 2 exhibited a negative correlation confirms that the proposed system effectively linked θ/β modulation to car speed in real-time, rewarding attentional engagement with superior performance, consistent with previous findings in BCI-based attention training [19]. In contrast, the weak positive correlation observed in Participant 1 likely reflects the signal's range of variation: unlike Participant 2, whose θ/β ratio fluctuated widely ($\approx$ 2–14), Participant 1 remained within a narrow range ($\approx$ 2–4) for most of the time.

This scenario is consistent with the hypothesis that Participant 1 operated predominantly within a relatively stable attentional state, close to the optimal level for game performance, leaving little residual variance in the biomarker to explain variations in speed. Such variance may be more closely associated with non-attentional factors, such as collisions with obstacles along the course, rather than the attentional regulation mechanism itself. If Participant 1's collisions occurred during periods of higher θ/β ratios, these isolated events might have influenced the regression trend, reflecting specific course characteristics rather than the actual relationship between regulation of θ/β ratios and speed. Furthermore,even with this positive correlation, the winner did not lose engagement during the training.

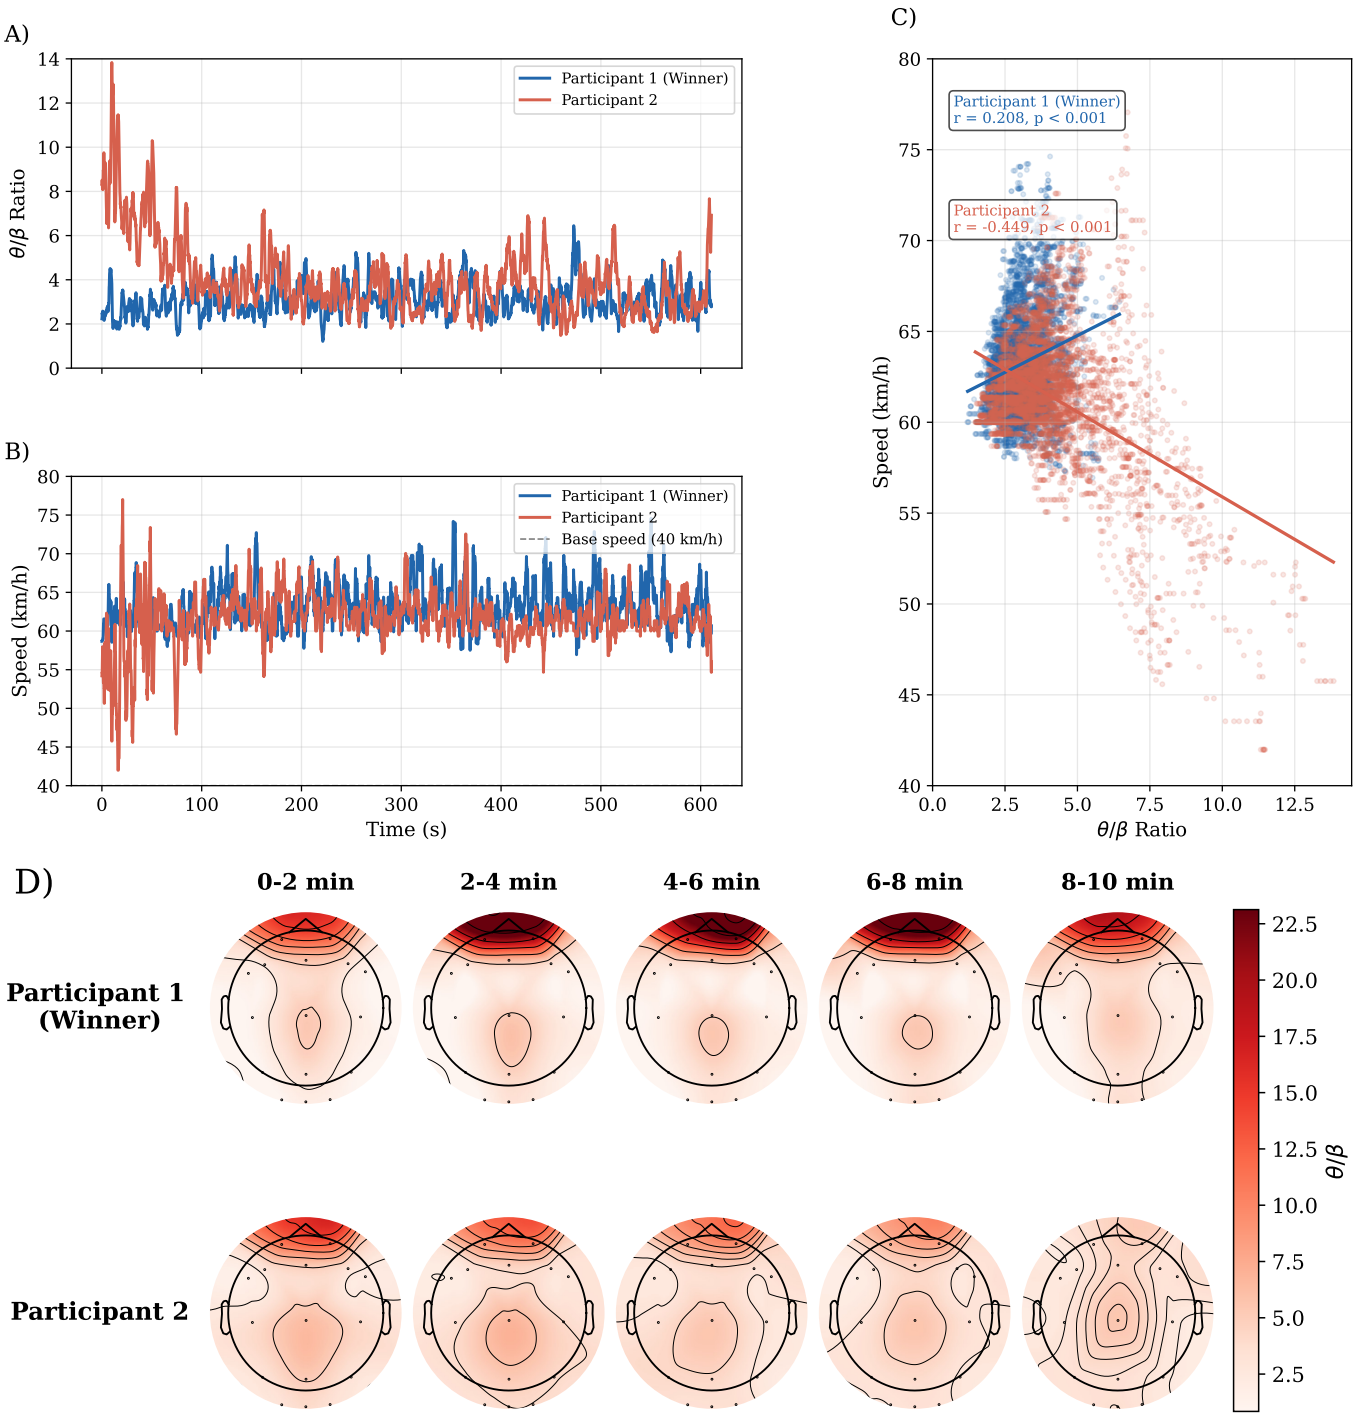

Fig. 3. Brain-to-brain collaboration dynamics during training session and topographic maps of the θ/β ratio. (a) θ/β ratio over time for the leader (Participant 1, blue) and follower (Participant 2, red), showing higher and more variable ratio values for the follower throughout the session. (b) Virtual car speed over time for both participants, computed as the sum of the 40 km/h keyboard base speed and the brain-modulated contribution. (c) Scatter plot showing the Pearson linear correlation between the θ/β ratio and speed. (d) Topographic maps illustrating the spatial distribution of the θ/β ratio segmented into continuous 2-minute time windows for both participants

These interpretations also align with findings indicating that the diagnostic validity and magnitude of the relationship between θ/β and attentional performance vary considerably across individuals and measurement protocols; this variability has led to heterogeneous and sometimes contradictory results in recent literature regarding this biomarker [20].

Taken together, these results suggest that the neurofeedback control model was particularly effective for the participant

with greater attentional variability. Studies with larger samples are needed to determine whether the positive correlation observed in Participant 1 represents a consistent individual pattern or a finding specific to this session.

Figure 3(d) presents the spaciotemporal evolution of the θ/β ratio for both participants throughout the BCI paradigm, segmented into continuous 2 minutes-windows, Visual analysis reveals distinct and dynamic topographic patterns between the winner (Participant 1) and Participant 2. Participant 1 exhibited persistently high θ/β ratio activity localized sharply in the frontopolar region (channels Fp1 and Fp2) throughout the 10-min task, In contrast,Participant 2 demonstrated a globally diffuse spatial distribution with a low θ/β ratio from the start of the task (0–8 minutes). However, starting from the 8–10 minute window, a generalized and progressive increase in relative power was observed in central and parietal areas. We noted that both participants exhibited a θ/β reduction over a large portion of the scalp during the BCI session, particularly across fronto-central regions. This behavior is consistent with a lower relative predominance of theta activity compared to low-beta activity during the neurofeedback task.

Besides, the reduction in the θ/β ratio observed suggests that the proposed neurofeedback paradigm promoted the expected modulation of brain activity associated with attentional processes, because the θ/β ratio reflects the balance between slower theta oscillations and faster low-beta activity, lower values indicate a shift toward a pattern commonly associated with greater cortical engagement and sustained attention. These observed changes in theta and beta oscillations are consistent with previous studies reporting an inverse relationship between the frontal θ/β ratio and attentional performance [21]. Furthermore, these findings align with research identifying cognitive improvements in individuals with attention deficit who reduced their θ/β power ratios following neurofeedback or BCI-based interventions [22]–[24].

Although these findings are encouraging and indicate that the proposed approach was able to induce the intended EEG modulation, they should be interpreted with caution. The present analysis is based on qualitative topographic observations from only two participants, further studies with larger samples and statistical analyses are required to confirm the consistency and significance of these findings.

IV. Conclusion

This pilot study demonstrated the technical feasibility of an EEG-based brain-to-brain collaborative interface for sustained attention training. The proposed adaptive neurofeedback paradigm effectively translated the user's cognitive modulation into real-time game control, allowing a high-performing reference participant to guide the training of a follower. The observed reductions in the θ/β power ratio during the collaborative task suggest an active shift toward greater cortical engagement, confirming the hypothesis that a higher-performing reference participant can effectively guide the brain wave modulation of a collaborative partner. While these preliminary findings support the potential of collaborative interface for cognitive enhancement, they are limited by the small sample size. Future work will implement this validated experimental protocol in a larger cohort, incorporating robust statistical validations, topographic connectivity analyses, and standardized cognitive assessments to comprehensively determine the system's clinical and practical efficacy.

***Abstract*—Neuronavigation enables subject-specific targeting for transcranial magnetic stimulation (TMS), while advances in brain parcellation, connectivity analysis, electric field modeling, robotics, and neurophysiological monitoring have expanded opportunities for personalized neuromodulation. However, these components are commonly distributed across independent software environments. This work presents an open-source, modular platform based on InVesalius that connects multiple stages of personalized image-guided TMS within a common neuronavigation environment. The platform integrates automated brain subparcellation, multimodal connectivity visualization, electric field estimate visualization, neuronavigation, communication with external robotic control software, dual-coil navigation, and motor mapping visualization. Structural MRI-based subparcellation enables cortical and subcortical regions to be used for stimulation planning, while diffusion MRI tractography and fMRI support connectivity-informed target selection. Electric field estimates generated by specialized modeling tools can be incorporated as an additional planning layer. Imaging-derived targets can be communicated to the external *tms-robot-control* framework for robot-assisted coil positioning, including dual-robot workflows. Motor evoked potential visualization further supports construction of motor maps during TMS sessions. The main contribution is the integration of these heterogeneous components into an extensible workflow rather than the independent development or validation of each underlying method. Quantitative benchmarking of the complete platform remains necessary to establish its accuracy, efficiency, usability, and reproducibility relative to existing workflows.**

***Index Terms*—Transcranial magnetic stimulation; neuronavigation; brain parcellation; diffusion MRI; functional MRI; structural connectivity; functional connectivity; robotics; motor mapping; open-source software.**

I. Introduction

Transcranial magnetic stimulation (TMS) has emerged as a powerful non-invasive technique for investigating brain function and modulating neural activity in both research and clinical settings. Applications of TMS range from functional brain mapping and studies of cortical excitability to the treatment of neurological and psychiatric disorders [1], [2]. As the field advances toward personalized neuromodulation, there is growing recognition that stimulation outcomes depend not only on the stimulation parameters themselves but also on individual variations in brain anatomy, connectivity, and network organization [3]. Consequently, the development of image-guided approaches capable of identifying subject-specific stimulation targets has become a major focus of contemporary TMS research.

Neuronavigation has become an essential component of modern TMS systems by enabling stimulation targets to be localized directly on subject-specific anatomical images [4]. Unlike conventional approaches based on scalp measurements or anatomical landmarks, neuronavigation uses three-dimensional reconstructions derived from magnetic resonance imaging (MRI), together with tracking systems, to continu-

FAPESP grants 2013/07699-0 and 2025/26818-7 (OB), 2022/14526-3 (RHM), 2024/07674-1 (TCM), 2025/06042-4 (MC). CAPES, grant no. 88887.197686/2025-00. CNPq, grant no. 408417/2024-2. Jenny and Antti Wihuri Foundation grant no. 00250241 (RHM).

ously estimate the position and orientation of the stimulation coil relative to the individual's brain anatomy. This capability improves targeting accuracy, reduces inter-operator variability, and facilitates reproducibility across sessions and subjects [5], [6].

Motor mapping is another important application of navigated TMS, allowing the characterization of corticospinal excitability and the spatial organization of motor representations. By recording motor evoked potentials (MEPs) elicited by stimulation at different cortical locations, TMS can be used to identify motor hotspots, estimate cortical excitability, and construct spatial maps of motor responses. When combined with neuronavigation, motor mapping enables MEP responses to be interpreted in relation to subject-specific cortical anatomy, supporting more accurate functional localization and reproducible assessment of stimulation effects [7], [8].

Recent developments in neuroimaging have expanded the role of neuronavigation beyond anatomical guidance. Automated brain parcellation [9], diffusion MRI tractography, functional MRI (fMRI), and network-based analyses now enable stimulation targets to be defined according to individual anatomical, structural connectivity, and functional connectivity profiles [10], [11]. Diffusion MRI tractography can be used to estimate white matter pathways and structural connections between brain regions, including in real-time tractography-assisted neuronavigation workflows for TMS [12]. In contrast, fMRI can be used to identify task-related activation patterns or resting-state functional connectivity networks [13], [14]. These advances create opportunities for personalized neuromodulation strategies in which stimulation is tailored to subject-specific brain organization.

Electric field modeling provides an additional layer for personalized TMS planning by estimating how coil position, coil orientation, head anatomy, and tissue properties influence the spatial distribution and magnitude of the induced cortical field. This information can complement anatomical and connectivity-informed targeting by providing an estimate of the stimulation dose delivered to cortical tissue. Recent work from our group has investigated electric field modeling for TMS, supporting its use as part of personalized stimulation planning and interpretation [15].

At the same time, robotic technologies have emerged as a promising solution for improving the accuracy and reproducibility of neuronavigated TMS [16]. While conventional neuronavigation systems provide visual guidance to the operator, robotic systems can actively position and maintain the stimulation coil at predefined targets, supporting compensation for subject motion and reducing operator-dependent variability [17]. Our recent robotic and electronic targeting approaches have demonstrated the feasibility of autonomous and accurate TMS targeting, including robotic–electronic platforms for autonomous transcranial magnetic stimulation targeting and precise multi-locus TMS stimulation workflows [17], [18]. The combination of neuronavigation and robot-assisted positioning enables imaging-derived targets to be translated into more reproducible physical stimulation procedures. Dual-site TMS further extends this concept by enabling two cortical targets to be stimulated or monitored within the same session, supporting the investigation of interactions between distributed brain regions [19], [20].

Despite these advances, personalized TMS workflows remain fragmented across software for image processing, connectivity analysis, electric field modeling, neuronavigation, robotic control, and neurophysiological assessment, often requiring manual data exchange. To address this limitation, we extended the open-source InVesalius environment [4], [21] to connect these stages within a modular workflow. The main contribution of this work is not the independent introduction of each underlying method, several of which rely on established or previously reported tools, but their integration with image-guided targeting and neuronavigation. Specifically, the platform incorporates FastSurfer-based subparcellation, visualization of multimodal imaging-derived information, communication with external robotic control, dual-coil navigation, dual-robot support, and motor-map visualization.

II. System Overview

The proposed platform extends InVesalius, an open-source medical imaging and neuronavigation environment, to connect anatomical reconstruction, brain subparcellation, multimodal data visualization, electric field estimates, neuronavigation, motor mapping, and external robotic control. These components have different levels of integration: some are implemented directly in InVesalius, whereas others rely on externally generated data or specialized control software. The platform also supports dual-site workflows involving two tracked coils and two robotic systems. The integration follows a modular data-flow architecture rather than a monolithic processing pipeline. Subject-specific anatomical data provide the common spatial reference in InVesalius, to which externally processed imaging information and stimulation targets can be registered. Neuronavigation then relates these image-space targets to tracked physical coordinates, while robot commands are exchanged with the external control framework. This separation allows specialized processing and control tools to remain independent while their outputs are incorporated into the navigation workflow.

The workflow starts with subject-specific structural MRI data, which are used for anatomical reconstruction and brain subparcellation. Segmented cortical and subcortical regions can be converted into masks or three-dimensional surfaces for visualization, target planning, and neuronavigation. Diffusion MRI tractography and fMRI can be incorporated to support structural and functional connectivity-informed targeting, while externally generated electric field estimates can provide complementary information about the induced cortical field for candidate coil positions and orientations [15].

After target definition, the neuronavigation module monitors the position and orientation of the TMS coil relative to the subject-specific anatomy. In dual-site mode, Fig. 1, two coils and two targets can be managed concurrently, with independent coil identification, target association, and

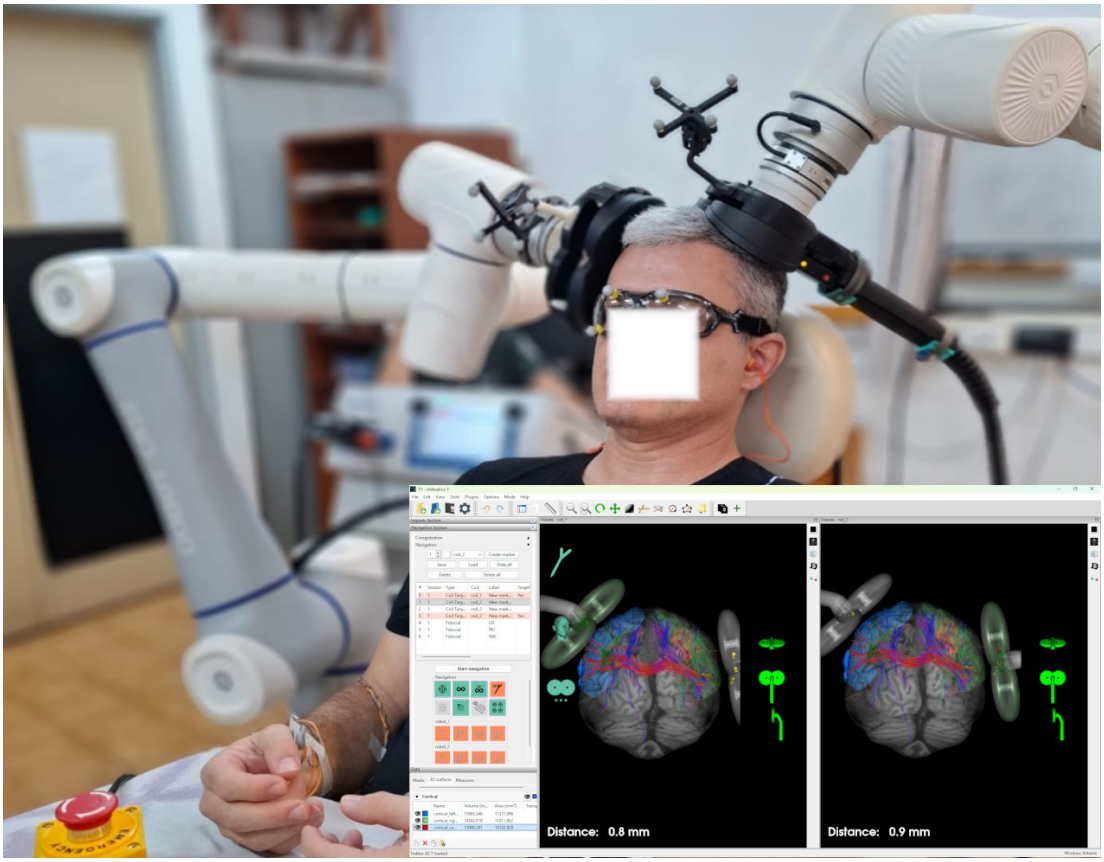

Fig. 1. InVesalius: integrated open-source platform for personalized TMS. The setup illustrates dual-site robot-assisted coil positioning, while the InVesalius interface supports image-guided target planning, brain subparcellation, tractography visualization, and navigation monitoring within a modular workflow.

navigation views. Robot-assisted positioning is implemented through communication with the external *tms-robot-control* framework, which handles robot communication and motion control while InVesalius remains responsible for image-based planning, visualization, tracking, and neuronavigation.

During stimulation sessions, motor evoked potential values can be projected onto reconstructed brain surfaces as heatmaps. Together, these components connect anatomical modeling, connectivity-guided targeting, electric field-informed planning, single- and dual-site neuronavigation, robot-assisted positioning, and motor response visualization.

III. Brain Subparcellation Module

A central component of the platform is the automated brain subparcellation module. This module was developed to segment anatomical subregions of the brain, including cortical and subcortical structures such as the precuneus, superior frontal cortex, hippocampus, and other regions commonly used in neuroimaging-based analysis and TMS planning.

The segmentation pipeline is based on FastSurfer, an open-source convolutional neural network framework for rapid brain segmentation and cortical parcellation [9]. To improve portability and facilitate integration into InVesalius, the module supports inference using both PyTorch and ONNX-compatible models. The FastSurfer models were converted to ONNX primarily to enable lightweight inference backends. A systematic quantitative equivalence analysis between the original PyTorch and converted ONNX models was not performed in the present study and remains necessary to characterize possible backend-dependent differences. The pretrained weights are available at https://github.com/invesalius/weights.

The implemented pipeline includes the following steps:

1) loading the structural MRI volume from the active InVesalius project;
2) applying the required image conformation and preprocessing operations;
3) performing neural network inference using PyTorch or ONNX-compatible execution;
4) post-processing the labelled segmentation volume;
5) mapping numerical labels to anatomical region names;
6) generating binary masks from selected labelled regions;
7) organizing the generated masks into anatomical categories.

The generated masks are automatically categorized in the InVesalius data panel. Cortical parcellation masks are grouped under a cortical category, while subcortical and other anatomical regions are organized into their respective categories. This organization improves usability, particularly when working

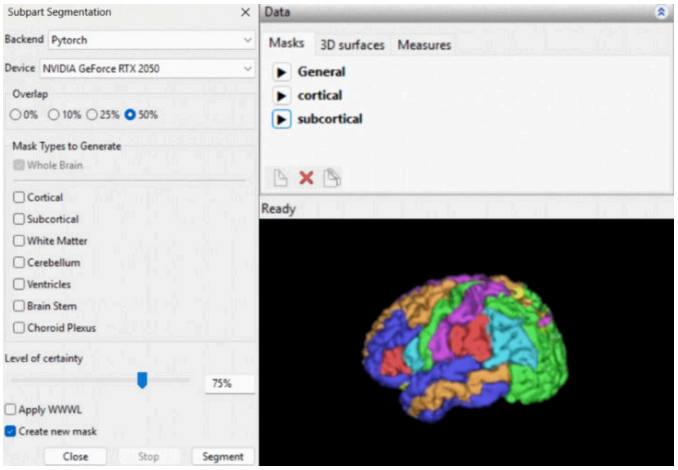

Fig. 2. Brain subparcellation module integrated into InVesalius. The interface allows the user to select the inference backend, processing device, mask types, overlap level, and segmentation confidence threshold. Generated masks are organized into anatomical categories, such as general, cortical, and subcortical regions, and can be converted into three-dimensional surfaces for visualization and TMS target planning.

with a large number of segmented brain regions.

Additional interface tools were implemented to support visualization and interaction. Category headers in the surface panel include hide/show and select-all controls, allowing users to manage multiple structures efficiently. A batch surface generation feature enables users to create three-dimensional surfaces from multiple selected masks simultaneously. These features allow anatomical subregions to be rapidly transformed into objects that can be used for visualization, target definition, and neuronavigation. Fig. 2 illustrates the brain subparcellation module, which generates anatomically categorized masks and surfaces from structural MRI.

IV. Multimodal Connectivity Visualization

The platform supports visualization of externally processed diffusion MRI tractography and functional MRI data rather than performing the underlying diffusion or fMRI processing pipelines. Diffusion MRI tractography provides information about structural connectivity by estimating white matter pathways between brain regions. Recent work has demonstrated the feasibility of real-time tractography-assisted neuronavigation for TMS [12]. Within InVesalius, these data can be visualized together with anatomical models and neuronavigation information to support connectivity-informed targeting. Fig. 3 illustrates this integration.

Functional MRI data can also be incorporated into the targeting workflow. Task-based fMRI activation maps may be used to identify cortical areas involved in specific motor, cognitive, sensory, or affective processes. Resting-state fMRI can be used to estimate functional connectivity between brain regions, supporting network-informed stimulation planning, as illustrated in Fig. 4. For example, a cortical target may be selected based on its functional relationship with a distributed network or with a clinically relevant region [22].

Within the integrated workflow, brain parcellation, structural connectivity, and functional connectivity are complementary. Parcellation provides anatomically defined regions of interest, diffusion MRI provides information about white matter organization, and fMRI provides information about functional activation or network coupling. The combined visualization of these data may assist in selecting cortical targets associated with specific anatomical structures, structural pathways, or functional networks.

V. Integration of Electric Field Modeling and Visualization

Electric field modeling provides subject-specific estimates of the spatial distribution and magnitude of the cortical field induced by TMS as a function of coil configuration, head anatomy, and tissue properties. In the present architecture, the underlying electric field simulations are not computed by InVesalius; estimates generated using specialized modeling tools can instead be incorporated and visualized together with subject-specific anatomy, as illustrated in Fig. 5. This integration provides a complementary biophysical layer for evaluating candidate targets and coil configurations alongside anatomical and connectivity information. Recent work from our group describes the underlying electric-field neuronavigation methodology [15]; the contribution considered here concerns its integration and visualization within the broader workflow.

VI. Robotic Neuronavigation and Robot Control

The neuronavigation component translates imaging-derived targets into physical stimulation procedures. Targets selected from anatomical models, subparcellation masks, structural connectivity maps, or fMRI-derived functional regions can be used to guide coil placement. Robot-assisted TMS is supported through communication with an external robotic control framework rather than by embedding low-level robot control directly inside InVesalius. In this architecture, InVesalius is responsible for image-based target definition, anatomical visualization, tracking, and neuronavigation, while the external control software handles robot communication, motion control, and automated coil positioning. The framework currently supports the Dobot CR10 (6-DoF, 10-kg payload), Elfin E5 (6-DoF, 5-kg payload), and Universal Robots UR10 (6-DoF, 10-kg payload), providing a common interface for robot-assisted TMS across different hardware platforms. The robotic control component used in this work is the open-source *tms-robot-control* framework developed by our group and available at https://github.com/biomaglab/tms-robot-control. Communication between InVesalius and *tms-robot-control* allows imaging-derived targets and tracking information to be translated into robot-assisted positioning commands while preserving modularity between image-guided planning and low-level robot control.

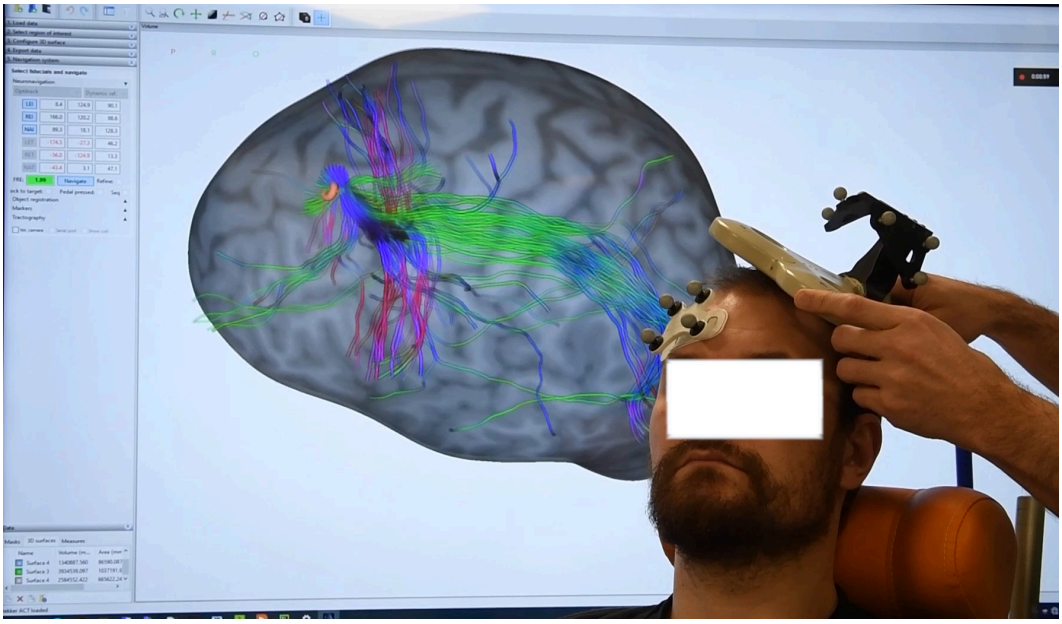

Fig. 3. Tractography-assisted neuronavigation for transcranial magnetic stimulation. Diffusion MRI-derived white matter streamlines are visualized together with the subject-specific cortical surface, while the tracked TMS coil is positioned over the participant's scalp. This visualization allows the operator to inspect the relationship between the stimulation site, cortical anatomy, and underlying structural connectivity during image-guided TMS procedures. Adapted from [12].

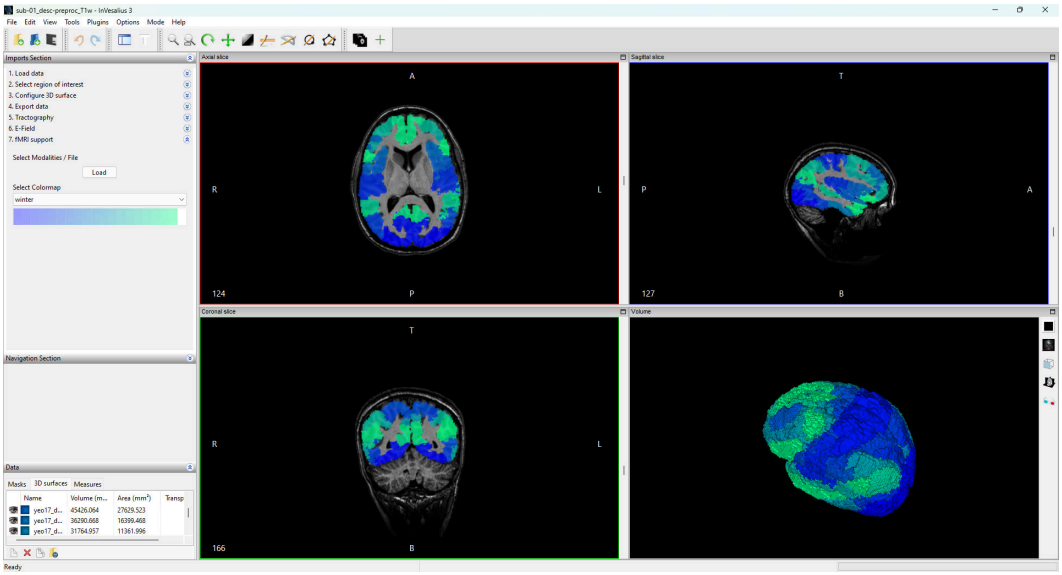

Fig. 4. Multimodal visualization of fMRI-derived information in InVesalius. Functional maps are overlaid on structural MRI slices in axial, sagittal, and coronal views, while the corresponding three-dimensional cortical representation is shown in the volume view. This visualization supports inspection of spatial relationships between anatomical structures and functional or connectivity-related information for image-guided TMS planning.

VII. Dual-Coil Navigation and Dual-Robot Control

In addition to single-coil neuronavigation, the platform has been extended to support simultaneous navigation of two TMS coils for dual-site stimulation protocols, Fig. 1. This development was motivated by the need to investigate and modulate distributed brain networks rather than isolated cortical regions [19]. While conventional TMS workflows typically focus on one stimulation target at a time, dual-site TMS enables the exploration of interactions between two brain areas, supporting studies of effective connectivity, network dynamics, and multi-region neuromodulation strategies [20].

The dual-coil navigation module adapts the InVesalius navigation architecture to manage two stimulation coils and two stimulation targets concurrently. Each coil can be independently identified, named, registered, and associated with a specific target. Coil naming can be performed through the

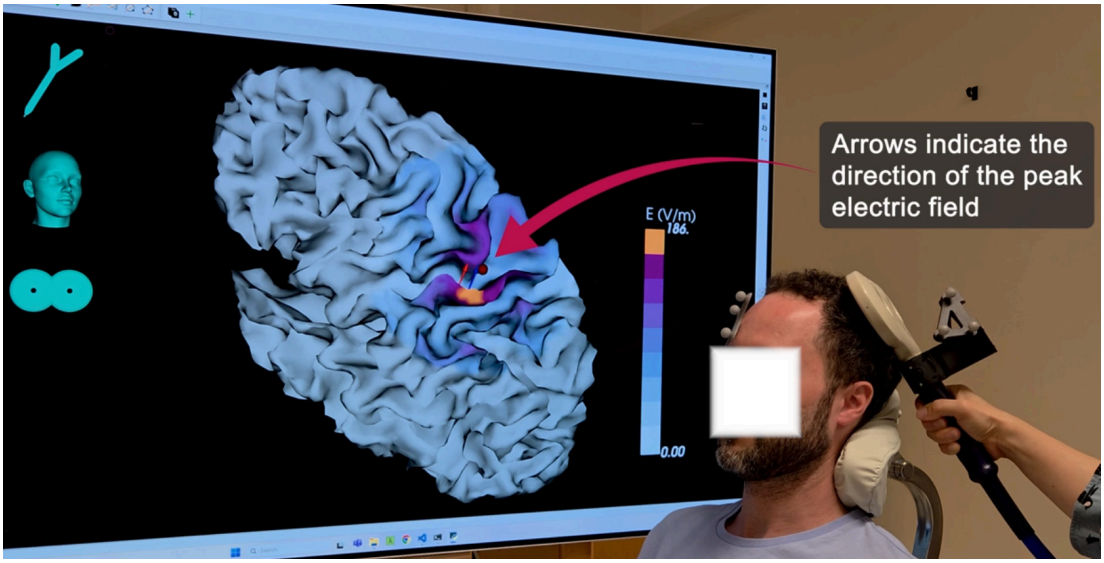

Fig. 5. Electric field modeling for personalized TMS planning. The predicted electric field distribution is visualized over subject-specific cortical anatomy, allowing candidate stimulation sites and coil configurations to be evaluated according to the estimated spatial distribution and magnitude of the induced cortical field. This information can complement anatomical, structural connectivity, and functional connectivity-based target selection. Adapted from [15].

coil registration window or through the coil selection panel, improving clarity when multiple tracked coils are present. The navigation panel was also extended to allow target creation to be associated with a selected coil, and the marker list displays the relationship between each coil and its corresponding target. Simultaneous navigation is activated through a dedicated multiple-target control in the navigation panel. When enabled, the interface provides two independent navigation scenes, each associated with a single coil. This allows the user to visualize and monitor the position and orientation of both coils relative to their respective anatomical targets. The display of tracking information was adapted to represent each coil with independent visual indicators, facilitating interpretation during dual-coil procedures. For dual-robot operation, two independent instances of the external robot-control framework communicate with InVesalius through a local server. A message-splitting mechanism routes commands and tracking information according to the robot identifier, allowing each robot-coil assembly to be controlled independently. The preferences window associates each robot with a specific coil. A preliminary collision-avoidance strategy approximates each coil as a sphere and exponentially reduces robot speed as the inter-coil distance approaches a predefined threshold. This mechanism should be regarded as a preliminary software safeguard rather than a validated safety system. Dual-robot synchronization, simultaneous positioning accuracy, communication latency, and behavior under head motion were not quantitatively evaluated in the present study and require dedicated validation. This extension enables manual and robot-assisted dual-site TMS workflows within the InVesalius-based neuronavigation environment.

VIII. Motor Mapping Visualization

The motor mapping module provides visualization and spatial association of MEP amplitudes. Each stimulation point is associated with its individual MEP value and corresponding stimulation coordinate. The motor map is generated using distance-based Gaussian interpolation, such that the influence of each measured response decreases with increasing distance from its stimulation location. The Gaussian kernel width therefore defines the spatial scale of the interpolation. Users can adjust the selected surface, colormap, display range, and Gaussian interpolation parameters, and the MEP values and visualization settings can be stored with the session.

IX. Discussion

The proposed platform addresses the fragmentation of tools used in personalized and image-guided TMS. Structural MRI processing, parcellation, connectivity analysis, electric field modeling, neuronavigation, robotic positioning, and neurophysiological analysis are commonly distributed across specialized environments. FreeSurfer [23], SimNIBS [24], commercial neuronavigation systems such as Localite TMS Navigator, and motor mapping tools such as TMSMap [25] provide established solutions for individual stages. The proposed platform does not aim to replace these specialized tools. Its principal contribution is an open and modular architecture that brings their outputs or complementary functions closer to image-guided targeting, navigation, robotic positioning, and response visualization within the InVesalius ecosystem.

Importantly, integration should not be interpreted as independent implementation or validation of every component. Brain subparcellation is incorporated through FastSurfer-based inference; tractography and fMRI information may originate from external processing; electric-field estimates rely on specialized modeling methods; and low-level robot control is handled by the external *tms-robot-control* framework. In this context, interoperability refers to modular exchange of imaging-derived information, targets, tracking data, and

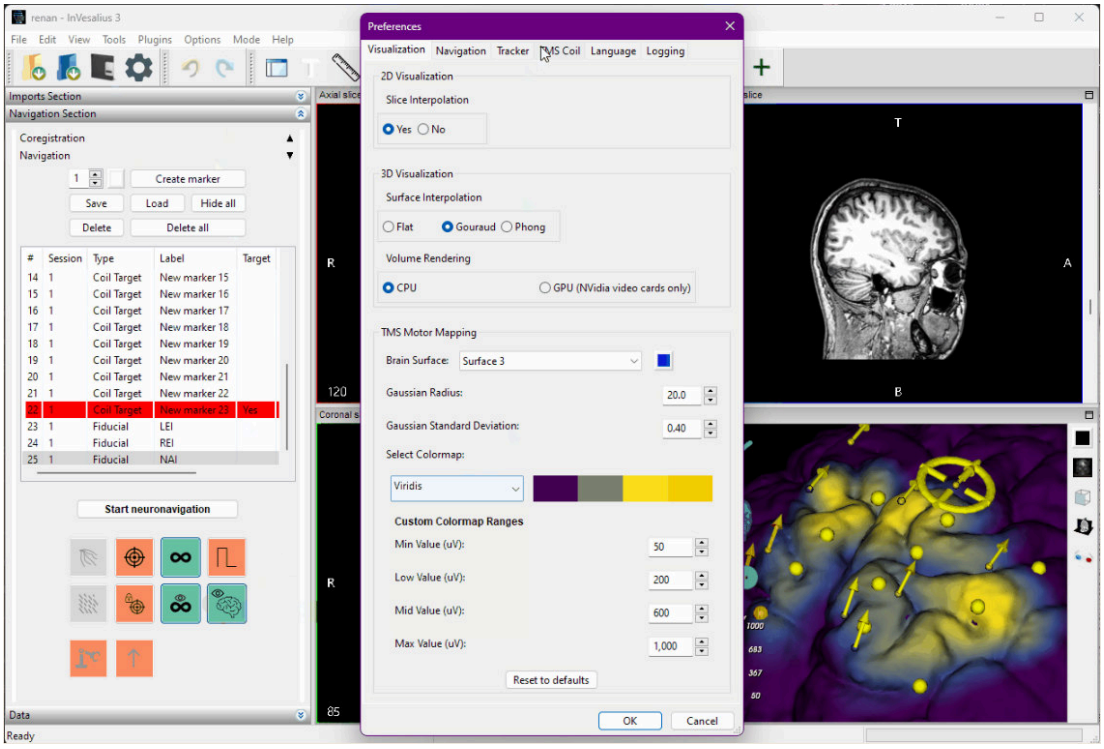

Fig. 6. Motor mapping visualization in the InVesalius-based platform. Motor evoked potential values are projected onto the reconstructed brain surface as a heatmap, allowing spatial exploration of corticospinal responses during TMS sessions.

control messages between supported components, rather than compliance with a formal clinical interoperability standard or demonstrated compatibility with arbitrary hardware.

A major limitation of the present study is the absence of a systematic quantitative evaluation of the complete platform. We did not perform a head-to-head comparison with commercial neuronavigation systems or conventional fragmented workflows, nor quantify end-to-end registration error, positioning accuracy, communication latency, failure rates, usability, workflow efficiency, or session-to-session reproducibility. Consequently, the present results demonstrate software integration and technical feasibility but do not establish superior accuracy, efficiency, reproducibility, usability, or safety relative to existing approaches.

The development process also highlighted practical lessons and research gaps. Maintaining specialized external components can preserve modularity, but heterogeneous imaging, tracking, robotic, and physiological data require consistent coordinate systems and interfaces. Dual-device operation further introduces synchronization and safety requirements beyond single-coil navigation. More broadly, multimodal visualization makes complementary information accessible within a common environment but does not by itself demonstrate improved targeting or clinical efficacy. Future work should therefore benchmark navigation and robotic accuracy, latency, reproducibility, ONNX segmentation equivalence, usability, and workflow efficiency; improve collision avoidance; and evaluate compatibility across additional hardware and multicenter settings. Clinical adoption will additionally require hardware-specific safety validation, robust error handling, standardized deployment, user training, and compliance with applicable medical-device requirements. The open-source nature of the platform facilitates inspection, modification, and extension of the software according to experimental needs. Future extensions will also investigate incorporation of TMS-evoked EEG responses, allowing neurophysiological information beyond motor responses to be explored within the same architecture.

X. Conclusion

We presented an open-source and modular extension of the InVesalius ecosystem aimed at connecting multiple stages of personalized image-guided TMS. The platform combines anatomical reconstruction and subparcellation with multimodal imaging visualization, electric-field estimates, neuronavigation, external robotic control, dual-coil and dual-robot workflows, and motor-response visualization. Its principal contribution is the integration of these heterogeneous components within a common image-guided environment rather than the independent development of all underlying methods.

The current implementation demonstrates the architecture and technical feasibility of this approach but does not establish improvements in accuracy, reproducibility, efficiency, usability, or safety relative to existing systems. Quantitative benchmarking, formal safety assessment of multi-robot operation, broader hardware evaluation, user studies, and multicenter validation remain necessary to establish the performance and translational value of the platform.

Code Availability

The platform is developed as part of the open-source InVesalius project and is available at https://github.com/invesalius/invesalius3. The robotic control framework is available at https://github.com/biomaglab/tms-robot-control.

Acknowledgment

The authors acknowledge the contributions of the InVesalius open-source community and the Google Summer of Code contributors (Shuvam Pal, Mohamed Gaafar, and Michael Chan) involved in the development of the brain subparcellation, motor mapping and functional MRI visualization modules.

***Abstract*—Studying the neural basis of instrumental memory requires behavioral platforms capable of delivering temporally precise circuit manipulations while continuously recording operant behavior. This paper describes the design, construction, and integration of an optogenetic stimulation system coupled to an automated operant conditioning apparatus for instrumental memory research in rats. The system combines a microcontroller-based trigger circuit, a fiber-coupled LED driver, custom and commercial optical fiber cannulas, and a rotary joint compatible with freely moving animals, synchronized in closed loop with a commercial operant chamber via TTL communication and custom Python scripts. We describe the fabrication and validation of the optical components, the surgical and viral-vector strategy for opsin delivery, the firmware logic for event-triggered and scheduled stimulation, the hardware/software synchronization architecture, and a four-stage behavioral protocol (pre-training, training, reactivation, and test) capable of probing distinct temporal windows of instrumental memory processing. The system was implemented and operated across 18 animals over a multi-month protocol without fiber failure or trigger malfunction, demonstrating its feasibility as a reusable and reproducible platform for combining optogenetics with operant behavioral assays.**

I. Introduction

Instrumental memory, the association between an action and its consequence, is central to adaptive behavior and depends on a distributed neural circuit involving the prefrontal cortex, hippocampus, amygdala, and striatum [1]. Understanding the causal contribution of specific nodes within this circuit to distinct temporal phases of memory processing — acquisition, consolidation, and reconsolidation — requires experimental tools capable of manipulating neural activity with high temporal precision while simultaneously recording operant behavior [2].

Pharmacological and lesion-based approaches have historically been the main tools for probing these circuits, but their relatively slow onset and long duration of action limit the temporal resolution with which distinct memory phases can be dissociated [2]. Optogenetics addresses this limitation by enabling reversible, cell-type-specific control of neuronal activity through light-sensitive opsins delivered by viral vectors [3]. Its main experimental advantage is temporal resolution: light delivery can be restricted to a few seconds around a specific behavioral event, such as a lever press or a memory-reactivation session, allowing dissociation between processing phases that occur only minutes apart [3], [4].

Realizing this advantage in practice, however, is non-trivial. Most commercial operant-conditioning platforms are designed as closed, self-contained systems for behavioral data acquisition and are not natively equipped for closed-loop optogenetic triggering [5]. Integrating optogenetic stimulation therefore typically requires custom hardware bridges and software synchronization layers built around the commercial platform, a step that is often under-documented in the neuroscience literature despite being a substantial practical bottleneck for laboratories adopting these techniques.

This paper addresses that gap by describing, in engineering detail, an integrated system developed to combine optogenetic manipulation with automated operant conditioning for the study of instrumental memory in rats. We detail the optical and electronic components and their validation, the surgical and viral-vector strategy for opsin delivery, the firmware logic used for event-triggered and scheduled stimulation, the synchronization architecture between the stimulation and behavioral-recording subsystems, and a four-stage behavioral protocol de-

signed to probe acquisition, consolidation, and reconsolidation. Rather than reporting the neuroscientific findings obtained with the platform, the present contribution focuses on the system itself, with the goal of providing a reproducible technical reference for laboratories seeking to implement similar closed-loop optogenetic-behavioral platforms.

The remainder of this paper is organized as follows. Section II briefly situates the system with respect to related closed-loop behavioral-optogenetic approaches. Section III describes the full system architecture and experimental methods. Section IV reports validation results obtained from operating the platform across a full experimental cohort. Section V discusses design trade-offs and limitations, and Section VI concludes the paper.

II. Related Work

Closed-loop optogenetic stimulation, in which light delivery is made contingent on a real-time behavioral or physiological event rather than delivered on a fixed schedule, has been increasingly adopted in behavioral neuroscience because it allows stimulation to be precisely anchored to the trial structure of a task [5]. Compared with open-loop protocols, in which light is delivered independently of ongoing behavior, closed-loop designs reduce temporal jitter between the neural manipulation and the behavioral event of interest, which is particularly important when probing short-lived processes such as post-reactivation memory destabilization [2].

A recurring practical challenge across laboratories implementing such designs is that commercial behavioral platforms (e.g., operant chambers, mazes, or head-fixation rigs) and optogenetic hardware (lasers or LED drivers) are typically supplied as independent systems, each with its own proprietary control software. Bridging them commonly relies on general-purpose microcontrollers or data-acquisition boards operating on the digital input/output (TTL) lines exposed by the behavioral platform [5]. The system described in this paper follows this general strategy, using an inexpensive microcontroller as the integration layer between a commercial operant chamber and a fiber-coupled LED driver, while adding a rotary-joint-based optical delivery path suited to chronic use in freely moving animals.

This pattern is reflected in the literature: several recent studies report similarly bespoke integrations built around commercial platforms such as Med Associates, each solving the bridging problem independently rather than following a shared, documented approach [6], [7], [8]. This fragmentation motivates presenting the present system's hardware and firmware design in enough engineering detail to be replicated directly.

III. System Description and Methods

A. Ethics and Subjects

All procedures were approved by the Animal Ethics Committee of Instituto Santos Dumont (CEUA-ISD, protocol 01/2020 ISD) and followed Brazilian federal law 11,794/2008 and the guidelines of the Conselho Nacional de Controle de Experimentação Animal (CONCEA). The system was implemented and operated using 18 adult male Wistar rats (*Rattus norvegicus*, $\sim$3 months old, 300–400 g), housed in groups of up to three under a 12h light/dark cycle, with controlled temperature ($\sim$22 °C) and humidity. Seven days before the behavioral protocol, animals were placed on a food-restriction schedule (16 g of chow per day, with water *ad libitum*) to increase motivation for the sucrose reward; restriction was maintained throughout the protocol.

B. Safety and Handling Procedures

Standardized handling procedures were established and followed by all operators: (i) the fiber-optic patch cable and implanted cannula were handled with forceps and connector sleeves rather than by hand, given the fragility of the fiber core; (ii) personal protective equipment (gloves, laboratory coat, long trousers, and closed shoes) was mandatory whenever an animal was being tethered or stimulated; (iii) all cables and connector sleeves were stored properly after each session to avoid mechanical damage; and (iv) only trained operators performed the tethering/untethering procedure to minimize torque on the implant.

C. System Overview

The platform is organized into three functional subsystems: (1) an optical stimulation subsystem, responsible for generating and delivering calibrated light to the implanted cannula; (2) a behavioral-recording subsystem, a commercial operant chamber responsible for stimulus presentation, reward delivery, and event logging; and (3) an integration layer, implemented in a microcontroller and a host computer, responsible for synchronizing the two other subsystems in closed loop. Table I summarizes the main hardware components and their function within the platform.

TABLE I
Main Hardware Components of the Optical Stimulation Subsystem

Component	Function
Microcontroller (Arduino)	Processes trigger logic and generates the digital signal that drives light delivery.
LED driver (Plexon LD-1)	Receives the digital trigger and supplies a constant, calibrated current to the light source.
Fiber-coupled LED light source	Converts electrical current into light at a specific wavelength (589 nm).
SMA connector	Precision, threaded mechanical coupling between the light source and the patch fiber, minimizing insertion loss.
Integrated rotary joint	Allows 360° fiber rotation without torquing or breaking the fiber, required for freely moving animals.
Interconnect / ceramic sleeve	Mechanically aligns and couples the patch fiber to the chronically implanted cannula.
Fiber-optic cannula	Surgically implanted interface, terminating in a short fiber segment delivering light to the target region.

D. Optical and Electronic Components

Two microcontroller firmware configurations were used, corresponding to the two stimulation modes required by the behavioral protocol.

The first configuration operates in *closed loop*: it monitors a digital input line (TTL) driven by the operant-chamber controller and, upon detecting a rising edge corresponding to a correct lever press, immediately sets the trigger output high, driving the LED for a fixed 20-second window at a constant output power of 16 mW; a software flag prevents retriggering while a stimulation window is already active, and the output is set low automatically once the window elapses. This logic was implemented as simple edge-detection combined with a non-blocking, `millis()`-based timer, avoiding the use of blocking delay calls so that the trigger circuit remains responsive throughout the session.

The second configuration operates *independently* of the behavioral platform, for use in the open-field post-reactivation stimulation stage. Upon receiving a start command over a serial connection, it executes a fixed pulsed schedule (5 s on / 5 s off) for a total duration of 30 minutes, after which it automatically returns to an idle state awaiting a new start command. This design allows the same hardware to be reused for both an event-contingent (closed-loop) protocol and a fixed-schedule (open-loop) protocol simply by loading the corresponding firmware.

E. Fiber-Optic Cannula Fabrication and Validation

Optical fiber cannulas (200 μm core diameter, 0.39 NA, 9 mm free-fiber length) were either sourced commercially (Plexon Inc.) or fabricated in-house by inserting and epoxy-fixing the fiber into 1.25-mm stainless-steel ferrules compatible with standard FC/PC connectors. Free-fiber length was mechanically polished and verified under a microscope to 9 ± 0.1 mm, following stereotaxic coordinates derived from a standard rat brain atlas. Every fabricated unit was validated prior to implantation by passing continuous-wave 589-nm light through the assembly and visually confirming transmission integrity and the absence of fiber breaks or excessive insertion loss; units that failed this test were discarded and not implanted.

F. Viral Vector Strategy

Opsin expression was achieved with the recombinant adeno-associated viral vector AAV-EF1a-NpHR3.0-EYFP, encoding the inhibitory opsin halorhodopsin (NpHR3.0) fused to an EYFP reporter. This vector class was selected for its low immunogenicity and stable long-term neuronal expression [3]. Following stereotaxic infusion, a three-week interval was allowed for adequate opsin expression before optical fiber implantation and the start of behavioral testing, consistent with standard AAV expression timelines.

G. Stereotaxic Surgical Procedures

Viral infusion and optical fiber implantation were performed as two separate stereotaxic procedures under general anesthesia, three weeks apart, to allow both surgical recovery and adequate opsin expression before optical access was established. Standard post-operative analgesia and individual recovery housing were used following each procedure. As the surgical protocol itself is not the focus of the present system-oriented description, full anesthetic, stereotaxic, and post-operative details are reported in a companion paper from our laboratory dedicated specifically to the surgical procedure.

H. Operant Chamber Integration and Data Pipeline

Behavioral sessions were conducted in sound-attenuated MedAssociates operant chambers equipped with two retractable levers, a central reward magazine with infrared nose-poke detection, a house-light, and cue lights positioned above each lever. The chamber controller and the optogenetic trigger circuit were synchronized through custom Python scripts communicating over the chamber's TTL input/output lines, ensuring that light delivery was tightly time-locked to specific behavioral events without requiring manual intervention during the session. Behavioral event logs exported by the chamber software were subsequently organized into structured tabular datasets and processed using a standard Python-based data-analysis pipeline, providing an end-to-end path from raw event timestamps to analysis-ready behavioral variables suitable for the statistical characterization reported separately.

I. Habituation Procedure

During habituation sessions, the entire optical stimulation subsystem remained powered off; a damaged (non-functional) patch cable was connected to the implanted cannula through the ceramic sleeve, reproducing the mechanical experience of tethering without any light delivery. This step was intended to dissociate the animals' behavioral response to physical tethering from any response driven by light stimulation.

J. Behavioral Protocol

The protocol implemented on this platform comprises four sequential stages. (1) *Pre-training*: a single 15-minute session with free reward delivery at fixed intervals and levers retracted, to familiarize animals with the reward magazine. (2) *Training*: up to ten daily 30-minute sessions under a fixed-ratio 1 (FR1) schedule, in which a correct response on the active lever delivers a sucrose pellet and, depending on the experimental condition, triggers closed-loop optogenetic stimulation. (3) *Reactivation*: a single session, 24 hours after the last training session, under a variable-ratio 20 (VR20) schedule, a reinforcement schedule associated with destabilization of previously consolidated instrumental memories; this session may be optionally followed by post-reactivation stimulation delivered in an open-field arena. (4) *Test*: a 30-minute extinction session (levers available, no reward delivered) to assess memory retention. This modular structure allows optogenetic manipulation to be selectively restricted to the training window, the post-reactivation window, or both, depending on the specific scientific question being addressed by the experimenter.

IV. System Validation

A. Optical and Mechanical Reliability

The platform was operated continuously across 18 animals over a multi-month experimental timeline encompassing up to ten training sessions, one reactivation session, and one test session per animal. All fabricated and commercial fiber-optic cannulas passed the pre-implantation light-transmission test described in Section III-D. No fiber failures or cable disconnections were recorded during the behavioral phase, indicating that the rotary-joint and interconnect-sleeve arrangement reliably tolerated repeated tethering and untethering cycles in freely moving animals across the full protocol duration.

B. Trigger Timing Reliability

The closed-loop firmware reliably delivered a stimulation pulse contingent on each qualifying lever press throughout training, with the non-blocking timer design preventing missed or overlapping trigger events during sustained bouts of responding. The independent pulsed-mode firmware reliably executed the fixed 30-minute open-field stimulation protocol without requiring manual timing by the experimenter, reducing a common source of human error in fixed-duration stimulation protocols.

C. Operational Throughput

Across the full cohort, the platform supported the complete four-stage protocol — pre-training, up to ten training sessions, reactivation, and test — without requiring hardware reconfiguration between animals or between stimulation modes, other than reflashing the appropriate firmware configuration onto the microcontroller. A full quantitative behavioral characterization of instrumental learning obtained with this platform, including group-level comparisons under different optogenetic manipulation conditions, is beyond the scope of the present technical description and is reported elsewhere.

D. Behavioral Performance Under Tethered Conditions

To assess whether the tethering and implant hardware itself interferes with normal instrumental behavior, we examined performance in animals that were fully connected to the optical stimulation subsystem but received no light delivery (Control condition, n = 9). These animals reliably acquired the operant task, reaching the learning criterion ($\geq$60 correct responses) within 4.67 $\pm$ 1.00 days on average, with 100% of animals reaching criterion within the 10-day training window, and discrimination indices approaching ceiling (¿0.95) by the fifth training day (Fig. 1). This performance is consistent with expected acquisition timelines for this task, indicating that the physical presence of the fiber-optic tether and rotary-joint assembly does not measurably impair normal instrumental learning.

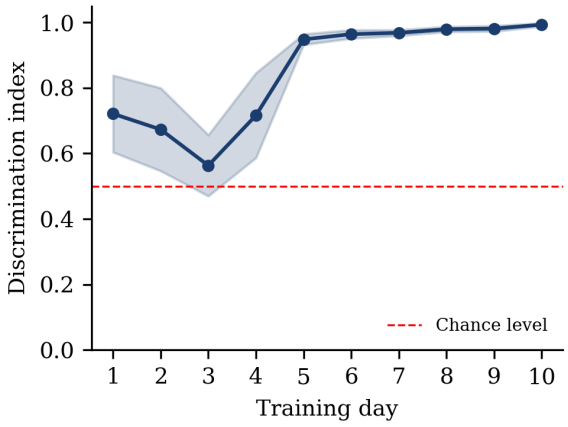

Fig. 1. Discrimination index across the 10-day training protocol for tethered Control animals (n = 9, mean $\pm$ SEM), showing normal task acquisition under the physical presence of the fiber-optic tether and rotary-joint assembly.

V. Discussion

The system described here addresses a practical bottleneck in circuit-level studies of instrumental memory: commercial operant-conditioning platforms do not natively support closed-loop optogenetic triggering, and integrating the two typically requires an *ad hoc* hardware/software bridge [5]. By using an inexpensive microcontroller as the trigger layer and TTL-based communication with the chamber controller, the present architecture keeps the behavioral platform largely unmodified while adding precise event-contingent optical control — a design choice intended to make the system easier to replicate in laboratories that already operate commercial operant chambers, without requiring proprietary hardware modifications.

The rotary-joint and sleeve-based fiber-coupling strategy was a key element enabling multi-week use in freely moving animals without mechanical fiber failure, which is a common practical limitation in chronic optogenetic experiments [3]. Separating viral infusion from fiber implantation by three weeks, following established practice for AAV-mediated opsin expression, further reduced the risk of implanting before adequate expression was achieved, avoiding wasted implantation surgeries on animals with insufficient opsin availability.

Using two interchangeable firmware configurations on the same microcontroller hardware — one event-contingent and one schedule-based — allowed a single low-cost hardware design to serve both stimulation modes required by the protocol, rather than requiring separate dedicated devices. This design choice reduces both hardware cost and the complexity of maintaining multiple stimulation circuits in parallel.

A limitation of the present configuration is the anatomical offset between the viral infusion coordinates and the fiber implantation coordinates, introduced to accommodate the angled implantation trajectory used in this protocol. Laboratories targeting small or anatomically subdivided nuclei should validate, on a pilot basis, that the illuminated tissue volume adequately overlaps the transduced region for their specific target, since a mismatch between expression and illumination sites could reduce the effective manipulation even when both individually appear successful. Future iterations of the system could

incorporate automated optical-power calibration and real-time logging of stimulation events alongside behavioral timestamps within a single unified data stream, further reducing manual verification steps and simplifying post-hoc alignment between neural manipulation and behavior. Additionally, the present validation did not include independent electrical or optical measurement of trigger latency and jitter (e.g., via oscilloscope or photodiode), nor systematic logging of expected-versus-delivered stimulation counts; these measurements would further strengthen claims of synchronization precision and are recommended for future iterations of the system.

VI. Conclusion

We described the design, construction, and validation of an integrated optogenetic and operant-conditioning system for instrumental memory research in rats, combining a microcontroller-based closed-loop trigger, a fiber-coupled LED driver, a rotary-joint fiber-delivery path suited to freely moving animals, and a four-stage behavioral protocol capable of probing acquisition, consolidation, and reconsolidation. The system operated reliably across 18 animals over a multi-month protocol without fiber failure or trigger malfunction, supporting its use as a reproducible, low-cost platform for laboratories investigating the neural circuit basis of instrumental behavior. Future work will incorporate automated light-power calibration and unified event logging to further streamline data alignment between neural manipulation and behavioral output.

Acknowledgment

I express my sincere gratitude to all my colleagues at the Instituto Santos Dumont (ISD) for their support. Special thanks go to my advisor, Ramón H. Lima, for his outstanding guidance and mentorship, and to M.Sc. candidate Aurea E. A. Silva, who led the broader research project for which this experiment was planned and conducted.

***Abstract*—Operational integration of brain-computer interfaces (BCIs) and functional electrical stimulation (FES), in which real-time neural signals trigger muscle activation, offers a neurobiologically grounded route to motor recovery, yet its technical scope has not been systematically mapped. We conducted a scoping review following PRISMA-ScR, searching PubMed, Scopus, and IEEE Xplore through March 2026. Eighty-two studies (2010–2025) were included. Stroke accounted for 72% of the clinical population and spinal cord injury for 28%; non-invasive EEG was dominant (94%), with motor imagery (48%) and movement execution or attempt (40%); surface FES was used in 93%. Thirty-two percent measured only system performance, without a clinical outcome. Of the 23 studies (28%) with a separate control group, 15 compared groups on a clinical outcome, with BCI-FES superior in 9 (8 of 14 independent cohorts), a vote count across mostly underpowered studies (median n=7) that should be read as a descriptive signal, not a measure of efficacy. Randomized trials numbered 15 (18%). FES frequency and pulse width were unreported in 41% and 39% of studies. Technical feasibility is suggested mainly in chronic upper-limb stroke, while efficacy evidence rests on a few small controlled studies and FES parameter reporting remains variable.**

***Index Terms*—brain-computer interface, functional electrical stimulation, motor rehabilitation, electroencephalography, scoping review**

I. Introduction

Stroke and spinal cord injury (SCI) are among the leading causes of permanent motor disability worldwide, imposing a substantial burden on individuals, caregivers, and health systems [1], [2]. Conventional rehabilitation approaches (physiotherapy, occupational therapy, task-oriented training) have shown limited efficacy in patients with severe deficits, motivating the development of neurotechnology-assisted interventions [3].

Brain-computer interfaces (BCIs) capture neural signals in real time, most commonly through electroencephalography (EEG), and translate them into commands for external devices, bypassing injured motor pathways [4]. Functional electrical stimulation (FES) delivers controlled electrical current to peripheral nerves or muscles, eliciting functional contractions in otherwise paralyzed limbs [5]. Both modalities have been investigated independently as rehabilitation tools; each, however, addresses only part of the neural-motor circuit.

When decoded cortical signals trigger the delivery of FES in real time, the result is a closed neuromuscular loop grounded in the principles of Hebbian plasticity. The simultaneous activation of the motor cortex and the peripheral muscle during intentional motor effort is hypothesized to strengthen corticospinal connections and to support long-term motor recovery [6], [7]. This rationale has sustained a growing body of experimental work over the past 15 years.

Existing systematic reviews and meta-analyses have examined the efficacy of BCI-FES in upper-limb rehabilitation after stroke [8]–[10]. This scoping review complements that evidence by characterizing the broader landscape: the populations studied, the technical configurations used, and the outcomes measured across all study designs, providing context for interpreting and extending the evidence from controlled trials. Previous reviews, including systematic and narrative syntheses focused on efficacy in specific populations [8]–[10], concentrated on the subset of controlled trials; to our knowledge, no prior scoping review has characterized the broader technical landscape of BCI-FES integration, spanning all study designs and populations, under the PRISMA-ScR framework.

This review aims to characterize study designs, populations, technical BCI and FES parameters, and reported outcomes in the BCI-FES integration literature, identifying patterns and gaps that may inform future research and reporting guidelines.

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) – Finance Code 001.

II. Methods

A. Study Design

This scoping review was conducted following the PRISMA extension for scoping reviews (PRISMA-ScR) [11], with the protocol, eligibility criteria, and search strategy defined a priori.

B. Search Strategy

Three electronic databases were searched through March 20, 2026. PubMed was selected for its clinical and biomedical coverage; Scopus for its interdisciplinary breadth; and IEEE Xplore for its engineering and neurotechnology publications, where a substantial share of BCI research appears and is not fully indexed in the other databases. The search combined terms related to brain-computer interfaces ("brain-computer interface", "BCI", "brain-machine interface", "BMI"), functional electrical stimulation ("functional electrical stimulation", "FES", "neuromuscular electrical stimulation", "NMES"), and motor rehabilitation ("motor rehabilitation", "motor recovery", "neurorehabilitation"). No language restriction was applied, and the strategy was adapted to the syntax of each database. The full search string is available from the authors on request.

C. Inclusion and Exclusion Criteria

Studies were included if they: (I1) involved adults ($\geq$18 years) with motor deficits secondary to a neurological condition; (I2) implemented real-time BCI-FES integration, defined as central neural signals captured by a BCI directly and continuously modulating FES delivery; (I3) reported at least one quantitative outcome from an implemented system; and (I4) were published between January 2010 and March 20, 2026, as full papers.

Studies were excluded if they: (E1) involved exclusively healthy participants; (E2) used BCI and FES in temporally separate phases, without real-time integration; (E3) controlled FES through electromyography, movement sensors, or manual control without an operational neural BCI; (E4) used a powered robotic exoskeleton as the primary effector without FES; (E5) were exclusively computational studies, simulations, or animal experiments; or (E6) were reviews, meta-analyses, editorials, protocols without collected data, or conference abstracts without a full paper.

D. Screening and Data Extraction

Titles and abstracts of 1,161 unique records were screened by a single reviewer; 168 full texts were assessed for eligibility. Single-reviewer screening is an acknowledged limitation, mitigated by requiring a supporting verbatim quotation from the source article for the six classification fields most subject to interpretation (design, control group, BCI paradigm, BCI-FES integration, outcome, and between-group superiority). Data were extracted using a standardized form with 52 fields across eight domains: study identification, participants, study design, BCI characteristics, FES characteristics, BCI-FES integration, intervention protocol, and outcomes. Categorical fields followed a closed vocabulary; any field without explicit information in the source article was coded "NR" (not reported), and inference was not permitted. The unit of analysis was the individual publication. Some groups contributed multiple articles, and a subset reports overlapping or identical participant cohorts: the Remsik et al. series (2018, 2019, 2021, 2022) [55], [60], [73], [80], derived from a common cohort; two publications from the same Krueger et al. cohort (2022, 2024) [15], [78]; two publications on the same patient by Bastos-Filho et al. [92], [93]; and two publications describing the same nine-patient cohort by Tan et al. (2010, 2011) [20], [22]. Participant totals should therefore be read at the report level, without assuming strictly independent samples. A post-hoc reliability check was subsequently conducted for all 82 included studies: a second author independently re-extracted the six critical fields listed above, blind to the original classification, and discrepancies were adjudicated by the author team; the figures reported below reflect this adjudication.

E. Classification Criteria

To reduce subjectivity, each categorical field followed an explicit rule. Design was classified hierarchically: randomized trial ($\geq$2 groups with random allocation), non-randomized controlled trial ($\geq$2 groups without randomization), single case (n=1), and, for single-arm samples with n$\geq$2, feasibility/pilot study (when the stated primary outcome was feasibility, accuracy, or safety) or case series (when it described clinical outcomes). The control-group field was coded as present only when a separate, prospectively allocated participant group existed; within-subject comparisons (e.g., A-B-A-B or condition-crossover designs) and historical controls were treated as the absence of a control group. The outcome was labeled according to what the study set out to measure: studies without any pre/post clinical comparison were coded "no clinical outcome", regardless of technical performance; the remainder were classified as positive, mixed, or negative by the prespecified clinical outcome, based on the Results section rather than the Discussion. Superiority was assigned only when a study reported a between-group statistical test on a clinical outcome.

III. Results

A. Study Selection

The database searches identified 1,301 records (PubMed: 118; Scopus: 981; IEEE Xplore: 202). After deduplication, 1,161 unique records were screened at the title and abstract level; 194 were sought for retrieval, of which 26 were not retrieved, yielding 168 articles assessed in full text. Of these, 82 met all inclusion criteria (Fig. 1). The most common reasons for full-text exclusion were reviews or records without primary data (n=24), the inclusion of healthy participants only (n=23), and FES driven by electromyographic, sensor, or manual control without an operational BCI (n=12); the full breakdown is shown in Fig. 1. Table III summarizes the 82 studies individually.

B. Publication Trends

The included studies were published between 2010 and 2025. Thirty-five percent of the corpus (n=29) appeared in the last five years (2021–2025), reflecting sustained growth in publication volume across the review period.

C. Study and Population Characteristics

Study designs were heterogeneous (Table I). Designs without a separate control group predominated: single-case studies (n=19, 23%), feasibility or pilot studies without control (n=16, 20%), and case series (n=12, 15%). Among designs with a comparator, non-randomized controlled trials accounted for 18 studies (22%), some using within-subject or historical comparison, and randomized trials for 15 (18%, including 2 randomized pilots); two studies had other designs (a technical parameter report and a case study). In total, 23 studies (28%) included a separate (between-subjects) control group, the denominator adopted for the superiority analyses below.

Stroke was the predominant clinical condition (n=59, 72%); SCI accounted for 28% (n=23). Among the 72 studies that reported the clinical phase, participants in the chronic phase were the most common (n=47, 65%), followed by the subacute phase (n=17, 24%), mixed-phase populations (n=7, 10%), and the acute phase (n=1, 1%).

Upper-limb rehabilitation was the primary focus in 78% of studies (n=64); lower-limb targets were addressed in 16% (n=13) and both segments in 5% (n=4). Sample sizes, defined as the number of participants recruited, ranged from 1 to 64 (median: 7; mean: 10.3). Twenty studies (24%) involved a single participant. Table I summarizes the corpus characteristics.

TABLE I
CHARACTERISTICS OF THE 82 INCLUDED STUDIES

Characteristic	Category	n (%)
Design	Single case	19 (23%)
	Feasibility/pilot, no control	16 (20%)
	Case series	12 (15%)
	Non-randomized controlled	18 (22%)
	Randomized trial	15 (18%)
	Other	2 (2%)
Clinical condition	Stroke	59 (72%)
	Spinal cord injury	23 (28%)
Clinical phase[a]	Chronic	47 (65%)
	Subacute	17 (24%)
	Mixed	7 (10%)
	Acute	1 (1%)
Target limb	Upper	64 (78%)
	Lower	13 (16%)
	Both	4 (5%)
	Not reported	1 (1%)
BCI type	Non-invasive EEG	77 (94%)
	Invasive (intracortical)	5 (6%)
BCI paradigm	Motor imagery	39 (48%)
	Execution/attempt	33 (40%)
	ERD/MRCP, attention, P300	8 (10%)
	Other	1 (1%)
	Not reported	1 (1%)
FES type	Transcutaneous	76 (93%)
	Peripheral nerve	1 (1%)
	Percutaneous	1 (1%)
	Not reported	4 (5%)
Outcome	Positive	44 (54%)
	Mixed	12 (15%)
	No clinical outcome	26 (32%)

[a]Phase percentages computed over the 72 studies reporting phase.

D. BCI Characteristics

Non-invasive EEG was the dominant BCI modality, used in 77 of the 82 studies (94%). Fully implanted intracortical arrays appeared in 5 studies (6%), aimed mainly at restoring grasp and reach in SCI [14]. Motor imagery (MI), in which participants imagined limb movement without physical execution, was the most common paradigm (n=39, 48%), followed by movement execution or attempt (ME), in which participants actively tried to perform the movement (n=33, 40%). MRCP/ERD-based paradigms without explicit MI/ME classification were used in 3 studies (4%), generally aimed at inducing associative neuroplasticity [18]; attention/concentration indices and P300 appeared in the remainder.

Recording channels were reported in 90% of studies (n=74), with a median of 16; the highest values correspond to the invasive intracortical studies. Electrode placement predominantly targeted the sensorimotor cortex: C3, C4, and Cz (the canonical hand and arm motor cortex positions in the 10-20 system) appeared in the large majority of configurations, often supplemented by frontocentral and centroparietal electrodes; frontal-pole electrodes (Fp1/Fp2) appeared in only 8 studies (10%). EEG frequency bands were reported in 90% of studies (n=74); the mu rhythm (8–13 Hz) and the beta band (13–30 Hz) were the primary features, with most studies applying broadband 8–30 Hz filtering that captures both. Classification algorithms were reported in 94% of studies (n=77), with LDA, threshold-based ERD detection, and SVM among the most frequent.

E. FES Characteristics

Transcutaneous FES was used in 76 studies (93%), intramuscular percutaneous FES in 1 (1%), peripheral nerve stimulation in 1 (1%), and 4 studies (5%) did not report the stimulation type. Among the 48 studies that reported the stimulation frequency, the median was 35 Hz; the parameter was not reported in 41% of studies (n=34). Pulse width had a median of 250 μs among the 50 studies that reported it, and was absent in 39% of studies (n=32). The most frequent target muscles were the wrist and finger extensors, followed by the flexors; in lower-limb studies, the ankle dorsiflexors, as in post-stroke foot-drop correction systems [17]. Devices were varied commercial stimulators (e.g., Hasomed RehaStim, Compex Motion, g.tec), unnamed in 16 studies. Table II summarizes the FES parameters.

TABLE II
REPORTED FES STIMULATION PARAMETERS

Parameter	Reported, n (%)	Median	Most frequent
Stimulation frequency	48 (59%)	35 Hz	n/a
Pulse width	50 (61%)	250 μs	n/a
Stimulation type	78 (95%)	n/a	Transcutaneous (n=76)
Device	66 (80%)	n/a	Varied

F. Intervention Protocols

The number of sessions was reported in 84% of studies (n=69), with a median of 12. Session duration had a median of 60 min, reported in 71% (n=58).

G. Outcomes and Results

The Fugl-Meyer Assessment for the Upper Extremity (FMA-UE) was the most used primary motor outcome (n=21 studies); the Action Research Arm Test (ARAT) appeared as a secondary measure in several additional studies.

Clinical outcome measurement varied with the developmental stage of the studies. Thirty-two percent (n=26) assessed only BCI system performance metrics, such as classification accuracy and signal quality; many are engineering or feasibility studies, in which technical performance is the outcome pertinent to that stage. Among the 56 studies that assessed clinical outcomes, 44 (54% of the full corpus) reported statistically significant improvements in at least one primary motor measure; 12 (15%) reported mixed or inconclusive results; and no study reported exclusively null or negative motor findings (the boundary between positive and mixed depends on the criterion of significant improvement in at least one primary motor measure, and the absence of negative studies is consistent with a publication filter).

Formal efficacy evaluation was infrequent. Of the 82 studies, 23 (28%) had a separate control group, but only 15 statistically compared the groups on a clinical outcome; the remaining 8 reported within-group results only. In those 15 studies, BCI-FES exceeded the control in 9 and did not differ significantly in the remaining 6. As two of the nine favorable reports describe the same trial (Krueger et al., 2022 and 2024), superiority corresponds to 8 of 14 independent cohorts.

This figure is a vote count of statistical significance across small and heterogeneous studies (median n=7) and should be read as a descriptive signal. Most reported significance only, without quantifying effect magnitude, which therefore could not be pooled; the absence of significance may reflect low statistical power, and publication bias favoring positive outcomes cannot be excluded.

IV. Discussion

A. Technical Profile and Methodological Fragmentation

The included studies describe a technically convergent field: non-invasive EEG capturing sensorimotor signals (predominantly at C3, C4, and Cz) to drive transcutaneous FES of the upper limb in stroke survivors. The predominance of the upper limb (78%) follows the clinical profile of the dominant population, since stroke survivors (72%) most commonly present hand and arm deficits. SCI accounted for 28% of studies, some using intracortical recording to restore grasp and reach, as in the demonstration by Ajiboye et al. [14]. The corpus thus ranges from non-invasive feasibility systems to invasive functional-restoration interfaces, and from designs in which the neural signal continuously modulates stimulation to those in which a classifier's discrete output triggers a preconfigured FES pattern, a heterogeneity worth weighing when interpreting aggregate counts under the single label "BCI-FES".

On this technical convergence rests a methodological fragmentation. Motor imagery (MI, 48%) and movement execution or attempt (ME, 40%) appear in similar proportions and rarely with explicit differentiation, although they engage distinct neural circuits [95] (MI activates cortico-cortical motor-simulation networks; ME recruits residual corticospinal pathways) and generate different EEG signatures in topography, latency, and frequency content. In plegic patients, the boundary between imagery and attempted movement is clinically thin, since the attempt may not produce observable movement. Treating neurophysiologically distinct paradigms as equivalent, together with the variability in FES parameter reporting discussed below, makes it difficult to pool results and compare protocols that, on the surface, appear similar.

B. Efficacy: A Narrow Evidence Base

Only 23 of the 82 studies (28%) included a separate control group and, of these, 15 conducted a between-group statistical comparison on a clinical outcome, with superiority reported in favor of BCI-FES in 9 (60% of those tested; 39% of controlled studies), or 8 of 14 independent cohorts (57%) after merging the two reports of the same Krueger trial. This result accompanies the positive randomized trials in the corpus: Biasiucci et al. [7] documented lasting arm motor recovery after stroke, Krueger et al. [15] attributed the gain to Hebbian plasticity induced by the temporal coincidence of intention and stimulation, and Chen et al. [16] reproduced the effect in chronic stroke; no SCI study in the corpus reported a formal between-group comparison favoring BCI-FES, leaving the favorable evidence concentrated in stroke. The meta-analyses of Ren et al. [9] and Liang et al. [10] estimate a moderate effect magnitude in upper-limb rehabilitation after stroke, compatible with the proportion observed here.

The broad reading, however, qualifies this signal. The meta-analyses synthesize only the controlled stroke subset, whereas the full mapping shows that such trials are a small fraction of the published work: most controlled studies had a small sample (median n=7), the 15 randomized trials (18%) follow the same size pattern, and 72% of studies included no comparator at all. The efficacy evidence remains preliminary: the 60% proportion results from vote counting of significance in small studies, which limits its interpretation as a measure of efficacy. Effect magnitude was rarely quantified: most controlled studies reported statistical significance only, and few reported a standardized effect size (for example, Biasiucci et al. [7], Cohen's d = 1.03; Krueger et al. [15], η^2 = 0.57; Ramirez-Nava et al. [86], Cohen's d = 0.99 on the Fugl-Meyer), which prevents a pooled magnitude estimate. Publication bias favoring positive outcomes also cannot be excluded.

C. FES Parameter Reporting: A Documented Variability

A contrast stands out in FES reporting. While nearly all studies described the mechanism by which the BCI triggers stimulation, the frequency was absent in 41% of articles and

the pulse width in 39%, proportions that remain relevant even among the controlled designs. The studies thus document how they integrate BCI and FES, but not always with which stimulation parameters. The omission has a practical consequence: a recent meta-analysis associated, in exploratory subgroup analyses, specific ranges with larger motor effects (frequency $>$50 Hz, pulse width 150 μs), although the between-subgroup comparison did not reach statistical significance [10], so that positive results obtained without recording these settings become difficult to reproduce or compare.

D. Scope of the Evidence: Motor BCIs and Cognitive Outcomes

Within the studies included in this review, FES control relied on sensorimotor-cortex signals; frontal-pole electrodes (Fp1/Fp2) rarely served as the primary source (8 studies, 10%), and cognitive outcomes appeared only as secondary endpoints (13 studies, 16%), never as a primary target. Some prefrontal attention-based systems (Fp1) drive rehabilitation through a powered pedaling robot rather than FES [12], [13]; they fall outside this review but point to a prefrontal attention-based approach (Fp1/Fp2) not yet combined with FES in the mapped corpus.

E. Limitations

The acknowledged limitations include: single-reviewer screening, partly mitigated by mandatory verbatim quotation for six critical fields and, post hoc, by an independent second-author re-extraction of those fields across the full corpus (Section II-D); the absence of a formal methodological quality assessment, consistent with scoping-review methodology [11]; a search restricted to three bibliographic databases, without grey literature or trial registries; probable publication bias favoring positive outcomes; cohort overlap among some publications from the same group, which inflates participant totals relative to the number of independent samples; and, in at least two randomized trials [7], [81], allocation by covariate minimization rather than simple randomization, a boundary case retained as "randomized trial" under the pre-specified rule but worth noting when interpreting the randomized-trial count.

F. Implications and Future Directions

Three directions emerge from this mapping. First, the variability in FES parameter reporting (Section IV-C) supports the adoption of a minimum reporting set for BCI-FES studies, a checklist containing stimulation frequency, pulse width, intensity, target muscles, and session regimen; without these items, protocols cannot be compared or replicated, and the ranges associated with larger effects by Liang et al. [10] become actionable only if these parameters are systematically recorded. Second, although technical feasibility is suggested mainly in chronic upper-limb stroke, with sparser demonstrations in other populations, the consolidation of therapeutic evidence depends on larger randomized trials, particularly in SCI, the lower limb, and the acute phase, underrepresented in the corpus and relevant for populations with gait deficits. Third, the prefrontal attention-based BCI approach (Fp1/Fp2), already explored with robotic effectors [12], [13], has not yet been combined with FES within the corpus mapped here; given the role of attention in engagement and in the effective training dose during rehabilitation, this integration represents a promising and as-yet-unexplored direction.

V. Conclusion

Eighty-two primary studies published between 2010 and 2025 characterize a field with a consistent technical profile: non-invasive EEG, motor-intention paradigms, and surface FES targeting predominantly the upper limb in stroke survivors. Among the studies that formally compared BCI-FES to a control, superiority was reported in about half of the between-group comparisons (9 of 15; 8 of 14 independent cohorts), a proportion qualified by small sample sizes (median n=7); randomized trials total 15 studies (18%). Substantial variability in FES parameter reporting is documented across study designs, and 32% of studies assessed system performance without measuring any clinical motor outcome. The corpus mapped here suggests technical feasibility concentrated in chronic upper-limb stroke, with sparser demonstrations in other populations and configurations and mostly in small studies, while protocol standardization and the replication of larger controlled evidence remain infrequent.

Abstract*— Alzheimer's disease (AD), the leading cause of dementia worldwide, has its underlying mechanisms incompletely understood. Although *in vitro* neuronal models have been widely employed to investigate AD pathophysiology, they fail to reproduce the complexity of neuron-glia interactions that play a critical role in disease progression. In this study, we compared two *in vitro* models of AD to investigate the contribution of astrocytes to the cellular response to AD-related oxidative stress, (i) a neuron-like monoculture composed of differentiated human neuroblastoma cells (SH-SY5Y) and (ii) a neuro-astrocytic co-culture consisting of differentiated SH-SY5Y and human glioblastoma cells (U87-MG), respectively. Oxidative stress was induced by hydrogen peroxide (H_2O_2) exposure to mimic a key pathological feature of AD. Cellular responses were evaluated by cell viability assays, bright-field morphology, and Congo Red staining to qualitatively assess amyloidogenic aggregate deposition. H_2O_2 exposure significantly compromised cell viability and induced morphological alterations in both models. However, the neuro-astrocytic co-culture exhibited greater preservation of cellular viability, cellular organization, and intercellular connectivity, as well as a qualitative tendency toward reduced Congo Red-positive aggregate deposition compared with the neuronal monoculture. These findings suggest that the presence of astrocyte-like cells mitigates oxidative stress-induced cellular damage, reinforcing the importance of neuron-glia interactions in AD pathophysiology. Furthermore, the proposed co-culture model provides a more physiologically relevant *in vitro* platform for investigating disease mechanisms and may facilitate the development of more representative experimental models for evaluating potential therapeutic approaches for AD.

Keywords*— *Alzheimer's disease, oxidative stress, SH-SY5Y, U87-MG, co-culture.

I. INTRODUCTION

Alzheimer's disease (AD) is a progressive neurodegenerative disorder and the leading cause of dementia worldwide [1]. As with other age-related neurodegenerative diseases, the increasing life expectancy of the global population is expected to contribute to a rise in its incidence over the coming years [2].

AD is characterized by a series of neuropathological alterations that progressively impair brain structure and function. Among the most well-established pathological features are oxidative stress, resulting from an imbalance between reactive oxygen species (ROS) production and the cellular antioxidant defense system, and the deposition of senile plaques composed of amyloid-beta (Aβ) aggregates [3]. These events are closely interconnected, as Aβ accumulation triggers inflammatory responses and enhances ROS generation, while increased oxidative stress further promotes Aβ aggregation. This self-perpetuating relationship contributes to mitochondrial dysfunction, impaired energy metabolism, and neuronal degeneration, establishing a sustained pathological cycle [4], [5], [6].

In this context, experimental models capable of reproducing the main pathophysiological features of AD are essential for investigating disease mechanisms and evaluating potential therapeutic strategies. Among the available *in vitro* models, differentiated human neuroblastoma SH-SY5Y cells represent a widely used neuronal model. Upon differentiation into a neuron-like phenotype through retinoic acid exposure [7], these cells reproduce key aspects of AD when subjected to oxidative stress-inducing agents, such as hydrogen peroxide (H_2O_2), while also offering the advantages of easy culture and manipulation [8], [9], [10].

However, despite their widespread use, neuron-like monocultures do not fully reproduce the complexity of brain tissue. Astrocytes, traditionally regarded as passive support cells, play an active role in AD neurobiology by modulating neuronal energy metabolism, maintaining ionic homeostasis, participating in neurotransmission, and contributing to the neuroinflammatory response. They also play a central role in the clearance of Aβ deposits [11], [12]. Nevertheless, under chronic stress conditions and during AD progression, astrocytes acquire a reactive phenotype that is closely associated with chronic inflammation and cognitive decline. Reactive astrocytes, particularly those surrounding Aβ

This work was supported by the Brazilian National Council for Scientific and Technological Development (CNPq) (Grants 152384/2024-3, 110869/2025-7, and 404952/2025-5), and the Coordination for the Improvement of Higher Education Personnel (CAPES) (Grant 88887.271538/2026-00).

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

plaques, may contribute to the pathological accumulation of Aβ by promoting its production and deposition [13], [14].

Comparing neuronal monocultures with neuro-astrocytic co-cultures may therefore provide important insights into the contribution of astrocytes to oxidative stress-induced cellular damage and amyloidogenic processes involved in AD. In this regard, the development of a neuro-astrocytic co-culture composed of differentiated SH-SY5Y cells as a neuronal model and U87-MG cells as a human astrocyte-like model provides a more physiologically relevant *in vitro* microenvironment, allowing the investigation of neuron-glia interactions involved in AD pathogenesis [15].

Therefore, the present study aimed to characterize two *in vitro* models of AD: (i) a neuron-like monoculture composed of differentiated SH-SY5Y cells and (ii) a neuro-astrocytic co-culture consisting of SH-SY5Y and U87-MG cells, both exposed to H_2O_2 to induce oxidative stress characteristic of AD. The physiological responses of these models to oxidative stress were evaluated through cell viability, morphological analysis, and assays indicative of Aβ deposition, providing a methodological basis for the development of more complex and physiologically relevant models of AD.

II. METHODOLOGY

A. Cell Culture

SH-SY5Y cells were cultured in Dulbecco's Modified Eagle Medium/Nutrient Mixture F-12 (DMEM/F12), whereas U87-MG cells were maintained in Dulbecco's Modified Eagle Medium (DMEM). Both culture media were supplemented with 10% fetal bovine serum (FBS) and 1% penicillin/streptomycin. Cells were maintained in 25 cm^2 culture flasks at 37 °C in a humidified atmosphere containing 5% CO_2, and the culture medium was replaced every 2–3 days to ensure adequate cell growth and nutrient supply.

B. Cell Seeding and Differentiation

Upon reaching confluence, cells were trypsinized and seeded into 24-well plates for the following models.

For the monoculture, SH-SY5Y cells were seeded in DMEM/F12 supplemented with 10% FBS and 1% penicillin/streptomycin at a final density of 1×10^5 cells per well.

For the co-culture, SH-SY5Y and U87-MG cells were seeded in DMEM supplemented with 10% FBS and 1% penicillin/streptomycin at a 1:1 ratio, corresponding to 5×10^4 cells of each cell line per well, resulting in a total density of 1×10^5 cells per well.

Cells were incubated for 24 h at 37 °C in a humidified atmosphere containing 5% CO_2. After this period, the culture medium was replaced with differentiation medium.

For the monoculture, neuronal differentiation was induced using DMEM/F12 supplemented with 0.5% FBS and 0.01% retinoic acid (RA).

For the co-culture, differentiation toward a neuro-astrocytic phenotype was performed using DMEM supplemented with 0.5% FBS and 0.1% RA.

Cells were maintained in differentiation medium for 3–5 days until complete differentiation.

The monoculture and co-culture models were established using different culture media and RA concentrations according to the differentiation conditions adopted for each experimental model.

C. Oxidative stress induction and experimental design

Following differentiation, cultures were exposed or not to 200 µM H_2O_2 diluted in their respective differentiation media for 1 h to induce oxidative stress. Control groups consisted of differentiated cells maintained in the corresponding differentiation medium without H_2O_2 exposure.

The experimental groups were as follows:

- Neuron-like
- Neuron-like + H_2O_2
- Neuron-like + Astrocyte-like
- Neuron-like + Astrocyte-like + H_2O_2

The assays were performed in two independent experiments, with each experimental condition evaluated in triplicate.

D. Cell viability assay

Cell viability was assessed using the Alamar Blue assay. Following oxidative stress induction, the differentiation medium was replaced with a solution containing 10% resazurin prepared in the corresponding differentiation medium. Cells were incubated for 2 h at 37 °C in a humidified atmosphere containing 5% CO_2, protected from light.

After incubation, the solution from each well was transferred to a new microplate, and fluorescence was measured using a microplate reader (bottom reading mode; excitation: 544 nm; emission: 590 nm). A solution containing 10% resazurin without cells was incubated under identical conditions and used as the negative control. Results were expressed as the percentage of the respective untreated control.

E. Morphological analysis

To evaluate cellular differentiation and the morphological alterations induced by oxidative stress, cells were fixed with 4% paraformaldehyde (PFA) in phosphate-buffered saline (PBS) for 10 min at room temperature. Photomicrographs were then acquired using a bright-field and phase-contrast inverted optical microscope to qualitatively assess neurite distribution and cellular morphology.

F. Amyloid-beta detection

To evaluate Aβ accumulation, previously fixed cells were incubated with 0.5% Congo Red solution prepared in PBS for 15 min. Subsequently, cells were washed three times with PBS to remove excess dye.

Bright-field images were acquired using an inverted phase-contrast microscope, allowing the visualization of Congo Red-positive regions indicative of Aβ deposits. Aβ accumulation was qualitatively assessed based on the stained areas.

G. Statistical analysis

Data are expressed as mean ± standard deviation (SD). Statistical analyses were performed using GraphPad Prism 5.0. Differences between the control and H_2O_2-treated groups within each experimental model were assessed using an unpaired Student's t-test. A p-value < 0.05 was considered statistically significant. Graphs were generated using OriginPro 9.

III. Results and Discussion

A. Effects of oxidative stress on cell viability

Cell viability, assessed using the Alamar Blue assay (Fig. 1), was significantly reduced following exposure to 200 µM H_2O_2 in both experimental models compared with their respective untreated controls. This result supports the use of H_2O_2 as an oxidative stressor capable of impairing cellular metabolic activity and inducing cytotoxicity [8], [9].

An important methodological consideration is that the neuronal monoculture and neuro-astrocytic co-culture were established using different culture media and RA concentrations. Therefore, the potential contribution of these experimental conditions to the differences observed between the models cannot be completely excluded. In the neuronal monoculture, viability decreased to approximately 56% of the control value ($p = 0.0018$), whereas the neuron–astrocyte co-culture retained approximately 74% viability after H_2O_2 exposure ($p = 0.0161$). Although oxidative stress affected both models, the smaller numerical reduction observed in the co-culture suggests protection to H_2O_2-induced cytotoxicity in the presence of astrocyte-like cells. This observation is consistent with studies indicating that neuronal monocultures are highly susceptible to oxidative and neurotoxic stressors when deprived of glial support [15].

The greater viability retained by the neuron–astrocyte co-culture may be associated with the physiological functions of astrocytes in redox homeostasis, antioxidant defense, metabolic support, and maintenance of neuronal survival under moderate stress conditions [16], [17]. However, because the Alamar Blue assay reflects the overall metabolic activity of the co-culture, the contribution of each cell type cannot be determined separately. Therefore, the results indicate increased resilience of co-culture. However, under sustained or severe oxidative stress, astrocytes may also undergo redox and metabolic dysfunction, which can compromise their homeostatic and neuroprotective functions and contribute to pathological processes associated with AD [13].

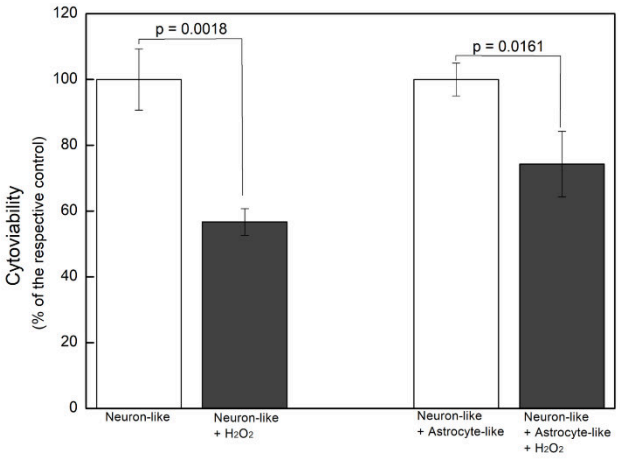

Fig. 1. Cell viability of differentiated SH-SY5Y neuron-like monocultures and SH-SY5Y/U87-MG neuron–astrocyte co-cultures following exposure to 200 µM H_2O_2, assessed by the Alamar Blue assay. Data are presented as mean ± SD and expressed as the percentage of the respective control group.

B. Morphological alterations induced by oxidative stress

Architectural integrity and the maintenance of intercellular connectivity are fundamental determinants of central nervous system function. Bright-field microscopy qualitatively (Fig. 2) revealed morphological differences between the experimental models following H_2O_2 exposure. In neuron-like monocultures, control cells exhibited elongated neuritic processes connecting adjacent cell clusters, indicating preserved neuronal morphology. Conversely, H_2O_2 exposure promoted extensive morphological disruption, characterized by neurite retraction, loss of intercellular connectivity, increased cell rounding, and the formation of compact cellular aggregates.

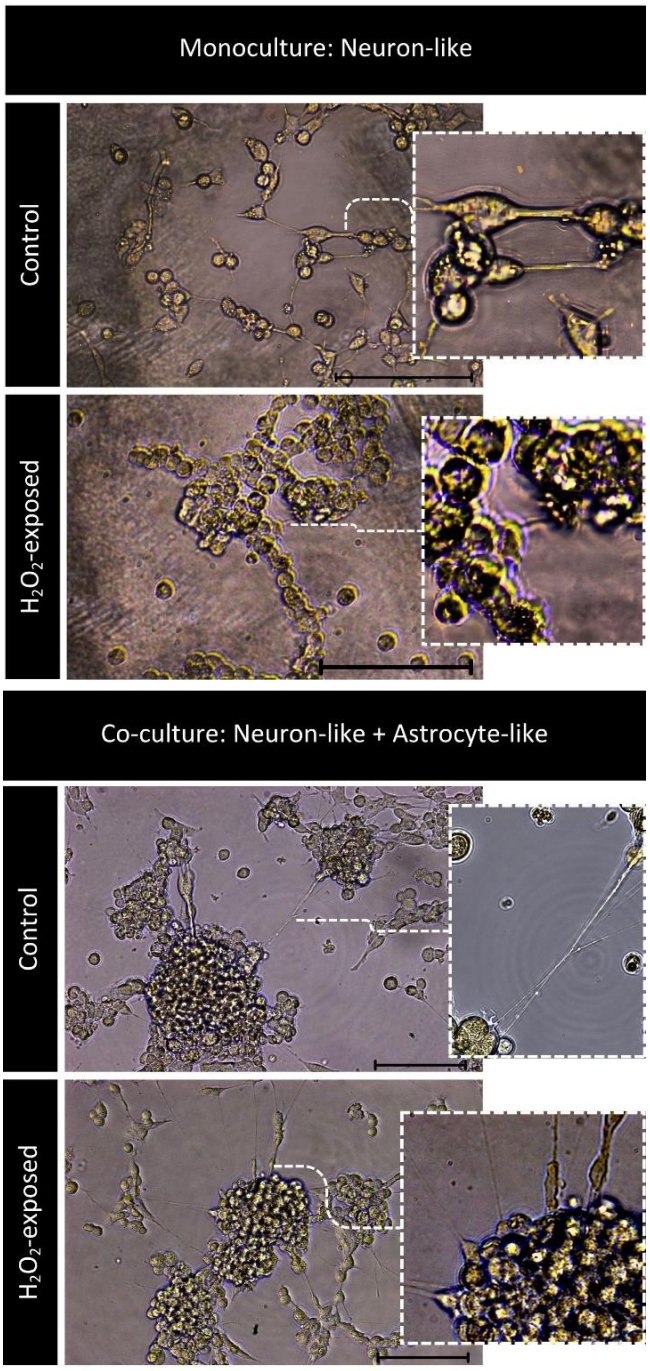

Fig. 2. Representative bright-field images of SH-SY5Y neuron-like monocultures and SH-SY5Y/U87-MG neuron–astrocyte co-cultures under control conditions and after exposure to 200 µM H_2O_2. Magnified panels highlight representative morphological features of each experimental model, including neurites in the monoculture and cellular extensions in the co-culture. Scale bars = 50 µm.

This pattern of degeneration reflects the intrinsic vulnerability of isolated neuronal populations to oxidative

stress. Under excessive reactive oxygen species (ROS) production, neurons undergo pronounced cytoskeletal depolymerization, leading to neurite collapse and disruption of neuronal networks [15]. Furthermore, acute oxidative stress severely impairs mitochondrial bioenergetic homeostasis and compromises cytoskeletal integrity in neuronal monoculture models [8], [9].

In contrast, neuron-like/astrocyte-like co-cultures displayed a more organized cellular architecture under basal conditions, with extensive cellular networks connecting large cell aggregates. Following oxidative stress, although slight morphological alterations were observed, the overall structural organization and intercellular connectivity remained largely preserved. Compared with monocultures, co-cultures exhibited reduced morphological damage after H_2O_2 exposure, suggesting that astrocyte-like cells confer structural protection against oxidative stress.

The preservation of neuritic processes and intercellular connectivity observed in the co-culture following oxidative stress is consistent with the well-established role of astrocytes in maintaining cytoskeletal homeostasis and neuronal structural integrity under cytotoxic conditions [17], [18]. Astrocytes provide extracellular matrix components and secrete neurotrophic factors that support neurite extension, synaptic organization, and the establishment of mature neuronal networks. Furthermore, astrocytes actively remodel the extracellular matrix and mitigate microenvironmental cytotoxicity, thereby contributing to the preservation of intercellular connections and limiting structural damage induced by oxidative stress [16], [19].

Overall, the comparison between the two experimental models indicates that the morphological disruption and loss of intercellular connectivity induced by H_2O_2 are attenuated in the presence of astrocyte-like cells. These findings are consistent with the established role of astrocytes in preserving cytoskeletal integrity, maintaining tissue organization, and promoting neuroprotection under oxidative stress.

C. Qualitative assessment of amyloidogenic aggregate deposition by Congo Red staining

Congo Red staining (Fig. 3) revealed qualitative differences in amyloidogenic aggregate deposition between the experimental groups. Under control conditions, both monocultures and co-cultures exhibited only sparse Congo Red-positive structures with weak staining intensity. Following H_2O_2 exposure, neuron-like monocultures showed a marked increase in Congo Red-positive aggregates, characterized by larger and more intensely stained deposits distributed throughout the cellular clusters. In contrast, although Congo Red-positive structures were also observed in H_2O_2-treated co-cultures, the staining appeared less extensive and more localized than in monocultures. These findings qualitatively suggest that astrocyte-like cells may attenuate oxidative stress-associated amyloidogenic aggregate accumulation while preserving overall cellular morphology.

The qualitatively reduced Congo Red-positive staining observed in the neuro-astrocytic co-culture is consistent with the well-established role of astrocytes in amyloid homeostasis [16]. Astrocytes produce and secrete proteolytic enzymes involved in extracellular Aβ degradation, whose expression is frequently upregulated in reactive astrocytes surrounding amyloid deposits as part of the attempt to restore the cerebral microenvironment [11], [16]. In addition, astrocytes possess an intrinsic capacity to internalize and degrade amyloid fragments through lysosomal pathways, thereby contributing to amyloid clearance [11], [20].

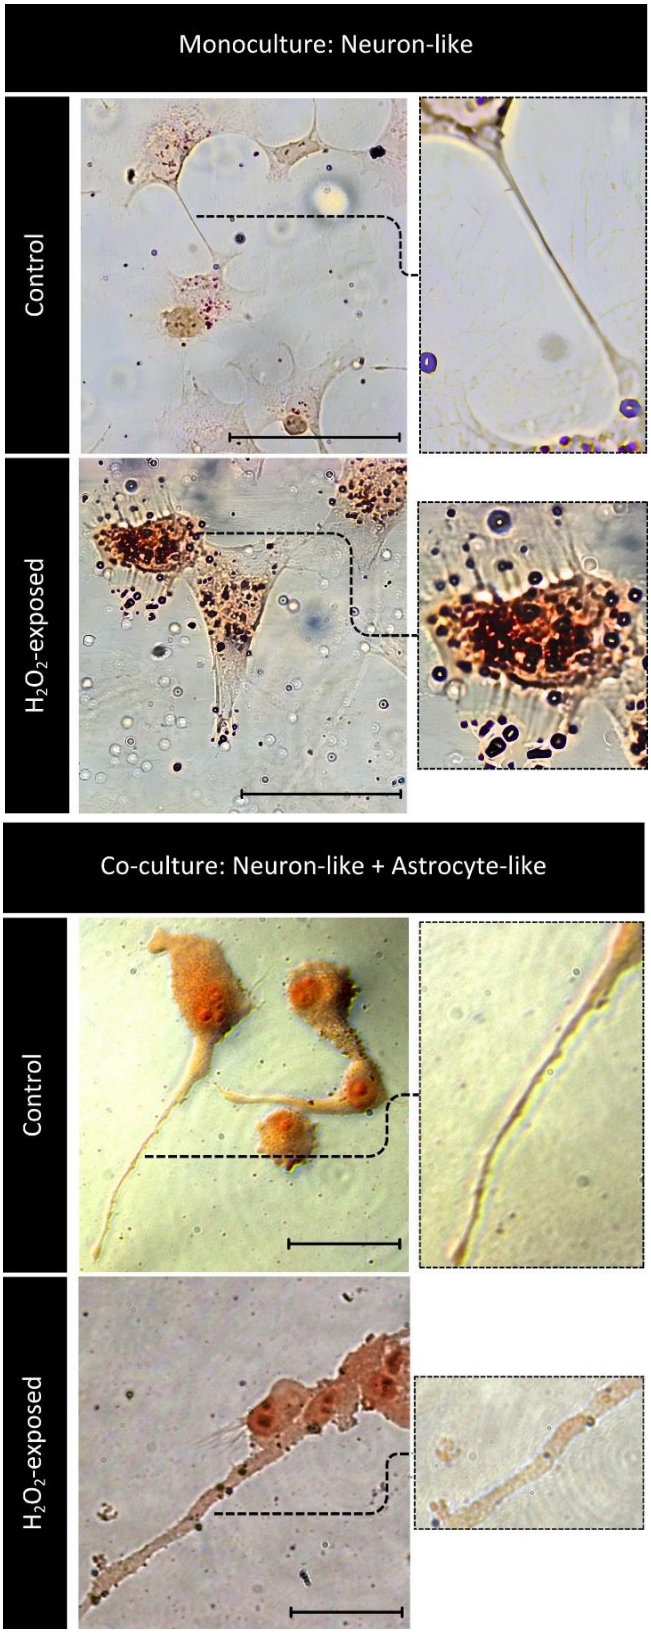

Fig. 3. Representative bright-field images of Congo Red-stained SH-SY5Y neuron-like monocultures and SH-SY5Y/U87-MG neuron–astrocyte co-cultures under control conditions and after exposure to 200 μM H_2O_2. Magnified panels highlight representative Congo Red-positive deposits observed in each experimental condition. Scale bars = 50 μm.

Beyond the direct removal or non-accumulation of extracellular aggregates, astrocytes also provide antioxidant precursors and neurotrophic factors that support neuronal homeostasis. By reducing oxidative stress within the cellular microenvironment, astrocytes may indirectly limit the oxidative processes that favor the formation and accumulation of new amyloidogenic aggregates [11], [13].

Congo Red staining was evaluated qualitatively in the present study, demonstrating aggregates morphology and arrangement within the groups. However, quantitative measurements of the aggregates, including number, location, average size and staining intensity are under analysis to provide an objective assessment of possible amyloidogenic aggregate deposition, as well as Aβ-specific antibody approaches to confirm the identity of the Congo Red-positive structures.

Collectively, this study demonstrates the first characterization steps of a novel neuro-astrocytic co-culture, compared with a conventional commonly used neuron-like monoculture, in order to produce a more physiologically relevant experimental platform. Importantly, as the co-culture system is being designed, both evaluated models differed in some cultivation conditions, to attend to both cellular requirements. Moreover, further assays are under development to validate and elucidate neurodegenerative pathways of the model and to specifically determine each cellular type response and activity within the co-culture model.

IV. Conclusions

The present study demonstrated distinct responses to oxidative stress in neuronal monoculture and neuro-astrocytic co-culture models of AD. Following H_2O_2 exposure, the co-culture showed a numerically smaller reduction in overall metabolic activity and greater preservation of cellular morphology and intercellular connectivity, together with a qualitative tendency toward reduced Congo Red-positive staining. Furthermore, by incorporating neuron–astrocyte interactions, the proposed neuro-astrocytic co-culture represents a more physiologically relevant experimental platform than conventional neuronal monocultures, representing an useful tool for investigating AD-related mechanisms and evaluating potential therapeutic strategies *in vitro*.

***Abstract*—Awake slow-waves are transient, sleep-like cortical dynamics associated with cognitive lapses. Proposing noninvasive neuromodulation strategies for experimental procedures intended to address these events requires accurate real-time prediction from electroencephalography (EEG). This study presents the development and evaluation of two deep-learning frameworks for awake slow-wave prediction. Using a public EEG dataset comprising resting-state and cognitive task recordings, a unidimensional CNN-based architecture and a comparable model augmented with a multihead attention mechanism were implemented. Results showed that both models performed well, with the CNN-attention model yielding an equivalent performance (test accuracy: 0.82, AUC: 0.90) compared to the CNN-only model (test accuracy: 0.81, AUC: 0.89), though with higher computational demand. Statistically significant but small differences between models were observed for effect sizes. Both architectures achieved higher sensitivity than specificity. Cross-condition generalization performances were better for training under resting-state than cognitive tasks. Finally, both models may be considered promising for awake slow-wave prediction, with training time constraints leveraging the cnn-only architecture.**

***Index Terms*—EEG, slow-waves, deep learning**

I. Introduction

Although electroencephalography-detected brain waves of low frequency and high amplitude are characteristic of sleep patterns, they are also observed during wakefulness for brief moments and are conceptualized as transient intrusions of non-REM-like cortical dynamics into the waking brain, reflecting local neuronal "OFF-states" within otherwise active networks. At the cellular level, slow waves arise from bistable membrane dynamics characterized by alternating depolarized (ON) and hyperpolarized (OFF) periods, a mechanism traditionally associated with sleep homeostasis but now observed locally during wakefulness [1].

During sleep, slow-wave activity is responsible for plasticity-related neuronal processes such as strengthening of connections between neuronal networks that, in practice, contribute to memory consolidation and acquisition of skills [2], [3]. Therefore, high rates of slow-wave episodes during sleep are associated with healthy quality of sleep in adults [3]

However, local slow-waves also occur during wakefulness in a use- and state-dependent manner, increasing with time awake and reflecting regional fatigue of cortical circuits, consistent with the framework of "local sleep" [4]. Functionally, their occurrence in wakefulness has been linked to fluctuations in vigilance, attentional lapses, and mind-wandering, suggesting that they transiently disrupt task-relevant processing [5].

Recent works are introducing investigations about where such ON/OFF effects are observed during wakefulness and how sleep-like brain activity patterns affect practical contexts in daily life. For instance, Pinggal et al. [6] found that slow-waves during vigilance are more frequent in neurodivergent subjects afflicted with ADHD when compared to typical individuals. The authors propose that this effect is correlated with common factors that pose impairments to the execution of daily activities due to cognitive drawbacks experienced by such individuals.

The work by Bernasconi et al. [7] also explores the occurrence of these events in Parkinson's disease, where it is proposed to relate to hallucinations and cognitive impairment. Together, these findings support the view that wake slow waves might indicate a mesoscale marker of cortical instability and local disengagement, bridging sleep homeostasis and moment-to-moment variability in cognitive performance.

Since, in wakefulness, slow-waves usually represent events associated with lapses in cognitive performance, it is hypothesized that mechanisms for their disruption during activities of intense information processing may provide potential interventions for the symptoms provoked in ADHD and Parkinson's. This proposition is supported by experiments that evaluate the opposite effect, where non-invasive neuromodulation strategies have successfully been employed to increase slow-wave activity during NREM sleep and subsequently improve processes of memory consolidation and learning [8], [9].

The development of an experimental setting aimed at evaluating the effects of awake slow-wave disruption via noninvasive neuromodulation is a future prospect of the current work. However, in order to carry out this endeavor, the development of a system for slow-wave forecasting in electroencephalography (EEG) is made necessary. This is due to the transient nature of awake slow-waves, which differ from sleep patterns and usually occur in a very brief and localized manner.

Currently, the employment of deep-learning models for EEG event prediction represents a widely explored field of investigation. Works such as Godoy's [10] aim at predicting

pathological episodes and compare the effectiveness of various techniques — such as convolutional neural networks (CNN), recurrent networks and attention-based Transformer models — in this example, designed to forecast epilepsy episodes in EEG.

In general, slow-wave-related works tend to use neural networks to assess sleep quality and predict pathological episodes, such as the following: Halder et al. [11], who Developed combined multi-resolution feature extraction and attention mechanisms to automatically detect A-phases of the cyclic alternating pattern from single-channel EEG; Ganglberger et al. [12] who trained a hybrid CNN-LSTM model on sleep EEG from large cohorts to predict cognitive function, neurodegenerative disease, and mortality risk, aiming to derive a brain health biomarker; and Lou et al. [13] who designed a multiscale attention deep learning model to both classify sleep quality and potentially guide sleep modulation strategies based on EEG signals.

In face of such demand for a reliable predictor of awake-specific slow-wave occurrences in EEG, the current work presents the development and evaluation of two deep-learning-based models for slow-wave detection. In this sense, two frameworks are analyzed under a public EEG dataset of cognitive load: a simple CNN architecture and a more complex CNN-Attention network.

II. Methodology

A. EEG data

The EEG dataset currently employed is provided by Zyma et al. [14]. It consists of 72 recordings from 36 participants in a resting-state setting and during the process of solving arithmetic tasks of serial subtractions of numbers. From the recordings that are made accessible, each rest condition lasts three minutes, while the cognitive task lasts one minute. Consequently, in addition to the previously described class imbalance, an asymmetry in EEG conditions is also present.

Participants were in good physical and psychological conditions. The volunteers also had matched ages and were all students of the Educational and Scientific Centre “Institute of Biology and Medicine”, National Taras Shevchenko University of Kyiv.

The provided data has a sampling frequency of 500 Hz and was originally preprocessed with band-pass filters and noise reduction using standard measures. Additionally, for the present proposal, the data was filtered again to a narrower band of frequencies (1-40 Hz), aiming to better account for the slow oscillations of interest. The data was also re-referenced to channels TP9 and TP10.

EEG recordings were subdivided into 1-second windows with an overlap of 0.5 seconds and a prediction horizon of 0.5 seconds. These values are in accordance with standard procedures of automated EEG prediction for neuromodulation, which usually apply 0.5- to 1-second windows to forecast the following 0.5 sec. [15], [16].

B. Slow-wave identification

Procedures for event detection were employed in accordance with the standard literature [6], [7]. First, a Chebyshev Type II band-pass filter limited signals to 1–10 Hz. Then, the occurrence of waves in the data was defined as two consecutive zero-crossings, and peak-to-peak (PTP) amplitude was calculated. A wave was then classified as ”slow” if it: (a) presented frequency under 7 Hz and (b) PTP amplitude above the 80th percentile for a given electrode, thus defining a personal amplitude threshold for each individual.

Slow-wave events were then rejected if they occurred within 1 second of any high-amplitude event ($>$150 μV) or if the positive peak exceeded 75 μV.

It is anticipated that cortical neurons do not engage in slow-wave-related bistability states as frequently as other brain activity dynamics during wakefulness. Thus, an imbalance of identification of events and their lack in a given set of windows is expected. When the total number of slow-wave events is quantified for each context, the assumption is fulfilled. Indeed, a class imbalance is identified for both the cognitive load setting (average of 44 events in a mean of 115 windows) and resting-state (average of 90 events in 349 windows).

C. Neural Networks

In the present proposal, two deep learning models were implemented and assessed: a simpler CNN architecture and an equivalent model with the addition of an attention mechanism. This double-framework evaluation provides comparable scenarios where it is possible to factor both model performance for the current task and relative demand for computational resources.

Both neural network models were implemented in Python/Tensorflow and are composed of a depthwise 1D convolution layer, a separable 1D convolution, and two standard 1D convolution layers. All of which followed by batch normalization and dropout. Finally, two blocks composed of global average pooling followed by dense layers were added. The CNN-attention network also included a multihead attention layer and normalization before pooling.

To mitigate class imbalance and improve model generalization, an online augmentation strategy was also implemented. It generates balanced mini-batches during training while applying lightweight EEG-specific transformations on-the-fly. This approach ensures that each training batch contains an equal number of positive and negative samples, addressing the inherent class imbalance in slow-wave detection. The augmentation pipeline applies four complementary transformations to each sample with certain probability: (1) random amplitude scaling to simulate inter-subject variability in signal amplitude, (2) additive Gaussian noise to enhance robustness to measurement noise, (3) circular time-shift (up to 8% of window length) to simulate minor latency variations across recording sessions, and (4) channel dropout (10% probability of zeroing a random subset of channels) to prevent overfitting to specific electrode configurations. Additionally, temporal masking (4% of window duration) was applied stochastically

to simulate brief signal artifacts or missing data segments. The augmentation probability was set to 0.75, allowing 25% of training samples to pass through unaugmented, maintaining a balance between regularization and training signal fidelity.

For the current implementation, model training was restricted to frontal channels, which correspond to the local foci of slow-wave formation across the cortical surface [3] and therefore also represent the main target regions for noninvasive neuromodulation procedures. All models were trained until the validation AUC stabilized at the same value for at least 5 epochs.

D. Evaluation procedures

For model training and performance assessment, a subject-wise split was performed using the group K-fold method (k = 6), which is intended to mitigate learning biases associated with windows of the same subject appearing in both training and testing sets. Similarly, to reduce condition-related biases, a cross-condition validation was also performed, aiming to evaluate the different models performances under isolated brain-state settings. Analyzed metrics were accuracy, ROC-AUC, sensitivity, specificity and F1. Additionally, in order to account for the usage of computational resources, the training time of each architecture was also quantified on the group K-fold method.

To assess whether the inclusion of the attention layer effectively enhanced model performance, a standard McNemar statistical test was implemented, considering correct and incorrect predictions from the k-fold test sets (training and testing included both task and rest). Furthermore, effect sizes were estimated via paired bootstrap resampling (10,000 iterations) of test samples to quantify inter-model (cnn-att − cnn-only) differences in accuracy and AUC, with 95% confidence intervals computed from the empirical percentiles of the bootstrap distribution.

Finally, the code developmentss of the current project was aided by various AI agents.

III. Results

In general, the neural network models succeeded in predicting slow-wave events for both resting-state and cognitive task settings when both conditions were present during training. Model performances were comparable for both deep-learning architectures. General metrics are displayed in Table I

TABLE I
MEAN TEST METRICS ACROSS FOLDS FOR CNN-BASED MODELS

Model	Accuracy	AUC	Sensitivity	Specificity
CNN-Attention	0.758	0.889	0.952	0.704
CNN-only	0.782	0.882	0.852	0.707

As observed from Table I, the absence of the attention mechanism yielded slightly superior testing performance in absolute accuracy values, while a relative tradeoff in sensitivity was indicated. However, the McNemar test for model comparison did not reveal significance under $\alpha = 0.05$ ($\chi^2 = 3.161$ p = 0.075). Although the attention-aided model yielded fewer false-positives and the cnn-only architecture missed fewer slow-wave occurrences in general, the absolute differences in model performances did not result in relevant effect sizes. Effect size evaluations for group K-fold showed a marginal difference between model accuracies (mean difference: 0.019; 95% CI: [0.0130, 0.0256]; bootstrap p-value: 0.000), and AUC displayed some improvement but overall maintained a similar trend (mean difference: 0.010; 95% CI: [0.006, 0.013]; bootstrap p-value: 0.000). Although the observed effect may be considered statistically significant, the corresponding magnitude of metric differences may not be relevant for practical purposes.

Both models also performed better when trained under resting-state and evaluated under the cognitive task condition than the opposite. Specifically, model training only on the task condition was shown to be impractical, since it was not possible to generalize the slow-wave detection task to the resting-state setting. Meanwhile, model training on resting-state displayed a slight enhancement in performance metrics when compared to the mixed-condition setting (group K-fold), which might indicate a preferable methodology for practical purposes. Test metrics are specified in Table II.

TABLE II
CROSS-CONDITION TESTING METRICS OF CNN-BASED MODELS

Condition and model		Accuracy	AUC	Sensitivity	Specificity
Rest→task	CNN-Att	0.820	0.898	0.802	0.816
	CNN	0.811	0.894	0.717	0.883
Task→rest	CNN-Att	0.259	0.334	1.000	0.001
	CNN	0.260	0.847	0.999	0.002

It is also possible to visualize the confusion matrices of all model evaluations in Fig. 1

Finally, total training time differed considerably for both architectures. While the CNN-only architecture varied between 7 to 12 minutes across folds, the inclusion of the attention mechanism increased training time to a range of 19 to 43 minutes. Differences in training time are highlighted in Fig. 2

IV. Discussion and conclusion

The present proposal describes the development and evaluation of two deep-learning frameworks for awake slow-wave prediction in EEG data. The first model, a unidimensional CNN-based architecture, provided satisfying results with a rapid training process and modest demand for computational resources. The second network, similar to the first one but with the addition of an attention mechanism, yielded an equivalent performance with marginal gains in sensitivity and was accompanied by a noticeably higher demand for resources and training time.

The neural network models were set to forecast slow-wave occurrences in two EEG acquisition scenarios: resting-state and cognitive task, where model training and testing were

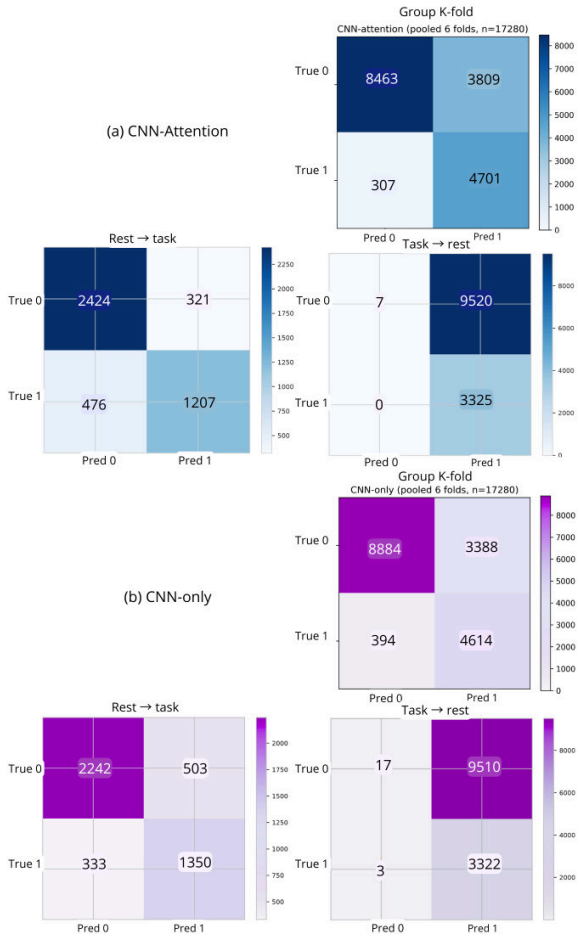

Fig. 1. Confusion matrices of both trained models and EEG contexts

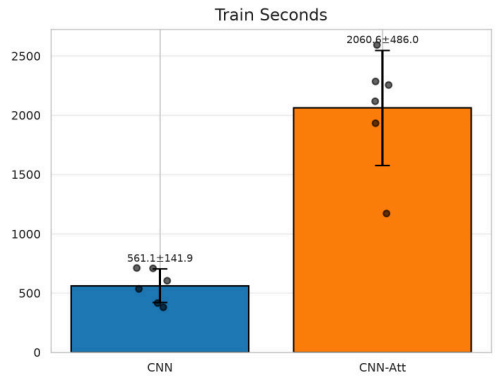

Fig. 2. Group K-fold training times

evaluated under cross-conditions. While the former scenario provides a baseline of brain activity patterns for model training, the latter represents the most relevant context for awake slow-wave prediction, since potential future applications are intended for the disruption of such events in order to attempt to reduce episodes of cognitive lapses.

In this regard, only the models that were trained on resting-state were able to generalize to the other condition. This methodology of model training further indicated superior suitability for slow-wave detection when compared to training under mixed conditions.

The observed deviation in model performances for training under the different contexts may be attributed to the overall profile of brain activity that characterizes each brain state (i.e., general low-frequency-high-amplitude signals for rest and the opposite for the cognitive task). Additionally, there is the influence of an asymmetry in sample size for the provided EEG settings since the cognitive task condition has $1/3$ the duration of resting-state. This issue was not addressed in the current project version in order to avoid hindering the training process by providing insufficient samples or biasing results by excessive data augmentation, but the employment of a larger dataset with more cognitive task samples may be considered a relevant future prospect for research.

Another potentially relevant aspect that may be considered for future enhancements in model performance is the window length provided for training. Currently, the window length has been set in accordance with the literature concerning general works of deep-learning models for EEG time-series prediction. However, an extension of each window may be considered in order to provide a more adequate foundation for model training in this particular context, since slow-wave detection might be hindered in single-second spans.

Since noninvasive neuromodulation therapies are generally safe and have no adverse effects, it is plausible to argue that, for this particular instance, the incidence of false-positives does not pose considerable harm risks if safety measures are carefully employed for experimental sessions. In this regard, it is possible to interpret the developed models' superior sensitivity metrics in comparison to specificity as an acceptable feature, although this consideration is not applicable to the task-to-rest training condition.

When comparing to performance reports of deep-learning models for EEG from the literature [10]–[13] (from 80 to around 90% accuracy, for example), the implemented models showed relatively inferior metrics for mixed conditions and comparable for rest-to-task training, which may be due to the limited sample size, especially under two conditions with considerable differences in brain activity patterns. Results could be subsequently improved in order to seek achievement of optimum reported values (accuracy around 98%) despite the differences in addressed scenarios.

In summary, this work demonstrates that both the standard CNN and the attention-augmented CNN are viable approaches for predicting awake slow-waves, with the choice between

them ultimately depending on the specific priorities of the application, namely, computational efficiency versus potential performance gains, although the present work did not display significant differences or noticeable effect sizes for the latter. The models' ability to generalize from resting-state to task-related EEG, despite the inherent challenges of class and context imbalance, underscores their potential for real-world use, in particular for the proposition and experimentation of non-invasive neuromodulation protocols. Future prospects aimed at enhancing the proposed predictors include further refining model architecture, implementing hyperparameter optimization, increasing the length of training windows, augmenting the sample size, and, mainly, evaluating performance on more datasets in order to better assess generalization capacity and mitigate the reported context asymmetry issue, especially by including more cognitive task-centered data.

***Abstract*—Background: Neurogenic bladder (NB) after spinal cord injury (SCI) contributes to urinary tract complications, including infections. Wistar rats are widely used as experimental models for translational studies of the NB. However, the accurate assessment of bladder urine volume remains challenging. Although methods such as the Credé maneuver and catheterization using intravenous catheters can be employed to estimate bladder urine volume, both approaches have important limitations. Therefore, noninvasive approaches integrating freehand ultrasonography and artificial intelligence-based image analysis, such as U-Net deep learning models, may provide a promising strategy for accurate and reproducible estimation of bladder urine volume in NB conditions.**

Objective: This study proposes a novel, accessible (non-invasive) alternative by adapting U-Net Deep Learning to analyze 2D free-hand ultrasound images of Wistar rat bladders, estimating bladder volume and generating 3D visualizations.

Results: The pre-trained U-Net achieved high segmentation accuracy across validation images within 250 training epochs, reaching a Dice Similarity Coefficient(Measures the spatial overlap between the manual segmentation and the U-Net prediction.) of 0.8615 (Dice Loss of 0.23). The 3D Voxel Interpolation (Convex Hull) model demonstrated superior volumetric accuracy compared to the pure prolate ellipsoid model, effectively preventing severe volume overestimation in distended neurogenic bladders, with absolute errors up to 3.63 mL vs. 7.33 mL, respectively.

Conclusion: This study demonstrated the feasibility of adapting a CT-trained U-Net convolutional neural network to segment 2D freehand ultrasound images and reconstruct 3D bladder surface models in Wistar rats with NB after SCI.

I. INTRODUCTION

Traumatic spinal cord injury (SCI) refers to spinal cord damage resulting from falls and traffic accidents. In general, SCI results in the complete or incomplete loss of sensory and/or motor function below the level of the injury, as well as various forms of autonomic dysfunction [1].

One of the consequences of SCI is neurogenic lower urinary tract dysfunction, also referred to as neurogenic bladder (NB) (Spinal Cord Injury 2016). NB remains a clinical challenge, especially in relation to the high risk of urine storage frequently observed in the presence of detrusor underactivity or overactivity combined with detrusor sphincter dyssenergia in humans and animal models of SCI [2] [3].

In SCI animal models, the Credé maneuver is necessary for bladder voiding [4], once animals develop a urine-retention bladder in the first two weeks post-injury [5]. This method can also be used to assess bladder urine volume while simultaneously performing bladder emptying required to maintain animal health. However, this method may be imprecise and may lead to variability among experimenters.

Although transurethral characterization can measure the real post-residue urine [6] in rodents, it presents a challenge to researchers because of their small size and fragility during invasive procedures [7]. Moreover, daily characterization may increase the risk of urinary tract infection, tissue injury, and pain or discomfort in animals. In this context, translational studies using rats are the most widely used models for investigating NB in SCI models [8] and new tools are needed to measure urine storage in rodents.

Ultrasonography (US) is a highly efficient, cost-effective, and non-invasive method for monitoring the urinary tract. It serves to assess bladder wall thickness, trabeculations, and the identification of sediment and vesical calculi [9]. In humans, US is useful for classifying bladder wall deformities associated with NB [10]. However, these morphological alterations do not reflect the degree of bladder filling or urinary retention. US as a measurement of vesical volume is a relatively new approach in the literature [12].

Bladder volume is conventionally estimated using geometric formulas, most notably the prolate ellipsoid model [11]. However, these formulas assume a regular geometry, which is anatomically inaccurate given the continuous morphological changes of the organ. Consequently, reconstruction methods capable of accounting for its irregular shape are necessary for reliable volume measurements [13].

In this context, the present study proposes the use of Deep Learning techniques for measuring vesical volume in the NB condition. For this purpose, a U-NET (Neural Network), originally pre-trained with human Computed Tomography (CT) scans, was adapted to work with 2D free-hand US images of Wistar rat bladders to estimate bladder volume and generate preliminary 3D visualizations.

This approach allows individuals with less professional experience (in emergencies or when a qualified professional is unavailable) or researchers with limited resources to achieve similar results, making US examination more accessible.

II. Methods

A. Ethical aspects

This preclinical study was approved by the Ethics Committee on Animal Use (CEUA) of the Santos Dumont Institute (ISD) under protocol number 2025-01-ISD.

B. Animals

Eight adult female Wistar rats (approximately 4 months old) were used. The rats were obtained from the institutional ISD animal facility. The animals were housed (3 per cage) in standard rodent cages under a 12-hour light/dark cycle, at a controlled temperature of 22 ± 2°C and 55% relative humidity, with food and water provided *ad libitum*.

C. Experimental design

After 24-hours, the animals that underwent the surgical procedure and presented normal locomotion (sham group) and those without or with minimal locomotor recovery (SCI group), according to the BBB scale [16], were included in the next steps of the study. Only for animals in the SCI group, the bladder was emptied twice a day using the credé maneuver until 21 postoperative day (POD). At 21 POD, an abdominal US examination was performed on the five sham and three SCI female rats. Following US, image data of the urinary bladders were pre-processed using ImageJ software. These images were then fed into a convolutional neural network (U-Net with CNN), originally designed to analyze bladder CT scans, to adapt it for interpreting bladder ultrasound images. Model training and evaluation were performed using a leave-one-animal-out cross-validation strategy on the base animal dataset. The overall workflow for ultrasound image processing and AI-based bladder volume estimation is illustrated in Fig1. 1.

D. Spinal Cord Injury Animal Model

Firstly, Sham and SCI animals were administered pre-anesthetic medication, including ketamine (70 mg/kg; IP) and atropine (3 mg/kg; IM). Subsequently, anesthesia was induced and maintained with inhaled isoflurane 1–5% in 2 L/min). For the SCI and Sham animals, the dorsal region was tricotomized once anesthetized. Each animal was placed in the prone position, and surgery started with a cranio-caudal incision along the dorsal region. After retracting and incising part of the thoraco-lumbar fascia, the vertebral column was exposed at the level of the eighth thoracic vertebra (Th8). The lamina of the Th8 was carefully sectioned to avoid injuring the spinal cord. In sham animals, the surgical procedure was concluded after completion of the laminectomy. In SCI animals, spinal cord compression was induced using an aneurysm clip with a calibrated closing force of 70 g applied for 30 seconds, following a method adapted from [14]. Twenty-four hours after surgery, treatment was started with the antibiotic enrofloxacin (5.0 mg/kg; SC BID), the opioid analgesic tramadol (5–10 mg/kg; SC BID), and the non-steroidal anti-inflammatory drug meloxicam (1.0 mg/kg; SC SID) for three consecutive days. In addition, the Credé maneuver began on the first POD.

E. Ultrasound image acquisition

Two days before the US examination, all animals were submitted to trichotomy in the abdominal region. To perform the US examination, all animals were anesthetized with 1-5 isoflurane % in 2 L/min). Images from the sham and

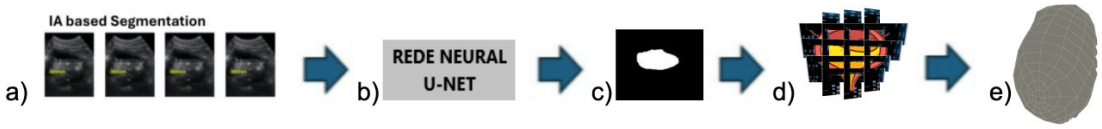

Fig. 1: Ultrasound image processing workflow using AI and expected results: a) selection of ultrasound images, b) input of images into the neural network, c) image binarization and bladder region selection, d) image overlay and organization, e) generation of a 3D bladder model for volumetric calculation and shape prediction

SCI animals were acquired at 21 POD. For recording, all animals were positioned in supine, and a linear probe (7.5 MHz) connected to a Z50 veterinary ultrasound unit (Mindray, Shenzhen, China) was applied to the abdominal region. A water-based transducer gel was used to eliminate air gaps between the probe and the skin surface, resulting in improved image resolution and allowing for accurate interpretation of anatomy, physiology, and diagnosis [15]. For each animal, seven ultrasonographic images of the urinary bladder were acquired3, including four in the transverse plane and three in the longitudinal plane. The first image in each plane was obtained at the region corresponding to the greatest bladder height and served as a reference for subsequent acquisitions. From this reference image, the remaining images were acquired at equidistant positions. In the longitudinal plane, two additional images were obtained, one parallel to the right and the other parallel to the left of the central reference image. In the transverse plane, one image was acquired cranial to the reference image, and two additional images were acquired caudal to it 2. To optimize bladder visualization, it was necessary to use sham animals with low urine volume at the time of the examination. One milliliter of saline solution was administered into the bladder via catheterization using 22 Gauge intravenous catheter (blue Jelco®. To assess post-ultrasound urinary retention. In SCI animals, transurethral catheterization was performed immediately following the US examination using a 22-Gauge intravenous catheter (Jelco®). The retained urine volume was evacuated and recorded to serve as a gold-standard reference for volumetric validation).

Fig. 2: Representation of image sections of the rat bladder.

F. Database Organization

Following US, image data (800x600 JPGs) of the urinary bladders of five Sham animals and three SCI-Animals were

Fig. 3: Seven ultrasound images of the bladder (800 × 600 pixels, RGB color format, .JPG) were used to reconstruct the three-dimensional (3D) bladder model

.

pre-processed using ImageJ software. Following the US examination, images of the bladder complete with calculated metrics—were obtained by taking screenshots of the ultrasound display using the built-in software tool. To organize the database, three folders were created on Google Drive: ”image base” (for the raw screen-shots) and ”mascara base” (for the images edited and binarized in ImageJ), with each image assigned to three-digit number based on its upload order

G. Image Editing

The US screenshots had a pixels and RGB color formatting, image editing and metric was performed using the *ImageJ* software (National Institutes of Health- NIH). Initially, a segmentation selection tool was used to measure the selected area (ROI)—defined by the bladder contour—in pixels for subsequent performance evaluation. Next, the ”flatten” command was applied to merge the segmentation and the original image into a single layer, which was then saved to a ”contour” folder used solely for comparison after neural network training. The mask was created using the ”fill” option to turn the selection interior white and the ”clean outside” function to delete the image content outside the selection. All images were saved in .jpg format 4.

H. Neural Network Training

The U-Net neural network based employed: Semantic segmentation with PyTorch library, can be used to be a previously trained image segmentation tool on urinary tract computed tomography images. To adapt it, the dataset was configured to use US image inputs and corresponding masks, aiming to produce an output contour as close as possible to the mask. To this end, 56 US base images were used; data

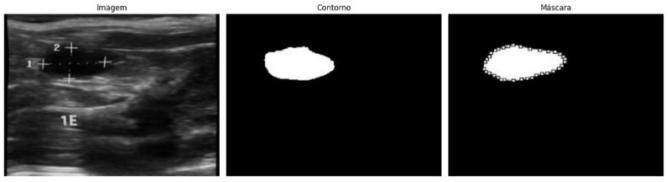

Fig. 4: (Left) Ultrasound image of the base of the rat bladder; (Center) Binarized image generated by the neural network; (Right) Image manually outlined and binarized in ImageJ for neural network feedback.

augmentation techniques were applied to expand the dataset, generating the elastic-deformed and rotated images mentioned earlier, resulting in a total of 280 images. The training process involved 250 epochs, with a Dice loss of 0.23, The Dice Similarity Coefficient (DSC) was used to evaluate the spatial overlap between the manual ground-truth segmentation by the expert and the prediction generated by the U-Net model. A DSC value closer to 1 indicates higher segmentation accuracy and agreement with the original image. To evaluate the model's accuracy and performance across all subjects, a leave-one-animal-out cross-validation approach was applied to the base animal dataset. Model performance was evaluated using the Dice coefficient, alongside a manual visual comparison between the generated contours and reference masks.

I. Statistic

The volume measured by transurethral characterization served as the gold standard for comparison against the volumes predicted by the models. In Sham animals (animals 1 to 5), the volume was standardized to 1.0 mL during ultrasound acquisition. Conversely, in SCI animals (animals 6 to 8), the volume was measured via post-ultrasound transurethral characterization to quantify retained urine (2.50 mL, 1,00 and 5.00 mL, respectively).

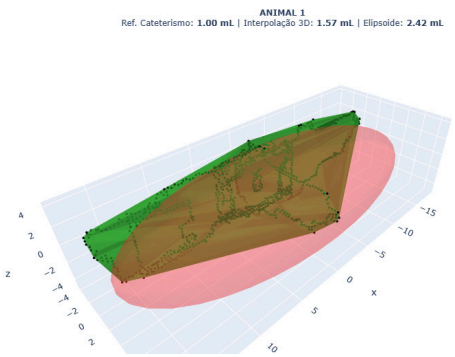
Height 3D reconstruction models were evaluated: (1) a **3D Convex Hull Interpolation**, in which the algorithm envelops the point cloud by creating a continuous 3D polygonal mesh (composed of multiple connected triangles) spanning the contours of neighboring and orthogonal slices; and (2) a **Pure Ellipsoid** model, in which the code extracts the absolute extreme values of the point cloud along the three spatial axes ($\max - \min$) to determine the total length, width, and height of the structure (D_x, D_y, D_z). using the Fórmula:(1):

$$V_{\text{ellipsoid}} = \frac{4}{3}\pi \cdot r_x \cdot r_y \cdot r_z = \frac{4}{3}\pi \cdot \left(\frac{D_x}{2}\right) \cdot \left(\frac{D_y}{2}\right) \cdot \left(\frac{D_z}{2}\right) \quad (1)$$

The calculated volumes from both models were converted to milliliters (mL) and evaluated against the transurethral catheterization gold standard for each animal. Performance was quantified by calculating both the absolute error (mL). Across the cohort, the 3D Voxel interpolation (Convex Hull) demonstrated superior accuracy compared to the traditional pure prolate ellipsoid model. While both methods showed low absolute errors in low-volume conditions (Sham group, A1–A5), the pure ellipsoid model significantly overestimated or distorted volume calculations in high-volume, neurogenic bladders (SCI group, A6–A8), reaching absolute errors up to 7.33 mL. In contrast, the 3D Convex Hull approach maintained higher fidelity to the actual geometry of the bladder, achieving lower absolute and percentage errors across all subjects.

III. Results and Discussion

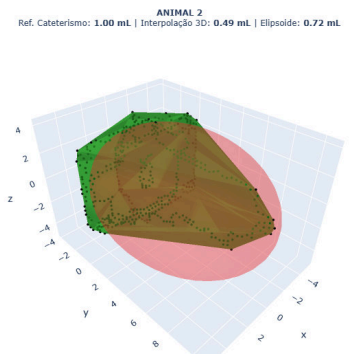
A. Mitigating Small Dataset Limitations via Transfer Learning and Data Augmentation



The acquisition of high-quality ultrasound image datasets in preclinical rodent models of NB presents significant logistical and anatomical challenges. In this study, the initial dataset was constrained to red 56 raw 2D freehand ultrasound images obtained from eight animals. In deep learning applications, such limited training data typically leads to severe overfitting, poor boundary segmentation, and high generalization error.

To overcome this limitation without increasing animal usage, we applied transfer learning by adapting a U-Net architecture originally pre-trained on human abdominal computed tomography (CT) scans. The pre-trained features enabled the network to leverage low-level edge and shape representations, significantly reducing the required convergence time for ultrasound image segmentation. Second, data augmentation techniques—specifically non-linear elastic deformations and random spatial rotations—were applied to expand the base dataset threefold to 280 images. This synthetic expansion effectively simulated real-world acoustic variations, transducer pressure artifacts, and anatomical morphological shifts during scanning. Consequently, the network achieved stable segmentation accuracy across unencountered validation images, reaching a Dice Loss below 0.23 within 250 training epochs.

Although this synthetic expansion successfully mitigated initial overfitting in this pilot proof-of-concept study ($N = 8$), a larger dataset remains essential to further reduce prediction errors during 2D ultrasound slice segmentation. Improving 2D boundary segmentation accuracy directly minimizes propagation errors in 3D point cloud generation, allowing more precise volume formulas and mathematical corrections when converting 2D slice contours into continuous 3D reconstructions. Future work will incorporate larger animal cohorts to evaluate broader morphological heterogeneity and refine slice-to-volume transformation algorithms.



The 3D volumetric estimations derived from the two surface reconstruction approaches yielded distinct representations of the bladder across all analyzed subjects (Fig. 5):

- **3D Voxel Interpolation (Convex Hull):** Wraps the segmented point cloud in a continuous bounding polygon. While it abstracts complex surface contours (lacking exact local geometric fidelity), it maintains high volumetric fidelity by tightly enclosing the segmented slices without overestimating unobserved spaces.
- **Pure Prolate Ellipsoid Model:** Extracted extreme axial dimensions (D_x, D_y, D_z) to calculate volume, assuming a perfectly symmetrical geometry.

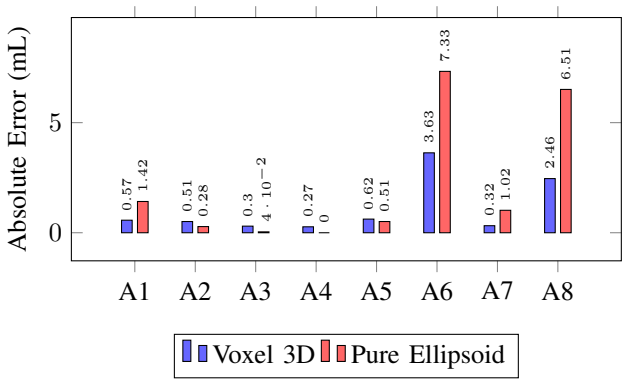

Fig. 6: Comparison of Absolute Errors (mL) between Voxel 3D Interpolation and Pure Ellipsoid methods per animal.

1) Comparison with Transurethral Catheterization (Gold Standard): Transurethral catheterization remains the clinical and experimental gold standard for measuring exact post-void residual urine volume. However, in small animal models such as Wistar rats, catheterization requires anesthesia, expert handling, and carries severe risks of urethral trauma, tissue scarring, and secondary urinary tract infections (UTIs)—factors that directly compromise longitudinal studies.

The Deep Learning-assisted ultrasound reconstruction method developed in this study provides a non-invasive, highly repeatable alternative. By mapping 2D ultrasound slices into standardized 3D continuous surface meshes ($1\ \text{cm}^3 = 1\ \text{mL}$), the proposed pipeline achieves volume estimations that closely track physical fluid infusion values without exposing fragile post-SCI rodents to invasive catheter insertion. This workflow democratizes rodent bladder evaluation, enabling reliable longitudinal monitoring even when operated by non-specialist researchers.

IV. CONCLUSION

In this study, we presented a non-invasive pipeline combining deep learning-based segmentation (U-Net) with 3D surface reconstruction algorithms (3D Voxel Interpolation via Convex Hull and Pure Prolate Ellipsoid models) to estimate rat bladder volume from 2D freehand ultrasound slices. The proposed workflow demonstrated high volumetric fidelity relative to the catheterization gold standard, effectively overcoming the severe volume overestimation limitations associated with conventional geometric formulas in distended neurogenic bladders.

These findings indicate that automated 3D ultrasound reconstruction offers a reliable, non-invasive alternative for longitudinal assessment of neurogenic bladder in rodent preclinical models. However, acquiring a larger dataset of 2D ultrasound images is essential for future work to reduce slice-level segmentation prediction errors, enabling fine-tuned mathematical volume corrections during 3D point cloud generation and further validating the model across broader anatomical variations.

***Abstract*—The posterior parietal cortex (PPC) is an associative cortical region involved in sensorimotor integration, spatial processing, and decision-related activity. Here, we characterized single-unit and population spiking activity in the anesthetized rat PPC using high-density extracellular recordings with a multi-shank silicon probe. Spike sorting and manual curation were used to identify single-unit activity (SUA) and multi-unit activity (MUA) clusters. For SUA units, we quantified firing rate, inter-spike interval metrics, burstiness, and waveform features. Population activity was analyzed across shanks by pooling SUA and MUA spikes, binning activity at 50 ms resolution, and computing the coefficient of variation (CV) of spike counts over time. A total of 186 SUA units and 703 SUA+MUA sorted units were included. SUA firing rates were broadly distributed, with a median firing rate of 0.62 Hz, and waveform analysis identified 78 narrow-spiking and 100 wide-spiking SUA units. Population CV analyses revealed temporally structured variability across shanks and animals, with example raster plots showing patterns consistent with UP/DOWN-like activity patterns under anesthesia. These results provide an initial quantitative description of unit-level diversity and population-level dynamics in the rat PPC and support the use of high-density recordings to characterize associative cortical circuits.**

***Index Terms*—cortical dynamics, high-density recordings, neuronal population dynamics, extracellular electrophysiology**

I. Introduction

Information processing in the mammalian brain emerges from the coordinated activity of neuronal populations distributed across hierarchically organized cortical circuits [31], [32]. Along this hierarchy, cortical areas differ in their functional order: lower-order regions process specific sensory or motor signals, whereas higher-order associative areas combine them to support flexible behavior [34].

Within the cortical hierarchy, the posterior parietal cortex (PPC) serves as a critical associative node that actively synthesizes incoming sensory, spatial, and motor variables [35], [36]. By acting as a functional bridge between sensory processing streams and motor command networks, the PPC plays a central role in attention, spatial representation, action planning, and decision-making, serving as a critical interface between sensory and motor networks. In rodents, PPC activity has been shown to encode spatial location, body position, movement intentions, tactile sensorimotor information, and choice-related signals that support goal-directed behavior [6], [7]. Crucially, these diverse signals are processed through distributed computations that unfold across thousands of interconnected neurons. Consequently, moving beyond single-cell properties to map how these population-level representations are structured in neural state-space is essential to deciphering how the PPC transforms sensory inputs into goal-directed motor outputs.

Finep, CNPq

Beyond advancing basic systems neuroscience, decoding this structured population activity is of profound practical interest for neuroengineering. Neurofeedback provides a closed-loop framework in which subjects learn to volitionally regulate their own neural activity from real-time feedback of a target signal [37]. Given its integrative role in intention and movement planning, the PPC is an attractive target for such closed-loop control, as its population activity can, in principle, be decoded and fed back to support self-regulation and neuroprosthetic applications.

Accessing this population-level organization, however, depends on the available recording methods. While classical studies have greatly advanced our understanding of single-neuron properties, recent work in extracellular electrophysiology has shown that many neural functions depend on the collective dynamics of large neuronal ensembles [1], [2]. High-density silicon probes now enable the simultaneous recording of dozens to hundreds of neurons, offering unprecedented access to population-level dynamics and the functional organization of cortical networks [8], [9], while advances in spike-sorting methods have improved the reliable identification and classification of neuronal units from large-scale recordings [10], [11].

Together, these advances make high-density silicon probes particularly well suited to studying the PPC, where the coordinated activity of large neuronal populations is thought to underlie sensory integration, decision-making, and motor planning. In the present study, the recordings primarily sampled deep cortical layers (V and VI), which contain projection neurons involved in corticocortical, corticothalamic, and subcortical communication, making them particularly relevant for investigating population activity in this associative cortical region [12]–[14].

Therefore, the present study aimed to characterize neuronal population activity in the rat posterior parietal cortex using high-density silicon probe recordings. By combining extracellular electrophysiological recordings with spike-sorting procedures, we sought to provide a detailed description of neuronal activity across deep cortical layers, contributing to a better understanding of neuronal dynamics within this important associative cortical region.

II. Materials and methods

A. Subjects

A total of six male Wistar rats (*Rattus norvegicus*) aged 3–4 months and weighing between 350 and 500 g were included in the study.

The rat was obtained from the Central Vivarium of the Federal University of Pernambuco (Recife, Brazil). The animal was housed using a 12-h light/dark cycle and had free access to water and standard laboratory chow. The project was approved by the Animal Use Ethics Committee (CEUA) of the UFPE (Protocol N^{o} 0014/2025) and all procedures were conducted in accordance with established guidelines for the care and use of laboratory animals.

B. Electrophysiology

In vivo experiments were performed to record neural activity from the posterior parietal cortex in animals anesthetized. Anesthesia was induced with ketamine (150 mg/kg) and xylazine (5 mg/kg), using concentrations of 100 mg/ml (ketamine) and 20 mg/ml (xylazine). An initial dose was administered, followed by supplemental doses of ketamine throughout the surgical procedure as required.

The animals were placed in a stereotaxic frame to ensure stability during the surgical procedure. Lidocaine (4%, s.c.) was applied locally to the scalp at the beginning of the surgery to provide additional analgesia. After confirming adequate anesthesia and analgesia, the scalp was incised, and the exposed area was carefully cleaned and dried prior to initiating stereotaxic procedures. Glucose (4 ml, 5%, s.c.) was administered to rehydrate the animals and maintain metabolic stability prior to probe insertion.

A craniotomy (2.5 mm in diameter) was performed at stereotaxic coordinates referenced to Bregma: anteroposterior (AP) -4.2 mm, mediolateral (ML) 2.5 mm, and dorsoventral (DV) 1.4 mm, targeting the posterior parietal cortex, corresponding to the parietal association cortex (PtA) as defined in the Paxinos and Watson atlas [18].

Electrophysiological recordings were performed using a 64-channel silicon probe (BuzsakiA64sp, sharp-tip configuration, NeuroNexus). The probe geometry consisted of 64 recording sites distributed across 6 shanks, with 10 sites per shank. The shanks were spaced 200 μm apart, and each recording site had an area of 160 μm^2, with an impedance ranging from 1 to 3 MΩ at 1 kHz. The recording sites were arranged in a staggered configuration along each shank, with an inter-site spacing of 20 μm, allowing for high-density sampling of neuronal activity across cortical layers. This configuration enables simultaneous recordings of local field potentials (LFPs) and neuronal spiking activity across multiple spatial scales [1], [11].

The probe was positioned over the craniotomy and aligned along the anteroposterior axis. The probe was maintained parallel to the horizontal plane and gradually advanced at a controlled rate of 100 μm/min using a micromanipulator, ensuring precise targeting and minimizing tissue damage. The probe was lowered to a final depth of approximately 1400 μm from the pia mater, allowing recordings across cortical layers. Each animal underwent a single recording session with an average duration of approximately 90 minutes. Analyses focused primarily on signals recorded between 900 and 1200 μm in depth, corresponding predominantly to cortical layers V and VI. These deeper cortical layers are characterized by a high density of pyramidal neurons with long-range projections, playing a central role in corticofugal output and integration of sensorimotor and associative information [12], [14].

The probe was carefully inserted into the target cortical area and connected to a NeuroNexus probe adapter. The signal was then routed via an Omnetics connector to a headstage (Intan, RHD2164), which performed amplification, filtering, and digitization of the analog signals. The digitized data were

transmitted to an Open Ephys acquisition board at a sampling rate of 30 kHz per channel with 16-bit resolution per sample. Data acquisition, synchronization, and real-time visualization of electrophysiological signals were performed using the Open Ephys Project software interface [20].

C. Spike sorting and unit classification

Spike detection and sorting were performed with Kilosort 4.0. Clusters were manually curated in phy 2.1.0rc1 [22] by inspecting waveform consistency, principal-component distributions, autocorrelograms (to assess refractory-period violations), and temporal stability across the session. Each cluster was classified as single-unit activity (SUA), multi-unit activity (MUA), or noise; noise clusters were excluded from all subsequent analyses [11]. Units were classified as SUA if the fraction of inter-spike intervals (ISIs) below 2 ms was less than 1 %; all other units were classified as MUA.

D. Waveform-based classification

SUA waveforms were extracted from the curated spike-sorting output using the SpikeInterface framework [27]. To standardize the profiles, mean waveforms were aligned to their respective troughs and normalized by their trough amplitudes. We then calculated the trough-to-peak duration for each unit, defined as the time interval between the global minimum (trough) of the waveform and its subsequent local maximum (peak). These duration values were subsequently fitted with a two-component Gaussian Mixture Model (GMM) to classify the neuronal population into narrow-spiking (NS) and wide-spiking (WS) units based on the GMM decision boundary. Finally, we compared the baseline firing-rate distributions between the classified NS and WS populations [41].

E. Population activity analysis,

Spike times from units classified as single-unit activity were used to quantify the temporal dynamics of neuronal population activity in the posterior parietal cortex. These metrics followed commonly used extracellular electrophysiology descriptors, including metrics implemented in CellExplorer [23]. Inter-spike intervals (ISIs) were computed from consecutive spike times, and the median ISI was used to summarize the typical temporal spacing between spikes. The proportion of long ISIs was defined as the fraction of ISIs longer than 3 s. Burstiness was quantified from the ISI distribution as

$$B = \frac{\sigma_{\mathrm{ISI}} - \mu_{\mathrm{ISI}}}{\sigma_{\mathrm{ISI}} + \mu_{\mathrm{ISI}}}, \tag{1}$$

where σ_{ISI} and μ_{ISI} are the standard deviation and mean of the ISI distribution, respectively.

Population activity analyses were performed using spike times from units classified as SUA or MUA. Following the approach used to characterize cortical states through spiking variability [21], [38]–[40], the recording was divided into non-overlapping 10 s time windows. Within each 10 s window, spikes from all SUA and MUA units belonging to the same shank were pooled and binned using 50 ms bins. For each shank and time window, the population firing rate was computed as

$$FR = \frac{N_{spikes}}{T}, \tag{2}$$

where N_{spikes} is the total number of spikes in the window and $T = 10$ s. Firing rate was expressed in Hz.

The coefficient of variation (CV) of the population activity was computed from the distribution of spike counts across the 50 ms bins within each 10 s window [21], [38]–[40]:

$$CV = \frac{\sigma}{\mu}, \tag{3}$$

where σ is the standard deviation and μ is the mean of the binned spike-count distribution. Thus, CV quantified the temporal variability of the summed population activity within each shank. Higher CV values indicate more irregular or burst-like population activity, whereas lower values indicate more regular activity across time bins. For the example population plots, CV was computed using non-overlapping 5 s windows over the first 60 min of each recording, with fixed 50 ms bins within each window. Example raster plots and population firing-rate traces were selected to represent windows with the lowest CV, highest CV, and median CV. For the across-animal summary, CV distributions were computed using non-overlapping 10 s windows and fixed 50 ms bins.

For the population firing-rate traces, spikes from all included SUA and MUA units were pooled, and spike counts in each 50 ms bin were divided by the bin duration and smoothed using a Gaussian kernel with a standard deviation of 150 ms. Therefore, population firing rate represented summed activity and was not normalized by the number of units. In contrast, unit-level firing rates were calculated separately by dividing the total number of spikes emitted by each unit by the corresponding recording duration.

To assess whether the pooled distributions were disproportionately influenced by individual recording sessions or by differences in unit yield, we additionally summarized population metrics at the shank level. For each animal and shank, the median population CV across non-overlapping 10-s windows was calculated from the summed SUA+MUA activity. Mean firing rate per shank was calculated by averaging the recording-wide firing rates of the SUA+MUA units assigned to that shank. These summaries preserved the nested structure of the dataset, with units grouped within shanks and shanks grouped within animals.

III. Results

A. Single-unit activity metrics

We first characterized the baseline spike-train properties of single units recorded in the PPC (Fig. 1). The experimental setup, including the stereotaxic targeting of the PPC and the high-density multi-shank silicon probe layout, is illustrated in (Fig. 1a). Across six recording sessions, our curated dataset yielded a total of 186 high-quality SUA clusters (Table I);

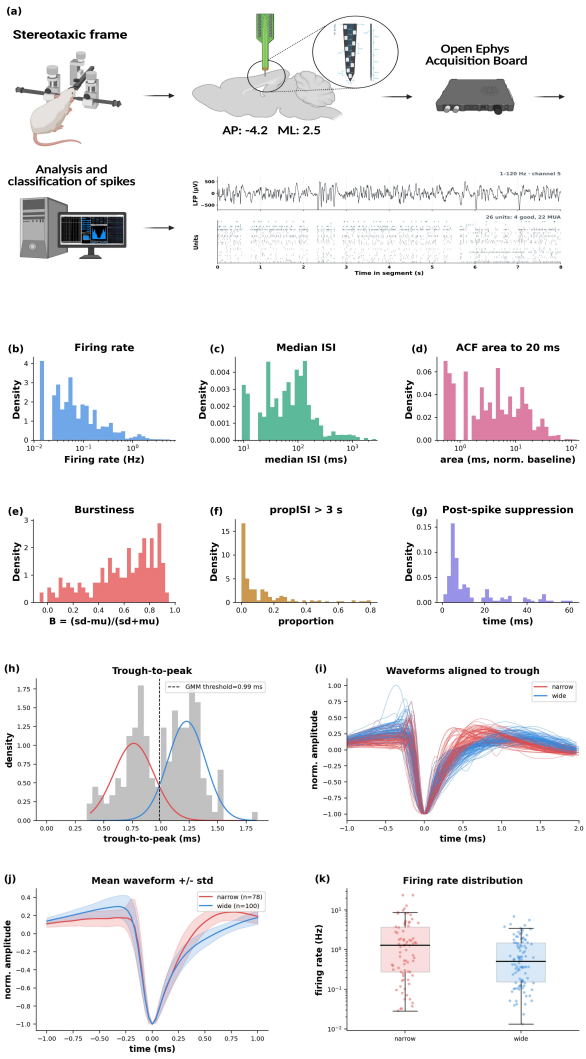

Fig. 1. **Single-unit spike-train metrics in rat PPC under anesthesia**. **(a)** Experimental workflow and setup. Extracellular recordings were obtained from PPC using a high-density multi-shank silicon probe. Wideband signals were acquired via an Open Ephys acquisition system and processed offline for spike sorting. A representative local field potential (LFP) trace (bandpass filtered at 1–120 Hz) and corresponding spike raster plot illustrate the recorded neural activity, highlighting the distinction between classified single units (SUA/"good" units, in blue) and multi-unit activity (MUA, in grey). **(b–g)** Distributions across SUA ($n = 186$) of: **(b)** mean firing rates, **(c)** median ISIs, **(d)** normalized ACF area (20 ms lag), **(e)** burstiness index $B = (\mathrm{SD} - \mu)/(\mathrm{SD} + \mu)$, **(f)** proportion of ISIs > 3 s, and **(g)** post-spike suppression. (**h**) Distribution of trough-to-peak durations (ms) across units. A two-component Gaussian mixture model was fit to the trough-to-peak values, separating narrow-spiking (red; n = 78) from wide-spiking (blue; n = 100) units; The dashed line indicates the GMM classification thresh-old at 0.99 ms. Colored curves show the two fitted Gaussian components. (**i**) All mean waveforms, amplitude-normalized and aligned to the trough, colored by class (red, narrow; blue, wide). (**j**) Class-averaged waveforms (mean ± SD) for narrow (red) and wide (blue) units. (**k**) Firing-rate distribution of units classified as narrow-spiking and wide-spiking. Each point represents one SUA unit, boxes indicate the interquartile range, horizontal lines indicate the median, and whiskers show the data range excluding outliers (Hz; log scale). *Created in BioRender. BEATRIZ VIEIRA COUTO DE LIMA, A. (2026). https://BioRender.com/hzntz9y*

when multi-unit activity (MUA) clusters were also included, a total of 703 sorted units were available for analysis (Table II).

Firing rates were broadly distributed and right-skewed, with most units firing at low rates and a smaller subset showing higher activity levels. The median firing rate was 0.62 Hz (interquartile range, IQR: 0.17–1.82 Hz).

Consistent with this firing-rate profile, the ISIs also showed a broad distribution across units, with a median of 200.9 ms (IQR: 108.3–823.1 ms). The proportion of long ISIs (>3 s) varied across units, with a median of 0.044 (IQR: 0.012–0.154), indicating heterogeneous silent-period structure across the SUA population. Burstiness values were mostly positive, with a median burstiness index of 0.64 (IQR:0.43–0.80), indicating that many SUA spike trains showed temporally clustered firing patterns.

B. Waveform-based unit classification

A total of 178 extracellular waveforms from single-unit activity were extracted and analyzed (Fig. 1). Waveforms were aligned to their trough and normalized by trough amplitude to enable comparisons across units. The trough-to-peak duration exhibited a bimodal distribution and was classified using a two-component Gaussian mixture model, separating units into narrow-spiking and wide-spiking populations (Fig. 1h.).

The GMM classification thresh-old at 0.99 ms. This classification identified 78 narrow-spiking units and 100 wide-spiking units. Narrow-spiking units exhibited shorter trough-to-peak durations (median: 0.78 ms), whereas wide-spiking units showed longer trough-to-peak durations (median: 1.23 ms) (Fig. 1i.). To illustrate the characteristic waveform shape of the recorded population, the mean normalized waveform was overlaid on the individual waveforms for each group (Fig. 1j.). Finally, firing-rate distributions were compared between waveform classes, showing that NS units tended to exhibit higher firing rates than WS units (Fig. 1k).

C. Population activity dynamics

Population activity dynamics were examined based on the variability of the neuronal population spiking activity over time [33], [38], [40], as illustrated in Fig. 2. As detailed in Methods (Sec. II-E), this variability was estimated using the coefficient of variation, CV(t), computed separately for each shank (Fig. 2a) and for the pooled population across all shanks (Fig. 2c). We have previously demonstrated strong coupling in neuronal population spiking dynamics within and among primary sensory cortices in rodents [38], but whether such coupling exists within the PPC remains unknown. Shank-wise CV(t) values showed temporal fluctuations throughout the recording, and the CV(t) correlation matrix summarized the similarity of population variability time series across shanks (Fig. 2b). For the pooled population (Fig. 2d), CV values ranged from 0.38 to 0.90, with a median of 0.63. Example raster plots and population firing-rate traces were selected from windows corresponding to the lowest CV, highest CV, and median CV(Fig. 2e-g).

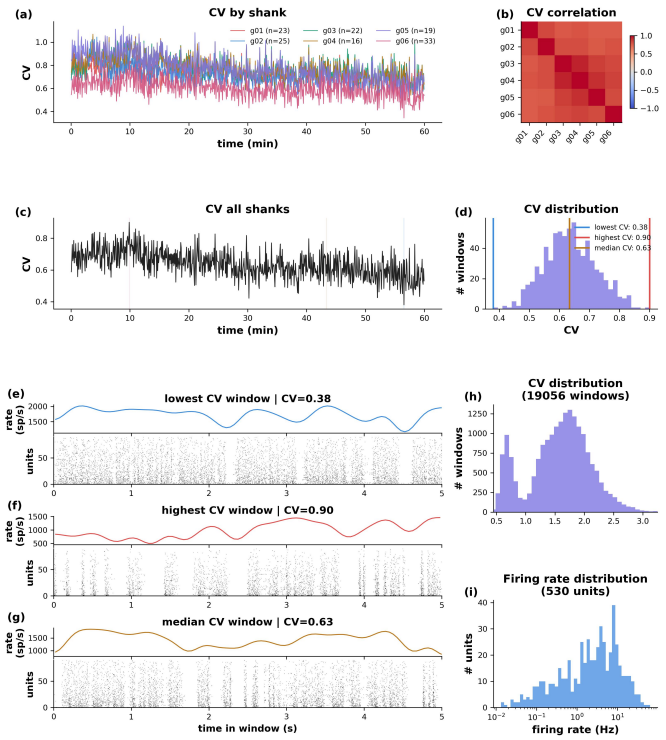

Fig. 2. **Population spiking variability in PPC recording.** (**a**) Coefficient of variation, CV(t), of population activity computed separately for each probe shank. Spikes from SUA and MUA clusters were pooled within each shank, binned using fixed 50 ms bins, and CV was computed in non-overlapping 5 s windows over the first 60 min of the recording. (**b**) Correlation matrix between shank-wise CV(t) time series. (**c**) CV(t) computed after pooling activity across all shanks. Colored vertical bands indicate the example windows selected for raster and firing-rate visualization. (**d**) Distribution of CV values across time windows for the pooled population activity. Vertical lines indicate the selected lowest, highest, and median CV windows. (**e-g**) Population firing-rate traces and raster plots for example windows corresponding to the lowest CV, highest CV, and median CV, respectively. In raster plots, each row represents one SUA or MUA unit and each tick corresponds to one spike. Example shown for animal 20260514. n = 138 units. (**h**) Distribution of population CV values computed from pooled SUA+MUA activity across all animals recorded from 2026-04-06 onward. For each shank, spikes were binned using fixed 50 ms bins, and CV was computed from non-overlapping 10 s windows. (**i**) Distribution of firing rates across SUA+MUA units, computed as the total number of spikes divided by the recording duration and shown on a logarithmic scale. n = 19,056 CV windows and 530 SUA+MUA units

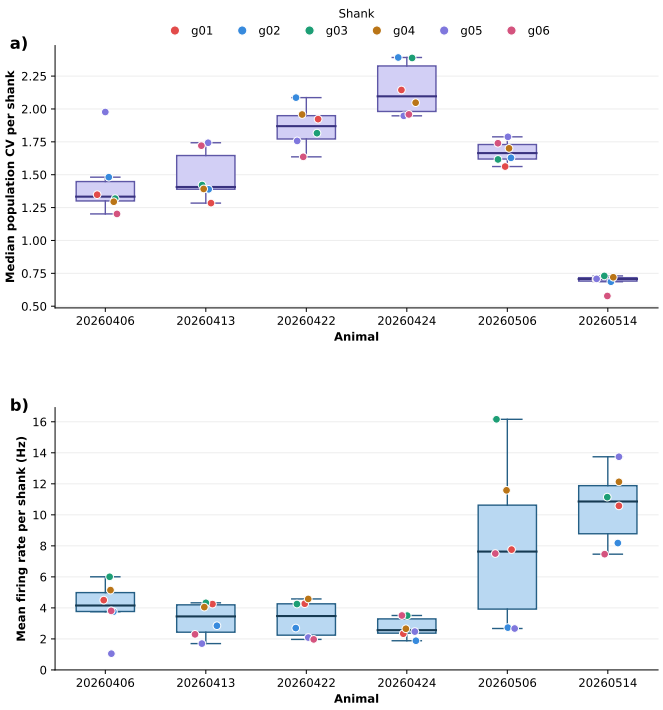

Fig. 3. **Population activity variability and firing rate across animals.** (**a**) Distribution of the population coefficient of variation across shanks for each animal. For each shank, spikes from all curated single-unit and multi-unit activity were pooled, binned at 50 ms within non-overlapping 10-s windows, and the median CV across windows was calculated. (**b**) Distribution of mean firing rates across shanks. For each shank,firing rates were calculated for individual SUA+MUA units over the recording session and then averaged across units. In both panels, each colored point represents one shank, with colors identifying the corresponding shank. Boxes show the interquartile range, horizontal lines indicate the median across shanks, and whiskers extend to 1.5 times the interquartile range.

TABLE I
NUMBER OF SINGLE-UNIT (SUA) CLUSTERS PER SHANK AND ANIMAL.

Animal	Sh1	Sh2	Sh3	Sh4	Sh5	Sh6	Total
2026-04-06	10	4	0	5	8	12	39
2026-04-13	7	12	7	6	9	4	45
2026-04-22	3	6	1	2	6	4	22
2026-04-24	5	0	0	1	5	0	11
2026-05-06	2	14	0	0	4	3	23
2026-05-14	7	13	4	4	5	13	46
Total	**34**	**49**	**12**	**18**	**37**	**36**	**186**

In addition, population variability and firing-rate distributions were summarized across all recordings (Fig. 2). Across six recordings, the SUA+MUA dataset included 530 units. The number of units per recording ranged from 61 to 138 units.

The distribution of population CV values was computed across shanks and recordings using fixed 50 ms bins within non-overlapping 10 s windows. Across 19,056 CV windows, the median CV was 1.62 (IQR:1.25–1.92), with values ranging from 0.41 to 4.64. Firing rates across SUA+MUA units were broadly distributed on a logarithmic scale, with a median firing rate of 2.68 Hz (IQR: 0.61–7.69 Hz). Together, these distributions summarize the range of population variability and unit firing rates observed across the recorded animals.

We further examined the distribution of population CV and firing rate using the shank as the summary level (Fig. 3). Each point therefore represented one shank rather than an individual time window or unit. Population CV and mean firing rate varied both within and across animals, indicating that the broad pooled distributions were not attributable to a single recording. Nevertheless, the visible between-animal variability suggests that recording identity and local sampling should be considered when interpreting pooled population metrics.

IV. DISCUSSION

In this study, we characterized SUA and population activity recorded from the rat PPC using a high-density multi-shank silicon probe.

Different recording modalities provide complementary views of population dynamics. Here, we focused on spiking activity because its cellular resolution allows us to characterize individual neuronal dynamics and population coding, whereas LFPs primarily capture broader network-level activity. LFP-based spectral analyses may therefore provide a complementary perspective on the network organization underlying the dynamics observed here.

Rather than examining behavior-related neural coding, our recordings capturedmspontaneous neuronal activity under ketamine/xylazine anesthesia, allowing us to characterize single-unit firing patterns and the temporal organization of population activity in the PPC. This baseline characterization provides a quantitative framework for understanding the intrinsic dynamics of neuronal ensembles in this associative cortical region and establishes a reference for future studies of cortical population dynamics and neural coding [1], [2].

Because anesthesia strongly shapes cortical dynamics, the anesthetic regime is a central consideration when interpreting the population activity reported here [21], [28]. Recordings were obtained under ketamine/xylazine rather than the urethane protocol previously adopted for acute recordings in our laboratory [30]. This choice was motivated by the associative nature of the PPC: as a higher-order region that relies on polysynaptic cortico-cortical and thalamo-associative transmission, the PPC is disproportionately sensitive to anesthetics that promote slow-wave states. Urethane, in particular, favors prolonged slow oscillations with extended DOWN states that attenuate precisely the polysynaptic transmission on which associative processing depends [28], [29]. Ketamine, an NMDA-receptor antagonist, combined with the α_2-adrenergic agonist xylazine, instead produces a comparatively more activated, desynchronized cortical state, with reduced low-frequency power and better preserved cortico-cortical engagement than urethane [28]. The broad, right-skewed firing-rate distributions and the wide range of population CV values observed here are consistent with such an activated regime, rather than with the stereotyped, highly synchronous slow-wave activity typical of deep urethane anesthesia.

The distribution of SUA firing rates was broad and right-skewed, with most units exhibiting low firing rates and a smaller subset displaying substantially higher firing rates. This heterogeneous distribution is consistent with previous observations in cortical and hippocampal populations, where neuronal firing rates span several orders of magnitude and often follow skewed or log-normal-like distributions [24]. Such heterogeneity likely reflects differences in intrinsic excitability, synaptic connectivity, neuronal subtype, and participation in local network events. Likewise, the broad distribution of ISIs and the predominance of positive burstiness values indicate that PPC neurons exhibit diverse temporal firing patterns rather than homogeneous discharge activity.

Waveform analysis further revealed two major groups of extracellularly recorded units based on trough-to-peak duration. This waveform-based classification has been widely used to describe the physiological diversity of neurons recorded using extracellular electrophysiological techniques [25]. In the present dataset, narrow-spiking and wide-spiking units exhibited consistent differences in waveform duration and firing-rate distribution, suggesting that PPC recordings captured electrophysiologically distinct neuronal populations. However, because extracellular waveform characteristics alone cannot unequivocally identify neuronal cell types, these groups should be interpreted as electrophysiological categories rather than definitive classifications of excitatory or inhibitory neurons.

At the population level, coefficient of variation analyses revealed pronounced temporal fluctuations in collective spiking activity across animals and recording shanks. Periods of lower CV were associated with more regular population firing, whereas higher CV values corresponded to more clustered or burst-like spiking patterns. These alternating activity regimes exhibit features consistent with UP/DOWN-like cortical dynamics, in which neuronal populations alternate between states of higher and lower activity. Similar state-dependent fluctuations have been reported during spontaneous cortical activity under anesthesia [21], [26], suggesting that the anesthetized PPC retains a temporally structured organization of population activity despite the absence of sensory stimulation or behavioral engagement.

The shank-level analysis provided an additional view of the hierarchical structure of the dataset. Population CV and mean firing rate showed variability both among shanks from the same animal and across animals. This indicates that the pooled distributions should not be interpreted as arising from a homogeneous population of independent observations. Differences in unit yield, local probe sampling, and animal-specific physiological conditions may all contribute to the observed dispersion. Summarizing the data at the shank level within each recording makes this variability explicit and reduces the disproportionate influence of recordings containing more units or time windows on the overall distributions.

Across animals, the distributions of CV values and firing rates demonstrated that PPC population activity varied across recordings. This variability may reflect differences in local circuit sampling across shanks, the number of recorded units per animal, and the functional state of the cortical network under anesthesia. Given that the PPC serves as an important associative hub responsible for integrating sensory and motor-related information, such variability may be particularly relevant for understanding how this region transitions between internally generated activity patterns and those associated

with information processing during behavioral tasks. Future studies comparing spontaneous activity under anesthesia with recordings obtained from awake animals during behavioral tasks may help clarify how these population patterns relate to the functional roles of the PPC.

Overall, these results provide an initial quantitative characterization of single-unit activity properties and the population dynamics of combined SUA and MUA recordings in the anesthetized rat posterior parietal cortex. The findings indicate that PPC activity exhibits heterogeneous single-unit firing patterns, waveform diversity, and temporally structured population-level variability. These features are consistent with the concept that PPC function depends on the coordinated dynamics of neuronal ensembles and provide a foundation for future investigations into cortical state organization within this associative cortical region.

V. Conclusion

This study provides an initial characterization of single-unit and population activity in the anesthetized rat posterior parietal cortex. SUA units displayed heterogeneous firing-rate, ISI, burstiness, and waveform properties, while SUA+MUA population activity showed temporally structured variability across shanks and animals. CV-based analyses and raster plots revealed epochs compatible with UP/DOWN-like dynamics, although further analyses combining spiking activity with additional state markers are required to confirm this interpretation. Together, these findings support high-density extracellular recordings as a useful approach to describe unit-level diversity and population-level dynamics in PPC circuits.

***Abstract*—Os ratos *Wistar* são amplamente utilizados em pesquisas de neurobiologia e engenharia biomédica, especialmente em estudos que empregam a optogenética como ferramenta de neuromodulação. A entrega de vetores virais e o implante de cânulas por meio de cirurgia estereotáxica são etapas críticas desse tipo de estudo, mas a literatura carece de um protocolo estruturado e padronizado que seja aplicável de forma consistente entre diferentes laboratórios. Este trabalho teve como objetivo desenvolver e descrever um Procedimento Operacional Padrão (POP) para a cirurgia estereotáxica de infusão viral e implante de cânula em ratos *Wistar*, dividido em quatro etapas: preparação pré-operatória e anestesia, procedimento cirúrgico estereotáxico, implante da cânula com infusão viral, cuidados pós-operatórios.O protocolo foi aplicado em 28 animais, dos quais 13 foram submetidos a cirurgia combinada (implante e infusão na mesma sessão) e 15 a cirurgias separadas. A taxa de sobrevivência geral foi de $85{,}7\%$, com os óbitos concentrados predominantemente na fase anestésica. Os resultados indicam que o POP proposto é tecnicamente viável e reprodutível, contribuindo tanto para a padronização experimental quanto para o bem-estar animal. A acurácia do posicionamento e a expressão viral foram validadas por confirmação histológica.**

I. Introdução

A estimulação optogenética estabeleceu-se como uma ferramenta indispensável na pesquisa em neuromodulação em roedores de laboratório, permitindo o controle preciso e a investigação detalhada de circuitos neurais específicos por meio da infusão de vetores virais [1]. Para que essa abordagem alcance a eficácia desejada, o sucesso metodológico depende criticamente da acurácia na cirurgia estereotáxica e na implantação de cânulas-guia para a entrega precisa do material genético no tecido cerebral de interesse [2]. Esse tipo de abordagem cirúrgica já foi descrito para diversas estruturas encefálicas, como a área tegmental ventral, o locus coeruleus e o núcleo dorsal da rafe, mas cada grupo de pesquisa tende a adaptar o procedimento às particularidades de sua própria linha de trabalho [3].

Apesar da ampla utilização dessas técnicas, a literatura aponta uma lacuna importante: a inexistência de um protocolo estruturado e padronizado que seja aplicável de forma consistente entre diferentes modelos animais e diferentes laboratórios. Revisões sistemáticas sobre boas práticas cirúrgicas em roedores mostram que há grande variabilidade na execução de procedimentos como assepsia, manejo perioperatório e cuidados pós-cirúrgicos, o que compromete tanto a reprodutibilidade científica quanto o bem-estar animal [4]. Estudos que buscaram refinar tecnicamente a cirurgia estereotáxica em roedores demonstraram que o aprimoramento e a padronização de etapas cirúrgicas reduzem significativamente o número de animais necessários por grupo experimental, além de diminuir

complicações e melhorar a recuperação pós-operatória [3].

A padronização por meio de um Procedimento Operacional Padrão (POP) é fundamental pois assegura a reprodutibilidade dos resultados entre diferentes execuções e operadores, reduzindo variáveis técnicas que poderiam confundir os desfechos experimentais, e protocolos bem definidos e refinados estão diretamente associados a menor morbidade, menor tempo cirúrgico e melhor manejo da dor, contribuindo para o bem-estar animal [5].

Diante disso, este artigo tem como objetivo apresentar e descrever um Procedimento Operacional Padrão (POP) para a cirurgia estereotáxica de infusão viral via cânula em ratos Wistar, com foco na padronização das etapas pré-operatórias, intraoperatórias e pós-operatórias, visando aumentar a reprodutibilidade experimental e assegurar o bem-estar animal em pesquisas de simulação optogenética.

II. Metodologia

Este estudo foi aprovado pelo Comitê de Ética no Uso de Animais do Instituto Santos Dumont (CEUA-ISD; protocolo n.º 01/2020 ISD), seguindo estritamente a Lei n.º 6.638/1979 e as normas regulamentadas pelo Conselho Nacional de Controle de Experimentação Animal (CONCEA).

A. Preparação Pré-Operatória e Anestesia

Foram utilizados ratos Wistar (*Rattus norvegicus*) machos, com aproximadamente 3 meses de idade e peso corporal entre 300 e 400 g. Os animais estão alojados no biotério do Instituto Santos Dumont (ISD), sob supervisão da médica veterinária e bioteristas. As caixas-moradia, feitas de acrílico transparente, abrigarão até três animais e serão preenchidas com maravalha autoclavada, garantindo a qualidade de vida para um bom procedimento.

Ao ser retirado do biotério, o animal é transferido para uma caixa de indução anestésica acoplada a um vaporizador calibrado de isoflurano. A indução tem início com uma concentração de $3,5\%$, sendo progressivamente ajustada conforme a resistência fisiológica apresentada por cada animal, até que seja atingido o plano anestésico adequado (perda do reflexo de endireitamento). Durante todo o procedimento, o animal permanece sob fluxo contínuo de oxigênio, mantido em 1 L/min, como observado na Figura 1 abaixo.

Uma vez adormecido, o animal recebe, por via intraperitoneal, dois fármacos calculados individualmente conforme o peso corporal: primeiro, a atropina, na dose calculada por peso (g) $\times\ 0,02/100$ mg, empregada para reduzir secreções e prevenir bradicardia reflexa; em seguida, a cetamina, na dose de peso (g) $\times\ 0,07/100$ mg. No intervalo de 5 minutos entre a aplicação dos dois fármacos, a tricotomia da região a ser operada é realizada utilizando como referência anatômica o Triângulo de Einthoven, delimitado pelos vértices superior direito, superior esquerdo e inferior, o que garante uma área de tricotomia padronizada entre os animais [6].

Após a administração da cetamina, o animal é transportado até o centro cirúrgico para o início do procedimento. A manutenção da anestesia é então realizada com isoflurano (2–3%) em fluxo contínuo de oxigênio.

(a) (b) (c)

Fig. 1: Sistema de anestesia inalatória e componentes preparatórios. (a) Bancada experimental contendo seringas preparadas para indução anestésica e câmara de indução de acrílico conectada ao sistema. (b) Fluxômetro acoplado à rede de oxigênio medicinal calibrado para fluxo contínuo. (c) Vaporizador calibrado específico para administração e controle de isoflurano.

Um cuidado adicional diz respeito à água do umidificador do sistema de oxigênio, que deve ser sempre substituída por água previamente tratada em centrífuga, tanto no oxigênio do centro cirúrgico quanto no da sala de infusão, onde é realizada a indução anestésica. Além disso, antes do início de qualquer procedimento anestésico, é fundamental que todo o maquinário do centro cirúrgico já esteja ligado e que as doses dos fármacos já estejam calculadas e preparadas.

B. Procedimento Cirúrgico (Estereotaxia)

Antes do início da manipulação do animal, o cirurgião e o auxiliar realizam a paramentação cirúrgica completa,envolvendo o avental estéril, degermação das mãos com esponja cirúrgica estéril de dupla face e luvas cirúrgicas de tamanho adequado, garantindo os cuidados de higiene e prevenção de contaminação. Os materiais utilizados nessa etapa (Figura 2) incluem:

- Avental cirúrgico;
- Campo estéril para a mesa cirúrgica;
- Campo estéril para a mesa acoplada onde colocam os materiais;
- Esponja cirúrgica estéril de dupla face;
- Luvas cirúrgicas;
- Cloreto de sódio (cinco unidades de NaCl de 10 mL);
- Uma caixa de amostras de swab;
- Saco de lixo para resíduos infectantes;
- Seis unidades de seringas de 1,0 mL);

O animal, já tricotomizado, é posicionado sobre uma cama térmica, a qual deve estar previamente aquecida no momento da chegada do animal, prevenindo a hipotermia intraoperatória. A cabeça do animal é então fixada ao aparelho estereotáxico por meio das barras auriculares e da barra incisiva, sendo essencial observar se os dentes incisivos centrais superiores estão corretamente posicionados no equipamento, de modo a permitir a expiração adequada e evitar o risco de sufocamento

Fig. 2: Equipamentos de proteção individual (EPIs) e insumos cirúrgicos estéreis organizados em bancada antes da etapa de paramentação e início do protocolo experimental.

do animal, como apresentado na Figura 3. Previamente ao início do procedimento, o aparelho estereotáxico deve estar conectado e calibrado por meio do software NeuroStar, responsável pela movimentação controlada do equipamento durante a cirurgia.

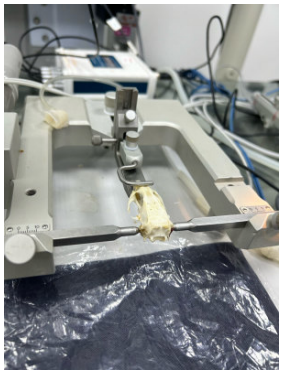

Fig. 3: Alinhamento e fixação estereotáxica do modelo animal. A imagem demonstra o posicionamento correto da cabeça no aparelho estereotáxico, evidenciando a fixação bilateral e simétrica através das barras auriculares inseridas nos canais auditivos externos.

Para a proteção ocular, é aplicada uma gota de NaCl em cada olho do animal, prevenindo o ressecamento da córnea, e um esparadrapo umedecido com NaCl é posicionado sobre os olhos durante toda a cirurgia. A temperatura corporal é monitorada continuamente por meio de termômetro retal, inserido com o auxílio de gel lubrificante íntimo.

Uma vez posicionado o animal no aparelho estereotáxico, é realizada a seguinte sequência padronizada de etapas: (1) limpeza da região do escalpo com solução degermante; (2) preparo da pele com solução antisséptica; (3) aplicação de uma dose de lidocaína diluída em NaCl, para anestesia local complementar; (4) abertura da pele com lâmina de bisturi; e (5), quando necessário, uso de água oxigenada para limpeza e hemostasia local, em casos de sangramento mais intenso. Ao longo de todo o procedimento, mantêm-se disponíveis NaCl, esparadrapos e swabs para conter eventuais sangramentos, conforme representado na Figura 4 abaixo.

Fig. 4: Etapa cronológica e sequencial de preparação para o início do procedimento cirúrgico.

C. Implante da Cânula e Infusão Viral

Ao todo, 28 ratos foram submetidos aos procedimentos cirúrgicos. Desses, 13 animais foram submetidos a uma cirurgia combinada, na qual o implante da cânula e a infusão do vetor viral foram realizados na mesma sessão cirúrgica, enquanto os 15 animais restantes foram submetidos a duas cirurgias separadas, uma exclusivamente para a infusão viral e outra, realizada posteriormente, para o implante da cânula de fibra óptica.

Após a exposição da superfície craniana, os pontos anatômicos de referência, bregma e lambda, são identificados e utilizados para verificar o nivelamento do crânio e para o cálculo das coordenadas estereotáxicas (anteroposterior, mediolateral e dorsoventral) relativas ao bregma, como apresentado na Figura 5 abaixo. A partir das coordenadas calculadas, é realizada a perfuração craniana com broca odontológica, tomando-se cuidado para preservar a integridade da duramáter.

Fig. 5: Alinhamento do crânio para o posicionamento correto da cabeça com o equipamento suporte de alinhamento.

Com o crânio já exposto e nivelado, o direcionamento das coordenadas no aparelho estereotáxico é realizado por meio do software NeuroStar, seguindo a sequência: *Set Bregma* (definição do bregma como ponto de origem) $\rightarrow$ inserção dos valores de AP e ML desejados $\rightarrow$ *Go To* (comando que desloca o braço do equipamento até a posição definida). Uma vez direcionadas as marcações de acordo com a coordenada desejada, são fixados dois parafusos na porção posterior do crânio, que auxiliam na sustentação das cânulas, necessários pois a superfície craniana do animal é lisa. Esses parafusos são posicionados sempre abaixo das cânulas, nunca sobre as suturas cranianas, a fim de evitar sangramentos desnecessários. Ao longo de toda a cirurgia, desde o seu início, os sinais vitais do animal são monitorados a cada 20 minutos.

Foram conduzidos dois experimentos independentes: (1) infusões virais intra-NAc e (2) infusões virais intra-HPCd. No primeiro experimento, foi realizada cirurgia estereotáxica para infusão bilateral do vetor viral contendo opsinas inibitórias AAV-EF1a-NpHR3.0-EYFP (VectorLabs) no núcleo accumbens (NAc), nas coordenadas em relação ao bregma (bregma = 0): AP $+1,4$ mm, ML $\pm 1,4$ mm e DV $-6,8$ mm. Para o posicionamento da agulha, a descida foi realizada gradualmente, em velocidade de 100 μm a cada 10 segundos, até atingir a profundidade determinada. O vírus foi então administrado com seringa Hamilton de 1 μL, a uma taxa de infusão de $0,2$ μL/min, com volume total de $0,5$ μL por hemisfério, conforme ilustrado na Figura 6. Ao final da infusão, a agulha permaneceu no local por 5 minutos, a fim de favorecer a difusão do vetor viral e minimizar o refluxo pelo trajeto da agulha, sendo então removida lentamente. O procedimento foi finalizado com sutura do tecido.

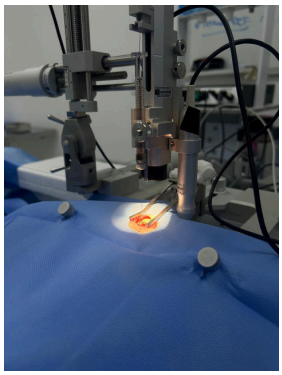

Fig. 6: Infusão do vírus por meio da seringa Hamiltin de 1 μL.

Três semanas após a infusão viral no NAc, foram implantadas bilateralmente cânulas de fibra óptica, com deslocamento das coordenadas para ML $\pm 1,6$ mm, AP $= 0$, em um ângulo de 10°, e DV $-6,9$ mm, permitindo a estimulação optogenética dos terminais axonais. Após o posicionamento, foi utilizada resina dental para manter a cânula fixada no local, complementando a fixação com o parafuso previamente instalado. Em seguida, a janela craniana é fechada com pontos de sutura, deixando a cânula exposta na parte externa da cabeça do animal. Ao término do procedimento, a concentração de isoflurano é reduzida gradualmente, permitindo que o animal desperte de forma lenta e controlada.

D. Cuidados Pós-Operatórios

Após os procedimentos cirúrgicos de implante da cânula ou fibra óptica, os animais foram alojados individualmente por uma semana, a fim de garantir a recuperação pós-cirúrgica e evitar lesões decorrentes de interação social. A analgesia pós-operatória foi realizada com meloxicam na dosagem de $0,5$ mg/kg. A primeira alimentação oferecida após a cirurgia foi umedecida, a fim de facilitar a hidratação, a deglutição e a mastigação do animal durante a fase inicial de recuperação. Todos os procedimentos de manipulação animal, incluindo os cuidados pós-operatórios, ocorreram exclusivamente durante o ciclo claro, entre 8 e 17 horas, minimizando o estresse associado à manipulação fora do período de atividade natural dos animais.

Após o período de uma semana de recuperação, os animais permaneceram com as fibras implantadas até o final do protocolo experimental e foram gradualmente habituados à estimulação optogenética, conectados ao estimulador, sem anestesia, com movimento livre em aparato de campo aberto e no aparato comportamental utilizado para o estudo de memórias instrumentais, antes do início efetivo dos experimentos.

RESULTADOS

Em síntese, 28 ratos *Wistar* foram submetidos aos procedimentos cirúrgicos descritos no protocolo, dos quais 13 animais (46,4%) foram submetidos à cirurgia combinada (implante de cânula e infusão viral na mesma sessão) e 15 animais (53,6%) foram submetidos a duas cirurgias separadas (infusão viral e, posteriormente, implante de cânula).

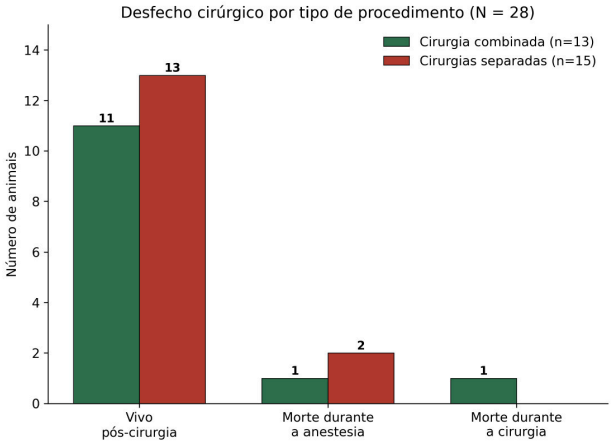
Do total da amostra, 24 animais (85,7%) sobreviveram ao procedimento cirúrgico, enquanto 4 animais (14,3%) foram a óbito, 3 (10,7%) durante a indução ou manutenção anestésica e 1 (3,6%) durante o próprio ato cirúrgico.

A taxa de sobrevivência foi semelhante entre os dois grupos:

- **Grupo submetido à cirurgia combinada ($n = 13$):** 11 animais (84,6%) sobreviveram, com 1 óbito por complicação anestésica (7,7%) e 1 óbito durante a cirurgia (7,7%);
- **Grupo submetido a cirurgias separadas ($n = 15$):** 13 animais (86,7%) sobreviveram, com 2 óbitos por complicação anestésica (13,3%) e nenhum óbito durante o ato cirúrgico propriamente dito.

Não houve, portanto, diferença expressiva na taxa de sobrevivência entre as duas abordagens cirúrgicas, embora a maior parte dos óbitos em ambos os grupos tenha ocorrido durante a fase anestésica, e não durante a manipulação cirúrgica em si, achado que reforça a importância do monitoramento contínuo dos parâmetros fisiológicos (oximetria, temperatura retal e frequência cardíaca) descrito na seção de metodologia.

A distribuição dos desfechos por tipo de procedimento está representada na Figura 7 abaixo.



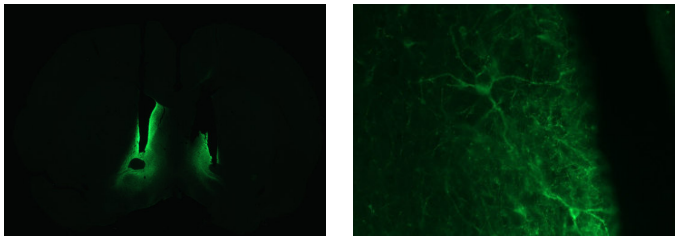


Fig. 7: Número de animais por desfecho cirúrgico (vivo pós-cirurgia, morte durante a anestesia ou morte durante a cirurgia), comparando o grupo submetido à cirurgia combinada (n = 13) e o grupo submetido a cirurgias separadas (n = 15).

Apesar da taxa de sobrevida similar, a avaliação técnica e operacional evidenciou vantagens expressivas da cirurgia combinada frente às intervenções separadas. O procedimento combinado apresentou um tempo cirúrgico médio de $204{,}09 \pm 21{,}38$ minutos ($SEM = 6{,}45$ min; intervalo de 160 a 234 minutos) em sessão única. Essa abordagem eliminou a necessidade de um segundo procedimento cirúrgico, dispensando uma nova montagem de campo estéril, nova indução anestésica e recalibração completa das coordenadas estereotáxicas em dias distintos. Além disso, a intervenção única reduziu o estresse tecidual cumulativo ao evitar a reabertura cirúrgica e a manipulação sobre tecido cicatricial craniano, concentrando o período inflamatório e de analgesia pós-operatória em uma única janela de recuperação.

Para validar o sucesso técnico e a precisão neuroanatômica do POP, os encéfalos dos animais sobreviventes foram submetidos à análise histológica pós-experimento por microscopia de fluorescência. A análise dos cortes coronais confirmou a acurácia estereotáxica do procedimento, evidenciando o trajeto de penetração e a terminação da cânula e agulha de infusão centrados nas coordenadas planejadas para o núcleo accumbens (NAc; AP +1,4 mm; ML ±1,4 mm; DV -6,8 mm), sem desvios laterais acentuados ou hemorragias ventriculares extensas.

Conforme ilustrado na Figura 8a, observa-se uma área de fluorescência bilateral compatível com o halo de difusão de 0,5 µL do vetor AAV-EF1a-NpHR3.0-EYFP restrito à citoarquitetura do NAc. Em aumento de 40× (Figura 8b), constatou-se transdução neuronal robusta e integrada, marcada pela fluorescência na membrana somática e ramificações dendríticas/axonais, demonstrando viabilidade celular e ausência de necrose focal excessiva no sítio de infusão. Esses achados confirmam que o protocolo padronizado não apenas preserva a sobrevida dos animais, mas atinge acurácia estereotáxica satisfatória e expressão gênica funcional no alvo de interesse.

(a) (b)

Fig. 8: Confirmação histológica do posicionamento e expressão viral no núcleo accumbens (NAc). (a) Corte coronal em aumento de 5× evidenciando o trajeto das cânulas e o halo de infusão do vetor AAV-EF1a-NpHR3.0-EYFP. (b) Fotomicrografia em 40× demonstrando neurônios expressando robustamente o fluoróforo EYFP.

Conclusão

O presente estudo teve como objetivo apresentar e padronizar um Procedimento Operacional Padrão (POP) para a cirurgia estereotáxica de infusão viral e implante de cânula em ratos Wistar, voltado à padronização de etapas até então descritas de forma heterogênea na literatura. A aplicação do protocolo em 28 animais resultou em uma taxa de sobrevivência de 85,7%, com desfechos semelhantes entre as abordagens de cirurgia combinada (84,6%) e cirurgias separadas (86,7%).

A concentração dos óbitos na fase anestésica, e não durante a manipulação cirúrgica propriamente dita, indica que os pontos críticos de atenção do protocolo estão relacionados sobretudo ao ajuste individualizado da anestesia e ao monitoramento fisiológico contínuo, orientando refinamentos futuros no cálculo das doses e no manejo anestésico. A comparação entre as abordagens demonstrou que a cirurgia combinada representa a estratégia metodologicamente superior: com duração média de $204,09 \pm 21,38$ minutos em etapa única, otimiza o tempo total de bancada, diminui o consumo de insumos cirúrgicos e anestésicos, e restringe a dor e o estresse pós-operatório a um único ciclo de recuperação.

Aliada à sobrevida, a confirmação histológica do sítio cirúrgico e da expressão do vetor viral no núcleo accumbens valida o sucesso neuroanatômico e experimental do POP. Dessa forma, o protocolo proposto comprova sua reprodutibilidade e eficiência técnica, oferecendo um guia confiável para estudos de neuromodulação e estimulação optogenética em roedores.

Abstract*—Introduction: Neuropathic pain (NP) is a complex clinical condition that affects approximately 58% of patients with spinal cord injury (SCI) and is often refractory to treatment. In such cases, transcranial direct current stimulation (tDCS) offers a potential alternative to improve symptoms. With this non-invasive neuromodulation modality, therapeutic effects can be enhanced through multiple sessions with short intervals between them; however, this schedule can limit access to and continuity of treatment for this patient population. Remotely supervised tDCS (RS-tDCS) has emerged as a solution, allowing home-based application monitored remotely by a trained professional; it holds promise for modulating central pain pathways and fostering better adherence and continuity of treatment. Given its applicability, individual neurophysiological factors—such as alterations in cortical activity measured by electroencephalography (EEG)—may influence the therapeutic response. Consequently, investigating potential cortical biomarkers could serve not only to characterize pain, but also to predict response to remote NP treatment. Objective: This exploratory study aimed to develop a classifier using supervised machine learning to identify predictive biomarkers within the theta, alpha, and beta frequency bands capable of distinguishing between responders and non-responders to RS-tDCS in individuals with SCI and neuropathic pain. Methodology: The cohort study included 14 participants with chronic neuropathic pain following SCI. The treatment regimen consisted of 20 RS-tDCS sessions (10 active and 10 sham) administered over seven weeks. Analgesic response was assessed using the Numerical Rating Scale (NRS), with a reduction of $\geq$ 1.8 points defining a responder. Resting-state 16-channel EEG was recorded before the intervention. Following preprocessing and Power Spectral Density (PSD) extraction, Linear SVM, RBF SVM, and LDA classifiers were used to predict treatment response based on the alpha band. Results: The mean PSD in the responder group was observed to be higher in the low-alpha frequency range. However, the classification models performed poorly: Linear SVM and LDA achieved only 33% accuracy (F1-score of 0.5), while RBF SVM achieved 16.7%. Confusion matrices revealed that all models struggled to correctly discriminate non-responders. Conclusion: Although RS-tDCS reduced pain intensity in the majority of participants, alpha-band EEG characteristics, when analyzed in isolation, did not demonstrate sufficient predictive accuracy to distinguish responders from non-responders. The limited performance of the classifiers was attributed to the small sample size, class imbalance, and high inter-individual variability in EEG signals. Future studies should utilize larger samples and incorporate additional metrics, such as peak frequency, to develop more robust predictive models.

***Index Terms*—Spinal Cord Injury (SCI), Neuropathic Pain (NP), Transcranial Direct Current Stimulation (tDCS)**

I. Introduction

Spinal cord injury (SCI) is a complex clinical condition associated with multifaceted challenges, including the management of neuropathic pain, resulting from dysfunction of somatosensory system [1]–[3]

The global prevalence of neuropathic pain in SCI is estimated at 58%, often presenting as refractory and difficult to manage [4]. Neuromodulation strategies, such as transcranial direct current stimulation (tDCS), have been employed to modulate pain processing within central pathways [5], [6].

tDCS is a noninvasive technique of cortical modulation that involves the application of anodal stimulation to the primary motor cortex (M1) [7] and has gained popularity because of its ease of application, safety profile, and the fact that side effects are mild and transient [8].

Although tDCS has shown potential for pain management [9], [10], both external and internal factors may contribute to poor treatment response. Poor adherence is an external factor that can be partially addressed through remote supervision (RS), which facilitates home-based tDCS administration [11], [12]. However, less attention has been given to individual neurophysiological factors that may influence RS-tDCS response and limit expected pain-relief outcomes. For example, alterations in cortical activity, assessed by electroencephalography (EEG), have been investigated as potential markers of therapeutic response [9].

EEG allows for the investigation of changes in cortical activity frequency bands and the identification of potential biomarkers linked to neuromodulation responses [13], [14].

This work was supported by the National Council for Scientific and Technological Development (CNPq) through its postgraduate program (Process No. 131182/2026-9).

Thus, identifying electrophysiological characteristics associated with the analgesic response to RS-tDCS can contribute to both understanding the neural mechanisms involved in neuropathic pain treatment and to decisions regarding the continued use of this approach [9], [10].

Studies have shown a tendency for increased low-alpha frequency (8–10 Hz) in patients with neuropathic pain, whereas high-alpha activity typically exhibits the opposite pattern [13]. Given this potential correlation between pain and alterations in this alpha-frequency sub-band, alpha activity may serve as a significant biomarker for characterizing neuropathic pain and predicting treatment response.

Consequently, machine learning-based methods are required to identify complex EEG patterns capable of predicting which individuals might achieve effective outcomes with RS-tDCS for neuropathic pain. In this context, this exploratory study aimed to develop a classifier using supervised machine learning to identify potential predictive biomarkers within the theta, alpha, and beta frequency bands able to distinguishing individuals with SCI between responders and non-responders to RS-tDCS based on the reduction in pain intensity in a protocol to management neuropathic pain.

II. Methods

A. Study type and ethical aspects

This cohort study was conducted using a non-public database derived from a single-group quasi-experimental study previously approved by the Research Ethics Committee of the Santos Dumont Institute (ISD) under the registration number CAAE 69887123.8.0000.0129.

B. Participants and clinical information

The data set consisted of 14 participants with neuropathic pain after SCI. The sample was recruited by convenience sampling from a list of users at rehabilitation centers located in the 7th Health Region of Rio Grande do Norte, Brazil, between October 2024 and January 2026. The eligibility criteria were as follows:

- Inclusion criteria: individuals of both sexes (aged over 18 years) diagnosed with chronic neuropathic pain—defined as a score of ≥ 4 on the Douleur Neuropathique 4 questions (DN4) scale—located at or below the level of the SCI (classified according to the International Standards for Neurological Classification of Spinal Cord Injury - ISNCSCI); pain intensity of at least 4 out of 10 on the Numeric Rating Scale (NRS); not currently undergoing pharmacological treatment or, if undergoing treatment, maintaining a stable therapeutic regimen for at least two weeks before the study start; access to the internet and basic proficiency with digital tools (smartphone, computer, and/or tablet, provided at no cost or personally owned); and having a companion or caregiver who commits to being present at all stages of the study.
- Exclusion criteria: individuals with severe pain of non-neuropathic origin (NRS ≥ 7 with high interference in daily activities); intolerance to the target tDCS current of 2mA during the in-person training period (NRS ≥ 7 regarding equipment tolerance); alcohol or other substance abuse; history of traumatic brain injury with residual sequelae; pregnancy or breastfeeding; epilepsy; metallic implants in the head and/or neck; use of a pacemaker; compromised skin integrity at or near the current application site; changes to pharmacological treatment during the study; and inability to adhere to the pre-established data collection schedule.

C. RS-tDCS treatment with remote supervision protocol

Individuals with neuropathic pain underwent intensive treatment lasting seven weeks, comprising 20 sessions of RS-tDCS: 10 sessions of sham RS-tDCS and 10 sessions of active RS-tDCS. To ensure safe administration of tDCS in the home environment, in-person training was conducted with participants and caregivers during the first week of intensive treatment. Participants were assessed using NRS and EEG before intervention (Assessment 1 - A1), post-sham (Assessment 3 - A3), and post-active RS-tDCS. The change in NRS scores was calculated as the delta (Δ) between post-treatment (A3) and pre-treatment (A1) scores ($\Delta\text{NRS} = \text{A3} - \text{A1}$). For the prediction model to explore responders and non-responders to RS-tDCS, only data from the A1 assessment were used.

D. Outcomes measures

- Numerical rating scale: Participants were considered RS-tDCS responders if they demonstrated a satisfactory analgesic effect, defined as a reduction in neuropathic pain intensity equal to or greater than the minimal clinically important difference (MCID) for the NRS in the SCI population (a reduction of ≥ 1.8 points) [15] at A3 when compared to A1.

- Electroencephalography (EEG): Brain rhythms were assessed using a 16-channel EEG connected to the V-Amp system (Brain Products), with wet adhesive electrodes (actiCAP Xpress, Brain Products) positioned according to the international 10-20 system over the FP1, FP2, F3, F4, FC1, FC2, C4, C3, Cz, CP2, CP1, P4, Pz, P3, O2, and O1 regions. The EEG electrodes were attached to the scalp by applying conductive gel at each electrode site, following prior cleansing of the scalp with alcohol and abrasive gel. Impedance was maintained below 10 kΩ, and the sampling rate was set at 512 Hz. The protocol included recording resting-state EEG with eyes open for a period of 2 minutes.

E. Signal Preprocessing

The EEG data were band-pass filtered within the 4–35 Hz frequency range, and a 60 Hz notch filter was applied to remove low-frequency components and high-frequency noise. Subsequently, spatial filtering was performed using the Common Average Reference (CAR) method, which involves calculating the average across all channels and subtracting the

mean from the signal at each electrode at every time point, thereby generating a re-referenced EEG signal.

The frequency bands of interest were theta (4–7 Hz), alpha (8–12 Hz), and beta (13–30 Hz) [16]. A 10-second windowing process was applied; the first two windows were discarded to account for the EEG stabilization period, and the final window was removed to standardize the data duration. Next, Welch's method was applied using 1-second Hamming windows with 50% overlap. Finally, Power Spectral Density (PSD) curves were extracted by averaging the windowed data from both groups—responders and non-responders—across the three target frequency bands.

F. Prediction model

After extracting features from the theta, alpha, and beta bands for each window, a matrix representing the subjects' averages was constructed for each subject. In this matrix, features from all windows belonging to the same individual were grouped, and the mean value for each feature was determined. Consequently, each row of the matrix represented a subject, while the columns represented the frequency power values for all analyzed channels. After this analysis, only the low-alpha and high-alpha bands were considered for the processing stage of the prediction model, since these frequencies showed the greatest potential to differentiate between responders and non-responders.

Next, the subjects were divided into a training group comprising four randomly selected responders and four non-responders and a test group consisting of the remaining subjects. Before the classifier training began, the data, newly split into training and test sets, passed through the StandardScaler to prevent data leakage.

Three types of classifiers were employed: Linear Support Vector Machine (SVM), Radial Basis Function (RBF) SVM, and Linear Discriminant Analysis (LDA); the performance of each classifier was evaluated using accuracy and F1-score.

Finally, confusion matrices were generated for each classifier, allowing for distinction between true positives, true negatives, false positives, and false negatives.

III. Results

Fourteen participants (11 men and 3 women), with a mean age of 45.7 years, were included in the study. Of these 14 participants, 9 were classified as responders to RS-tDCS, and 5 were classified as non-responders (Figure 1). A summary of the participant demographics is presented in Table I.

A. Global PSD characteristics during resting-state EEG differed between responders and non-responders

We observed that mean PSD in the responder group was higher than in the non-responder group in the Low Alpha frequency (Figure 2) at A1. Mean PSD values in the High Theta and High Beta frequencies were also slightly higher for responders, although the difference was not as pronounced as that observed in the Alpha band. Based on this result, to confirm that the Low Alpha frequency can serve as a biomarker for individuals likely to respond positively to RS-tDCS for NP, we used three classifiers: linear SVM, SVM RBF, and LDA.

B. Associating EEG cortical activity as a predictive model of responders or non-responders to RS-tDCS

Among the classifiers trained using the subject-average model, the Linear SVM and LDA achieved the best results, with 33% accuracy and an F1-score of 0.5 for both (Table II). The RBF SVM achieved 16.7% accuracy and an F1-score of 0.28. These values indicate that, when analyzed in isolation, the features extracted from the alpha band were insufficient to discriminate between responders and non-responders.

The confusion matrix for the three classifiers presented in figure 3 showed that all models struggled to discriminate non-responders, as they misclassified data belonging to this group. Regarding the responder group, the Linear SVM and LDA classifiers correctly identified two out of five subjects, whereas the RBF SVM correctly identified only one.

IV. Discussion

We found that RS-tDCS is able to reduce the neuropathic pain intensity in most investigated participants, but unfortu-

TABLE II
COMPARISON BETWEEN THE CLASSIFIERS

Classifier	Accuracy	F1-score
SVM Linear	0.333	0.500
SVM RBF	0.167	0.286
LDA	0.333	0.500

nately the EEG features did not demonstrate sufficient predictive accuracy to distinguish between responders and non-responders to RS-tDCS for NP treatment.

Identifying patterns in cortical activity could contribute to the personalization of interventions, thereby increasing the precision and efficacy of neuromodulation treatment [10]. In this context, machine learning techniques have shown promise in recognizing patterns and identifying biomarkers capable of predicting protocol success based on each patient's individual neurophysiological characteristics.

According to Mussigmann et al. (2022) [13], one of the most consistent biomarkers for neuropathic pain in the literature is a Peak Frequency Shift (PFS) within the theta-alpha bands (4–12 Hz), characterized by a "slowing" of the alpha rhythm. This shift occurs when the brain, instead of oscillating at the normal (faster) alpha rhythm, begins to oscillate predominantly at slower frequencies (theta and low alpha), which is considered a hallmark of thalamocortical dysrhythmia, a process that involves a disruption of the harmony between the brain and the thalamus. This alters brain oscillation patterns and contributes to changes in pain perception. Studies have also observed a possible association between neuropathic pain and reduced activity in the upper-alpha and lower-beta bands; however, the relationship between pain intensity and alterations in the alpha band remains controversial [13].

Given this background, the present study investigated the spectral characteristics of the low-alpha frequency band derived from resting-state EEG as potential predictive biomarkers for the RS-tDCS response in individuals with SCI suffering from neuropathic pain. Although exploratory analysis revealed differences in alpha-band PSD between groups, the classification models (linear SVM, RBF SVM, and LDA) performed poorly when analyzing mean PSD values per subject. This

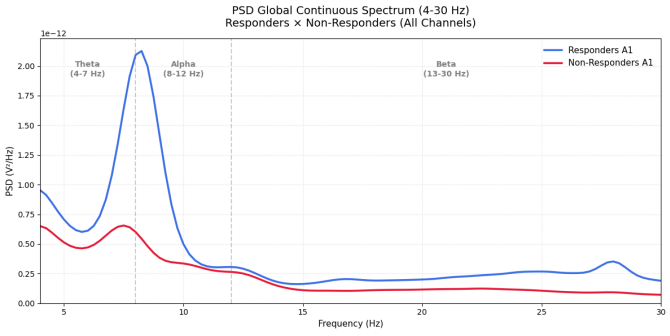

Fig. 2. Power Spectral Density (PSD) global mean for responders (blue) and non-responders (red) in Theta, Alpha and Beta frequencies.

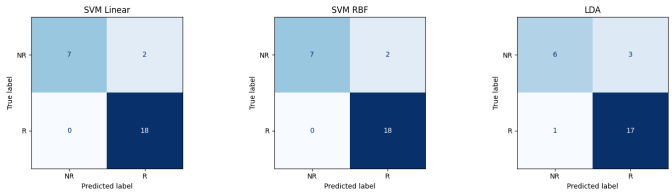

Fig. 3. Confusion matrix. NR, non-responder; R, responder; SVM Linear, Linear Support Vector Machine; RBF SVM, Radial Basis Function Support Vector Machine; LDA, Linear Discriminant Analysis

suggests that, when investigated in isolation, these characteristics were not sufficiently consistent to enable classification between responders and non-responders to tDCS. The linear SVM served as the starting point for the analysis, allowing for the establishment of a performance baseline before testing new classifiers [17]. As a simpler model requiring the tuning of only one hyperparameter—the soft-margin constant (C)—it offers less flexibility and a lower risk of overfitting compared to non-linear SVM models with more tuning parameters, such as RBF. Consequently, the linear SVM classifier is presumed to have outperformed the RBF SVM because the sample's features and classes are predominantly linear.

In addition to SVM, LDA was also employed, which is suitable for data classification and dimensionality reduction. It relies on analyzing between-class and within-class variance to establish a distance that allows for a clear separation between groups to be visualized [18]. When applied to this sample, the model achieved an accuracy similar to that of the Linear SVM (33%), which is below the chance level. Thus, it can be inferred that the features extracted based solely on the alpha-band PSD were insufficient to serve as a predictive biomarker.

Therefore, to develop a more robust predictive model, more complex models that incorporate other features, such as PFS, must be used. Furthermore, it is crucial to utilize a larger dataset with more balanced classes, which would enable classifiers to be trained by considering not only different data features but also each individual's neurophysiological response to neuromodulation, thereby optimizing the models' ability to accurately discriminate between groups.

A. Limitations

The relatively small number of participants constitutes a significant limitation of this study, as it may reduce statistical power and limit the generalizability of the findings. The imbalance between the Responder (9) and Non-responder (5) classes hindered the classifier's ability to identify the smaller group. Given the lack of additional available participants, the results should be considered preliminary and require confirmation in larger, independent cohorts.

Furthermore, EEG datasets often contain multiple segments from the same participant; this can lead to overly optimistic performance estimates if segments from the same individual are included in both the training and testing sets, potentially resulting in data leakage. Therefore, participant-level validation, such as leave-one-subject-out cross-validation or group K-fold,

may be preferable for assessing generalization to participants not included in the classifier's training. In the present study, processing using LOSO was performed (data not shown), and the results indicated significant data leakage. Thus, although other strategies may be more suitable for a more precise analysis of prediction data, the sample size limitation remains an issue that needs to be addressed in future studies.

V. Conclusion

The trained classifiers struggled to distinguish between responders and non-responders due to the small sample size and the high heterogeneity of cortical responses related to neuromodulation. Future studies require a more robust sample, as well as the analysis of new characteristics, such as peak frequency. Therefore, the present analyses do not allow us to determine which frequency bands are specifically involved in the response to treatment for neuropathic pain.

Abstract*—Loss of hand motor function substantially compromises independence and quality of life, making prosthetic and orthotic devices important resources for individuals with amputations, spinal cord injuries, stroke, and neuromuscular disorders. However, conventional myoelectric control depends on the presence of functional residual musculature, which limits its use in these populations. As an alternative, electroencephalography (EEG)-based brain-computer interfaces (BCIs) enable non-invasive detection of movement intention directly from cortical activity. This study presents a low-complexity and accessible EEG-based system capable of controlling an anthropomorphic robotic hand using signals acquired during motor execution and motor imagery tasks. The proposed architecture is organized into two sequential classification stages. The first stage distinguishes rest from motor activity and provides the command used to actuate the robotic hand. The second stage, applied to segments classified as movement, discriminates motor execution from motor imagery using features derived from *Common Spatial Patterns* (CSP) and is evaluated *offline*. In the current processing pipeline, training uses 1 s sliding windows with a 0.1 s step, spatial preprocessing is kept consistent between training and validation, and temporal decision stabilization is applied. In addition to demonstrating robotic-hand actuation, an event-based quantitative evaluation was performed using the LED synchronization channel exclusively as a temporal reference for comparison with classifier output. The first stage achieved an accuracy of 91.08%, whereas the second stage achieved 71.43%. In the event-based evaluation, 26 of 30 activation commands and 28 of 30 return-to-rest commands were detected, corresponding to detection rates of 86.7% and 93.3%, respectively, and an overall detection rate of 90.0%. A total of 61 isolated false positives were recorded, equivalent to 11.6 false positives per minute of recording. Computational latency between data-block availability and classification output had a mean of 128.5 ms, a median of 112.9 ms, and a 95th percentile of 209.8 ms. These results demonstrate the feasibility of the proposed approach while also highlighting the need to reduce false activations and optimize latency for assistive and motor-rehabilitation applications.

***Index Terms*—brain-computer interface, EEG, motor imagery, motor rehabilitation, real-time processing, robotic hand**

I. Introduction

This study presents a real-time EEG-based system for controlling a 3D-printed anthropomorphic robotic hand during ME and MI tasks. Unlike recent BCIs that rely on high-density EEG acquisition and advanced decoding techniques, the proposed framework prioritizes accessibility, lower hardware complexity, and reproducibility by combining a clinical EEG acquisition system with an 11-channel montage based on the international 10-20 system.

The proposed framework combines established preprocessing, feature-extraction, and classification methods in a reproducible two-stage architecture. The first stage distinguishes rest from movement by grouping ME and MI into a single movement class and provides the command used to actuate the robotic hand. The second stage discriminates ME from MI using *Common Spatial Patterns* (CSP), with performance evaluated *offline*. Training is performed using sliding windows synchronized with experimental events, whereas continuous operation uses only EEG data for decision making. Operational performance is additionally evaluated by quantifying command detection, false activations, and computational latency, with the LED synchronization channel used only as a temporal reference for validation and not as an input to the classifier.

This work represents an initial step toward validating the proposed approach; with further testing across diverse conditions and populations, the framework may eventually contribute to rehabilitation programs and to the development of prosthetic and orthotic devices.

The objectives of this study are: (i) to develop and implement a two-stage EEG-based classification architecture capable of distinguishing rest from movement and, subsequently, motor execution from motor imagery, using a reduced 11-channel montage; (ii) to evaluate the *offline* performance of both classification stages; and (iii) to assess the operational feasibility of the system in a real-time (or near-real-time,

sequential-replay) setting by quantifying command detection rates, false activations, and computational latency during control of a 3D-printed robotic hand.

II. Materials and Methods

The development of this study comprised complementary experimental stages. The first stage involved EEG acquisition under three conditions: motor execution (ME), action observation with simultaneous execution, and motor imagery (MI). ME and MI recordings were used to characterize movement related cortical activity and to train the proposed classification model, whereas the action observation and execution condition served as a familiarization stage before the motor imagery task. The system was subsequently used for *online* control of an anthropomorphic robotic hand based on motor activity decoded from EEG. Finally, a complementary quantitative evaluation was performed through sequential replay of an independent recording, preserving block by block processing and using the LED synchronization channel exclusively as a temporal reference for measuring command detection, missed commands, false activations, and computational latency.

Fig. 1 illustrates the overall workflow of the proposed system, from EEG acquisition to real time robotic hand control, and summarizes the methodological stages described in the following sections.

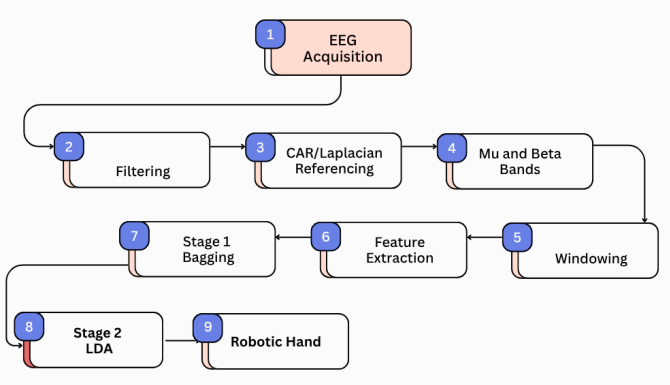

Figure 1. Overview of the proposed methodology, including EEG acquisition, preprocessing, frequency band decomposition, temporal windowing, feature extraction, two stage classification, robotic hand actuation, and event based quantitative evaluation.

A. Participants and Experimental Setting

A total of three healthy male volunteers, aged between 20 and 50 years, were recruited to participate in the experimental procedures. Participants were selected by convenience sampling based on their availability, willingness to participate, and self reported good health. Participation was voluntary.

Before data acquisition, each volunteer received a detailed explanation of the study objectives, experimental procedures, EEG recording protocol, and the tasks that would be performed during the experiment. Participants were given the opportunity to clarify any questions before the beginning of the recordings. After agreeing to participate in the study, all volunteers provided written informed consent by signing the Informed Consent Form. Personal information and participant identities were kept confidential throughout the study, and the data were handled in a manner that preserved participant privacy.

All recording sessions were conducted in a controlled indoor environment. Participants were invited to sit comfortably in a chair and were positioned in a relaxed posture throughout the experiment. The room temperature was controlled to provide stable and comfortable recording conditions. Before each acquisition session, participants were instructed to remain as relaxed as possible, avoid unnecessary body movements, and follow the visual cues presented during the experimental protocol.

EEG data were acquired across multiple recording sessions. In each session, each participant completed three experimental conditions synchronized with a visual stimulus provided by a light emitting diode (LED). The experimental sequence was designed to investigate cortical activity associated with actual hand movement and imagined hand movement while maintaining a standardized timing structure across conditions.

During the first condition, the participant observed and simultaneously performed repeated hand opening and closing movements. During the second condition, the participant observed the same movement while performing motor imagery without physical execution. During the third condition, the participant performed motor imagery without visual observation of the movement.

The first condition involved actual motor execution and therefore provided reference epochs with precisely defined movement periods, allowing characterization of movement related cortical activity. The second condition served as a familiarization and imagery induction stage, allowing participants to associate the observed movement with its mental representation before performing motor imagery without visual guidance during the third condition.

B. EEG Signal Acquisition

EEG signals were acquired at a sampling rate of 500 Hz using an EMSA clinical electroencephalograph. A reduced 11 electrode montage was used, with electrodes positioned according to the international 10–20 system at scalp locations Fp1, Fp2, F3, F4, Fz, C3, C4, Cz, P3, P4, and Pz. The reference electrode was placed on the earlobe, and the ground electrode (GND) was positioned over the mastoid process.

The selected montage covered frontal regions, represented by Fp1, Fp2, F3, F4, and Fz; central sensorimotor regions, represented by C3, C4, and Cz; and parietal regions, represented by P3, P4, and Pz. The central electrodes were selected because of their proximity to cortical areas involved in hand motor control and their relevance for detecting event related desynchronization and synchronization associated with motor execution and motor imagery.

The frontal electrodes were included primarily to support the identification of activity potentially associated with ocular artifacts, whereas the parietal electrodes provided complementary information regarding the spatial distribution of sensori-

motor activity. This configuration was intended to preserve relevant cortical information while maintaining a reduced number of acquisition channels.

Before electrode placement, the participant was positioned comfortably in the chair, and the electrodes were arranged according to the international 10–20 system. After preparation of the EEG montage, signal quality was visually inspected before the beginning of the experimental protocol. Participants were instructed to minimize head, facial, and body movements during the recordings, except for the hand movements explicitly required during the motor execution condition.

Task timing was controlled by an Arduino Uno, which generated a digital signal synchronized with the visual LED stimulus. Logic high (*HIGH*) represented the active task period, whereas logic low (*LOW*) represented the resting period. This digital signal was connected to the FOTO trigger channel of the EEG acquisition system, allowing the onset and offset of each experimental task to be recorded simultaneously with the EEG signals.

The FOTO channel was used exclusively for temporal synchronization and subsequent identification of the experimental events. It was not used as an input feature for the EEG classification models. Therefore, classification decisions were based exclusively on EEG activity.

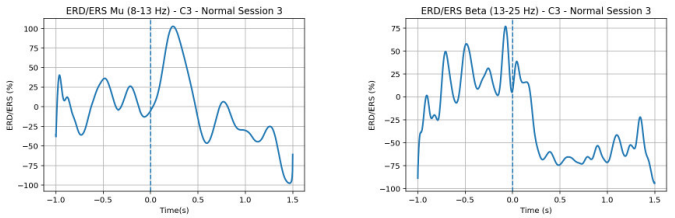
C. Experimental Protocol

Each experimental recording began with an initial resting baseline of 10 s. During this period, the participant remained seated in a relaxed position without performing the task. The baseline was followed by 30 task and rest cycles. Each cycle consisted of 3 s of active task followed by 7 s of rest, resulting in a cycle duration of 10 s.

Considering the initial 10 s resting baseline and the 30 experimental cycles, each condition had a total duration of 310 s, corresponding to 5 min 10 s. The same temporal structure was maintained for all participants and experimental conditions.

Three experimental conditions were performed:

- **Motor execution (ME):** when the LED was turned on, the participant performed a hand closing movement and maintained the hand in the closed position during the 3 s active period. When the LED was turned off, the participant relaxed the hand and returned to the resting state for 7 s.
- **Action observation and execution:** the participant observed a visual demonstration of repeated hand opening and closing movements while simultaneously reproducing the same movement. This condition was used as a familiarization stage to facilitate the association between visual observation, motor execution, and the mental representation of the movement. The data acquired during this condition were inspected as part of the experimental protocol but were not included as a separate class during classifier training.
- **Motor imagery (MI):** when the LED was turned on, the participant was instructed to vividly imagine performing the hand closing movement without producing any voluntary physical movement. During the 3 s active period, the participant maintained attention on the imagined movement. When the LED was turned off, the participant discontinued the imagery task and returned to a relaxed resting state for 7 s.



The same instructions were provided to all participants before each condition to maintain consistency across recording sessions. Participants were reminded to avoid unnecessary movements, facial contractions, excessive blinking, and changes in posture whenever possible because these factors could introduce artifacts into the EEG recordings.

The synchronization signal generated by the Arduino Uno enabled precise temporal alignment between the experimental protocol and the EEG recordings. The transition from *LOW* to *HIGH* indicated the beginning of each active period, whereas the transition from *HIGH* to *LOW* indicated the return to the resting period. These temporal markers were subsequently used to segment the EEG signals and identify the corresponding periods of motor execution, motor imagery, and rest.

For classifier development, recordings obtained during the motor execution and motor imagery conditions were used to generate the EEG segments associated with motor activity and rest. The action observation and execution condition was retained as a familiarization stage and was not treated as an independent classification class. This organization allowed the proposed system to focus on distinguishing resting cortical activity from movement related activity and, subsequently, on discriminating motor execution from motor imagery.

D. Preprocessing

A preliminary ERD/ERS analysis was performed in the mu (8 to 13 Hz) and beta (13 to 25 Hz) frequency bands. As illustrated in Fig. 2 for channel C3, the beta band exhibited desynchronization and synchronization patterns that were more consistent with those reported in the literature for motor tasks [1]. Consequently, subsequent analyses focused primarily on this frequency band, although both bands were retained during feature extraction.

(a) Mu band (8 to 13 Hz) (b) Beta band (13 to 25 Hz)

Figure 2. ERD/ERS relative to the resting baseline in channel C3 for the motor execution and motor imagery conditions. Time $t = 0$ corresponds to the onset of the visual stimulus. Negative values indicate ERD, whereas positive values indicate ERS. The figure illustrates the temporal evolution of the ERD/ERS response and does not correspond to the analysis windows used during classification.

Task timing was recovered from the *trigger* channel, FOTO, by detecting the rising edges of the LED synchronization

signal, which defined the onset of each experimental cycle. The sampling rate was estimated from the median interval between consecutive *triggers*, considering the known 10 s duration of each cycle. For the recordings used in this study, estimated values remained close to 500 Hz.

EEG signals were preprocessed using fourth-order Butterworth filters applied with zero-phase forward and reverse filtering. A 59 to 61 Hz band-stop filter attenuated 60 Hz power-line interference, followed by a 1 to 50 Hz band-pass filter to preserve the frequency range of interest. The signals, originally referenced to the earlobe, were subsequently rereferenced using the common average reference (CAR) and spatially filtered using a surface Laplacian to enhance local activity over the sensorimotor cortex.

Let $v_i[n]$ denote the signal recorded at channel i and sample n. The CAR subtracts from each channel the instantaneous mean across the M recording channels, according to Eq. (1),

$$v_i^{\mathrm{CAR}}[n] = v_i[n] - \frac{1}{M}\sum_{j=1}^{M} v_j[n], \tag{1}$$

thereby attenuating spatially widespread activity common to all electrodes. The surface Laplacian was then applied to emphasize local cortical activity by subtracting the average of neighboring channels, according to Eq. (2),

$$v_i^{\mathrm{LAP}}[n] = v_i^{\mathrm{CAR}}[n] - \frac{1}{|\mathcal{N}_i|}\sum_{j\in\mathcal{N}_i} v_j^{\mathrm{CAR}}[n], \tag{2}$$

where $\mathcal{N}_i$ represents the set of neighboring electrodes associated with channel i, and $|\mathcal{N}_i|$ represents its cardinality. The adopted neighborhood sets are listed in Table I. Although electrodes Fp1, Fp2, P3, P4, and Pz were not used in the subsequent feature-extraction stage, they were retained in the acquisition montage because they contribute to computation of the Laplacian spatial filter.

Table I
NEIGHBORING CHANNEL SETS USED IN THE LAPLACIAN FILTER.

Channel	**Neighbors ($\mathcal{N}_i$)**	$\lvert\mathcal{N}_i\rvert$
F3	Fp1, C3, Fz	3
F4	Fp2, C4, Fz	3
Fz	F3, F4, Cz	3
C3	F3, P3, Cz	3
C4	F4, P4, Cz	3
Cz	Fz, C3, C4, Pz	4

The spatially filtered signals were then decomposed into the mu (8 to 13 Hz) and beta (13 to 25 Hz) frequency bands using band-pass filters.

To quantify the ERD/ERS response, the first 10 s of each recording were adopted as the resting baseline, from which the reference power in each frequency band was estimated using the Hilbert envelope. Let $x_b[n]$ denote the signal filtered in frequency band b, and let $\mathcal{H}\{\cdot\}$ denote the Hilbert transform. Instantaneous power was obtained from the envelope of the corresponding analytic signal according to Eq. (3),

$$P_b[n] = \left|x_b[n] + j\,\mathcal{H}\{x_b[n]\}\right|^2, \tag{3}$$

whereas the ERD/ERS response was calculated as the percentage change relative to the mean baseline power, P_b^{ref}, according to Eq. (4),

$$\mathrm{ERD/ERS}[n] = \frac{P_b[n] - P_b^{\mathrm{ref}}}{P_b^{\mathrm{ref}}} \times 100\%, \tag{4}$$

such that negative values indicate ERD and positive values indicate ERS.

Finally, signal segmentation was performed using 1 s windows with a 0.1 s step. For the movement class, windows were extracted from the interval between 0.5 and 2.0 s after each *trigger* to reduce the influence of the visual response immediately following LED onset and to concentrate the analysis on the period associated with sensorimotor modulation. For the rest class, windows were extracted from the interval between 5 and 7 s after each *trigger*. The same segmentation procedure was used for the motor execution and motor imagery recordings.

E. Sliding-Window Classification

EEG signals were classified in two sequential stages: rest versus movement, followed by ME versus MI. In the first stage, windows from the motor execution and motor imagery conditions were combined into a single movement class and compared with rest windows. In the second stage, only movement windows were used to discriminate motor execution from motor imagery.

The *offline* evaluation was performed using stratified five-fold cross-validation. Because 1 s windows were shifted in 0.1 s steps, consecutive windows had 90% temporal overlap. This characteristic increases the number of available samples but may also introduce dependence between neighboring windows. For this reason, accuracy values obtained with this strategy should be interpreted as a characterization of performance within the available recording set, while event-grouped or session-grouped validation remains important for evaluating generalization under more stringent conditions.

F. Feature Extraction

Different feature sets were adopted for the two decision stages.

For the first stage, rest versus movement, each 1 s window was represented by 11 features extracted from each of the six sensorimotor channels after filtering in the mu and beta bands: root mean square (RMS), variance, mean absolute value (MAV), waveform length (WL), energy, integrated EMG (IEMG), zero crossings (ZC), slope sign changes (SSC), ERD response estimated from the Hilbert envelope relative to the resting baseline, beta-band energy, and the ratio between mu- and beta-band power. Each window was therefore described by a 66-dimensional feature vector (6×11), combining conventional time-domain descriptors with ERD-related spectral features.

For the second stage, feature extraction was based on CSP, calculated independently for the mu and beta bands. Spatial filters were estimated from the mean covariance matrices of the two classes, normalized by their trace. Let X_e denote the data matrix of epoch e. The mean covariance matrix for class c is given by Eq. (5),

$$\Sigma_c = \frac{1}{|\mathcal{E}_c|} \sum_{e \in \mathcal{E}_c} \frac{X_e X_e^\top}{\operatorname{tr}(X_e X_e^\top)}, \qquad c \in \{1, 2\}, \tag{5}$$

and the spatial filters $\mathbf{w}$ were obtained by solving the generalized eigenvalue problem

$$\Sigma_1 \mathbf{w} = \lambda (\Sigma_1 + \Sigma_2) \mathbf{w}, \tag{6}$$

whose eigenvectors associated with the largest and smallest eigenvalues maximize the variance of one class while minimizing that of the other. For each band, the first two and last two spatial filters were retained, resulting in four spatial projections. Log-variance, log-energy, and RMS were extracted from each projected signal, and the features from both bands were concatenated into a single feature vector.

G. Two-Stage Classification

The proposed framework consisted of two sequential classification stages. The first discriminated rest from movement, whereas the second distinguished ME from MI. The classifiers adopted at each stage were selected to balance classification performance and computational efficiency. Computational efficiency was particularly important because the EEG system does not provide direct real-time data transmission. Instead, EEG data are continuously retrieved from a proprietary `.plg` file, introducing an inherent acquisition delay. Therefore, computationally demanding classifiers that could further increase latency and compromise robotic-hand actuation were avoided.

The first stage used a *bagging* ensemble of 200 decision trees, with a maximum depth of 20 levels per tree, whereas the second stage used Linear Discriminant Analysis (LDA) with a least-squares solver and automatic *shrinkage* regularization. Tree depth was limited to control ensemble complexity and reduce computational cost without changing the input feature structure.

LDA assumes that class-conditional feature distributions are Gaussian and share a common covariance matrix Σ. Under this assumption, the discriminant function for class c is given by Eq. (7),

$$\delta_c(\mathbf{x}) = \mathbf{x}^\top \Sigma^{-1} \boldsymbol{\mu}_c - \frac{1}{2} \boldsymbol{\mu}_c^\top \Sigma^{-1} \boldsymbol{\mu}_c + \ln \pi_c, \tag{7}$$

where $\boldsymbol{\mu}_c$ is the class mean vector and π_c is its prior probability. The feature vector $\mathbf{x}$ is assigned to the class that maximizes $\delta_c(\mathbf{x})$.

Although the dimensionality of the feature space was substantially lower than the number of training windows, the 90% temporal overlap between consecutive windows introduced dependence among observations, while some of the extracted features were potentially correlated. These factors can reduce the effective amount of independent information available for covariance estimation and affect the stability of the covariance matrix used by LDA. Therefore, *shrinkage* regularization was applied to improve covariance estimation, numerical stability, and classifier generalization according to Eq. (8),

$$\hat{\Sigma}_\gamma = (1 - \gamma)\hat{\Sigma} + \gamma \frac{\operatorname{tr}(\hat{\Sigma})}{p} \mathbf{I}, \tag{8}$$

where $\hat{\Sigma}$ is the sample covariance matrix, p is the dimensionality of the feature space, and $\mathbf{I}$ is the identity matrix. The *shrinkage* coefficient $\gamma \in [0, 1]$ was estimated automatically using the Ledoit-Wolf method.

LDA was selected because it combines low computational complexity with robust performance and has been widely adopted in EEG-based brain-computer interface applications.

H. Real-Time Operation and 3D-Printed Robotic-Hand Actuation

The trained model was used in continuous operation to control the robotic hand. Inference was performed as new EEG data became available from the acquisition system. After an initial 10 s resting baseline, the signals underwent the same preprocessing used during training, including filtering, common average reference (CAR), spatial Laplacian filtering, and decomposition into the mu and beta bands. First-stage classification was performed on 1 s windows updated every 100 ms.

To improve temporal stability, consecutive decisions were subjected to majority voting. In the configuration used for the quantitative evaluation, the five most recent classifications were considered, and the movement state was assumed when at least three of them indicated movement. This procedure reduces the influence of isolated decisions and makes the output more suitable for controlling a physical end effector.

The hand was controlled by an ESP32 microcontroller, with one SG90 servomotor assigned to each finger. Communication between the computer and the microcontroller was established through a serial interface at 115200 *baud*. The servomotors were powered by an external 5 V, 3 A supply, and a 1000 μF electrolytic capacitor was connected in parallel with the power supply to reduce voltage drops during simultaneous finger movements.

Because the first-stage classifier groups motor execution and motor imagery into a single movement class, both conditions can generate the hand-closing command. The second-stage classifier, responsible for distinguishing motor execution from motor imagery, remained restricted to *offline* evaluation and was not integrated into the actuation loop.

I. Event-Based Quantitative Evaluation

To complement the physical demonstration of the system, a quantitative evaluation was performed through sequential replay of an independent recording in `.ASC` format. Data were supplied to the pipeline in blocks corresponding to approximately 100 ms, preserving the temporal order of the recording and reproducing the logic of continuous acquisition.

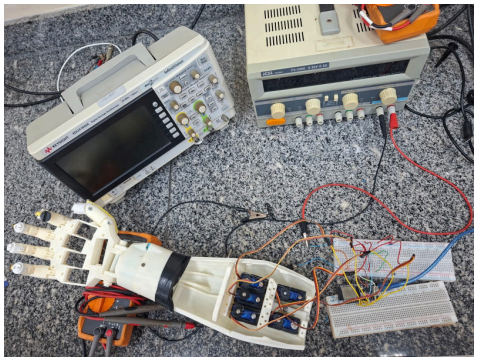


Figure 3. Robotic-hand actuation circuit.

The same preprocessing and the same trained classifier were applied at each update. The first 10 s were used to compute the baseline.

In this evaluation, the FOTO channel was used exclusively as a temporal reference, or *ground truth*, to determine the expected activation and rest periods. The channel was not included in the feature vector and was not provided to the classifier. Thus, the decision continued to be obtained exclusively from EEG signals, whereas the FOTO channel enabled subsequent comparison of the stabilized classifier output with the expected commands.

Each transition to the active LED state was treated as an ON command associated with hand closing, whereas each transition back to the inactive state was treated as an OFF command associated with return to rest and hand opening. For each command type, the total number of events, detected events, and missed events were counted. The detection rate for each condition was calculated as

$$\text{Detection rate} = \frac{N_{\text{detected events}}}{N_{\text{expected events}}} \times 100\%. \tag{9}$$

Episodes of unintended activation outside the expected periods were also counted and reported as isolated false positives. The false-positive rate per minute was calculated relative to the total recording duration,

$$FP/\text{min} = \frac{N_{FP}}{T_{\text{recording}}/60}, \tag{10}$$

where N_{FP} represents the number of false-positive episodes and $T_{\text{recording}}$ is the total duration in seconds. In addition to point estimates, 95% confidence intervals were obtained for the event-detection rates.

Computational latency was measured in each classification cycle as the interval between data-block availability for processing and classifier-output generation. This measure includes preprocessing applied to the available block, feature extraction, standardization, classifier inference, and decision stabilization implemented in the evaluated processing pipeline.

III. Results

A. Offline Classification Performance

The dataset used in the first stage contained 4046 windows, each represented by 66 features. Of these, 2618 windows belonged to the rest class and 1428 to the movement class, corresponding to an approximate class ratio of 1.83:1. For the second stage, 1428 movement windows were used, represented by 24 features after CSP application, including 726 motor-execution windows and 702 motor-imagery windows.

Using stratified five-fold cross-validation, the first classification stage, responsible for distinguishing rest from movement, achieved an accuracy of 91.08%. The second stage, designed to discriminate motor execution from motor imagery, achieved an accuracy of 71.43%. The similar numbers of motor-execution and motor-imagery samples in the second stage reduce the effect of class imbalance in this comparison, whereas the first stage shows a moderate predominance of rest windows.

B. Event-Based Command Detection

In the quantitative evaluation, 30 ON events and 30 OFF events were analyzed, totaling 60 expected state transitions. Among the ON events, 26 were detected and four were missed, resulting in a detection rate of 86.7% and a 95% confidence interval from 74.5% to 98.8%. Among the OFF events, 28 were detected and two were missed, corresponding to a detection rate of 93.3% and a 95% confidence interval from 84.4% to 100.0%.

Considering ON and OFF transitions together, 54 of the 60 expected events were detected, resulting in an overall detection rate of 90.0% and a miss rate of 10.0%. The 95% confidence interval for overall detection ranged from 82.4% to 97.6%. A total of 61 isolated false positives were also recorded throughout the recording, equivalent to 11.6 false positives per minute when normalized by the total recording duration.

Table II
Command-detection performance in the event-based evaluation.

Metric	Value
Expected ON events	30
Detected ON events	26
Missed ON events	4
ON detection rate	86.7%
95% CI for ON detection	[74.5%; 98.8%]
Expected OFF events	30
Detected OFF events	28
Missed OFF events	2
OFF detection rate	93.3%
95% CI for OFF detection	[84.4%; 100.0%]
Overall detection rate	90.0%
Overall miss rate	10.0%
Isolated false positives	61
False positives per minute	11.6

C. Computational Latency

A total of 3045 classifications were performed during sequential replay of the recording used in the quantitative

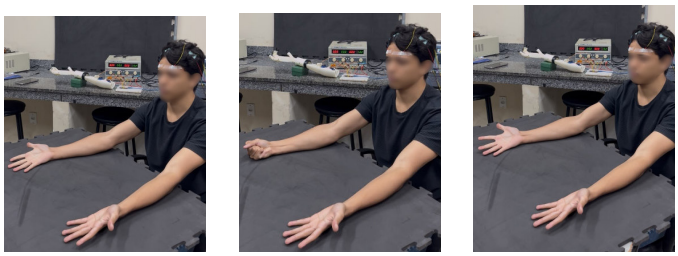
evaluation. Mean computational latency was 128.5 ms, with a median of 112.9 ms and a standard deviation of 44.3 ms. The minimum recorded latency was 81.5 ms, and the maximum was 766.1 ms. The 95th percentile was 209.8 ms, indicating that 95% of processing cycles were completed within this value, whereas the 99th percentile was 274.1 ms.

Table III
COMPUTATIONAL-LATENCY STATISTICS MEASURED BETWEEN DATA-BLOCK AVAILABILITY AND CLASSIFICATION OUTPUT.

Metric	Value
Number of measurements	3045
Mean	128.5 ms
Median	112.9 ms
Standard deviation	44.3 ms
Minimum	81.5 ms
Maximum	766.1 ms
95th percentile	209.8 ms
99th percentile	274.1 ms

The difference between the mean and median, together with the observed maximum value, indicates the presence of processing cycles with execution times above the typical range. For this reason, percentile values provide complementary information to the mean and are particularly useful for characterizing the temporal stability of the pipeline.

D. Real-Time Operation and Robotic-Hand Actuation



During validation with the physical end effector, the system continuously processed EEG data without using the *trigger* as a decision input. After temporal stabilization of the classifications, commands were transmitted to the ESP32, which actuated the five SG90 servomotors. During rest, the robotic hand remained open. During motor execution, identification of the movement class caused the hand to close. During motor imagery, the hand could also close because the first stage groups execution and imagery into the same movement class.

Fig. 4 presents the three states used in the physical demonstration. This demonstration confirms the integration of acquisition, processing, classification, and actuation. However, the quantitative results of the event-based evaluation show that the system response should not be described as invariably correct because missed commands and false activations were observed. The physical demonstration and the quantitative evaluation should therefore be interpreted as complementary assessments.

IV. DISCUSSION

Table IV compares the proposed approach with recent studies on EEG-based BCIs for end-effector control. The comparison should be interpreted as indicative rather than as a direct equivalence among studies because they differ in participant numbers, tasks, channel counts, classifiers, and validation protocols.

The 91.08% accuracy obtained in the first stage demonstrates that the reduced montage and 66-feature set preserve discriminative capability for separating rest from motor activity. This performance is close to the 91.5% reported by Araujo *et al.* [2] for robotic hand-exoskeleton control. These results reinforce the feasibility of using a reduced number of electrodes for motor-state detection, supporting systems with lower instrumentation complexity.

(a) Rest (b) Motor execution (c) Motor imagery

Figure 4. Robotic-hand response under the three evaluated conditions: (a) rest, with the hand open; (b) motor execution; and (c) motor imagery. Both motor conditions are associated with the hand-closing command when the first stage identifies the movement class.

Table IV
COMPARISON WITH STUDIES ON EEG-BASED BCI SYSTEMS WITH END-EFFECTOR ACTUATION.

Study	Channels	Partic.	Task	Acc.
Araujo *et al.* [2]	16	1	Rest *vs.* MI	91.5 %
An *et al.* [3]	16	4	MI (*offline*)	78 %
An *et al.* [3]	16	4	MI (operation)	62 %
Ding *et al.* [4]	128	21	MI, 2 fingers	80.56 %
Ding *et al.* [4]	128	21	MI, 3 fingers	60.61 %
Yong and Menon [5]	N/A	12	Same-limb MI	66.9 %
This work	**11**	**3**	Rest *vs.* mov.	**91.08 %**
This work	**11**	**3**	ME *vs.* MI	**71.43 %**

The second stage achieved an accuracy of 71.43% in discriminating motor execution from motor imagery, which is consistent with results reported for tasks involving related motor states [5], [6]. This classification is inherently more complex because of the overlap between the cortical networks involved and the similarity of ERD patterns in the mu and beta bands [7]. Even approaches using higher electrode density and deep-learning methods face similar challenges [4]. Thus, the obtained results indicate that the proposed architecture can distinguish these states with meaningful performance, while future optimization may support integration of this stage into real-time physical control.

The event-based quantitative evaluation added an important operational perspective to system performance. Of the 30 ON commands, 26 were detected, corresponding to 86.7%, whereas 28 of the 30 OFF commands were recognized, resulting in 93.3%. Considering both conditions, 54 of the 60 expected events were identified, yielding an overall detection rate of 90.0%. These results show that the system recognized most state transitions during continuous operation, with slightly better performance in identifying the return to rest.

Continuous-behavior analysis also identified activation episodes outside the expected intervals. A total of 61 isolated false positives were recorded, corresponding to 11.6 false positives per minute when normalized by total recording

duration. This metric complements the command-detection rate and contributes to a broader characterization of operational stability. Future work should investigate adjustments to temporal voting and state-transition criteria to further improve system response during continuous use.

Computational latency had a mean of 128.5 ms and a median of 112.9 ms, with a 95th percentile of 209.8 ms and a 99th percentile of 274.1 ms. These values indicate that most classifications were completed within short intervals compatible with the proposed continuous-processing framework. The difference between the mean and median, together with the occasional occurrence of higher processing times, suggests that future computational optimization may help make processing more uniform.

Comparison with An *et al.* [3] reinforces the importance of complementing *offline* results with evaluations that more closely reflect continuous operating conditions. In the present study, sequential replay of the recording enabled quantification of event detection and computational latency, whereas physical actuation demonstrated functional integration with the robotic hand. Together, these evaluations provide a broader characterization of system behavior.

Finally, the reduced electrode montage is a relevant feature of the proposed approach because it lowers acquisition complexity without preventing identification of patterns associated with motor activity. Recent studies indicate that appropriate spatial electrode distribution may be more important than simply increasing channel density [3], [4]. Increasing the number of participants and sessions, together with refinement of event detection and temporal response, represents a natural continuation of this work and may help consolidate the proposed system as an accessible alternative for brain-computer interface and motor-rehabilitation applications.

V. Conclusion

This study presented a methodology for EEG acquisition, preprocessing, classification, and application to the control of an anthropomorphic robotic hand using a reduced 11-channel montage based on the international 10-20 system. The architecture was organized into two decision stages. The first distinguished rest from movement and provided the command used for robotic-hand actuation. The second discriminated motor execution from motor imagery using CSP-based features and remained restricted to *offline* evaluation. The current processing pipeline preserved the same filtering and spatial-processing chain between training and validation, used 1 s windows updated every 0.1 s, and incorporated temporal decision stabilization.

The first stage achieved an accuracy of 91.08%, whereas the second achieved 71.43%. In addition to window-based evaluation, the system was analyzed at the event level to assess its ability to recognize state-change commands. A total of 26 of 30 ON events and 28 of 30 OFF events were detected, corresponding to detection rates of 86.7% and 93.3%, respectively. The overall detection rate was 90.0%, with six missed events among the 60 expected events. The analysis also identified 61 isolated false positives, equivalent to 11.6 false positives per minute of recording, showing that reducing unintended activations remains an important requirement for practical applications.

Temporal analysis provided an additional quantitative characterization of the pipeline. Across 3045 classification cycles, mean computational latency was 128.5 ms, with a median of 112.9 ms, a 95th percentile of 209.8 ms, and a 99th percentile of 274.1 ms. These values correspond to the interval between data-block availability and classification-output generation and should not be interpreted as the complete latency from motor intention to physical hand movement. Validation with the robotic end effector demonstrated functional integration among signal processing, decision making, ESP32 communication, and actuation of the five servomotors.

Overall, the results demonstrate the feasibility of an accessible, low-complexity brain-computer interface for translating cortical motor activity into robotic commands while objectively identifying the main aspects that require improvement. Future work should increase the number of participants and sessions, use event-grouped or session-grouped validation, reduce the frequency of false positives, optimize computational cost, measure end-to-end latency from intention to physical actuation, and improve the second classification stage to enable its integration into real-time control and support more specific commands.

Resumo*—A utilização de fatia hipocampal para simular os danos causados no tecido nervoso pelo estado de crise contínua, através da indução das atividades epileptiformes não sinápticas (AENS) in vitro, encontra similaridade com a injúria provocada pelo status epilepticus (SE) em modelos experimentais in vivo. Vários estudos apontam que o SE in vivo pode causar danos neuronais em regiões do sistema límbico, tanto em modelos experimentais quanto em humanos. A utilização do protocolo de zero $Ca2^{+}$ e alto K^{+} para induzir atividades epileptiformes (AE) se constitui, por excelência, em um modelo de atividades ictais que reproduzem o estado tônico-clônico das crises epilépticas. Trata-se, portanto, de um modelo de SE devido ao fato de apresentar recorrência dos eventos ictais em períodos com duração superior a 30 minutos e com potencial de gerar danos celulares similares aos observados nas condições in vivo. Neste trabalho foi avaliada a influência do exercício físico, praticado por ratos Wistar durante o desenvolvimento cerebral, sobre a capacidade de preservação neuronal diante dos danos provocados pela indução de AENS nas fatias hipocampais. Os resultados encontrados neste estudo demonstram que o exercício físico durante o desenvolvimento cerebral proporcionou maior preservação do tecido neuronal da camada granular (CG) do giro dentado (GD) do hipocampo.

***Palavras-chave*—epilepsia; exercício físico; histologia**

I. INTRODUÇÃO

O estado de mal epiléptico ou SE é caracterizado por uma convulsão continua ou convulsões múltiplas com duração acima de 30 minutos, sem recuperação da consciência nos intervalos entre as crises [1]. O SE é uma condição de emergência médica, pois o prolongamento das crises convulsivas pode levar o paciente a sérios prejuízos neurológicos que, além de aumentar o risco de desenvolver epilepsia, pode também levá-lo a óbito [2]. Há uma incidência de SE em torno de 20 para cada 100.000 pessoas e a taxa de mortalidade varia entre 3% a 40% dependendo da etiologia, idade, tipo e duração do SE [3]. Fortes evidências apontam que o SE pode causar danos neuronais principalmente em regiões do sistema límbico, tanto em pacientes humanos quanto em modelos experimentais [4, 5].

A utilização de modelos animais para simular o estado de crise contínua, seja *in vivo* ou *in vitro*, envolve manipulações experimentais nas quais a condição de sustentação prolongada do hipersincronismo resulta em danos neuronais similares aos observados como consequência de um episódio agudo de SE. De acordo com [6] em modelos experimentais *in vivo* de SE, a morte neuronal na CG do GD está associada ao insulto neurológico inicial e não com as crises espontâneas ocorridas após o processo de epileptogênese que segue ao SE.

Nesse sentido, um estudo desenvolvido por [7] constatou a ocorrência de morte neuronal por necrose em diversas regiões do sistema límbico de ratos adultos submetidos a SE induzido por ácido caínico. No referido estudo, os neurônios necróticos apresentaram formação de núcleos picnóticos, condensação de cromatina e DNA em escada [7]. O processo de morte celular induzida por SE é iniciado pela liberação pré-sináptica de glutamato, que é responsável por ativar os receptores NMDA (N-metil-D-aspartato) dos neurônios pós-sinápticos, desencadeando assim um excessivo influxo de Na^{+} e Ca^{2+} e caracterizando um quadro de excitotoxicidade. Essa dinâmica resulta na ativação intracelular de proteases e síntese de óxido nítrico, com geração de radicais livres. Em consequência, observam-se danos nas membranas celulares, na estrutura de proteínas e enzimas essenciais, culminando em necrose celular [8].

Um importante aspecto a ser considerado sobre as condições experimentais do SE *in vitro* é a recorrência de eventos que se assemelham às crises *in vivo*. A utilização de fatias de cérebro são as mais convenientes preparações para o estudo *in vitro*, uma vez que a preservação dos circuitos neuronais inerentes à fatia a torna adequada ao estudo das AE sob condições de controle da hiperexcitabilidade. Um importante aspecto a ser considerado sobre as condições experimentais *in vitro* é a ocorrência cíclica de eventos que se assemelham às crises [9]. Fatias hipocampais perfundidas com fluido cerebroespinhal artificial com alta concentração de potássio podem deflagrar e sustentar por horas e de forma cíclica, disparos de potenciais tipo tônico-clônicos [10]. Esses eventos cíclicos e autorregenerativos, se repetidos por tempo suficiente, tem o potencial de reproduzir o risco de lesão

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

neuronal causado pelo SE *in vivo* [11], fazendo com que a indução de AE persistente no hipocampo se caracterize, de fato, como um modelo *in vitro* de SE. Nesse sentido, desde 1982, manobras experimentais utilizando fatias de hipocampo têm mostrado que AE podem ser geradas na ausência de Ca^{2+} [12, 13]. As AENS registradas no GD, quando induzidas por meio do protocolo de alto K^+ e zero-Ca^{2+}, são caracterizadas por *bursts* espontâneos apresentando período ictal prolongado, variação negativa e lenta da linha de base do potencial extracelular (PE) e a ocorrência de *population spikes* (PS) com grandes amplitudes [14]. O modelo de alto K^+ e zero-Ca^{2+}, utilizando fatias de hipocampo é, por excelência, um modelo de atividades ictais, portanto associadas ao chamado período tônico-clônico das crises de epilepsia. A indução deste tipo de atividade neuronal em fatias de hipocampo se apresenta como uma ferramenta muito importante para o entendimento das possíveis influências promovidas pelo exercício físico.

Investigações têm demonstrado que o exercício físico praticado durante o período de desenvolvimento é capaz de promover plasticidade no hipocampo [15]. Outros estudos mostram que o exercício físico pode ser capaz de proteger o hipocampo contra danos advindos do estresse oxidativo, reduzindo a ocorrência de morte celular [16, 17]. As possíveis mudanças promovidas pela prática regular de exercício físico parecem também estar relacionadas com maior preservação do tecido nervoso. Em pesquisa realizada em nosso grupo, foi demonstrado que a prática de exercício físico favoreceu neurogênese em ratos submetidos a SE, numa situação em que a perda neuronal é sabidamente acentuada [18].

Contudo, o conhecimento dos mecanismos celulares e moleculares pelos quais o exercício físico é capaz de produzir ainda são muito limitados. Tendo isso em vista e, considerando-se a abordagem translacional para a condição humana, uma investigação sobre os benefícios da prática regular de exercício físico frente a um episódio agudo de SE, pode contribuir para o entendimento de como o cérebro de um indivíduo fisicamente ativo pode reagir a um insulto com condições de levá-lo a desenvolver uma desordem neurológica, tal como a epilepsia.

Um estudo recente demonstra que a realização de um protocolo de exercício físico exerce forte influência na frequência e intensidade dos sintomas motores induzidos no modelo experimental *in vivo* [19]. Porém, poucos são os trabalhos que relacionam o efeito que o exercício físico exerce na capacidade do cérebro de resistir aos danos provocados por um episódio agudo de SE [19, 20]. O conhecimento dos mecanismos celulares e moleculares pelos quais o exercício físico é capaz de produzir neuroproteção ainda são muito limitados [21, 22]. No presente trabalho, a indução prolongada de AENS foi utilizada como modelo *in vitro* de SE com o objetivo de verificar a capacidade de preservação da CG do GD em razão do exercício físico durante o desenvolvimento cerebral contra os danos observados nas fatias de hipocampo submetidas ao SE não sináptico *in vitro*.

II. Métodos

A. Animais

O estudo seguiu o protocolo aprovado pela Comissão de Ética em Pesquisa Envolvendo Animais da UFSJ – protocolo 08/2017 (CEUA-UFSJ). Ratos machos da linhagem *Wistar* foram mantidos em condições controladas de luz, temperatura e umidade, com acesso livre à água e comida. Os animais foram submetidos a um protocolo de exercício físico em esteira por 40 dias, iniciando aos 21 dias de idade. Dois grupos foram estabelecidos: o Grupo Controle (Ctrl), que não recebeu exercício, e o Grupo Exercício (Exc), que foi submetido ao programa de exercício físico.

B. Programa de exercício físico

O protocolo de exercício físico seguiu o modelo proposto por [15] consistindo em duas fases: adaptação à esteira e programa de exercício físico. Ambos os grupos, Ctrl e Exc, passaram por familiarização com a esteira por três dias: P21 a P23, com critérios de treinabilidade para inclusão. O programa de exercícios ocorreu dos dias P24 a P60, aumentando gradualmente em duração e intensidade para minimizar o estresse. O grupo Ctrl foi submetido às mesmas condições ambientais que o grupo Exc durante o experimento.

C. Eletrofisiologia - SE in vitro

Os animais foram eutanasiados por decapitação em guilhotina. O hipocampo foi isolado e seccionado em fatias de 400 µm de espessura. Após 40 minutos em uma câmara de perfusão, as fatias foram transferidas para uma câmara de interface para indução das AENS. Os registros do PE foram realizados com eletrodos com fio de prata cloretada, inseridos em pipetas de boro-silicato, preenchidas por 2M de NaCl (5-10 MΩ) e inseridas na CG do GD. O eletrodo foi conectado a uma *head-stage* (Modelo AI 402x50, ULTRALOW NOISE AMPLIFIER – AXON INSTRUMENTS) para aquisição do sinal. Os registros eletrofisiológicos foram realizados no GD em fatias de hipocampo inicialmente mantidas em solução de *Ringer*, com a seguinte composição: NaCl 127mM, KCl 2mM, $MgSO_4$ 1.5 mM, $NaHCO_3$ 26 mM, KH_2PO_4 1.1 mM, glicose 10 mM e $CaCl_2$ 2mM. A indução das AE foi promovida por meio de solução de *Ringer* modificada, com alta concentração de K^+ (8.1 mM) e sem adição de Ca^{2+}, solução capaz de deflagrar AE no GD de fatias de hipocampo de ratos. As soluções foram mantidas sob constante borbulhamento de mistura carbogênica (95% de O_2/ 5% de CO_2) para ajuste do pH em torno de 7.4. Após a indução das AENS o registro era iniciado. A figura 1 ilustra imagens de lesão em tecido neuronal causadas pelo SE *in vivo* e pelo SE *in vitro*.

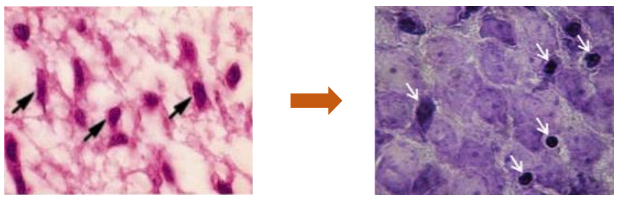

Figura 1 – As duas imagens mostram a formação de núcleos picnóticos (apontadas pelas setas) como resultado da morte celular causada pelo SE tanto no modelo *in vivo* como no modelo *in vitro*. Adaptado de [23].

D. Método de Nissl para análise histológica

Após os registros eletrofisiológicos, as fatias hipocampais utilizadas nos registros (uma fatia por animal) foram coletadas com o intuito de avaliar o perfil histológico de morte celular provocada pelo SE não sináptico *in vitro*. Para isso, as fatias foram acondicionadas em tubos de *Eppendorf* e fixadas em solução de paraformol 4%, temperatura em 4ºC.

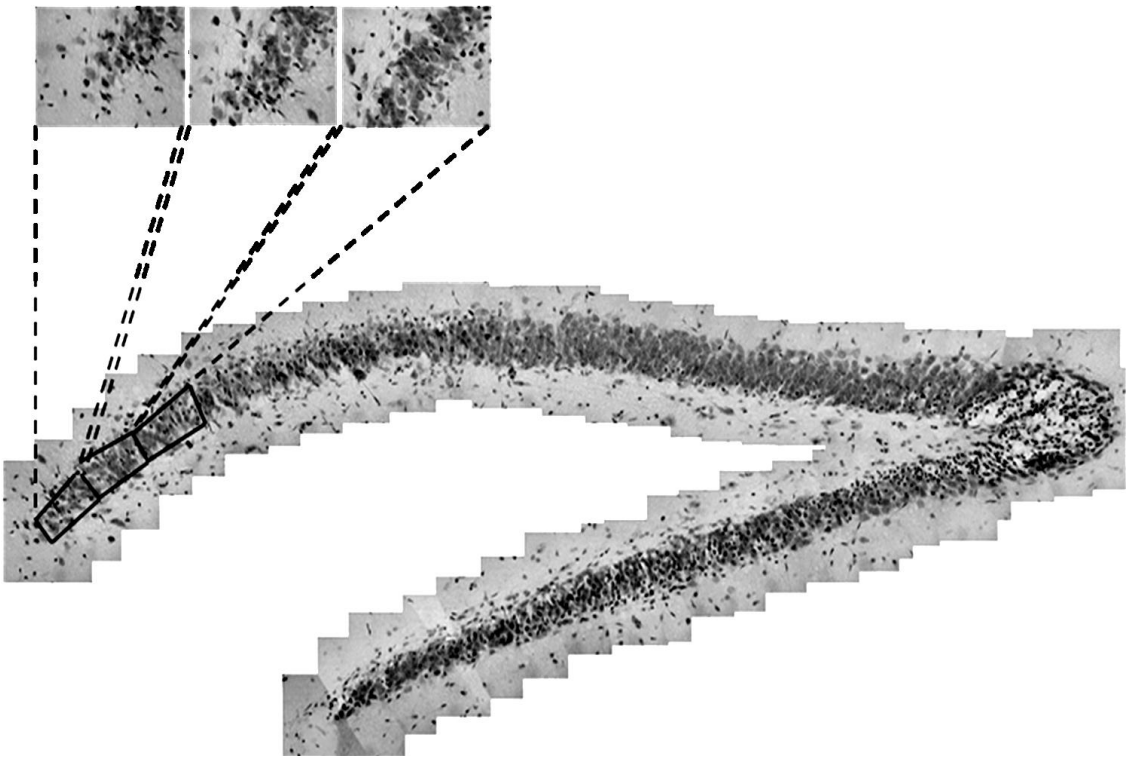

Figura 2 - Marcação de *Nissl* com trechos da camada granular do giro dentado capturados por câmera digital e abaixo a imagem, reconstruída e com a ampliação de 400x utilizada para a quantificação da área preservada.

Após período de duas semanas, as fatias de 400 µm foram resseccionadas em fatias de 15 µm, por meio de um vibrátomo (*Leica* VT 1000S). Para o procedimento de ressecção em fatias de 15 µm foi utilizado um emblocamento em ágar (1,25g de Agar-Agar diluídos em 25 ml de água destilada), com fixação no porta blocos do vibrátomo e imersão em solução salina (9g de NaCl são diluídos em 1000 ml de água destilada) resfriada.

As fatias resseccionadas (6 fatias de 15 µm por animal) foram, então, posicionadas sobre duas lâminas de vidro previamente gelatinizadas (3 fatias por lâmina). Após a montagem das lâminas, estas permaneceram na capela de exaustão (*Sppencer Scientific Equipament*) para secagem e posterior coloração. A figura 2 mostra o resultado da coloração de uma fatia, onde podem ser observados os núcleos celulares.

O método de *Nissl* foi aplicado imergindo-se as lâminas por 5 minutos em água destilada (hidratação) e 35 minutos em violeta de cresila (*Synth*) para coloração. O processo de desidratação consistiu na imersão das lâminas por 2 vezes em álcool 70%, 7 vezes em álcool 95%, 8 vezes em álcool 100%. O processo de diafanização foi concluído imergindo-se as lâminas em solução xilol 1 (1 minuto) e em solução xilol 2 (5 minutos).

E. Quantificação da área preservada

Para cada animal, foi utilizada uma única fatia de 400 µm (uma fatia por animal), da qual foram obtidas seis seções de 15 µm, fixadas em paraformol (4%) e coradas pela técnica de *Nissl.* O valor de área preservada de cada animal correspondeu à média aritmética dos percentuais de área preservada das seis seções analisadas, de modo que cada animal contribuiu com uma única observação independente na análise estatística (N=10 por grupo). Após a fixação das lamínulas com *Entellan* (*Merck*), as lâminas foram levadas ao microscópio (*Axio Scope*.A1 – *Zeiss*), que, acoplado a uma câmera digital (*PowerShot* A650IS, *Canon*), permitiu a captura de partes das imagens da CG com capacidade de ampliação de 400x.

As imagens de toda a área da CG do GD de cada fatia de 15 µm foram reconstruídas utilizando-se um Sistema convencional (*Adobe® Photoshop* CS2, versão 9.0) que integra cada uma das partes capturadas e permite obter uma imagem única de toda a camada, como mostrado na figura 2. Para a realização do cálculo da área preservada das fatias, foi utilizado o método de delimitação das regiões da CG com o auxílio de um Sistema computacional MATLAB®.

Cada imagem montada foi quantificada traçando-se uma poligonal ao redor do GD do hipocampo, conforme a figura 3. O sistema computacional utilizado permitiu estimar a área delimitada pela poligonal, em número de *pixels*. Para fins de normalização, o percentual da área preservada foi calculado em relação à área total da CG do GD de cada fatia. Ela corresponde à extensão de tecido que permaneceu íntegro após a indução do SE não sináptico *in vitro*, de modo que valores mais altos indicam menor dano à camada.

F. Análise estatística

Após a aplicação do teste de normalidade de *Shapiro-Wilk* para verificação de distribuição normal dos dados, procedeu-se à comparação da área preservada total da CG do GD entre os dois grupos experimentais, por meio do teste t de Student não pareado para amostras independentes, sendo o animal a

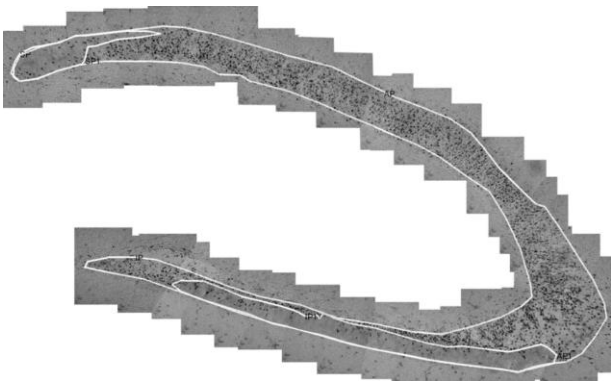

Figura 3 – Representação das poligonais traçadas ao redor das áreas preservadas da CG do GD.

unidade experimental (N=10 por grupo). A análise envolveu uma única variável de desfecho, não havendo necessidade de ajuste para comparações múltiplas. O nível de significância de probabilidade de erro utilizado foi de 5%.

III. Resultados

A. *Validação do protocolo de lesão por SE não sináptico in vitro*

O padrão de lesão observado nas células das fatias de hipocampo submetidas às AENS *in vitro* encontra similaridade ao padrão de lesão observado no SE *in vivo*, conforme mostra a figura 1.

B. *Quantificação celular pela técnica de Nissl*

Utilizando as técnicas de histologia descritas, nosso trabalho investigou a hipótese de que o exercício físico exerce influência benéfica na preservação das células da CG do GD do hipocampo de ratos de fatias submetidas a SE não sináptico *in vitro*. Assim, os cortes histológicos dos hipocampos dos animais dos grupos Ctrl e Exc foram analisados e os valores de área preservada por fatia analisada foram obtidos.

A análise estatística do parâmetro área preservada demonstrou um valor significativamente maior no grupo Exc, quando comparado ao grupo Ctrl (Ctrl: 29.10 ± 13.40 média % área preservada N=10; Exc: 44.04 ± 14.32 % área preservada N=10; t= 2.335; df= 18; p= 0.0313). A diferença média entre os grupos foi de 14,94 pontos percentuais, com IC 95% de 1,50 a 28,38 pontos percentuais.

IV. Discussão

Mesmo com o tempo médio total de duração do SE não sináptico *in vitro* no grupo Exc sendo maior do que o observado no grupo Ctrl medido em [24], a análise estatística apontou para alterações significativas induzidas pelo exercício físico, com o grupo Exc apresentando um perfil de maior preservação do tecido quando comparado com as fatias dos animais do grupo Ctrl (figura 4). Essa evidência mostra que o treinamento na esteira foi capaz de promover neuroproteção, mitigando os danos provocados pelo SE não sináptico *in vitro*. Essa hipótese, defendida na presente investigação, se fundamenta no argumento de que o exercício físico pode exercer influência benéfica simultânea sobre a demanda e o metabolismo energético durante as AENS. Conforme estudo prévio do nosso grupo de pesquisa [24], apesar do maior tempo total de sustentação do SE *in vitro*, a redução na intensidade e duração dos eventos epileptiformes no grupo Exc, tende a favorecer a redução da demanda energética para o reestabelecimento dos gradientes iônicos da célula neuronal. Por outro lado, uma maior demanda das reações oxidativas para liberação de energia, pode favorecer o aumento na produção de espécies reativas ao oxigênio que tem o potencial de degradar a estrutura da Na^+/K^+ ATPase, e comprometendo sua funcionalidade, agravando o quadro de excitabilidade e morte neuronal [25, 26]. Tais mecanismos não foram medidos aqui diretamente, sendo uma hipótese sustentada por evidências apontadas pela literatura científica [24, 25, 26]. Portanto, a potencial redução da demanda

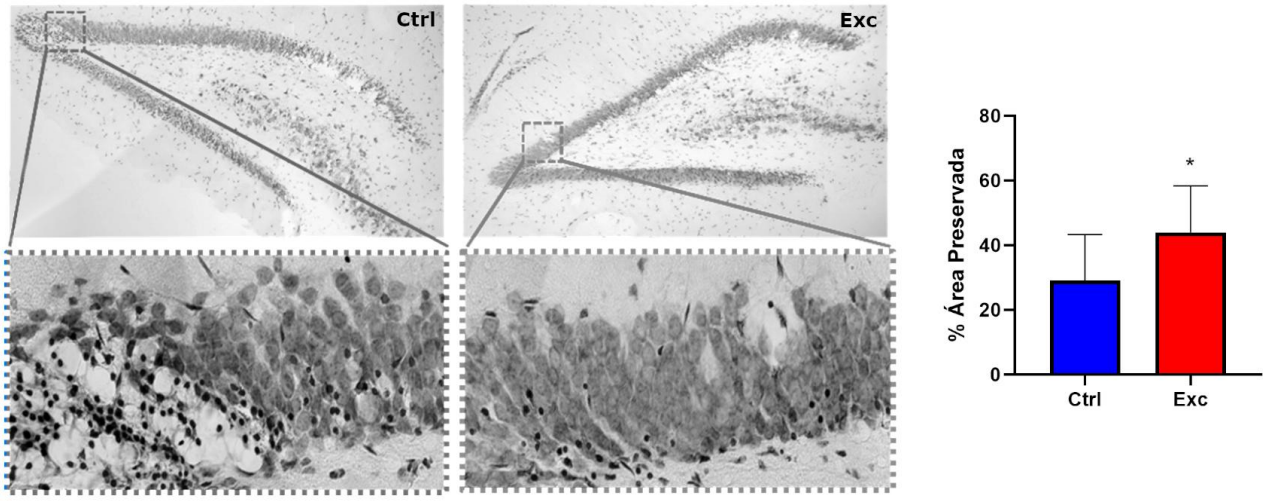

Figura 4 – Aspectos morfológicos da CG do GD dos grupos Ctrl e Exc (coloração pelo método de *Nissl*). As imagens superiores possuem ampliação de 50 vezes e as inferiores possuem ampliação de 400 vezes, destacando células edemaciadas e núcleos picnóticos na região de registro. O asterisco, quando indicado, representa diferença significativa ao nível de 5% pelo teste T não pareado. Os valores dos gráficos estão expressos no formato de media ± erro padrão. Número de amostras por grupo (Ctrl = 10; Exc = 10).

energética requerida nas AENS do grupo Exc durante toda a duração do SE não sináptico *in vitro*, pode ter favorecido uma menor produção de radicais livres nas reações envolvidas na produção de ATP pelas células da CG do GD, concedendo uma maior resiliência ao tecido neuronal quando comparado ao grupo Ctrl (figura 5). Tal condição pode contribuir para a manutenção da funcionalidade de proteínas essenciais, como a Na^+/K^+ ATPase, favorecendo a manutenção da homeostase iônica, aumentando a resiliência do tecido neuronal frente a estados de hiperexcitabilidade sustentada e configurando-se como um potencial mecanismo de neuroproteção em condições experimentais de epilepsia. Nesse sentido, estudos relacionados à formação de reserva neural por meio da atividade física em idade precoce corroboram nossos achados [21]. Segundo [21], essa reserva neural seria capaz de proteger o cérebro contra danos decorrentes do estado sustentado de hiperexcitabilidade do tecido nervoso, como observado durante as crises convulsivas e as AENS.

V. Conclusão

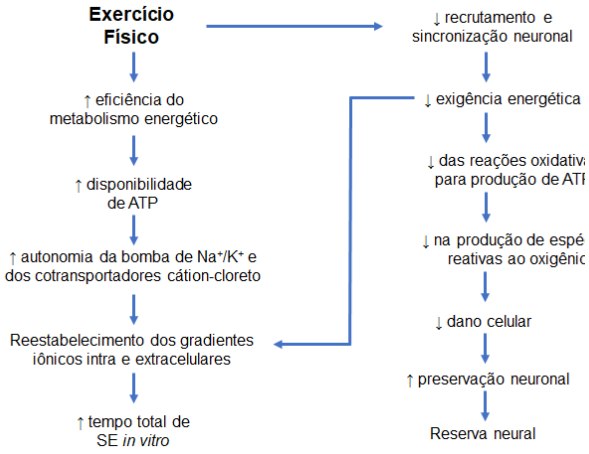

Figura 5 – Representação esquemática da influência do exercício físico na preservação da CG do GD hippocampal.

Estudos posteriores com marcadores complementares de viabilidade celular e correlação entre carga eletrofisiológica e preservação tecidual podem esclarecer de forma mais aprofundada os achados aqui descritos. Contudo, mesmo considerando exclusivamente os dados obtidos por meio da coloração de *Nissl* e o tempo de duração diferente do SE não sináptico in vitro entre os grupos, tomando em conjunto a preservação da camada granular associada ao exercício físico observada em nossos resultados e os achados eletrofisiológicos previamente descritos em [24], observa-se que o exercício físico exerce efeito modulador sobre a dinâmica das AENS e seus impactos sobre a integridade do tecido neuronal no GD, promovendo neuroproteção na região de ocorrência do SE não sináptico *in vitro*.

Agradecimentos

Os autores agradecem à Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), ao Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), à Fundação de Amparo à Pesquisa do Estado de Minas Gerais (FAPEMIG), ao Instituto Federal de Educação, Ciência e Tecnologia de Minas Gerais (IFMG), ao Instituto Federal de Educação, Ciência e Tecnologia do Sudeste de Minas Gerais (IF Sudeste MG), à Universidade Federal de São João del Rei (UFSJ) e à Universidade Federal de São Paulo (UNIFESP) pelo apoio financeiro e institucional.

***Resumo*—Este artigo investiga os efeitos da estimulação vibrotátil na regulação de forças isométricas máximas e submáximas do dedo indicador. O estudo contou com onze voluntários saudáveis que realizaram tarefas de contração voluntária máxima (MVC) e contrações isométricas com fases de rampa e platô a 30% e 45% da MVC, nas condições com e sem estimulação vibrotátil. Nas tarefas submáximas, a realimentação visual da força produzida foi retirada após os 2 segundos iniciais da rampa, enquanto a força-alvo permaneceu visível. Na amostra analisada até o momento, não foi detectada diferença significativa na força máxima entre as condições. Por outro lado, para a taxa de incremento da força, foi identificado efeito significativo da estimulação vibrotátil durante a fase de rampa. Já durante o platô, não foram observados efeitos significativos da estimulação sobre a força média ou o coeficiente de variação. Esses resultados fornecem evidências preliminares de que, nas condições avaliadas, a estimulação vibrotátil pode afetar de maneira específica a fase dinâmica de incremento da força, sem alterações significativas nas variáveis analisadas durante a fase de contração isométrica.**

***Palavras-chave*—estimulação vibrotátil, controle motor, variabilidade da força**

I. Introdução

A capacidade de modular e regular a força muscular é essencial para a realização de atividades motoras em diferentes contextos cotidianos. Essa regulação depende de uma complexa integração entre os sistemas sensoriais e motores, sendo continuamente influenciada por mecanismos neurais centrais e periféricos. Como parte desse processo, a atividade do núcleo motor é modulada por diferentes tipos de entradas sensoriais, incluindo estímulos táteis, proprioceptivos e visuais.

Nesse contexto, a informação tátil desempenha um papel essencial na orientação de movimentos precisos. Em especial, a estimulação vibrotátil aplicada à pele ativa receptores cutâneos de adaptação rápida, cujos sinais influenciam diretamente a informação trafegada nos circuitos neurais da medula espinhal, do tronco encefálico e de estruturas corticais. Dessa forma, diversas evidências sugerem que esse tipo de estimulação favorece o recrutamento de unidades motoras [1]–[3], aumenta a excitabilidade motora [4] e promove um ganho de força em contrações isométricas [5], além de atuar na redução da variabilidade da força em contrações de baixa intensidade [6]–[8].

Além da estimulação tátil, a realimentação visual é um fator determinante na modulação do controle motor, pois permite correções e ajustes em tempo real do movimento. Quando esse feedback está ausente, o sistema nervoso enfrenta um desafio maior, o que geralmente altera a variabilidade e aumenta o erro na força produzida [9], [10]. Isso, por sua vez, pode interferir na interpretação dos efeitos de intervenções sensoriais, como a tátil. Diante disso, investigar os efeitos da estimulação vibrotátil, especificamente na ausência de realimentação visual, é fundamental para compreender seu efeito sobre desempenho motor.

Dessa forma, este artigo propõe investigar os efeitos da estimulação vibrotátil na capacidade de geração de força máxima e na regulação de intensidades submáximas em tarefas de contração isométrica, concentrando-se especificamente no comportamento motor sob a ausência de realimentação visual. Com isso, pretende-se contribuir para o entendimento dos mecanismos sensoriais e neurais envolvidos no controle neuromuscular e para o desenvolvimento de estratégias não invasivas de modulação sensório-motora com potencial aplicação em contextos de reabilitação e treinamento.

II. Metodologia

A. Comissão de Ética

O estudo foi conduzido em estrita conformidade com a Resolução 466/2012 do Conselho Nacional de Saúde e recebeu aprovação prévia do Comitê de Ética em Pesquisa da Universidade Estadual de Campinas (UNICAMP) sob o número de CAAE 88364525.6.0000.5404.

Até o estágio atual do desenvolvimento da pesquisa, participaram onze voluntários destros e saudáveis, sendo seis mulheres e cinco homens, com idade média de $26,18 \pm 4,67$ anos e faixa etária entre 19 e 40 anos. Dessa forma, indivíduos que não fossem destros ou que não atendessem aos critérios de saúde não eram elegíveis para participar do estudo. Além disso, para a caracterização da amostra, os participantes também foram questionados sobre histórico de fraturas na mão, prática de atividades esportivas e uso de óculos; essas informações foram registradas, mas não constituíram critérios de exclusão. Por fim, antes do início dos procedimentos, todos receberam orientações sobre a dinâmica das tarefas e assinaram voluntariamente o Termo de Consentimento Livre e Esclarecido.

B. Aparato Experimental

Durante as sessões experimentais, os participantes permaneceram sentados em uma cadeira, em frente a um monitor digital que exibia a força produzida e a força-alvo por meio de um marcador móvel e de uma barra móvel, respectivamente.

Para assegurar o isolamento do movimento voluntário, o antebraço e a mão correspondentes ao lado dominante do voluntário foram devidamente fixados e imobilizados em um dispositivo mecânico especialmente projetado para aprimorar a ergonomia e a experiência geral do usuário (Fig. 1).

A mensuração da força exercida pelo músculo primeiro interósseo dorsal foi realizada por uma célula de carga multiaxial (Nano25, ATI Instruments), cujos sinais analógicos foram digitalizados por um sistema de aquisição de dados multifuncional (USB-6343, National Instruments) sob uma taxa de amostragem de 2000 Hz. Adicionalmente, os sinais de força foram submetidos a uma filtragem digital passa-baixas com frequência de corte em 30 Hz.

O estímulo tátil foi aplicado próximo à articulação metacarpofalângica no dedo indicador por meio de um atuador ressonante linear (C10-100, Precision Microdrives). Este atuador operou em sua frequência de ressonância de 175 Hz e aceleração de 0,9 G, sendo o controle de ativação da vibração gerenciado pela saída do sistema de aquisição de dados multifuncional (USB-6343, National Instruments). Um programa desenvolvido em LabVIEW foi utilizado para controlar as condições experimentais, fornecer a realimentação visual e registrar os sinais de força.

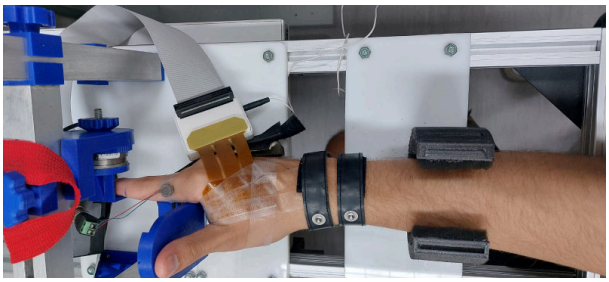

Fig. 1. Aparato Experimental

C. Protocolo Experimental

O protocolo experimental foi estruturado de forma sequencial e iniciou-se obrigatoriamente com a determinação da Força Voluntária Máxima (MVC, do inglês, *maximum voluntary contraction*) de cada participante. Esse parâmetro é fundamental e utilizado como a referência para as etapas subsequentes do experimento. Para o estabelecimento dessa referência, os voluntários realizaram três tentativas de contração isométrica máxima em cada condição experimental: sem vibração (Controle) e com vibração (Vibração). Cada tentativa teve duração de 10 segundos, com intervalo de repouso de 1 minuto entre as repetições. Em cada condição, o maior valor obtido entre as três tentativas foi adotado como a respectiva MVC. Para a normalização das tarefas submáximas, contudo, utilizou-se o maior valor de MVC obtido na condição Controle. Dessa forma, uma única referência foi mantida para ambas as condições, evitando que o uso de diferentes valores de normalização influenciasse a comparação entre Controle e Vibração. A ordem de apresentação das condições foi aleatorizada individualmente para cada participante.

Antes do início das tentativas experimentais, os participantes foram familiarizados com a tarefa de força trapezoidal por meio de dez repetições realizadas com realimentação visual da força produzida e da força-alvo. As repetições incluíram níveis-alvo entre 5% e 70% da MVC, abrangendo as intensidades de 30% e 45% analisadas neste estudo. Durante essa fase, a força produzida e a força-alvo foram apresentadas visualmente, sendo essa trajetória-alvo composta por fases de rampa de subida e descida a uma taxa de 5% MVC/s e por um platô de 15 s.

Em seguida, os participantes realizaram contrações trapezoidais em diferentes intensidades (5%–70% da MVC) com a realimentação visual, cujos resultados não são objeto de análise neste trabalho. Essas etapas foram fundamentais e suficientes para viabilizar a execução da fase experimental sem a realimentação visual.

Na etapa analisada neste estudo, os participantes realizaram contrações nos níveis de 30% e 45% da MVC, calculados exclusivamente a partir da MVC obtida na condição Controle. A trajetória-alvo apresentou taxa de incremento de 5% da MVC/s, sendo a mesma referência utilizada nas condições Controle e Vibração. Nessa fase, a realimentação visual da força produzida foi apresentada apenas nos 2 s iniciais da rampa de subida, enquanto a força-alvo permaneceu visível durante toda a tarefa. Após esse período, os participantes passaram a depender exclusivamente de informações sensório-motoras para continuar o incremento da força e manter o platô o mais estável possível por 15 s. Ao término de cada tentativa, um sinal visual indicava o encerramento da tarefa.

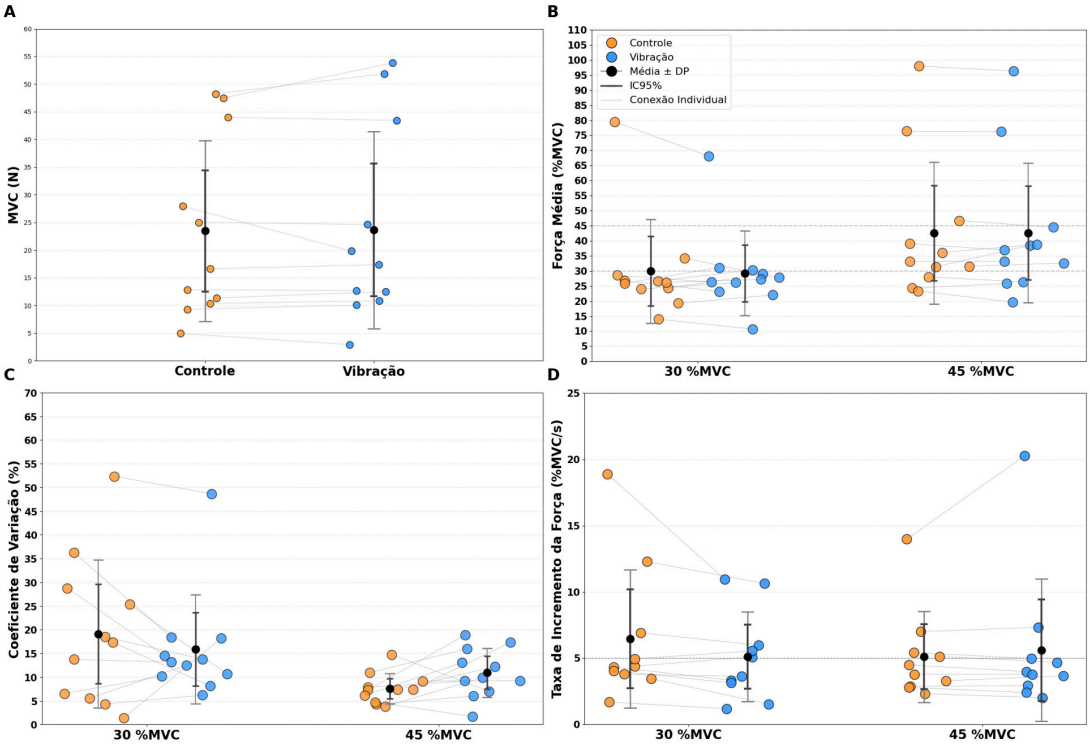

Fig. 2. (A) Força voluntária máxima (MVC) nas condições Controle e Vibração. (B) Força média, (C) coeficiente de variação da força e (D) taxa de incremento da força durante a rampa nas condições Controle e Vibração para as duas intensidades de força-alvo. Os pontos representam os participantes, as linhas conectam os resultados do mesmo participante e os marcadores pretos representam as médias do grupo, acompanhadas das respectivas barras de desvio-padrão e de intervalo de confiança de 95%.

Foram realizadas três repetições para cada combinação entre estimulação (Controle e Vibração) e intensidade de força (30% e 45% da MVC), totalizando doze tentativas por participante. A ordem de execução dessas tentativas foi definida previamente por meio de uma tabela de randomização elaborada em planilha eletrônica, que atribuiu uma sequência individual de apresentação a cada participante. Foi adotado um intervalo de repouso de 1 min entre as tentativas para reduzir possíveis efeitos de fadiga.

D. Análise de Dados

Todos os dados de força coletados foram armazenados digitalmente e processados offline por meio de rotinas e algoritmos desenvolvidos em Python. As variáveis dependentes extraídas para a análise da MVC, a taxa de incremento de força ao longo da rampa após a retirada da realimentação visual, a força média sustentada no platô e a variabilidade da força no platô, medida pelo coeficiente de variação (CoV).

A taxa de incremento de força foi estimada pelo coeficiente angular de uma regressão linear ajustada ao sinal de força durante o período da rampa sem realimentação visual. As variáveis associadas ao platô foram calculadas a partir dos 14 s finais dessa fase, excluindo-se o primeiro segundo de análise devido à presença de efeitos transitórios.

Para a análise estatística, a comparação da MVC entre as condições experimentais foi realizada por meio de uma ANOVA de um fator com medidas repetidas. Já para as variáveis extraídas nas tarefas isométricas sem realimentação visual (força média, CoV e taxa de incremento), empregou-se a ANOVA de medidas repetidas de dois fatores, adotando o estímulo (Controle e Vibração) e a intensidade da força como fatores (30% e 45% MVC). O nível de significância empregado foi de $0{,}05$. Adicionalmente, foi calculado o eta-quadrado parcial (η_p^2) para estimar o tamanho do efeito. Valores entre 0,01 e 0,05 será considerado como efeito pequeno. Entre 0,06 e 0,13 será considerado efeito médio e acima de 0,13 efeito grande. Na Fig. 2, os marcadores pretos representam as médias do grupo, acompanhadas pelas respectivas barras de desvio-padrão e de intervalo de confiança de 95%. Na Tabela I, os resultados são apresentados como média $\pm$ margem do intervalo de confiança de 95%.

III. Resultados

A. Força Máxima Voluntária (MVC)

A Fig. 2A revela uma heterogeneidade entre indivíduos na capacidade de gerar força, com registros variando de 5 a 55 (N), o que justifica o elevado desvio padrão observado na tendência central do grupo. A análise estatística não indicou diferença significativa entre as condições avaliadas ($\eta_p^2 = 0{,}003$, $p = 0{,}875$).

B. Força Média e Coeficiente de Variação

A maioria dos voluntários mostrou-se treinada para realizar a tarefa sem realimentação visual, uma vez que conseguiu

Tabela I

Média ± margem do intervalo de confiança de 95% das variáveis analisadas nas condições Controle e Vibração ($n = 11$).

	30% MVC		45% MVC	
Variável	Controle	Vibração	Controle	Vibração
Força média (%MVC)	$29{,}94 \pm 11{,}57$	$29{,}24 \pm 9{,}43$	$42{,}54 \pm 15{,}82$	$42{,}63 \pm 15{,}53$
CoV da força (%)	$19{,}10 \pm 10{,}49$	$15{,}85 \pm 7{,}73$	$7{,}60 \pm 2{,}14$	$10{,}94 \pm 3{,}48$
Taxa de incremento (%MVC/s)	$6{,}34 \pm 3{,}33$	$5{,}38 \pm 2{,}24$	$5{,}95 \pm 2{,}88$	$6{,}21 \pm 3{,}67$

reproduzir a trajetória de força relativamente bem. Isso é comprovado pelas forças médias próximas ao valor-alvo (Fig. 2B). Ainda assim, observa-se certa dispersão entre os sujeitos, o que revela a dificuldade da tarefa na retirada do auxílio visual. A análise estatística revelou um efeito significativo do fator intensidade da força ($\eta_p^2 = 0{,}341$, $p = 0{,}046$), conforme esperado, mas não do fator estímulo ($\eta_p^2 = 0{,}011$, $p = 0{,}744$), o que demonstra que a aplicação da estimulação vibrotátil não alterou a capacidade do grupo de manter a força média próxima ao alvo. Por fim, a ausência de uma interação significativa entre a força e o estímulo ($\eta_p^2 = 0{,}019$, $p = 0{,}667$) indica que esse comportamento nulo da vibração foi consistente e independente do nível de esforço dos participantes.

Em relação à variabilidade da força, a análise estatística revelou dependência significativa da intensidade de contração ($\eta_p^2 = 0{,}335$, $p = 0{,}048$), mas não da estimulação vibrotátil ($\eta_p^2 < 0{,}001$, $p = 0{,}982$). Da mesma forma, não foi observada interação estatisticamente significativa entre a intensidade de força e a estimulação vibrotátil ($\eta_p^2 = 0{,}293$, $p = 0{,}068$). Entretanto, observa-se, na Fig. 2C, um comportamento com redução do CoV a 30% da MVC e aumento a 45% da MVC na condição de Vibração. O tamanho do efeito foi considerado grande, mas a interação não atingiu significância estatística.

C. Taxa de Incremento

A Fig. 2D evidencia, novamente, elevada variabilidade interindividual, refletida pelos amplos desvios-padrão observados. Esse comportamento sugere diferentes níveis de controle motor entre os participantes ao executarem uma tarefa desafiadora e fortemente dependente da percepção sensório-motora. A análise estatística revelou efeito significativo do fator estímulo ($\eta_p^2 = 0{,}352$, $p = 0{,}042$), mas não da intensidade de força ($\eta_p^2 = 0{,}006$, $p = 0{,}809$). Esse resultado é consistente com o fato de que a taxa de incremento da força-alvo foi mantida constante entre as condições de 30% e 45% da MVC, além dos participantes não terem conhecimento prévio da intensidade-alvo a ser executada. Adicionalmente, a ausência de interação entre os fatores estímulo e intensidade de força ($\eta_p^2 = 0{,}068$, $p = 0{,}413$) indica que o efeito da vibração sobre a taxa de incremento da força foi semelhante nos dois níveis de esforço avaliados.

IV. Discussão

Na amostra analisada, não foi detectada diferença significativa na MVC entre as condições Controle e Vibração. Esse resultado indica ausência de evidência de alteração da força máxima nas condições avaliadas, mas não permite concluir sobre recrutamento ou frequência de disparo das unidades motoras.

Por outro lado, nas tarefas submáximas, o protocolo incluiu uma fase dinâmica de incremento de força (rampa de 5% MVC/s), durante a qual a remoção da realimentação visual associada à aplicação do estímulo vibrotátil reduziu significativamente a taxa de incremento da força. A realimentação visual é reconhecidamente um fator importante para os ajustes motores em tempo real, e sua ausência tende a comprometer a precisão do controle motor e a produção de força [9], [10]. Os resultados obtidos indicam que, nas condições experimentais avaliadas, a presença da estimulação vibrotátil esteve associada a uma menor taxa de incremento da força. Esse achado sugere que a vibração pode influenciar mecanismos sensoriais envolvidos na estimativa da força produzida, levando os participantes a adotar uma estratégia motora mais conservadora à medida que a força aumenta. Entretanto, a possibilidade de a vibração ter influenciado a percepção da força produzida permanece limitado às condições avaliadas neste estudo e como uma hipótese a ser investigada.

A esse respeito, Pearcey et al. [5] observaram um efeito oposto, no qual a estimulação cutânea promoveu um aumento agudo da força durante rampas de flexão plantar. Entretanto, diferenças metodológicas importantes devem ser consideradas, incluindo a natureza do estímulo aplicado (elétrico versus mecânico), a disponibilidade de realimentação visual e o grupo muscular avaliado. De fato, os próprios autores não observaram efeito da estimulação cutânea durante tarefas de dorsiflexão plantar. Assim, os resultados do presente estudo corroboram a ideia de que os efeitos da estimulação sensorial sobre o controle motor dependem fortemente do contexto experimental e da tarefa executada. Em particular, em nossos achados a vibração esteve associada a mecanismos envolvidos no controle dinâmico da força, reduzindo a taxa de aumento da força dos indivíduos quando guiados predominantemente por informações sensório-motoras internas, ou seja, sem realimentação visual, nas condições experimentais avaliadas.

Durante a fase isométrica, foi observado efeito significativo da intensidade de contração sobre o coeficiente de variação. Entretanto, não foi identificado efeito significativo da estimulação vibrotátil nem interação estatisticamente significativa entre estimulação e intensidade. Dessa forma, os resultados obtidos até o momento não permitem afirmar que a estimulação vibrotátil tenha modificado a variabilidade da

força durante o platô ou produzido efeitos diferentes entre as intensidades avaliadas.

A. Limitações do estudo

Os resultados devem ser interpretados considerando algumas limitações. Para exemplificar isso, o reduzido tamanho amostral ($n = 11$) limita o poder estatístico das análises e pode ter dificultado a identificação de efeitos de menor magnitude. Essa limitação é relevante diante da elevada variabilidade interindividual observada nas variáveis analisadas, indicando que os efeitos da estimulação vibrotátil podem não ocorrer de maneira uniforme entre os participantes. Além disso, a inclusão somente de voluntários saudáveis restringe a generalização dos resultados para populações clínicas. Portanto, os achados devem ser considerados preliminares e não permitem estabelecer recomendações definitivas.

B. Implicações práticas

O efeito significativo da estimulação vibrotátil foi identificado somente na taxa de incremento da força, enquanto não foram observados efeitos significativos sobre a força média ou o coeficiente de variação durante o platô. Esse padrão constitui evidência preliminar de um possível efeito seletivo da estimulação nas condições avaliadas, sem permitir, contudo, estabelecer sua relevância funcional. Na prática, esse resultado pode ser relevante para tarefas que exigem um aumento gradual e controlado da força. Entretanto, a redução observada não deve ser interpretada necessariamente como melhora ou prejuízo do desempenho, pois sua aplicabilidade dependerá do objetivo funcional e das exigências da tarefa.

C. Principais aprendizados

O presente estudo demonstrou a importância de analisar separadamente as diferentes fases da produção de força. Ademais, destacou-se a importância de controlar a disponibilidade da realimentação visual da força produzida, permitindo analisar a contribuição da estimulação vibrotátil em uma condição mais dependente das informações sensório-motoras internas. Por último, a elevada variabilidade interindividual mostrou que a resposta ao estímulo não é homogênea e que a análise dos valores individuais deve complementar a interpretação dos resultados médios do grupo.

D. Lacunas de pesquisa

A continuidade da pesquisa, com a ampliação da amostra, permitirá avaliar a consistência dos resultados observados até o momento e reduzir as limitações associadas à variabilidade interindividual. Além disso, estudos futuros deverão incluir populações clínicas, visto que o presente protocolo considera apenas voluntários saudáveis, a fim de verificar a aplicabilidade dos achados em contextos de reabilitação motora. Por fim, pode ser necessário investigar diferentes parâmetros da estimulação vibrotátil, como frequência, amplitude, duração e local de aplicação, além de outras intensidades de contração e tarefas motoras.

V. Conclusão

Na amostra analisada até o momento, não foi detectada diferença significativa na força máxima entre as condições controle e vibração. Nas tarefas submáximas, foi identificado efeito significativo da estimulação vibrotátil sobre a taxa de incremento da força durante a fase de rampa sem realimentação visual da força produzida. Durante o platô, não foram observados efeitos significativos sobre a força média ou o coeficiente de variação. Esses resultados constituem evidências preliminares de um possível efeito seletivo da estimulação vibrotátil sobre a fase dinâmica da produção de força nas condições avaliadas. Entretanto, os dados obtidos não permitem determinar os mecanismos sensoriais ou neurais responsáveis pelo resultado. Assim, a continuidade do estudo, com a ampliação da amostra, e futuras investigações serão necessárias para confirmar os achados e esclarecer os mecanismos envolvidos.

Agradecimentos

Os autores agradecem a bolsa de iniciação científica concedida pelo Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), por meio do Programa Institucional de Bolsas de Iniciação Científica (PIBIC), e a Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP, processo 2024/08318-4).

***Abstract* — Ischemic stroke is frequently associated with cognitive deficits that negatively impact patients' functionality and life quality. Transcranial photobiomodulation (tPBM) has emerged as a non-invasive therapeutic approach with potential to modulate neural activity and promote neuroplasticity. The aim of this study was to evaluate the effects of tPBM on cognitive function in post-stroke patients using the Mini-Mental State Examination (MMSE) as the primary outcome measure. This randomized, controlled, single-blind, longitudinal clinical trial was conducted in a home-based setting. The sample consisted of 16 patients allocated into two groups: an intervention group (active tPBM, n = 8) and a control group (Sham, n = 8). The protocol was applied three times per week for four weeks. Statistical analyses were performed using the Wilcoxon and Mann–Whitney tests, adopting $p < 0.05$. Significant intragroup improvements in MMSE scores were observed both in the tPBM group ($p = 0.0078$) and the Sham group ($p = 0.0384$). In the intergroup comparison, the tPBM group demonstrated superior cognitive improvement compared with the control group ($p = 0.0382$). These findings suggest a possible benefit of tPBM on the global cognitive function of post-ischemic stroke patients. However, these findings should be interpreted as preliminary evidence, considering the small sample size, the baseline difference between the groups, and the exclusive use of the MMSE.**

I. INTRODUCTION

Stroke remains one of the leading causes of disability worldwide, with the ischemic subtype accounting for most cases. In addition to motor deficits, cognitive impairments are highly prevalent and directly impact functional independence, quality of life, and long-term prognosis. Alterations in domains such as attention, memory, and executive functions are frequently observed, highlighting the need for therapeutic strategies capable of acting not only on motor recovery but also on the functional reorganization of cognitive systems [1].

In recent years, Transcranial Photobiomodulation (tPBM) has emerged as a promising non-invasive approach in neurological rehabilitation. This technique is based on the application of light in the red to near-infrared spectrum, capable of interacting with intracellular chromophores, particularly cytochrome c oxidase, promoting increased adenosine triphosphate (ATP) production and improving cellular bioenergetic efficiency. Additionally, tPBM may modulate cerebral blood flow, oxidative stress, and inflammatory processes, contributing to stabilization of neuronal activity and functional dynamics of neural networks involved in cognition [1–2].

From this perspective, experimental and clinical evidence suggests that tPBM may act as a modulator of neuroplasticity processes following ischemic stroke, promoting neuronal survival, synaptic function, and cortical reorganization. Although early studies indicate benefits regarding cognitive function, this area remains underexplored, especially in randomized clinical trials using standardized and measurable cognitive outcomes [1–5].

Despite these advances, an important gap remains in the literature regarding the systematic evaluation of the effects of tPBM on cognitive function in post-ischemic stroke patients, particularly in controlled studies using validated clinical instruments. The Mini-Mental State Examination (MMSE) stands out as a widely used tool for global cognitive assessment, being sensitive to alterations in different cognitive domains and suitable for monitoring therapeutic interventions, however, because it is a global screening instrument, it presents limited sensitivity to detect specific changes in executive functions, attention, processing speed, and memory [5-7].

Therefore, the present study aimed to evaluate the effects of transcranial photobiomodulation on global cognitive function in patients with ischemic stroke through a randomized pilot clinical trial, using the MMSE as the primary outcome measure.

II. MATERIALS AND METHODS

A. Ethical Considerations

This study was approved by the Research Ethics Committee of Centro Universitário de Itajubá – FEPI (CAAE: 74363523.6.0000.5094) and registered in the Brazilian Registry of Clinical Trials (ReBEC) under registration number U1111-1304-8858. Patients who agreed to participate in the study signed an informed consent form before the beginning of treatment.

This was a randomized, controlled, single-blind, longitudinal clinical trial conducted in a home-based setting.

B. Sample Characterization

The sample of the present study consisted of 16 patients clinically diagnosed with ischemic stroke, of both sexes, aged

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

between 50 and 70 years. Inclusion criteria included a clinical diagnosis of ischemic stroke, clinical stability, and minimum cognitive capacity to understand and perform the proposed assessments. Exclusion criteria included the presence of other associated neurological diseases, a history of neoplasms, photosensitivity disorders, severe psychiatric disorders, or any clinical condition that could interfere with the application of photobiomodulation or cognitive assessment.

It is important to note that participants were not necessarily undergoing physiotherapeutic follow-up during the study period. Before the beginning of the protocol, a comprehensive initial evaluation was performed, including the collection of personal, sociodemographic, and clinical data, as well as the assessment of vital signs. This stage aimed to characterize the sample and verify possible baseline differences between groups, contributing to initial homogeneity and the appropriate interpretation of the results throughout the study.

Cognitive function was assessed using the Mini-Mental State Examination (MMSE), a widely validated instrument commonly used in clinical practice and research for global cognitive evaluation. The instrument was administered at two distinct time points: before the intervention (pre-intervention assessment) and after completion of the protocol (post-intervention assessment). This longitudinal approach allowed for a direct comparison of the obtained scores, enabling analysis of the evolution of cognitive performance and identification of possible changes associated with the proposed intervention. Assessments were conducted by a previously trained evaluator following a standardized administration protocol. It should be noted, however, that the MMSE is a global screening instrument and does not replace a comprehensive neuropsychological battery.

C. Cognitive Function Assessment (MMSE)

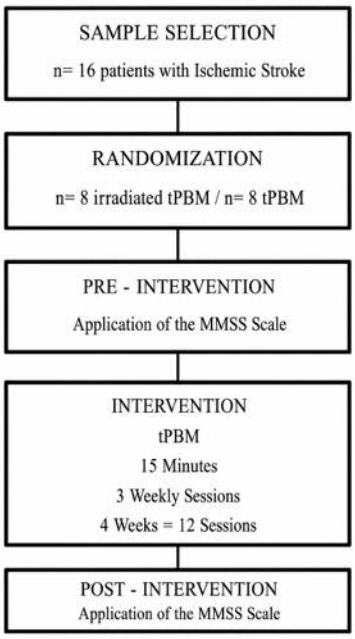
Mini-Mental State Examination (MMSE)

The MMSE is an instrument used for global cognitive assessment, allowing the evaluation of different domains such as temporal and spatial orientation, immediate memory, attention and calculation, recall, language, and visuoconstructive ability. In the present study, the MMSE was used as the primary cognitive outcome measure to verify possible changes in participants' cognitive performance before and after the tPBM protocol.

The test was administered in a quiet environment, with the participant comfortably seated and free from external interference that could compromise attention or performance. Before the beginning of the assessment, the patient was instructed regarding the procedure and asked to respond to the tasks proposed by the evaluator according to their cognitive capacity at the time of application.

During the assessment, tasks related to temporal and spatial orientation, word registration and recall, attention, calculation, naming, repetition, comprehension of verbal commands, reading, writing, and figure copying were administered. The total MMSE score ranges from 0 to 30 points, with higher scores indicating better global cognitive performance.

The instrument was administered at two distinct time points: before the intervention and after completion of the therapeutic protocol. Comparison between pre- and post-intervention scores allowed analysis of participants' cognitive function evolution throughout the study and verification of possible effects of transcranial photobiomodulation on global cognitive performance in patients with ischemic stroke.



D. Group Allocation

Sixteen patients clinically diagnosed with ischemic stroke were selected to participate in the study and randomly allocated into two groups: the Intervention Group (irradiated tPBM), composed of 8 patients who received active tPBM with the helmet turned on, and the Control Group (Sham), composed of 8 patients submitted to the same protocol, although with the inactive device. This was a pilot study designed to evaluate protocol feasibility and estimate the effect of the intervention in patients with ischemic stroke.

Participant allocation was performed through randomization, ensuring equivalent distribution between groups and reducing possible selection biases. The study followed a single-blind design in which participants were unaware of the group to which they belonged.

Interventions were performed three times per week for four consecutive weeks, totaling 12 sessions per participant. The tPBM protocol was applied in a standardized manner in all sessions, respecting the same parameters for the intervention group and simulated conditions for the control group. Figure 1 presents the experimental design of the study, including pre-intervention assessment, protocol application, and post-intervention reassessment.

E. tPBM Protocol for Cognitive Function in Post-Stroke Patients

The tPBM intervention was performed using a helmet composed of gallium-aluminum-arsenide (GaAlAs) light-emitting diodes (LEDs), arranged to cover cortical regions related to motor control. The device was designed to provide homogeneous distribution of light radiation over the scalp, favoring light penetration into encephalic structures.

The helmet emitted near-infrared radiation at a wavelength of 808 nm, a value widely described in the literature due to its high tissue penetration capacity and interaction with cytochrome c oxidase, favoring cellular bioenergetic effects. The device presented an acrylic encapsulation and an approximate diameter of 5 mm per emitter. The system had a total optical power of 6 W and a power density of 3.41 mW/cm², allowing application for 900 seconds, with an approximate energy density of 3.07 J/cm² per session.

During the application, the patient remained in a comfortable position with the helmet properly adjusted to the cranial region, ensuring adequate contact and uniform light distribution. To ensure appropriate biosafety conditions, the device was disinfected with 70% alcohol after each session.

F. Statistical Analysis

Statistical analysis was performed using GraphPad Prism 8.0 software (GraphPad Software Inc., La Jolla, CA, USA). Considering the reduced sample size and the ordinal nature of the MMSE scores, non-parametric statistical tests were adopted.

For intragroup comparison of MMSE scores between pre- and post-intervention periods, the paired Wilcoxon test was used. For intergroup comparison (Intervention Group vs Sham Group), the Mann–Whitney test was employed on the individual variations of the scores (Δ = post-intervention − pre-intervention). The data was presented as mean and standard deviation. A significance level of $p < 0.05$ was adopted. To complement the p-values, the mean difference between individual variations and the rank-biserial correlation (r_rb) were estimated as a measure of effect size for the intergroup comparison, with 95% confidence intervals obtained by bootstrapping with 10,000 resamples.

III. RESULTS

The study sample consisted of 16 patients clinically diagnosed with ischemic stroke, distributed into two groups: the irradiated tPBM group (n = 8) and the Sham group (n = 8). Table 1 presents the initial characterization of participants regarding age, sex, and time since injury. Descriptive data are presented as mean and standard deviations. Statistical analysis demonstrated no significant differences between groups regarding age ($p > 0.05$), sex distribution ($p > 0.05$), and time since injury ($p > 0.05$). However, the absence of statistical significance does not prove equivalence between the groups. In addition, a baseline difference was observed in MMSE scores, with a mean of 24.4 ± 2.5 in the irradiated tPBM group and 20.0 ± 3.8 in the Sham group, an aspect that must be considered in the interpretation of the results.

Table 1 - Initial characterization of participants in the irradiated tPBM and Sham groups.

Variables , avarage (DP)	Irradiated tPBM	tPBM Sham	*p*-value
Age (years)	58,1 (6,7)	60,5 (7,4)	p > 0,05
Sex (F/M)	4/4	4/4	p >0,05
Time Since Injury (years)	2,0 (1,1)	3,0 (2,5)	p >0,05

Caption: Female Sex; M: Male Sex
Source: Personal Archive

Considering the reduced sample size and the ordinal nature of MMSE scores, non-parametric statistical tests were adopted. Table 2 presents MMSE scores of the irradiated tPBM and Sham groups in the pre- and post-intervention periods, as well as p-values related to intragroup and intergroup analyses, expressed as mean and standard deviations.

Intragroup analysis demonstrated statistically significant improvement in cognitive performance after the intervention in both groups, with significant differences observed in the irradiated tPBM group ($p = 0.0078$) and in the Sham group ($p = 0.0384$), although with different magnitudes.

Regarding comparison between groups, the tPBM group demonstrated superior cognitive improvement compared with the Sham group, and this difference was statistically significant ($p = 0.0382$). Descriptively, the mean variation was 2.13 ± 1.13 points in the irradiated tPBM group and 0.88 ± 0.83 points in the Sham group. The mean difference between the variations was 1.25 points (95% bootstrap CI: 0.38 to 2.13), and the rank-biserial correlation was $r_rb = 0.61$ (95% bootstrap CI: 0.16 to 0.92).

Considering the pilot nature of the study and the reduced sample size, the findings suggest a positive effect of tPBM on cognitive function in patients with ischemic stroke, indicating a potential benefit of the intervention. However, these results should be interpreted as preliminary evidence, and larger samples are necessary to confirm the current findings. Although the direction and magnitude of the observed effect favored the irradiated tPBM group, the width of the confidence intervals highlights imprecision in the estimates, especially in light of the small sample size and the baseline difference in MMSE scores. Thus, the results do not allow establishing the definitive clinical efficacy of the intervention.

Table 2 - Evaluation of MMSE scores in the irradiated tPBM and Sham groups, pre- and post-intervention, with intragroup and intergroup analyses.

Group	Pre, mean (SD)	Post, mean (SD)	*Intragroup p-value*
Irradiated tPBM	24,4 (2,5)	26,5 (2,5)	0,0078

FBMT Sham	20,0 (3,8)	20,9 (3,7)	0,0384
Intergroup comparison of pre-post variations (*Mann-Whitney Test*)			$p = 0,0382$

Caption: SD: Standard Deviation
Source: Personal Archive

Improvement in MMSE scores was observed in both groups, although it was more meaningful in the group submitted to tPBM.

IV. DISCUSSION

Scientific literature demonstrates that ischemic stroke is frequently associated with cognitive deficits that significantly compromise individuals' functionality and quality of life. Alterations in domains such as memory, attention, and executive functions reflect dysfunctions in the organization and dynamics of neural networks, making cognitive recovery one of the main challenges in neurological rehabilitation [12–13]. tPBM has emerged as a promising approach, acting in the modulation of neural activity through bioenergetic and neurovascular mechanisms. In general, the interaction between near-infrared light and intracellular chromophores is associated with increased neuronal metabolic efficiency, modulation of oxidative stress, and improvement in cerebral perfusion, creating a favorable environment for cerebral neuroplasticity and cortical reorganization [1–3]. According to Gottesman and Hillis (2020), post-stroke cognitive alterations are strongly associated with reduced functional independence and worse long-term clinical prognosis. Likewise, Cramer (2008) highlights that functional cerebral reorganization represents one of the main mechanisms related to neurological recovery after ischemic stroke.

The results of the present study demonstrated significant improvement in MMSE scores in the group submitted to tPBM, with greater improvement than that observed in the Sham group. Despite the pilot nature of the study and the reduced sample size, the findings suggest positive effects of the intervention on cognitive function in patients with ischemic stroke. In the intergroup comparison of pre-post variations, the mean difference was 1.25 points (95% CI: 0.38 to 2.13), and the rank-biserial correlation was 0.61 (95% CI: 0.16 to 0.92), indicating an effect magnitude favorable to the irradiated tPBM group. However, the width of the confidence intervals highlights imprecision in the estimates.

These findings are aligned with recent studies pointing to the potential of tPBM in improving cognitive performance in neurological populations, demonstrating gains in functions such as memory, attention, and processing speed following tPBM application, reinforcing the consistency of the results observed in the present study. Similar findings were described by Naeser et al. (2020), who observed improvements in cognitive performance after transcranial tPBM application, especially in functions related to memory and attention. In addition, Li, Wong, and Ng (2024) suggest that tPBM presents therapeutic potential in post-stroke functional recovery due to its ability to modulate neurovascular and metabolic mechanisms involved in cortical reorganization. However, differences between populations, protocols, and assessment instruments require caution in comparing results.

Despite the improvement observed in both groups, possibly associated with factors such as learning effects or spontaneous recovery, the statistically significant intergroup difference suggests that tPBM may have exerted a specific effect on cognitive function [5–7]. Nevertheless, since this was a pilot study with a reduced sample size, these findings should be interpreted with caution and more appropriately considered preliminary evidence. In addition, the baseline difference in MMSE scores, with a higher initial score in the irradiated tPBM group, may have influenced the magnitude of the observed variation and favored the occurrence of a ceiling effect.

The improvement observed in the Sham group also deserves attention, since part of this result may be related to non-specific intervention effects, such as placebo effects, in addition to familiarization with the assessment instrument itself. Reapplication of the MMSE may facilitate participants' performance simply due to prior contact with the tasks. Furthermore, post-stroke patients frequently present some degree of spontaneous recovery over time, which may also influence the results. These aspects reinforce the importance of studies with greater methodological control, longer follow-up periods, and the use of complementary cognitive instruments [1,6]. Arevalo-Rodriguez et al. (2021) emphasize that repeated cognitive testing may be influenced by learning effects, especially in global cognitive screening assessments such as the MMSE.

Overall, the findings of the present study are consistent with recent literature suggesting tPBM as potentially useful strategy in modulation of cognitive function in neurological populations. Studies conducted by Liebert et al. (2021), Hamblin (2021), and Mitrofanis (2020) reported improvement in parameters related to neural activity and cognitive performance following tPBM application in neurological populations, supporting the plausibility of the results observed in the present study. However, the heterogeneity of the studied populations, irradiation protocols, assessment instruments, and methodological designs limits direct comparison between studies.

From a clinical perspective, the magnitude of improvement observed in the group submitted to tPBM highlights the potential of the technique as a complementary resource in post-stroke cognitive rehabilitation. This is a non-invasive intervention, relatively simple to apply. In this sample, no relevant adverse events were observed, other than the report of heating during application. These characteristics broaden its possibilities for use, including in home-based settings. This aspect is especially relevant when considering the functional limitations frequently present in this population and the difficulties in accessing specialized services [1,4,8]. However, statistical significance alone does not demonstrate clinical relevance. Since a minimal clinically important difference has not been defined for the MMSE and functional or quality-of-life outcomes were not evaluated, it is not possible to state that the difference observed between the groups represents a relevant clinical benefit [1,4,8].

Regarding biophysical aspects, it is possible that the observed effects are related to the irradiation parameters used, such as wavelength, energy density, and exposure time. These factors may influence the neuronal response to tPBM,

suggesting a possible dose-dependent behavior [2–4]. However, the response to tPBM depends on the combination of parameters, including emission mode, irradiated area, and total energy, making it impossible to attribute the result to a single parameter. The heterogeneity of devices and protocols available in the literature also limits direct comparisons. Therefore, this interpretation should be approached with caution and still requires further investigation in future studies.

Finally, some limitations must be considered, such as the small sample size, which limits statistical power and increases the possibility of unstable estimates of the observed effect. The relatively wide confidence intervals reinforce the imprecision of these estimates. The sequential allocation of participants, performed according to the order of acceptance, may also have introduced selection bias and contributed to baseline differences between the groups. The short intervention period and the absence of longitudinal follow-up prevent verifying the maintenance of the results. Furthermore, the use of a single cognitive assessment instrument may not address all dimensions of cognition, especially executive functions, attention, processing speed, and memory [13,14]. The absence of functional or quality of life outcomes also prevents determining whether the improvement observed in the MMSE translates into relevant clinical benefits. Another limitation corresponds to the incomplete characterization of the sample regarding the location and extent of the lesions, initial severity of the stroke, education level, current medications, and concomitant rehabilitation interventions. Therefore, new studies with larger samples, randomized allocation, better control of baseline differences, longer follow-up time, more detailed clinical characterization, and multimodal cognitive assessment are needed to confirm the findings and clarify the role of tPBM in post-stroke cognitive rehabilitation.

V. Conclusion

The results of the present study suggest a potential effect of tPBM in the modulation of cognitive function in patients with ischemic stroke, evidenced by greater gains in MMSE scores compared with the control group. However, the findings must be interpreted as preliminary evidence, considering the small sample size, the baseline difference between the groups, and the exclusive use of the MMSE.

Due to its non-invasive nature, low risk, and ease of application, tPBM presents potential as a complementary approach in post-stroke cognitive rehabilitation. However, confirming these results in studies with larger samples, a more comprehensive neuropsychological assessment, functional outcomes, and longitudinal follow-up is fundamental before its clinical application can be recommended.

***Abstract*—Deep brain stimulation (DBS) is an established therapy for the motor symptoms of Parkinson's disease (PD), but conventional systems deliver stimulation continuously and at fixed parameters, independent of the patient's fluctuating neurological state. Closed-loop or adaptive DBS (A-DBS) addresses this limitation by sensing neural activity and adjusting stimulation in real time. This paper reviews the engineering foundations of closed-loop DBS and the role of machine learning (ML) in personalizing therapy. This review explains Parkinson's disease as a control problem, summarizes the neural and imaging biomarkers used as feedback signals, particularly subthalamic beta-band local field potentials (LFPs) and diffusion/functional imaging correlates of stimulation response, and examines supervised and reinforcement learning approaches to real-time parameter selection. We further discuss clinical evidence supporting A-DBS, the regulatory and hardware constraints specific to implantable devices, and open challenges related to personalization, safety, and generalization across patients. The review concludes that the integration of neural biomarkers, wearable sensing, and machine learning represents a methodological template that is likely to extend beyond Parkinson's disease to other conditions treated by invasive neuromodulation.**

***Index Terms*—deep brain stimulation, machine learning, Parkinson's disease, Adaptative neuromodulation.**

I. Introduction

Parkinson's disease (PD) is among the most common neurodegenerative disorders, being characterized by tremor, rigidity, bradykinesia, and postural instability, alongside other motor and non-motor symptoms, arising from disrupted electrical signaling within the basal ganglia. Degeneration of dopaminergic neurons in the substantia nigra pars compacta disturbs the balance of excitation and inhibition throughout the motor circuit, producing abnormal, pathologically synchronized oscillatory activity that locks the motor system into a dysfunctional state.

Deep brain stimulation (DBS) has been used to treat the motor symptoms of PD since the pioneering work of Benabid and colleagues in the early 1990s [1]. By implanting electrodes in specific subcortical targets and delivering continuous high-frequency electrical pulses, DBS disrupts pathological oscillatory patterns and produces substantial motor improvement. It is now the standard of care for patients whose symptoms can no longer be adequately controlled with medication alone or suffer from the side effects of said treatment.

Despite this success, conventional DBS remains an open-loop system ,where stimulation parameters are set by a clinician during periodic outpatient visits and then held constant, regardless of how symptoms fluctuate over the course of the day. This mismatch between a static controller and a dynamic physiological system motivates closed-loop, or adaptive DBS (A-DBS), in which neural signals recorded from the implanted electrode are used to continuously adjust stimulation to the patient's current state. Machine learning is increasingly central to this transformation, providing the means to extract patient-specific control policies from neural and behavioral data. This review examines the engineering basis of DBS, the biomarkers available for closed-loop control, the machine learning methods being applied to this problem, and the clinical and regulatory context in which they must operate. This work aims to clarify the engineering principles underlying machine learning strategies for A-DBS.

II. Search strategy

The selection of literature in this narrative review was primarily informed by the author's clinical and research background in deep brain stimulation for Parkinson's disease, rather than a predefined systematic search protocol. This initial selection was complemented, during manuscript revision, by targeted searches in PubMed and Google Scholar using combinations of "adaptive deep brain stimulation," "machine learning," and "closed-loop," conducted to verify claims, identify recent evidence, and address specific gaps regarding quantitative comparison across studies, cross-patient generalization and reinforcement-learning safety. As a narrative rather than a systematic review, no PRISMA protocol or formal quality appraisal was applied, and the coverage of evidence reflects the reviewer's judgment rather than an exhaustive database query, a limitation acknowledged here.

III. Parkinson's Disease as a Control Problem

From an engineering standpoint, PD can be framed as the failure of a biological feedback control system. The motor system normally operates through parallel loops connecting the cortex, basal ganglia, and thalamus, which refine and gate motor commands to enable smooth, coordinated movement. Dopamine released from the substantia nigra acts as a neuromodulator that calibrates these loops, enhancing intended movements and suppressing unwanted ones.

As dopaminergic neurons degenerate, this balance shifts toward excessive thalamic inhibition and reduced cortical drive for voluntary movement, and neural firing across the basal ganglia becomes abnormally synchronized, particularly within the beta frequency band (13–30 Hz). Under normal conditions, beta oscillations are brief and transient, but in PD they become persistent and pathologically amplified, locking the motor circuit into a dysfunctional attractor state [3]. Because beta power fluctuates with symptom severity, diminishing with dopaminergic medication and rising during symptom worsening, it is a natural candidate feedback signal for closed-loop control.

IV. DBS Hardware and Stimulation Mechanism

A DBS system consists of an implanted electrode lead, an implantable pulse generator (IPG), and an extension cable. The lead, typically 1.27 mm in diameter and carrying four to eight contacts, is stereotactically placed in the target nucleus, most often the subthalamic nucleus (STN) or globus pallidus interna (GPi) for PD. The IPG, implanted subcutaneously below the clavicle, delivers charge-balanced biphasic pulses (A primary pulse followed by a charge-recovery phase of opposite polarity) preventing net charge accumulation and electrochemical damage on the neural tissue around the lead.

Four stimulation parameters can be adjusted on the therapy: frequency (typically 130–180 Hz is standard for PD but in some cases can be as low as 60 Hz), amplitude (the amount of electric current discharged by each pulse, generally 1.0 – 3.6 mA), pulse width (the duration of each pulse, usually 60 – 90 microseconds), and contact configuration (which contacts are active and their polarity). Newer directional leads with segmented contacts allow the stimulation field to be steered in three dimensions, improving selectivity for the target nucleus while sparing adjacent structures, therefore avoiding areas that could cause unwanted effects. Programming these systems to find an optimal parameter combination is time-consuming and represents a significant clinical and economic burden, motivating algorithm-assisted programming, as well as fully closed-loop control.

The mechanism underlying the therapeutic effect of high-frequency stimulation has been debated, but current evidence favors a disruption model in which DBS overrides pathological low-frequency synchronized oscillations with high-frequency, temporally irregular firing, decoupling the circuit from its dysfunctional state rather than simply inhibiting or exciting it [2].

TABLE I
Candidate Biomarkers for Closed-Loop DBS Control

Signal	What It Reflects	Maturity
STN beta power (13–30 Hz)	Overall pathological synchronization	Clinically validated [4]
Beta bursts	Duration/magnitude of transient beta episodes	Research stage [6]
Gamma / HFO (60–90 Hz)	Correlates with therapeutic stimulation effect	Research stage
DTI tractography	Electrode-target connectivity, contact placement	Preoperative planning
Resting-state fMRI	Whole-brain connectivity correlates of DBS response	Research stage [11]
Wearable IMU	Tremor, gait, bradykinesia (peripheral)	Clinically available

V. Neural and Imaging Biomarkers for Closed-Loop Control

A closed-loop system requires a reliable, real-time signal reflecting symptom severity. The most extensively studied candidate is the beta-band local field potential (LFP) recorded from the stimulation electrode itself. LFPs reflect the summed synaptic activity of neuron populations near the contacts and, unlike single-unit recordings, are robust and stable over years, allowing the same macroelectrode contacts to be used for both stimulation and sensing.

Landmark work by Little and colleagues demonstrated that STN beta power correlates with motor symptom severity within individual patients, a relationship stable enough to serve as a control signal in human trials [4]. Subsequent analysis by Tinkhauser and colleagues showed that it is not overall beta power but the duration and magnitude of discrete beta "bursts", episodes of elevated activity lasting roughly 100 to 500 ms, that correlates most specifically with motor impairment, with long-duration bursts being pathological and brief transient bursts appearing to be part of normal motor processing [6]. A well-designed closed-loop controller should ideally distinguish between the two.

Beyond electrophysiology, neuroimaging contributes a pre-operative dimension to biomarker-driven DBS. Diffusion tensor imaging (DTI) of white matter tracts can help predict which electrode contacts are optimally positioned relative to therapeutic targets, reducing the empirical parameter search after implantation, while resting-state functional MRI connectivity patterns have been associated with DBS response, offering a surgery-independent predictor of outcome. Several groups have demonstrated the feasibility of integrating such imaging biomarkers with neural signal classifiers to build patient-specific therapy models [11]. Gamma-band activity and high-frequency oscillations have also been associated

TABLE II
COMPARISON OF CONTROL STRATEGIES FOR CLOSED-LOOP DBS

Approach	Principle	Advantage	Limitation / Risk
Threshold control	Fixed beta-power threshold triggers on/off stimulation	Simple, low power, easy to validate	Threshold drifts over time; single-feature
Supervised learning	Classifier (SVM, RF, shallow NN) trained on labeled LFP/kinematic states	Multivariate; higher classification accuracy	Requires labeled clinical data; may not generalize across patients
Reinforcement learning	Agent learns policy from reward signal (e.g., reduced beta, tremor score)	No pre-labeled data; adapts online	Exploration risk; requires constrained/safe action space

with therapeutic stimulation effects, and wearable inertial sensors and electromyography provide complementary peripheral measures of tremor, gait, and bradykinesia. Integrating these heterogeneous data streams into a single control signal is an active engineering challenge that is well suited to machine learning methods.

VI. MACHINE LEARNING IN THE LOOP

Threshold-based controllers, which switch stimulation on or off according to a fixed beta-power threshold, were an important first step but have clear limitations: the optimal threshold varies between patients and may drift as the disease progresses, and a single-feature controller discards most of the information present in the LFP and peripheral sensors. Machine learning approaches address both limitations by learning patient-specific, multivariate control policies directly from data.

Supervised learning algorithms, including support vector machines, random forests, and shallow neural networks, trained on combined LFP and kinematic features have demonstrated reliable classification of on/off medication states, bradykinesia severity, and dyskinesia presence. Once trained on clinical session data, such classifiers can in principle be deployed onboard an implantable pulse generator to drive real-time parameter selection.

The most ambitious approach applies reinforcement learning (RL) directly to stimulation parameter optimization: an agent explores the parameter space and receives a reward signal based on outcomes such as reduced beta power or improved accelerometer-derived tremor scores, learning a policy that maps brain state to optimal stimulation without requiring pre-labeled training data. The principal safety concern with RL in an implanted device is exploration, since an agent probing unfamiliar regions of the parameter space could transiently cause side effects; constrained RL formulations that restrict the agent to a pre-validated safe envelope are an active research direction, conceptually related to the ”safety layer” and ”shielding” approaches developed for safety-critical RL outside neuromodulation, where the policy's proposed action is projected back into a feasible set before being executed. Recent DBS-specific simulation work such as SEA-DBS [15] addresses a related concern, unstable exploration in the discrete action spaces typical of implantable hardware, using a predictive reward model to reduce reliance on live physiological feedback during learning; however, this and comparable approaches remain validated in biologically realistic simulation rather than in implanted human subjects. A clinically deployable system would also need an explicit fail-safe hierarchy: continuous monitoring of signal quality, automatic reversion to the clinician's last validated conventional settings whenever the policy proposes an out-of-envelope action, and a clinician override capable of halting autonomous adaptation at any time or of triggering fallback to safe conventional stimulation whenever sensing is unavailable or signal quality is poor. Typical supervised pipelines can extract spectral power, beta burst duration, entropy measures, and wearable-derived kinematic features.

TABLE III
COMPARISON OF MACHINE LEARNING ALGORITHMS FOR CLOSED-LOOP DBS

Algorithm	Input Data	Strengths	Limitation
Support Vector Machine (SVM)	LFP features IMU signals	High accuracy with small datasets; computationally efficient; robust to high-dimensional data	Limited adaptability; requires offline retraining when disease characteristics change
Random Forest (RF)	LFP, wearable sensors, clinical variables	Interpretable; resistant to overfitting; handles heterogeneous features	Larger memory footprint; limited online adaptation
Convolutional Neural Network (CNN)	Raw LFP time series, spectrograms	Automatic feature extraction; captures complex temporal and spectral patterns	Requires large datasets and greater computational resources; limited interpretability
Reinforcement Learning (RL)	Continuous neural feedback and symptom-related reward	Learns personalized stimulation policies; adapts online without labeled data	Exploration may induce unsafe stimulation; requires constrained learning and extensive validation

Models are generally evaluated using cross-validation, with performance reported through accuracy, sensitivity, specificity, F1-score, or area under the ROC curve.

Beyond algorithmic performance, several practical barriers still limit the widespread clinical adoption of machine learning-driven adaptive DBS. First, inter-patient variability remains substantial. Neural biomarkers such as beta oscillations differ in amplitude, spatial distribution, and temporal stability across individuals, making models trained on one population difficult to generalize without patient-specific calibration. Disease progression, medication adjustments, electrode migration, and long-term changes in neural tissue may further alter signal characteristics, requiring periodic model updates throughout the patient's lifetime.

Hardware limitations also impose significant constraints. Implantable pulse generators operate under strict power budgets, limited onboard memory, and low-latency requirements. Although deep learning models may achieve superior classification performance, their computational cost can exceed the capabilities of current implantable hardware. Consequently, lightweight classifiers such as SVMs or decision-tree ensembles remain attractive for near-term clinical deployment, while more complex models may rely on edge computing or hybrid architectures in which intensive processing is performed externally before transmitting optimized stimulation parameters to the implant.

From a regulatory perspective, adaptive algorithms introduce challenges that extend beyond conventional medical devices. Regulatory agencies increasingly require evidence not only of safety and efficacy but also of algorithm robustness, explainability, cybersecurity, and reliability under unexpected operating conditions. Machine learning models capable of updating themselves over time raise additional concerns regarding software validation, version control, and post-market surveillance. Future clinical systems will therefore likely combine interpretable AI methods with strict safety constraints, allowing autonomous adaptation while preserving clinician oversight and the ability to revert immediately to conventional continuous stimulation whenever abnormal system behavior is detected.

A recurring challenge across ML-based DBS approaches is the tension between personalization and generalization: models trained solely on one patient's data are precise but require extensive per-patient data collection, while population-level models are more readily deployable but miss individual variation. Transfer learning—pretraining on a large multi-patient dataset and fine-tuning on limited data from a new individual, is a promising strategy for addressing this tension.

Validation strategy strongly shapes how these accuracy figures should be read. Many supervised classifiers reviewed above are evaluated with random k-fold cross-validation, which allows samples from the same patient to appear in both training and test folds and can inflate apparent performance through within-subject correlation. Leave-one-subject-out (LOSO) cross-validation, in which an entire patient's data is withheld from training, provides a more realistic estimate

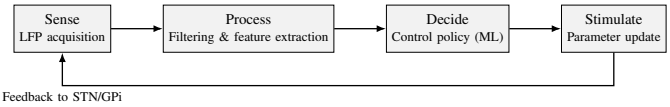

Fig. 1. Functional stages of a closed-loop DBS system. The stimulate stage feeds back into the sense stage, forming a continuous control loop operating at approximately 10–20 Hz.Reported closed-loop latencies vary with the control strategy: threshold-based beta-power controllers typically operate with control-loop update rates around 10–20 Hz (50–100 ms per cycle, as depicted in Fig. 1), while burst-aware controllers must additionally resolve individual beta bursts, which last roughly 100–200 ms under physiological conditions and 200–1,000 ms when pathological [17]. Across published closed-loop implementations, end-to-end latency between biomarker detection and stimulation adjustment has generally been reported below 400 ms, with some systems achieving under 800 ms [17]; this places an upper bound on how fast a burst the controller can meaningfully act on before it has already ended.

of how a model will perform on a new individual and is increasingly treated as the minimum standard for claims of generalizability in neural decoding [5]. External validation, testing a model on a dataset collected at a different center, with different hardware or recording montages, goes a step further and remains rare in the closed-loop DBS literature specifically, in contrast to adjacent fields such as EEG-based PD detection, where multi-site external validation is becoming more common. Transfer learning offers a practical middle ground: a population-level model is pretrained on a multi-patient dataset and then fine-tuned on a short calibration recording from the new individual, reducing the data-collection burden of a fully patient-specific model while retaining much of its accuracy. Merk et al. [**?**] formalize a set of good practices for training and testing in this context, including subject-wise data splitting and reporting of both within- and across-subject performance, which future ML-based aDBS studies, including the clinical closed-loop trials summarized in Table IV, should adopt to make claims of generalization verifiable. Notably, none of the ML classifiers discussed in Table III have yet been validated in closed-loop, in-device deployment at comparable scale to the threshold- and burst-based trials in Table IV; classifier work remains largely offline and retrospective.

VII. Clinical Evidence and Current Devices

Clinical validation of closed-loop DBS has accelerated substantially. In pivotal work by Little and colleagues, beta-triggered adaptive DBS reduced motor symptoms by approximately 50% relative to conventional continuous stimulation in a within-patient crossover study, while also reducing total stimulation energy by roughly 40%, demonstrating that adaptive stimulation can be simultaneously more effective and more efficient [4]. Arlotti and colleagues subsequently showed that eight hours of continuous adaptive DBS was safe, well tolerated, and produced consistent motor benefit under more clinically realistic conditions [9], and Herron and colleagues demonstrated a wearable closed-loop architecture using cortical recordings to trigger adaptive stimulation in an essential tremor patient, showing that the control loop need not be entirely implanted [10].

TABLE IV
KEY STUDIES UNDERPINNING CLOSED-LOOP AND ML-BASED DBS

Study	N (patients)	Signal(s)	Validation	Outcome / Performance	Compute / Device
Little *et al.* 2013 [4]	8 STN	Beta power, fixed threshold	Within-patient crossover (aDBS vs. cDBS vs. off)	∼50% greater motor improvement; ∼40% less stimulation energy vs. continuous	Threshold detector; externalized research platform
Tinkhauser *et al.* 2017 [6]	13 Patients (16 Hemispheres)	Beta burst duration/amplitude	Within-patient, off-medication	Burst amplitude scales with duration; long bursts track motor impairment	Offline analysis; externalized platform
Arlotti *et al.* 2018 [9]	13 STN	Beta power	Perioperative, 8 h continuous	Safe, well tolerated, consistent motor benefit	Externalized aDBS device
Herron *et al.* 2017 [10]	1 Patient (essential tremor)	Cortical ECoG + wearable IMU	Single-case	Feasibility of a partly-external closed loop	Wearable hub + cortical sensing
Oehrn *et al.* 2024 [16]	4 Patients	Stimulation-entrained gamma (STN or motor cortex)	Blinded randomized crossover	Personalized gamma-based aDBS outperformed conventional DBS	Chronic sensing-enabled IPG (Percept-class)
H. M. Bronte-Stewart et al. 2025 [14]	68 Patients	Single-/dual-threshold beta control	Multi-site nonrandomized trial	Feasibility of algorithm-driven single/dual-threshold control at scale	Embedded closed-loop IPG

The 2020 regulatory approval of the first commercially available bidirectional sensing-capable IPG, Medtronic's Percept PC, marked the transition of closed-loop DBS from research tool to clinical product, enabling gradual accumulation of patient-specific LFP datasets during normal use that can support the training and validation of personalized algorithms. DBS systems remain classified as high-risk implantable medical devices, and any autonomous algorithm that adjusts stimulation must demonstrate robust performance across failure modes, patient populations, and device interactions before clinical deployment a regulatory burden that is appropriate given the consequences of malfunction in a device implanted intracranially. Reviews of the closed-loop DBS field more broadly have emphasized that data streams from neural and wearable sensors do not fully capture a patient's moment-to-moment experience, arguing for hybrid systems that combine neural and wearable biomarkers with structured patient-reported outcomes, and for clinical decision-support tools that inform rather than replace clinician judgment [7], [8].

VIII. FUTURE DIRECTIONS AND CHALLENGES

Several converging developments are likely to shape the next generation of closed-loop DBS systems. Wearable integration continuous data from smartwatches, in-ear accelerometers, and smartphone-based gait analysis, can supplement implanted LFP sensing with a richer picture of daily motor function, updating patient-specific models on a rolling basis as the disease progresses. Architectures combining implanted sensing, edge processing on a wearable hub, and cloud-connected model updating, as proposed for epilepsy management [12], illustrate a general design pattern that is directly applicable to PD.

Miniaturization and power efficiency remain central engineering constraints, since every onboard computation draws from the same battery that powers stimulation; neuromorphic and ultra-low-power analog signal processing architectures may eventually allow more sophisticated onboard inference within existing power budgets. The therapeutic reach of closed-loop neuromodulation is also expanding beyond PD to essential tremor, dystonia, and, under active investigation, treatment-resistant depression, obsessive-compulsive disorder, and epilepsy [13]; the underlying engineering problem—identifying a reliable biomarker, designing a safe control policy, and validating it within a regulatory framework, is structurally similar across indications, making PD-focused closed-loop algorithms a methodological template for the broader field.

IX. CONCLUSION

Closed-loop DBS reframes Parkinson's disease as a control engineering problem, replacing static, clinician-programmed stimulation with therapy that continuously adapts to the patient's neurological state. Beta-band LFP activity remains the most validated feedback signal, but neuroimaging biomarkers, wearable sensing, and multimodal machine learning models are increasingly complementing it, moving the field from simple threshold controllers toward patient-specific, multivariate control policies. Realizing this potential at scale will depend as much on solving hardware, power, and regulatory constraints as on further algorithmic development, and on treating machine learning as a tool that supports, rather than replaces, clinical judgment. Ultimately, the future of adaptive DBS will likely rely on hybrid approaches combining patient-specific machine learning, multimodal biomarkers, and clinician-guided optimization, balancing personalization with safety, computational efficiency, and regulatory compliance.

***Resumo*—O presente estudo teve como objetivo explorar as possíveis alterações nos índices da VFC durante a taVNS com corrente senoidal, utilizando 100 Hz (Condição 1) e 2 kHz (Condição 2). Após a exclusão dos registros com ruído significativo, foram analisados nove participantes saudáveis em cada condição, dos quais cinco participaram de ambos os protocolos. O eletrocardiograma foi registrado durante 15 minutos, divididos em períodos de pré-estimulação, estimulação e pós-estimulação. Foram calculados os índices SDNN, RMSSD, LF, HF e a razão LF/HF. As comparações temporais pareadas foram realizadas pelo teste de Wilcoxon, com correção de Bonferroni ($\alpha = 0{,}017$), e o tamanho do efeito foi calculado para cada comparação. Na condição de 100 Hz, o SDNN apresentou aumento durante a estimulação, com tamanho de efeito grande ($r = 0{,}64$), mas sem significância estatística. Na condição de 2 kHz, o RMSSD apresentou discreto aumento, também com tamanho de efeito grande ($r = 0{,}64$), enquanto a razão LF/HF apresentou redução durante a estimulação. Entretanto, essas alterações não foram estatisticamente significativas. A comparação exploratória entre as condições, realizada nos cinco participantes submetidos a ambos os protocolos, também não identificou diferenças significativas para SDNN, RMSSD ou LF/HF. Em relação à percepção sensorial, foram observados perfis distintos entre as condições, com predominância de descritores previamente associados a fibras finas em 100 Hz e a fibras grossas em 2 kHz, sem que esses achados permitam inferir recrutamento seletivo de fibras. Conclui-se que os resultados devem ser interpretados como exploratórios e podem contribuir para o planejamento de estudos futuros com um maior número de participantes, delineamento cruzado, condição placebo e maior padronização dos parâmetros de estimulação.**

***Palavras-chave*—neuromodulação autonômica, estimulação transcutânea auricular do nervo vago, corrente senoidal, variabilidade da frequência cardíaca**

I. Introdução

O nervo vago (NV), décimo par craniano, constitui uma importante via parassimpática de comunicação entre o sistema nervoso central e os órgãos viscerais, participando da regulação autonômica cardiovascular, gastrointestinal e imunológica. Por essa razão, tornou-se um alvo relevante para intervenções de neuromodulação [1]–[3]. Enquanto a estimulação vagal invasiva possui aplicações clínicas estabelecidas em condições como epilepsia refratária e depressão resistente ao tratamento [4], existe uma alternativa não invasiva destacada que é investigada para a abordagem de condições associadas à disfunção autonômica. A estimulação transcutânea auricular do nervo vago (*transcutaneous auricular vagus nerve stimulation* – taVNS). A taVNS se baseia na aplicação de estímulos elétricos em regiões da orelha que apresentam inervação total ou parcial pelo ramo auricular do nervo vago, como a concha, o trago, a fossa triangular e outras regiões auriculares [2]. Os protocolos de taVNS são geralmente configurados para estimular fibras grossas aferentes mielinizadas Aβ, cujos sinais podem ser transmitidos a estruturas do tronco encefálico, incluindo o núcleo do trato solitário, e alcançar circuitos envolvidos na regulação autonômica [2], [3].

Nesse contexto, a variabilidade da frequência cardíaca (VFC) tem sido empregada em estudos de taVNS para avaliar possíveis alterações na modulação autonômica cardíaca e inferir, de forma indireta, na modulação vagal [5], [6]. A VFC corresponde às variações temporais entre intervalos NN consecutivos, obtidos a partir dos intervalos RR após a identificação e a correção de artefatos e batimentos ectópicos, refletindo a influência dinâmica simpática e parassimpática [5], [7].

A VFC pode ser analisada nos domínios do tempo e da frequência [6], [7]. No domínio do tempo, o SDNN (*standard deviation of normal-to-normal intervals*) representa a variabilidade global dos intervalos NN durante o período analisado, enquanto o RMSSD (*root mean square of successive differences*) apresenta maior relação com a modulação parassimpática cardíaca [5]–[7]. No domínio da frequência, o componente de alta frequência (HF; 0,15–0,40 Hz) está predominantemente relacionado à modulação vagal associada à arritmia sinusal respiratória. O componente de baixa frequência (LF; 0,04–0,15 Hz), por sua vez, envolve mecanismos barorreflexos e influências simpáticas e parassimpáticas. Da mesma forma, a razão LF/HF deve ser interpretada com cautela, pois não representa diretamente o equilíbrio entre os ramos simpático e parassimpático [5]–[7].

Estudos que avaliaram os efeitos da taVNS sobre a modulação autonômica cardíaca apresentaram resultados het-

erogêneos. Alguns trabalhos relataram alterações em índices temporais e espectrais da VFC após a estimulação, sugerindo que a taVNS pode influenciar a regulação autonômica cardiovascular [8]–[12]. Enquanto estudos identificaram modificações em índices como SDNN ou RMSSD, outros não observaram diferenças significativas entre a estimulação ativa e o placebo [13]–[15].

Essas divergências podem estar relacionadas à elevada heterogeneidade metodológica dos protocolos, incluindo o local e a lateralidade da estimulação, a intensidade da corrente, a frequência, a largura de pulso, a duração da estimulação e a forma de onda utilizada [2], [14], [16]. A ausência de padronização desses parâmetros limita a comparação entre os estudos e dificulta a identificação das condições mais adequadas para produzir alterações consistentes na modulação autonômica.

A maior parte dos protocolos descritos na literatura utiliza pulsos retangulares ou bifásicos, enquanto os efeitos de formas de onda contínuas, como a senoidal, tem sido pouco explorados [2], [14]. A estimulação cervical do nervo vagal com uma senoide de 5 kHz tem sido investigada em pessoas sadias [17] e utilizada em investigação do COVID-19 [18]. Entretanto, ao nosso melhor conhecimento, não foram encontrados trabalhos com taVNS.

A estimulação elétrica senoidal caracteriza-se pela variação contínua da amplitude ao longo do tempo e pela presença de uma frequência fundamental definida. Estudos realizados em nervos cutâneos periféricos sugerem que a frequência da corrente senoidal pode influenciar o padrão de ativação das fibras sensoriais. Frequências elevadas, particularmente 2 kHz e 3 kHz, têm sido associadas a respostas predominantemente compatíveis com a ativação de fibras Aβ, que apresentam maior diâmetro e grau de mielinização. Frequências mais baixas, por outro lado, podem produzir respostas relacionadas a diferentes combinações de fibras Aβ, Aδ e C. Entretanto, essa possível neuroseletividade permanece controversa e pode variar conforme a intensidade do estímulo, o local de aplicação e as características individuais [19]–[21].

Martins et al. (2013) observaram que a estimulação senoidal entre 1 e 3 kHz produziu predominantemente descritores sensoriais e tempos de reação compatíveis com maior contribuição de fibra grossa mielinizadas Aβ. Por outro lado, os autores, em frequências entre 1 e 500 Hz obtiveram maiores descritores relacionados a fibra fina (Aδ e C), sendo o tempo de reação maior do que as altas frequências.

O presente estudo teve como objetivo investigar a taVNS com senoidal de frequências de 100 Hz e 2 kHz por meio das alterações dos índices da VFC.

II. Materiais e métodos

Participaram deste estudo 17 voluntários saudáveis, com idade entre 18 e 38 anos. Todos os participantes foram previamente informados sobre os procedimentos experimentais e assinaram o Termo de Consentimento Livre e Esclarecido conforme o comitê de Ética em Pesquisa aprovado nº 64138022.4.1001.5257. Os participantes foram orientados a evitar o consumo de café, bebidas energéticas e outras substâncias estimulantes 4 horas antes ao experimento. Não foram incluídos no estudo indivíduos que faziam uso de medicamentos que afetam o sistema nervoso e aqueles com histórico de doenças cardiovasculares. O participante foi acomodado em uma cadeira confortável, em um ambiente controlado 25 ± 1 °C , e orientado a permanecer em repouso durante 5 minutos. Inicialmente, as regiões de contato dos eletrodos descartáveis com a pele foram higienizadas com álcool. Para o registro do eletrocardiograma (ECG) foi utilizada uma configuração bipolar correspondente à derivação I com o eletrodo ativo foi posicionado abaixo da clavícula esquerda, o eletrodo referência abaixo da clavícula direita e o eletrodo terra na última costela esquerda. Os eletrodos para estimulação elétrica foram colocados na orelha esquerda na região da fossa triangular. Foi utilizado gel condutor para reduzir a impedância eletrodo–pele. Os sinais de ECG foram registrados, utilizando o sistema de aquisição de sinais MADQ [22], em duas condições experimentais:

- Na primeira condição participaram 11 indivíduos. Se utilizou um estímulo senoidal de 100 Hz, aplicado em ciclos compostos por 500 ms de estimulação (ON) seguidos por 800 ms sem estimulação (OFF), totalizando 1,3 s por ciclo [23], por meio de um eletrodo tipo spike (cátodo) e um eletrodo de ouro (ânodo). O sinal de ECG foi coletado a 1 kHz.
- Na segunda condição participaram 11 indivíduos, sendo que 5 também participaram da etapa anterior. Aqui, se adotou um estímulo senoidal de 2 kHz, aplicado em ciclos compostos por 30s de estimulação (ON) seguidos por 30 s sem estimulação (OFF) [23], por meio de dois eletrodos de ouro tipo disco (diâmetro de 5mm). O sinal de ECG foi coletado a 8 kHz.

Primeiro, foi determinado o limiar sensorial (LS) para cada participante [23]. A seguir, aplicou-se um procedimento para caracterizar a resposta cognitiva pela estimulação no LS. Para isso, foi solicitado ao participante realizar uma escolha forçada de três palavras dentre as oito palavras apresentadas ao azar associadas às sensações de ativação da fibra fina (calor, agulhada, beliscada, picada) e fibra grossa (contração, formigamento, vibração e pressão) [23]. A intensidade da estimulação foi ajustada 1,5 vezes acima do valor sensorial determinado individualmente, com ausência de desconforto.

Após a determinação do LS, foi concedido um período adicional de 5 minutos de repouso para o retorno ao estado basal. O registro dos sinais ECG ocorreu de maneira contínua durante 15 minutos, diferenciando três períodos denominados como: pré-estimulação (5 minutos sem estimulação); estimulação (5 minutos) e; pós-estimulação (5 minutos sem estimulação).

A. Processamento dos sinais de ECG

O processamento dos sinais de ECG foi realizado no software MATLAB. Inicialmente, foi removido o componente DC do sinal e aplicado um filtro notch em 60 Hz para atenuar interferências elétricas. O ECG foi filtrado em uma

banda de 5 Hz a 20 Hz [24]. A detecção dos picos R foi realizada utilizando o algoritmo de Pan-Tompkins, com um limiar mínimo correspondente a 0,3 vezes o desvio-padrão mais média do ECG e um limiar máximo correspondente a 4,3 desvios-padrão acima da média do ECG [25], [26]. Em seguida, foram calculados os intervalos RR para a obtenção do tacograma cardíaco. Para a remoção de artefatos e de possíveis batimentos ectópicos, foi utilizado um algoritmo baseado na mediana móvel, considerando uma janela de cinco amostras dos intervalos RR [25], [26]. Os intervalos que apresentaram desvio superior a 20% em relação à mediana local foram removidos. Posteriormente, os valores faltantes foram interpolados por meio de spline cúbica, gerando a série de intervalos NN (normal-to-normal). Para o monitoramento dos índices da VFC no domínio do tempo, SDNN e RMSSD, e da frequência, LF e HF, foram utilizadas janelas de 60 s com deslocamento de 30 s, resultando em uma sobreposição de 50%. Para a obtenção dos índices LF e HF, os intervalos NN foram interpolados, reamostrados a 10 Hz, e a densidade espectral de potência (*power spectral density* – PSD) foi estimada por meio de um modelo autorregressivo (AR) de ordem 13, utilizando o método de Yule-Walker [27].

B. Análise Estatística

Para a análise estatística dos índices da VFC, os intervalos NN foram agrupados em três janelas de 300 s (5 min.), correspondentes aos períodos experimentais de pré-estimulação (Janela 1), estimulação (Janela 2) e pós-estimulação (Janela 3). Foram obtidas estatísticas descritivas de média, mediana e quartis Q1-Q3 para cada período. Para a comparação entre as condições, os valores de cada índice foram transformados por meio do logaritmo natural, com o objetivo de reduzir a assimetria e a dispersão dos dados. Utilizou-se o teste de Wilcoxon para amostras pareadas, com aplicação da correção de Bonferroni às três comparações temporais realizadas para cada índice. Dessa forma, adotou-se um nível de significância ajustado de α=0,017. Além disso, calculou-se o tamanho do efeito para cada comparação por meio da expressão $r = Z/\sqrt{N}$, em que Z corresponde ao valor padronizado do teste de Wilcoxon e N ao número de pares analisados, permitindo avaliar a magnitude das diferenças observadas [29]. Para a interpretação da magnitude do tamanho do efeito, foram adotados os seguintes critérios: efeito pequeno para $0{,}10 \leq |r| < 0{,}30$, efeito moderado para $0{,}30 \leq |r| < 0{,}50$ e efeito grande para $|r| \geq 0{,}50$ [29].

Os resultados para 100 Hz e 2 kHz, dos cinco participantes que realizaram os experimentos para ambas as frequências, foram comparados. Para tanto, o valor durante a estimulação foi normalizado (em cada frequência) com o valor da pré-estimulação e o logaritmo foi aplicado. Foi utilizado o teste de Wilcoxon para amostras pareadas e calculado o tamanho do efeito. Devido ao limitado tamanho amostral, os resultados foram interpretados de forma exploratória.

III. Resultados

Os sinais de ECG de 2 participantes em cada condição apresentaram presença de ruído significativo causado pelo excessivo movimento dos participantes, sendo excluídos na apresentação de resultados. Assim o número de participantes em cada condição foi de n=9, sendo que 5 participaram de ambas as condições. A media do limiar de sensibilidade (LS) foi 89,71 ± 118,40 µA e 1445,45 ± 528,4 µA, para o estímulo de 100 Hz e 2 kHz, respectivamente. Em relação à sensação percebida pelo participante, a porcentagem do número de palavras relacionadas a fibra fina foi de 74% (20 de um total de 27) para o estímulo de 100 Hz, enquanto que para o estímulo de 2 kHz, a porcentagem para sensações de fibra grossa foi de 96% (26 de um total de 27).

A Figura 1 apresenta o sinal de ECG registrado ao longo do protocolo experimental de um participante ilustrativo (#10). A Figura 1a mostra a detecção dos picos da onda R utilizando o algoritmo de Pan-Tompkins. A Figura 1b apresenta o tacograma dos intervalos normal-normal (NN), obtido após a remoção de artefatos e de batimentos ectópicos, seguida da interpolação por spline cúbica.

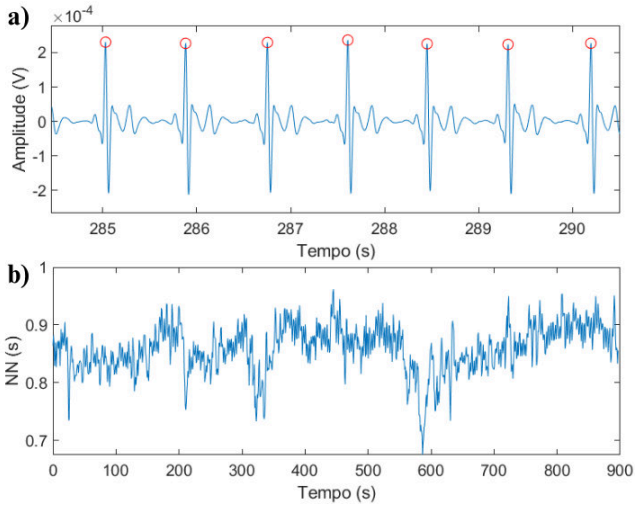

Fig. 1: a) Sinal de ECG e deteção de picos R, b) tacograma NN do participante #10 durante estimulação de 100 Hz

A Figura 2 apresenta a evolução temporal dos índices de variabilidade da frequência cardíaca de um participante ilustrativo (#10) durante o protocolo com estimulação de 100 Hz. A Figura 2a mostra a evolução do SDNN ao longo dos 15 minutos de registro (900 s). Nos primeiros 300 s, correspondentes ao período pré-estimulação, os valores permaneceram entre aproximadamente de 20 a 40 ms. Durante a estimulação (300–600 s), observou-se um aumento do SDNN no primeiro minuto e meio (300–400 s) e novamente no último minuto e meio (500–600 s). Após o término da estimulação, os valores retornaram gradualmente para níveis semelhantes aos observados no período basal.

Comportamento semelhante foi observado para o RMSSD (Figura 2b). Entretanto, nesse caso, os valores permaneceram

elevados durante a maior parte do período de estimulação, retornando progressivamente aos níveis basais após o término do estímulo.

A Figura 2c apresenta a evolução temporal da razão LF/HF. Durante o período pré-estimulação (30–300 s), a razão permaneceu relativamente estável. Após o início da estimulação, observou-se um aumento da razão LF/HF durante o primeiro minuto e meio (300–400 s), seguido de uma redução no intervalo entre 400 e 500 s. Nos 100 s finais da estimulação (500–600 s), a razão voltou a aumentar. Após o término da estimulação, observou-se uma redução gradual da razão LF/HF, aproximando-se dos valores observados no período basal.

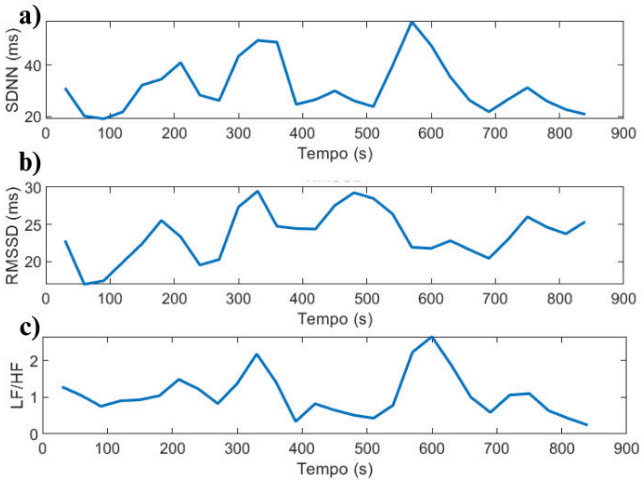

Fig. 2: Evoluçaõ temporal dos índices de VFC do participante #10 na frequência de 100 Hz. a) Índice SDNN b) Índice RMSSD c) Razão LF/HF

As Tabelas I e II apresentam, respectivamente, as estatísticas descritivas e os resultados das comparações pareadas dos índices da VFC entre as diferentes condições experimentais da condição 1 (100 Hz). Para o índice SDNN, os valores observados durante a estimulação apresentaram média e mediana superiores às registradas nos períodos de pré-estimulação e pós-estimulação. Essa diferença, entretanto, não atingiu significância estatística após a aplicação da correção de Bonferroni ($\alpha = 0{,}017$), embora tenha sido identificado tamanho de efeito grande (r = 0,64).

Para o RMSSD, as médias foram semelhantes entre as condições de pré-estimulação e estimulação, enquanto a mediana foi discretamente maior durante a estimulação. Apesar dessa variação descritiva, não foi observada diferença estatisticamente significativa entre as duas condições ($p > 0{,}017$).

No domínio da frequência, a razão LF/HF apresentou média e mediana mais elevadas durante a estimulação em comparação com o período de pré-estimulação. Contudo, essa diferença também não alcançou significância estatística após o ajuste para comparações múltiplas ($p > 0{,}017$).

Nas comparações complementares envolvendo o período de pós-estimulação, o SDNN apresentou diferença entre pré-estimulação e pós-estimulação antes da correção para comparações múltiplas (p = 0,02), acompanhada de tamanho de efeito grande (r = 0,87). Entretanto, esse resultado não permaneceu estatisticamente significativo após a correção de Bonferroni, uma vez que o valor de (p) foi superior ao nível de significância ajustado de (0,017).

Para os demais índices e comparações, não foram observadas diferenças estatisticamente significativas após a correção para comparações múltiplas. Ainda assim, algumas comparações apresentaram tamanhos de efeito de magnitude pequena a moderada.

A Figura 3 ilustra a evolução temporal dos índices de VFC de um participante ilustrativo (Participante #2) durante a estimulação com onda senoidal de 2 kHz. Na Figura 3a, o índice SDNN apresenta um comportamento variável ao longo do tempo. Durante a estimulação, os valores da SDNN permaneceram predominantemente entre 20 e 40 ms. Entre aproximadamente 400 e 500 s, verificou-se uma redução do SDNN, seguida por um aumento, mantendo-se posteriormente relativamente estável na faixa de 20 a 35 ms.A Figura 3b apresenta a evolução temporal do índice RMSSD. Entre aproximadamente 30 e 400 s, os valores permaneceram relativamente estáveis. A partir de cerca de 500 s, observou-se um aumento do RMSSD, com um pico mais pronunciado nos minutos finais do registro, correspondentes ao período de estimulação e início

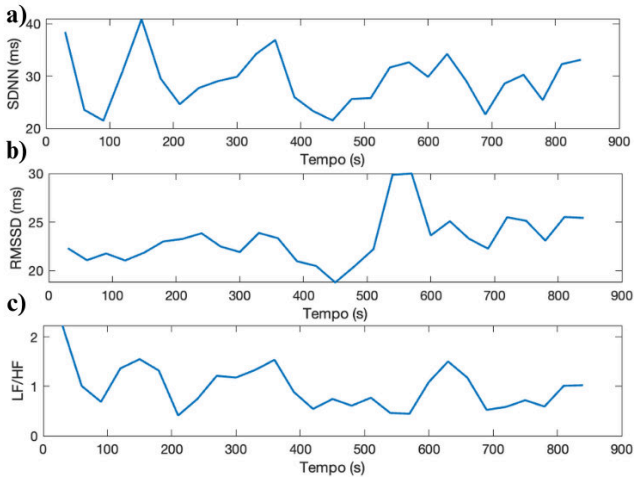

Fig. 3: Evoluçaõ temporal dos índices de VFC do participante #2 na frequência de 2 kHz a) Índice SDNN b) Índice RMSSD c) Razão LF/HF

do período pós-estimulação. Na Figura 3c, referente à razão LF/HF, observam-se valores relativamente estáveis durante os primeiros minutos (30–400 s). Entre aproximadamente 500 e 600 s, período em que o RMSSD apresentou aumento, verificou-se uma redução da razão LF/HF, seguida de um retorno a valores semelhantes aos observados no início do registro.

As Tabelas III e IV apresentam, respectivamente, as estatísticas descritivas e os resultados das comparações pareadas dos índices da VFC entre as diferentes condições experimentais da condição 2 (frequência 2 kHz).

O índice SDNN apresentou redução dos valores médios e medianos durante a estimulação em relação ao período de pré-estimulação. Entretanto, essa diferença não atingiu significância estatística após a aplicação da correção de Bonferroni ($\alpha = 0{,}017$), embora tenha apresentado tamanho de efeito moderado (r = 0,38).

Para o índice RMSSD, verificou-se aumento descritivo da média e da mediana durante a estimulação em comparação com o período de pré-estimulação. Apesar dessa variação descritiva, não foi observada diferença estatisticamente significativa entre as condições ($p > 0{,}017$).

Em relação à razão LF/HF, tanto a média quanto a mediana diminuíram durante a estimulação quando comparadas ao período de pré-estimulação. Contudo, essa redução também não alcançou significância estatística após o ajuste para comparações múltiplas ($p > 0{,}017$).

De modo geral, não foram observadas diferenças estatisticamente significativas entre os períodos de pré-estimulação, estimulação e pós-estimulação para nenhum dos índices analisados. Ainda assim, a análise dos tamanhos de efeito indicou magnitudes grandes em algumas comparações.

Na comparação entre estimulação e pós-estimulação, os índices LF e LF/HF apresentaram tamanhos de efeito grandes (r = 0,64 e r = 0,56, respectivamente), embora sem significância estatística.

TABELA V: Comparação dos índices da VFC entre as condições de 100 Hz e 2 kHz nos cinco participantes avaliados em ambas as condições, apresentando os valores de significância estatística (p) e o tamanho do efeito (r)

Índice	p	r
SDNN	0,18	0,73
RMSSD	0,79	0,20
LF/HF	0,28	0,60

A Tabela V apresenta a comparação dos índices de variabilidade da frequência cardíaca (VFC) entre as Condições 1 e 2 nos cinco participantes avaliados em ambas as condições. Não foram encontradas diferenças estatisticamente significativas entre as condições para os índices SDNN (p = 0,18), RMSSD (p = 0,79) e LF/HF (p = 0,28), considerando o nível de significância ajustado pela correção de Bonferroni ($\alpha = 0{,}017$). Assim, os resultados não forneceram evidências estatísticas de diferenças entre as Condições 1 e 2. Por outro lado, no tamanho do efeito, foram observados efeitos grandes para os índices SDNN (r = 0,73) e LF/HF (r = 0,60), enquanto o RMSSD apresentou tamanho de efeito pequeno (r = 0,20).

IV. Discussão e Conclusão

Neste estudo, avaliaram-se as respostas da variabilidade da frequência cardíaca (VFC) durante duas condições de estimulação transcutânea auricular do nervo vago com corrente senoidal, utilizando frequências de 100 Hz e 2 kHz. Participaram nove indivíduos em cada condição, dos quais cinco participaram de ambas as condições. De modo geral, não foram encontradas diferenças estatisticamente significativas entre os períodos de pré-estimulação, estimulação e pós-estimulação para nenhum dos índices analisados, considerando o nível de significância ajustado pela correção de Bonferroni . Entretanto, foram observadas alterações descritivas e tamanhos de efeito moderados ou grandes em algumas comparações.Considerando o reduzido tamanho amostral e a ausência de significância estatística, esses resultados devem ser interpretados como achados exploratórios. As condições de estimulação estudadas apresentaram perfis distintos de percepção sensorial. O limiar sensorial foi menor no protocolo de 100 Hz (89,71±118,40 μA) e maior no protocolo de 2 kHz (1445,45±528,4 μA). Na estimulação de 100 Hz, 74% dos descritores selecionados pelos participantes estavam relacionados a sensações previamente associadas a fibras finas, enquanto, em 2 kHz, 96% estavam relacionados a sensações associadas a fibras grossas. Entretanto, os descritores sensoriais são respostas subjetivas e não permitem identificar diretamente quais fibras nervosas foram recrutadas.

Na condição 1, o aumento descritivo do SDNN observado durante o protocolo de 100 Hz indica uma alteração descritiva da variabilidade cardíaca global, mas não necessariamente um aumento específico da modulação vagal, uma vez que não foi acompanhado por alteração significativa do RMSSD. Esse resultado apresenta semelhanças com os achados de Atanackov et al. (2025), que observaram aumento do SDNN em determinadas combinações de frequência e largura de pulso, sem modificações no RMSSD [12]. De Couck et al. (2017) também identificaram alterações principalmente no SDNN, dependentes da duração da estimulação, da lateralidade e do sexo dos participantes [9]. De forma semelhante, Gharabaghi e Keute (2025) encontraram aumento do SDNN em algumas condições experimentais, sem mudanças correspondentes no RMSSD [15].

Deve-se mencionar que a análise considerou apenas os valores médios da SDNN em cada período de estimulação. Nesse sentido, seria interessante avaliar também a dinâmica temporal desse parâmetro, especialmente por meio da comparação entre os 100 segundos iniciais e os 100 segundos finais do período de estimulação,pois podem ocorrer alterações transitórias nos índices da VFC ao longo do período de estimulação. As Figuras 2 e 3 sugerem visualmente essa possibilidade, que deverá ser investigada posteriormente.

Na condição 2, com estimulação senoidal de 2 kHz, o SDNN apresentou redução da média e da mediana durante a estimulação, indicando que não houve aumento da variabilidade global mensurada pelo SDNN. Por outro lado, o RMSSD apresentou discreto aumento e tamanho de efeito grande na comparação com o período de pré-estimulação ($r = 0{,}64$). A razão LF/HF também apresentou redução da média e da mediana. Essas alterações não permitem inferir aumento da modulação vagal ou redução da atividade simpática, uma vez que não permaneceram estatisticamente significativas após a correção para múltiplas comparações, e a razão LF/HF não constitui uma medida direta do equilíbrio simpatovagal.

Os resultados da condição 2 podem ser relacionados aos achados de Borges, Laborde e Raab (2019), que observaram aumento do RMSSD ao longo do tempo, mas sem diferenças entre a estimulação ativa e o placebo. Dessa forma, os autores não puderam atribuir a alteração especificamente à estimulação vagal [13]. Machetanz et al. (2021) também observaram que as alterações no SDNN e no RMSSD dependiam do local de aplicação e dos parâmetros de estimulação utilizados [11].

A redução descritiva da razão LF/HF observada na condição de 2 kHz apresentou direção semelhante à relatada por Clancy et al. (2014). Utilizando taVNS com pulsos de 30 Hz, os autores observaram redução significativa da razão LF/HF e da atividade nervosa simpática muscular, embora as potências LF e HF, analisadas separadamente, não tenham apresentado alterações significativas [28]. Porém, no presente estudo, a ausência de significância estatística para a razão LF/HF e de uma medida direta da atividade nervosa autonômica permite apenas reconhecer uma semelhança descritiva entre os resultados, sem confirmar a ocorrência do mesmo mecanismo fisiológico.

Na comparação entre as duas condições, realizada com os cinco participantes submetidos a ambos os protocolos, não foram encontradas diferenças estatisticamente significativas para SDNN ($p = 0{,}18$), RMSSD ($p = 0{,}79$) e LF/HF ($p = 0{,}28$). Quanto ao tamanho do efeito, foram observados efeitos grandes para os índices SDNN ($r = 0{,}73$) e LF/HF ($r = 0{,}60$), enquanto o RMSSD apresentou tamanho de efeito pequeno ($r = 0{,}20$). Esses resultados devem ser interpretados de forma exploratória, devido ao número reduzido de participantes avaliados em ambas as condições. Os tamanhos de efeito obtidos podem ser utilizados como informação preliminar para auxiliar no planejamento de estudos posteriores, mas não devem ser interpretados, isoladamente, como evidência de diferenças fisiológicas entre as frequências avaliadas.

Além disso, as condições diferiram não apenas quanto à frequência da corrente, mas também quanto ao tipo e à configuração dos eletrodos, ao ciclo de estimulação e à frequência de amostragem do ECG. Portanto, as diferenças observadas entre as condições não podem ser atribuídas isoladamente às frequências de 100 Hz ou 2 kHz. Para investigar especificamente o efeito da frequência da corrente senoidal, estudos posteriores deverão empregar um delineamento cruzado, no qual os mesmos participantes sejam submetidos às duas frequências, mantendo constantes o tipo e a posição dos eletrodos, a duração e o ciclo de estimulação e os parâmetros de aquisição do ECG. Recomenda-se também a randomização da ordem das sessões para reduzir possíveis efeitos relacionados à sequência das condições experimentais.

A ausência de diferenças estatisticamente significativas é

compatível com a heterogeneidade dos resultados encontrados na literatura. Yap et al. (2020) verificaram que alguns estudos relataram aumento de indicadores relacionados à modulação parassimpática, enquanto outros não encontraram diferenças entre a estimulação ativa e o placebo [14]. Farmer et al. (2021) destacaram que a falta de padronização dos parâmetros de estimulação e dos métodos de aquisição e análise dos sinais limita a comparação entre os estudos e dificulta a identificação de respostas autonômicas reprodutíveis [16].

Algumas limitações metodológicas devem ser consideradas na interpretação dos resultados. A exclusão de quatro registros (18,2%) devido à presença de ruídos reduziu a amostra disponível para nove participantes em cada condição. Além disso, a comparação entre os protocolos foi realizada com apenas cinco participantes que participaram de ambas as condições. A quantidade de registros excluídos mostra a importância de se obter sinais de ECG com boa qualidade, especialmente em ambientes menos controlados como na clínica. Outra limitação importante é a ausência de uma condição placebo, o que dificulta distinguir possíveis efeitos específicos da estimulação. Além disso, antes da aquisição do período considerado basal, os participantes foram submetidos à estimulação elétrica durante o procedimento de determinação do limiar sensorial. Dessa forma, não é possível excluir a possibilidade de que essa estimulação prévia tenha produzido efeitos autonômicos residuais e influenciado os valores utilizados posteriormente como referência. Estudos futuros deverão incluir uma condição placebo e estabelecer um período de recuperação entre a determinação do limiar sensorial e a aquisição do período basal, de modo a minimizar possíveis efeitos residuais da estimulação prévia.

Em conclusão, nas condições avaliadas neste estudo exploratório, não foram detectadas alterações estatisticamente significativas nos índices de VFC. Porém, foram identificadas alterações descritivas e tamanhos de efeito moderados e grandes que podem ser um indicativo de possíveis alterações da VFC. Estudos futuros, com maior número de participantes, delineamento cruzado, randomização da ordem das sessões, condição placebo e padronização dos parâmetros de estimulação, são necessários para investigar de forma mais robusta os possíveis alterações autonômicas da estimulação senoidal.

***Abstract*—Upper limb amputation is an event that brings major life changes. The use of a prosthesis can help restore some of the function lost, but after the fitting process and training to use it, the lack of somatosensory feedback often leads to its abandonment. Transcutaneous Electrical Nerve Stimulation (TENS) emerges as a promising non-invasive technique to restore this lost sensory information. This case study aims to evaluate the somatosensory perception evoked by TENS in two volunteers with upper limb amputation, comparing the results with data previously collected from healthy subjects. Biphasic balanced rectangular pulses were applied using a custom-developed electrical stimulator. The protocol consisted of identifying the sensation and pain thresholds, followed by incremental and decremental frequency modulation at fixed current amplitudes and pulse width to assess intensity perception, frequency discrimination, and sensory descriptors. Results indicated that the amputees' sensation threshold was similar to that of healthy volunteers, while the pain threshold was higher. Furthermore, the perceived intensity exhibited a logarithmic behavior relative to the stimulation frequency, as expected. Frequencies below 50 Hz were predominantly described as a pulsing sensation. These findings suggest that TENS can evoke distinguishable and comfortable sensations, providing fundamental parameters for optimal stimulus modulation in sensory feedback restoration for upper limb prostheses.**

***Index Terms*—TENS, electrotactile feedback, amputee, stimulus modulation**

I. Introduction

Upper limb amputation results not only in loss of motor capacity but also in loss of sensory abilities important for daily life, drastically impacting the quality of life of the amputee. The rehabilitation process for the use of prostheses is extensive and requires extremely high physical and mental effort. However, the abandonment rates for prostheses remain high, and one of the main factors for this rejection is the absence of sensory feedback [1]. Without tactile feedback, such as naturally provided by the skin's mechanoreceptors, the user becomes highly dependent on visual feedback to monitor object manipulation. This generates a high cognitive load and results in movements that are less natural and more difficult to control. Furthermore, the inability to feel touch impairs the subject's interaction with their environment, which destroys the chance to develop a sense of ownership of the artificial limb to the body. These aspects are pointed out as fundamental for both motor skills and psychological well-being [2].

Given this scenario, the restoration of sensory feedback in amputees becomes a crucial demand for greater adherence and improved usability of upper limb prostheses. By closing the control loop and providing tactile information to the user, manipulation becomes more intuitive [3], [4]. More importantly, continuous sensory feedback directly acts on brain plasticity, facilitating the incorporation of the prosthesis into the individual's body schema (embodiment) and making its use more natural [5].

The skin mechanoreceptors are responsible for providing tactile signals to the nervous system. They are associated with two primary types of afferent fibers: rapidly adapting (RA) and slowly adapting (SA) fibers. RA fibers fire intensely at the onset and offset of a stimulus. In contrast, SA fibers discharge more moderately and continuously throughout the stimulus duration. This mechanism ensures that the brain remains constantly aware of sensory events without becoming cognitively overloaded. For instance, this is why humans can ignore the constant sensation of wearing clothes, yet distinctly feel them when they direct attention to the area [6].

Therefore, to successfully restore sensory feedback in prostheses, a stimulus modulation strategy is necessary to keep the user constantly aware of tactile interactions. In [7], the authors successfully modeled skin mechanoreceptors, enabling the identification of stimulus location on an artificial skin with a resolution approximating that of biological skin. This

was achieved using spiking patterns that mimic real neuronal behavior through the Izhikevich model. The next step involves translating the data captured by these artificial sensors into electrical stimuli, thereby delivering a sensation to the individual that is as close to physiological as possible.

Several approaches have been proposed to restore the lost sensitivity; among them, Transcutaneous Electrical Nerve Stimulation (TENS), a technique with already widely consolidated use in physiotherapeutic practice for pain treatment (analgesia) [8], stands out as a promising non-invasive alternative [9]. By properly modulating the electrical parameters of the stimulus, TENS has the capacity to activate preserved afferent nerve fibers, evoking artificial tactile sensations that can restore lost sensory feedback, whether due to amputation or neurodegenerative diseases [10].

Despite its potential, the challenge lies in mapping the optimal stimulation parameters that are comfortable and generate sensations easily interpreted by the brain [11], [12]. Therefore, this case study aims to evaluate the stimulation parameters that optimize the perception evoked, without causing discomfort, in an arm amputee.

The main contributions of this work are: the evaluation of TENS-evoked somatosensory perception in upper limb amputees; a direct comparison with previously collected able-bodied data using an identical protocol; and empirical evidence on comfortable stimulation parameters for closed-loop sensory feedback design.

II. Methodology

The research of which this work is part was approved by the Ethics Committee of the Federal University of Uberlândia (CAAE: 82612724.4.0000.5152).

A. Materials

The electrical stimulator used was developed at the Biomedical Engineering Laboratory (BioLab) of the Faculty of Electrical Engineering at the Federal University of Uberlândia, being bench-validated in [13] and validated in human subjects in [14]. It was built aiming at the restoration of sensory feedback; thus, the stimulus control parameters must be highly controllable and have high accuracy between the programmed and actual current. In [13], the authors proved through bench validation that the equipment meets these requirements.

The stimuli applied in the experiment consisted of rectangular, balanced biphasic waveforms, featuring a cathodic first phase and a 10 µs interphase interval. These parameters were selected because the rectangular waveform provides a fast rise time, thereby hindering nerve fiber accommodation. Additionally, the balanced biphasic nature drastically reduces the net electrical charge delivered to the skin, which prevents tissue damage when properly applied [15].

The electrode used to stimulate the volunteers was of a concentric circular type, made of siliconized carbon mesh, previously fabricated at the BioLab by [11], with the outer ring functioning as the anode and the inner one as the cathode, as shown in Figure 1.

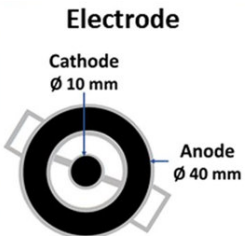

Fig. 1: Electrode used on the stimulation protocol. Figure taken from [7] with the author permission.

B. Stimulation protocol

The protocol consisted of two phases. The first phase was dedicated to determining the sensation threshold — defined as the lowest current amplitude at the lowest stimulation frequency that elicited any identifiable sensation by the volunteer — and the pain threshold, defined as the highest amplitude at the highest stimulation frequency that caused mild discomfort. These measurements were performed in triplicate with a 2-minute interval between each trial. The mean of these results was then used to calculate the amplitudes for the subsequent experimental phase, which were set as follows:

1) 50% above the sensation threshold;
2) 80% of the pain threshold;
3) The mean between the values obtained in steps 1 and 2.

The second phase was divided into three stimulation blocks. In each block, the current amplitude and pulse width were kept constant while the frequency was varied. Each stimulus lasted between 3 and 5 seconds, after which the volunteer answered a four-question survey. The questions were:

1) What was the intensity of the perceived sensation on a scale from 0 to 10?
2) Did the sensation feel more discrete or continuous?
3) Was there any change in the frequency of the last stimulus compared to the previous one (did it increase, decrease, or remain the same)?
4) What sensations were experienced during the application of the stimulus?

To answer question 4, the volunteer had on their hands a list of descriptors to choose from, presented in Table I.

TABLE I: List of descriptors taken from [16].

Tingling	Prickling	Electrical	Shocking
Sharp	Pricking	Stinging	Itching
Stabbing	Pressure	Touch	Cramping
Squeezing	Throbbing	Pounding	Aching
Pinching	Vibrating	Pulsing	Buzzing
Flutter	Tapping	Fizzing	Tickling
Movement	Pulling	Twitching	Contracting
Tensing	Tugging		

The interval between stimuli wasn't standardized since each volunteer responded to the questions in their own time. Also,

the stimulus could be replayed upon the volunteer's request. In this protocol, the response of sense accuracy was vital.

In every block, the stimulation frequency was varied first in an ascending order and immediately followed by a descending order. Throughout the experiment, the volunteer was blinded to the stimulation order, and the pulse width was maintained at 500 μs.

The same stimulation protocol was used in [14] to collect data with able-bodied people.

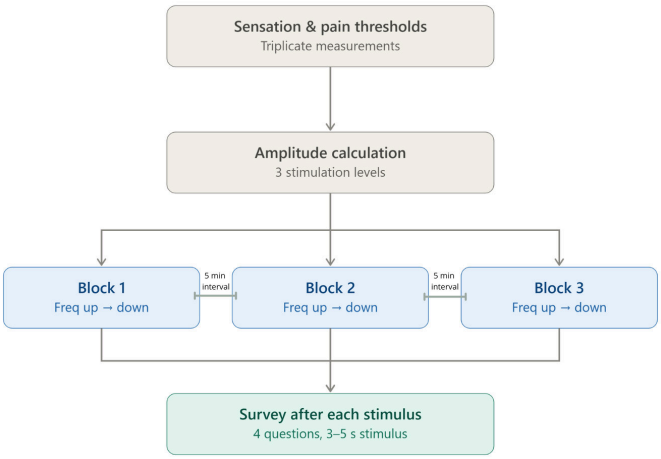

Fig. 2: Stimulation protocol fluxogram.

In this study, the first volunteer was a 55-year-old male with a wrist disarticulation amputation resulting from trauma 6 years prior. When questioned about his phantom limb, he reported a constant sensation of a clenched fist; therefore, it was not possible to map specific digits on the phantom limb. The second volunteer was a 64-year-old male with a transradial amputation, also, resulting from trauma 59 years ago. He reported feeling the phantom limb when moving the healthy arm, but without specificity, which made unable to map specific digits.

III. Results and Discussion

Data from Block 1 from the first volunteer were excluded from the figures and tables, as he reported no discernible sensations during this block — likely because the stimulation amplitude applied was insufficient to evoke clearly distinguishable sensations.

A. Sensation and pain thresholds

The sensation threshold previously found in experiments with healthy volunteers, as described in [14] presented a mean of 0.27 mA with a standard deviation of 0.06 mA. This indicates a high similarity among the volunteers in these measurements, as expected. It was anticipated that the amputee volunteers would exhibit a higher sensation threshold than the healthy group, given that the sensory receptor density at the fingertips is significantly greater than in other regions of the upper limb. However, a sensation threshold of 0.25 mA was identified in both volunteers, which is comparable to that of the healthy volunteers.

Conversely, the mean pain threshold for the healthy volunteers was 1.29 mA with a standard deviation of 0.7. Although this standard deviation might seem relatively broad, a comparison of the absolute values reveals that the comfortable range of current amplitudes varies finely across individuals. The lowest measured value was 0.57 mA, whereas the highest was 2.67 mA. If the stimulation amplitude tailored for the individual with the highest threshold were applied to the one with the lowest, it would cause substantial discomfort. For a system intended for continuous daily use, comfort must be prioritized. In the amputee volunteers, the pain threshold was measured at 5.24 mA for both of them. These results show a higher pain threshold between the amputee volunteers than in the healthy volunteers, which makes the range of possible current amplitudes to use on amputees bigger. These are a desired result, as the goal is to elicit as many sensations as possible.

B. Intensity

In the experiment with healthy volunteers conducted in [14], the perceived intensity exhibited the same logarithmic behavior reported by [11]. This is consistent with the electrical model of the skin, which consists of a resistor and a capacitor in parallel acting as a passive high-pass filter. Consequently, the perceived intensity tends to increase during the ascending phase of the stimulation blocks and decrease as the frequency drops during the descending phase. The logarithmic nature of this relationship occurs because this increase is not indefinite; biologically, there is a saturation limit to the recruitment of nerve fibers in the stimulated region. In the data collected from the amputee volunteers, this same behavior can be observed, although with a noisier trend due to the lower data density. This logarithmic behavior is particularly highlighted in Figure 3 (block 3 - decremental), which presented a correlation coefficient of $R^2 = 0.8961$, and Figure 4 (block 02 - incremental) with $R^2 = 0.8104$.

It can be observed that during the decremental phase, the same frequencies tend to receive a lower intensity rating. This is expected, as the stimuli are delivered over a prolonged period. Even at different frequencies, sensory perception varies depending on whether the nerve fibers are in a resting state or have already been excited; consequently, a stronger stimulus is required to reach the depolarization threshold.

C. Perception of varying frequency

Question 3 aimed to evaluate how frequency variations are perceived by the user. Thus, evaluating if, depending on the target sensory response, specific frequencies may be more suitable than others.

Given that the protocol was applied in an ascending order followed by a descending order, while the volunteers remained blinded to this sequence, the objective was to analyze the frequency of iteration ranges that produced a discernible difference in the perceived sensation. In [14], with able-bodied

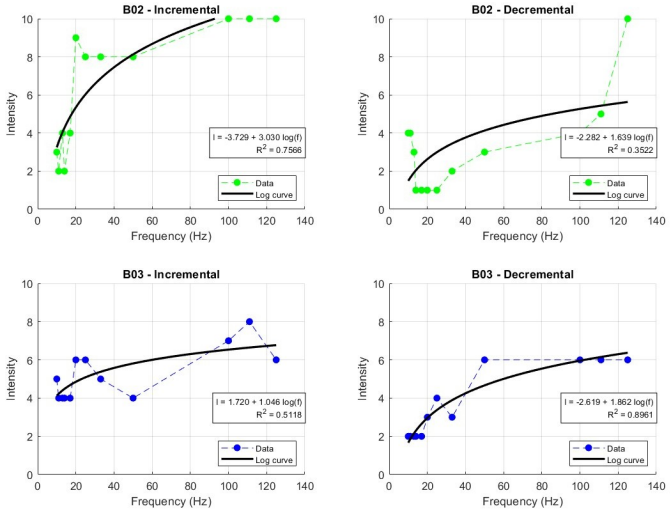

Fig. 3: Logarithmic regression of the relationship between perceived stimulus intensity and applied frequency of volunteer number 1.

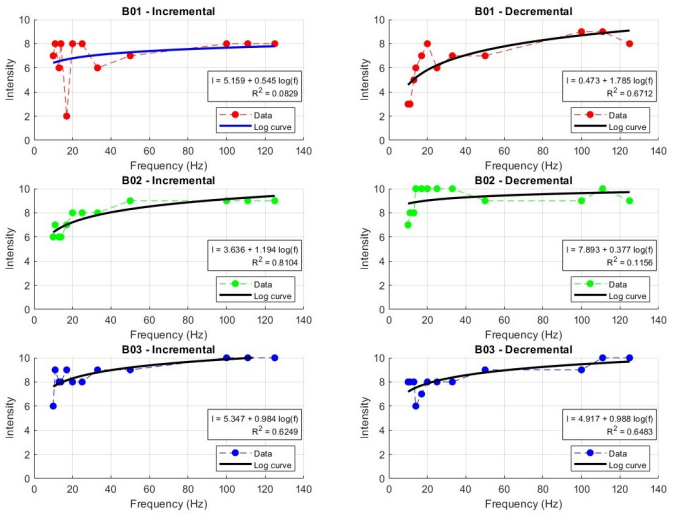

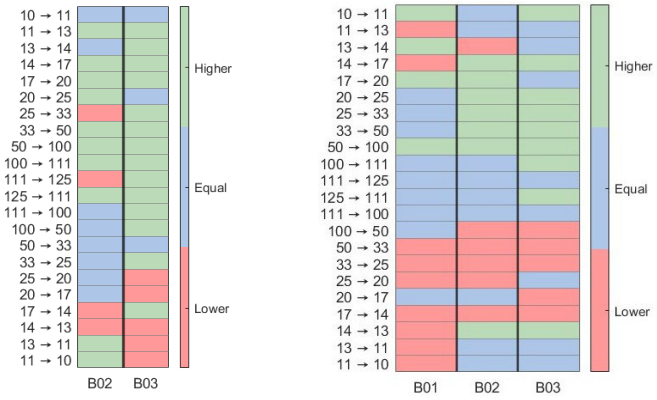

Fig. 4: Logarithmic regression of the relationship between perceived stimulus intensity and applied frequency of volunteer number 2.

volunteers, a decrease in this perception error was observed over the successive blocks. This trend is not well defined in the experiment with amputees. However, the "block 3 - incremental" phase had a significant drop in the error rate for both volunteers. But it didn't continue in the following experiment phase, as shown in Table II.

When seeing the data collected in [14], it is believed that the amplitude value was an essential factor for this error decrease. Additionally, due to the staircase design of the protocol, a learning effect may have occurred; the volunteer might have begun to recognize the stimulation pattern, thereby reducing the error rate. This conclusion cannot yet be extended to amputees, given the limited number of participants in the present study, and further trials with a larger amputee sample are required.

TABLE II: Change in frequency perception error rate. "V1" refers to the responses from volunteer 1 and "V2" refers to the responses from volunteer 2.

Block	V1	V2
Block 01 - incremental	-	63.63%
Block 01 - decremental	-	36.36%
Block 02 - incremental	63.63%	45.45%
Block 02 - decremental	45.45%	54.54%
Block 03 - incremental	18.18%	36.36%
Block 03 - decremental	90.90%	54.54%

(a) Responses collected from volunteer 1.

(b) Responses collected from volunteer 2.

Fig. 5: Changing frequency perception collected during the protocol application. Each column represents the responses from one block, and each line represents a changing frequency.

The results obtained with the amputee volunteer followed a similar trend, showing a decrease in the number of errors during block 3 in the incremental phase for the first volunteer. The second volunteer had similar numbers throughout the experiment.

D. Discrete vs continuous

The first subject reported experiencing only continuous sensations. Therefore, there was no variation in the responses regardless of the experimental block. Therefore, we hypothesize that the volunteer did not fully comprehend the distinction between discrete and continuous stimuli. Consequently, no comparable results could be obtained.

The second subject reported different responses to discrete and continuous stimuli, as shown in Figure 6. The lower frequencies (10-33 Hz) were mostly described as discrete and the higher ones (50-125 Hz) as continuous. These results are similar to the data collected from healthy volunteers in [11].

E. Descriptors

Lower frequencies (10–20 Hz) predominantly elicited comfortable, mechanoreceptive-like sensations, described by the

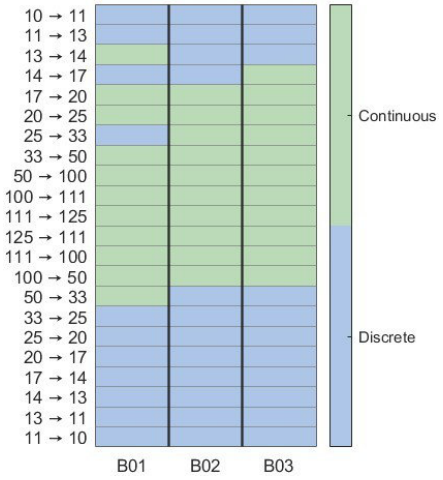

Fig. 6: Color map of responses regarding question 2 from volunteer 2. Columns represent the blocks, and lines represent the frequency change.

volunteers as predominantly ”pulsing” and ”tapping”. However, as the frequency increased towards 100–125 Hz, or when a higher current amplitude was applied, the tactile sensations rapidly transitioned into paresthetic and nociceptive descriptors, such as ”electrical shock”, ”prickling” and ”pinching”. Across all frequencies, ”tingling” was commonly used by both volunteers. Similar results were obtained by [12]. It is noticeable that the staircase protocol highlighted the phenomenon of neural adaptation and sensory hysteresis. For instance, in volunteer 1 Block 2, a 50 Hz stimulus was perceived as a ”shock” during the ascending phase, but the same frequency was described as ”tapping” during the descending phase. This indicates that prior excitation states significantly alter the subsequent perception, emphasizing the need for dynamic stimulus modulation to maintain consistency in prosthetic applications [17].

IV. Conclusion

This study evaluated the somatosensory perception evoked by TENS in two individuals with upper limb amputation, aiming to begin to establish viable parameters for the restoration of sensory feedback in upper limb prostheses. By applying the same psychophysical protocol previously validated in able-bodied individuals, this work provides direct within-protocol comparisons between amputee and able-bodied TENS-evoked perception, offering an empirical basis for parameter selection that aims to restore tactile feedback through electrostimulation.

The results demonstrated that the amputees' sensation threshold (0.25 mA) is comparable to that of healthy individuals, indicating the preservation of sensitivity to electrical stimulation. Conversely, the pain threshold was found to be considerably higher (5.24 mA), which is a positive finding as it provides a wider and more comfortable dynamic range of stimulation for daily user application.

Furthermore, it was observed that the perception of stimulation intensity follows a logarithmic behavior concerning frequency variation, respecting the biological limits of nerve fiber recruitment as seen in related works. It was also noted that stimulation frequencies below 50 Hz generate more distinguishable sensations, predominantly described as ”pulsing”.

As a study limitation, we observed the first volunteer's difficulty in distinguishing between discrete and continuous stimuli, which precluded a direct comparison of these approaches and indicates the need to refine prior training in future protocols. Test-retest reliability was not assessed in this study, as each volunteer completed the protocol in a single session; future work should increase sample size for statistical validation and repeat the protocol across multiple sessions to evaluate the stability of the measured thresholds. Additionally, the fixed ascending-then-descending frequency order may have introduced learning or adaptation effects, so a randomized, counterbalanced presentation is needed to isolate true frequency discrimination thresholds. Finally, the stimulation parameters identified here should be validated through closed-loop functional tasks — including stimulus recognition accuracy, grip force control, and object manipulation performance.

Despite these limitations, this case series contributes an initial, empirically grounded set of stimulation parameters for individuals with upper limb amputation, narrowing a gap between protocols validated only in able-bodied populations and the clinical population that would ultimately use them.

The ultimate goal will be to translate information from artificial tactile sensors into electrostimulation patterns that closely approximate the physiological response, thereby promoting a sense of limb ownership and reducing prosthesis abandonment rates.

***Abstract*—Transcranial photobiomodulation is a non-invasive therapeutic technique that uses light in the red and near-infrared spectrum to modulate cellular processes, especially those related to mitochondrial function, showing therapeutic potential in neurological diseases and brain injuries. Among its applications, hypoxic-ischemic encephalopathy (HIE) stands out, a condition frequently associated with perinatal asphyxia and characterized by alterations in neonatal neurological development. However, the optimization of the technique's parameters is still limited by insufficient knowledge of the optical properties of target brain tissues, which are essential for determining light distribution within the tissue.**

This study aimed to determine the optical absorption coefficient (μa) of brain tissue from mice SAMP8 at neonatal periods P4 and P8, comparing control and anoxia-subjected animals, in order to investigate changes in optical properties induced by hypoxic insult and development. Measurements of incident and transmitted light intensity were obtained by optical spectrophotometry, allowing the estimation of the absorption coefficient at 808 nm, a wavelength commonly used in transcranial photobiomodulation protocols.

The results demonstrated a significant difference among the evaluated groups (Kruskal-Wallis, H = 17.15; p $<$ 0.001), with a large effect size (ϵ^2 = 0.7859), indicating that approximately 78.6% of the variance in μa values was attributed to the experimental condition. Post hoc analysis (Dunn's test) revealed a significant difference between the Anoxia P4 and Anoxia P8 groups (p = 0.001), evidencing a temporal change in optical properties after anoxia exposure, with a higher absorption coefficient at the earlier period (0.0444 vs. 0.0197 mm^{-1}). Furthermore, the Anoxia P4 group differed significantly from the Control P8 group (p = 0.022), suggesting that anoxic tissue at P4 presents optical properties distinct from those observed in physiological development at P8. In contrast, no significant differences were observed between Control P4 and Control P8 (p = 0.370), indicating that physiological neonatal development did not promote expressive changes in the absorption coefficient within the evaluated interval. Likewise, there was no significant difference between Anoxia P8 and Control P8 (p = 1.000), suggesting possible recovery or adaptation of tissue optical properties in periods later after injury.

Taken together, these results indicate that neonatal anoxia modifies the temporal trajectory of brain optical properties during development, promoting significant changes in the early period (P4) that do not persist in the later period (P8), when anoxic tissue presents characteristics similar to the control. The characterization of these properties is essential to improve the application of transcranial photobiomodulation, allowing greater precision in defining therapeutic parameters, such as dose and application time, for conditions such as hypoxic-ischemic encephalopathy and other neonatal brain injuries, especially considering that therapeutic windows at P8 may offer greater predictability in light delivery to the tissue.

I. Introduction

A. Photobiomodulation

Photobiomodulation consists of the use of light in the red or near-infrared bands to regenerate or protect injured or at-risk tissues [2]. Transcranial photobiomodulation (t-PBM), in turn, presents great potential as a non-invasive therapeutic method for brain injuries [3]. t-PBM has proven effective both in animal models and in clinical trials for the treatment of stroke, traumatic brain injury (TBI), psychiatric disorders such as anxiety and depression, and even neurodegenerative diseases such as Alzheimer's and Parkinson's [1].

There are two mechanisms associated with the cellular effect of photobiomodulation. One is specific, which is due to the resonant interaction of light with chromophores present in the cell, such as mitochondria, nitrosyl cytochrome complexes of the electron transfer chain, hemoglobin, etc. On the other

Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP)

hand, the non-resonant interaction of light with cell membrane proteins represents a non-specific mechanism. However, it is important to emphasize that the non-specific mechanism does not pose a risk to the cell, whereas the specific mechanism can damage the membrane or cellular behavior through what is known as photodynamic damage. Therefore, it is important to determine the appropriate light dose for photobiomodulation, as very high intensities cause cell damage [4].

There is still no consensus on the best parameters and protocols for photobiomodulation application. Nevertheless, some parameters are essential for the good effectiveness of photobiomodulation: wavelength, energy, power, illuminance, irradiance, pulse mode and duration, and treatment repetition. All these parameters are still highly variable in the literature. Furthermore, [5] demonstrated that the number of mitochondria also influences the efficacy of photobiomodulation, such that cells with a greater number of mitochondria respond better to the technique than those with fewer, probably due to the specific mechanism of the technique, which, as mentioned earlier, interacts with cell chromophores.

Finally, the optical properties of the target tissue are also relevant for the action of photobiomodulation, since they interfere with photon transport through the tissue, which are the particles that actually interact with the molecules that compose it [6].

B. Light-Tissue Interaction Mechanisms

As mentioned earlier, light interacts with tissue in two ways to generate the photobiomodulation effect: resonantly, the specific mechanism of the technique, and non-resonantly, the non-specific mechanism. The effect of these interactions can be considered specific or non-specific depending on the optical phenomenon each causes [4].

Resonant interaction occurs when the frequency of light (or the photon energy) corresponds to one of the characteristic energy levels of a substance. When light interacts resonantly with biological material, it can excite molecules or atoms to a higher energy level. In other words, light has energy that corresponds to an energy transition of molecules that compose biological tissue [27].

The characteristics of this type of interaction include: high efficiency; since light has the same energy as the energy transitions of the biological system, the absorption or emission of energy is very efficient. Specificity; the interaction occurs in a highly specific manner due to the correspondence between light frequencies and the energy transitions of molecules or atoms present in the tissue [27].

Finally, the optical phenomena that can be observed from a resonant interaction are: light absorption by chromophores; biological molecules such as proteins or pigments (e.g., hemoglobin, chlorophyll, or melanin) absorb light at specific wavelengths. When the light frequency exactly matches the electronic transition frequency of the chromophore, resonant absorption occurs. Fluorescence: after photon absorption, one or more electrons of the molecule can be excited to a higher quantum state. When they return to their lower energy state, they emit a photon with a different frequency (and longer wavelength), a phenomenon known as fluorescence [27].

On the other hand, in non-resonant interaction, light does not directly correspond to any specific energy transition within the biological tissue. Instead, light can interact with molecules in a more general way, without exciting a specific energy state [27].

The characteristics of this type of interaction are: lower efficiency; there is no absorption or emission of energy as efficient as in resonant interaction, since there is no correspondence between light frequency and the material's energy transitions. Greater diffusion; the interaction tends to be less specific, affecting molecules more generally without causing direct excitation [27].

Finally, the optical phenomena observed in this case are: scattering effect; resulting from light scattering by molecules or structures of biological tissue without resonant absorption. This phenomenon occurs when molecules or structures do not absorb light but deviate its path, as happens with Rayleigh or Mie scattering. Thermal effects: occur when light is absorbed, but not resonantly. Thus, part of the energy is converted into heat, resulting in an increase in tissue temperature. This is typical in techniques such as phototherapy, where temperature increase can be used to treat certain types of tissue or cells [27].

C. Perinatal Asphyxia

Perinatal asphyxia (PA) consists of the transient interruption of body oxygenation and results from the low level of oxygen available to cells when the supply-demand balance of the gas is unbalanced. With an incidence of 1% to 6% in live births, one of its consequences is mitochondrial degeneration, impairing cellular energy metabolism [13]. In a study with cardiac cells, [14] demonstrated that the mitochondrial respiratory chain was damaged by the hypoxia-ischemia process and, although some recovery was observed after reoxygenation, mitochondrial activity will not return to its normal level.

The brain, especially during its developmental period, is particularly sensitive to oxygen deprivation. Thus, PA is directly related to cognitive sequelae such as learning deficits and impaired spatial memory. The condition, responsible for 23% of newborn deaths worldwide, can cause multiple organ failure and results in hypoxic-ischemic encephalopathy [15; 13].

D. Hypoxic-Ischemic Encephalopathy and t-PBM

Hypoxic-ischemic encephalopathy (HIE) is a clinical condition that affects, as mentioned earlier, newborns. It is characterized by moderate to severe metabolic acidosis at birth and is associated with global impairment of neonatal neural function [9]. Worldwide, the incidence of HIE is 0.15% in full-term infants, and when considering premature infants, the incidence can increase by up to 60%. Thus, HIE demonstrates a significant risk for newborns worldwide [10].

t-PBM shows potential as a treatment for HIE, as it increases adenosine triphosphate (ATP) production by cell mitochondria.

Cytochrome c oxidase, an enzymatic complex that plays an important role in the mitochondrial energy production chain, absorbs light at wavelengths near 830 nm and stimulates ATP production. Additionally, photobiostimulation activates secondary cell signaling pathways that also contribute to the normalization of ATP levels in cells [11].

Thus, cellular energy metabolism, impaired by the ischemic process of HIE, is improved by t-PBM, preventing the spread of cell death in the penumbra region, where cells are at reversible risk of death. There is also evidence that t-PBM increases neurogenesis and the production of endogenous neurotrophic factors (molecules responsible for neuronal growth and survival of mature neurons), contributing to the recovery of brain function lost due to HIE [11].

Many cases of HIE result from perinatal asphyxia (PA) and, even with the application of already established PA treatments (e.g., therapeutic hypothermia), about 45% of newborns with HIE die or present significant sequelae, such as epilepsy, neurological and/or cognitive deficits, and cerebral palsy [12].

E. Senescence-Accelerated Mouse Prone 8 (SAMP8)

SAMP8 is an animal model of accelerated senescence developed by [16]. When compared to a model resistant to accelerated senescence (SAMR1), the differences are evident: the average lifespan of SAMR1 is 18 months, while SAMP8 lives only 12 months on average. Furthermore, SAMP8 presents, at the 8th month of life, a higher score than SAMR1 on the senescence grading scale, which evaluates cellular aging through rates of irreversible cell activity arrest and production of substances that contribute to the development of aging-related diseases [17; 18].

Additionally, [19] demonstrated that energy deposition in brain tissues by t-PBM decreases with increasing age. Thus, appropriate parameters depend on the patient's age, so they should be adapted to the individual's developmental and/or aging stage [20]. Therefore, SAMP8 proves to be an interesting model for evaluating laser parameters for t-PBM, as it allows assessing the impact of age over a short period.

F. Optical Properties of Cerebral Tissue

The development and improvement of phototherapy techniques, such as photobiomodulation, is due to advances in biophotonics studies, a field of physics that aims to elucidate the mediators of the interaction between light and biological systems. By determining the optical properties of tissues, it is possible to estimate the direction of photon propagation in the irradiated tissue, as well as the light fluence rate distribution. Therefore, it is essential to know these properties to predict both absorption and energy distribution throughout the tissue, which shape the therapeutic effects of irradiation [7].

One of the main optical properties that affects how light interacts and propagates through a tissue is its absorption coefficient [7]. In order to determine it for biological tissues, such as brain tissue, it is possible to use, with reservations, the Lambert-Beer Law. To do so, it is necessary to determine the spectral absorbance of mouse brain slices, for example. From the absorbance, it is possible to estimate the absorption coefficient (μa) using the relation derived from the Lambert-Beer law:

$$\mu_a = \frac{ln(10).A}{L}$$

where A is the measured absorbance and L is the sample thickness. This step will provide a preliminary estimate of μa, acknowledging that optical scattering effects may contribute to the attenuation of transmitted light [24]. The use of light in the near-infrared (NIR) band, on the other hand, is due to its high tissue penetration power, since the chromophores water and hemoglobin absorb little light in the wavelength range of 600 to 900 nm, which encompasses part of the NIR [8].

Therefore, this project proposes to measure the optical absorption of brain tissue samples from SAMP8 mice, using optical absorption spectrophotometry, to determine the absorption coefficient of brain tissue, in order to allow a better understanding of the brain-light interaction and, consequently, contribute to the definition of the most appropriate t-PBM parameters for the treatment of HIE and PA.

II. Objectives

Determination of the optical absorption coefficients of brain tissue in SAMP8 mice at ages P4 and P8, in control conditions and after submission to neonatal anoxia at stage P3. To identify whether there is an influence of age and mitochondrial numbers on the optical properties of brain tissue in SAMP8 mice.

III. Methods

A. Experimental Animals

All experiments were carried out in accordance with the Ethical Principles of Animal Experimentation adopted by the Brazilian College of Animal Experimentation (COBEA) and approved by the Ethics Committee on the Use of Animals of the Federal University of ABC (protocols 8852240517 and 3572091023).

SAMP8 mice, an animal model of accelerated senescence, were used at postnatal days 4 and 8. For each age, there were two different groups: animals subjected to neonatal anoxia and control animals. The animals were housed in the animal facility of the Federal University of ABC, São Bernardo do Campo campus, under a 12-hour light/dark cycle (with the light phase starting at 7:00 AM), maintaining a constant temperature of (22 ± 1°C. They had unrestricted access to water and food. Both males and females were used for breeding, and groups were formed based on their litters.

Based on literature data [25], a minimum detectable difference of 2 mm^{-1} and a standard deviation of 0.8 mm^{-1} were estimated. Sample size calculation for ANOVA with α= 0.05 and 80% power indicated the need for 5 to 6 animals per group. Thus, n = 6 per group was adopted, totaling 24 animals, based on international guidelines that recommend considering adequate sample sizes to ensure greater statistical robustness, compensate for possible experimental losses, and ensure result reproducibility, as indicated by [26].

B. Neonatal Asphyxia Experimental Model

To simulate the perinatal asphyxia process, the neonatal anoxia model previously described by Takada et al. [21] was adopted. P3 pups were exposed to a continuous flow of 10.5 L/min of pure nitrogen (100%) for 12 minutes, at a temperature of 37°C, in a semi-hermetic chamber. The control group underwent the same procedure, but without the nitrogen flow.

C. Transcardial Perfusion

The animals, after being anesthetized with urethane (1000 mg/Kg), were subjected to transcardiac perfusion with 0.9% saline solution (pH 7.4). Perfusion was maintained until whitening of peripheral tissues was observed, which characterizes complete blood removal. Subsequently, the brains were dissected and post-fixed in 4% PFA solution for 24 hours at 4°C. This is because Moy et al.[22] demonstrated that the presence of blood in the tissue compromises the accuracy of optical absorption measurements, and its complete removal is recommended for reliable spectral analyses. The brains were stored in phosphate-buffered saline (PBS) at 4°C until the time of measurement, preventing dehydration and enzymatic degradation [23].

D. Spectrometry

Each sample (brain) of the mice was placed in a holder to ensure stable fixation and was irradiated by the laser, in continuous wave mode. Transmittance measurements were acquired using the Ocean Optics spectrometer with the OceanView software. To ensure repeatability, each measurement was performed three times, and the average value was used for the final analysis. The reduced scattering coefficient was assumed as $\mu s'$ = 1 mm^{-1}, a typical average value reported in the literature for brain tissues [29].

E. Experimental Setup

- Microscope slides with samples were carefully positioned and aligned on the spectrophotometer, and 3 scanning measurements (400–900 nm) of the tissue optical absorption were performed.
- A dental diode laser source (808 nm) was positioned perpendicularly to the slide with the sample, and the optical fiber was positioned off-axis from the incident beam, in order to capture only diffuse components and avoid direct light. The respective diffuse transmittances, information required to determine the absorption coefficients, were measured separately.

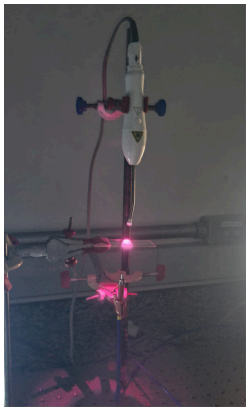

Fig. 1. Experimental Setup.

IV. Results

The analysis of the optical properties of brain tissue was performed by determining the optical absorption coefficient (μa) at the wavelength of 808 nm. After exploratory data analysis, an outlier value was identified in the Control P8 group, which was excluded from subsequent statistical analyses.

The descriptive statistics of the absorption (Table I) coefficient (μa) revealed differences in the distribution of values among the experimental groups. The Anoxia P4 group presented the highest mean absorption coefficient (0.04440 mm^{-1}), followed by the Control P4 group (0.03638 mm^{-1}), Control P8 group (0.03318 mm^{-1}), and Anoxia P8 group (0.01971 mm^{-1}). The Anoxia P4 group also showed a relatively narrow distribution, with values ranging from 0.03834 to 0.05623 mm^{-1}, whereas the Control P8 group exhibited the greatest variability, with values ranging from 0.02238 to 0.06569 mm^{-1}. The median absorption coefficients were 0.04104 mm^{-1} for Anoxia P4, 0.01748 $mm^{-1}$for Anoxia P8, 0.03749 mm^{-1} for Control P4, and 0.02626 mm^{-1} for Control P8. Overall, these descriptive results indicate a lower absorption coefficient in the Anoxia P8 group compared with the other experimental groups, particularly when compared with Anoxia P4.

TABLE I
DESCRIPTIVE STATISTICS OF THE ABSORPTION COEFFICIENT (μ_a) FOR EACH EXPERIMENTAL GROUP.

Group	n	Mean	SD	Median	Minimum	Maximum
Anoxia P4	6	0.04440	0.00712	0.04104	0.03834	0.05623
Anoxia P8	6	0.01971	0.00668	0.01748	0.01222	0.02803
Control P4	6	0.03638	0.00447	0.03749	0.02891	0.04144
Control P8	5	0.03318	0.01825	0.02626	0.02238	0.06569

The μa values showed differences among the experimental groups. Statistical analysis using the Kruskal-Wallis test indicated a significant difference among the four evaluated groups (H = 17.15; p = 0.00066), with an effect size of ϵ^2 = 0.7859, indicating a high effect of the experimental condition on the absorption coefficient.

Since the data did not meet the assumptions of parametric statistical tests, non-parametric methods were used for the

analysis. When a significant overall difference was identified by the Kruskal–Wallis test, post hoc pairwise comparisons were performed using Dunn's test to determine which groups differed significantly from each other. To account for the increased risk of Type I error resulting from multiple pairwise comparisons, p-values were adjusted using the Benjamini–Hochberg procedure, which controls the false discovery rate (FDR). This approach was selected as it is appropriate for non-parametric data and allows for the identification of significant differences between specific groups while limiting the proportion of false-positive findings among the statistically significant results.

TABLE II
DUNN'S POST HOC PAIRWISE COMPARISONS WITH BENJAMINI–HOCHBERG CORRECTION.

Comparison	**Adjusted p-value**
Anoxia P4 vs. Anoxia P8	0.003299*
Anoxia P4 vs. Control P4	0.728374
Anoxia P4 vs. Control P8	0.027198*
Anoxia P8 vs. Control P4	0.055263
Anoxia P8 vs. Control P8	1.000000
Control P4 vs. Control P8	0.226556

* $p < 0.05$.

Multiple comparisons among groups (Table II) revealed significant differences between the Anoxia P4 and Anoxia P8 groups (p = 0.003299), as well as between the Anoxia P4 and Control P8 groups (p = 0.027198). The Anoxia P4 group presented a higher absorption coefficient (mean = 0.0444 mm^{-1}) compared with both the Anoxia P8 group (mean = 0.0197 mm^{-1}) and the Control P8 group (mean = 0.0269 mm^{-1}). No statistically significant difference was observed between the Control P4 (mean = 0.0364 mm^{-1}) and Control P8 groups (p = 0.226556). Similarly, no significant differences were observed between the Anoxia P4 and Control P4 groups (p = 0.728374), or between the Anoxia P8 and Control P8 groups (p = 1.000000). The comparison between Anoxia P8 and Control P4 also did not reach statistical significance (p = 0.055263).

Also, the distribution of the absorption coefficient (μ_a) across the experimental groups is illustrated in Fig. 2. The boxplot shows a higher central tendency of μ_a in the Anoxia P4 group compared with the other groups, whereas the Anoxia P8 group exhibited the lowest values and greater variability. The Control P4 and Control P8 groups showed intermediate absorption coefficients, with a relatively narrower distribution in the latter group. The Anoxia P4 group also presented a broader range of values and a high individual value, while the Anoxia P8 group displayed a wider dispersion of measurements. Overall, the observed distribution is consistent with the statistical analysis, particularly the significant differences involving the Anoxia P4 group, and suggests that the optical absorption properties of brain tissue may vary according to both developmental stage and exposure to hypoxic-ischemic insult.

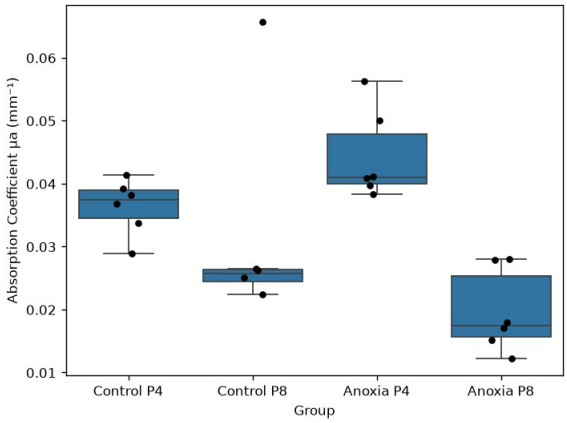

Fig. 2. Boxplot of Results.

These preliminary results suggest that hypoxic-ischemic insult may be associated with changes in the optical properties of brain tissue during neonatal development, particularly at the P4 developmental stage, as indicated by the higher absorption coefficient observed in the Anoxia P4 group.

V. DISCUSSION

The results demonstrated significant differences in the optical absorption coefficient (μa) of brain tissue among the experimental groups of SAMP8 mice. The Kruskal–Wallis test indicated an overall effect of experimental group on μa(H = 17.15; p $<$ 0.001), with a large effect size (ϵ^2 = 0.7859). This indicates that a substantial proportion of the variability observed in the absorption coefficient was associated with the experimental groups. However, the overall result should be interpreted together with the pairwise comparisons and the uncertainty associated with the estimated group values.

Descriptive statistics showed that the highest mean $\mu a$was observed in the Anoxia P4 group (0.0440 ± 0.00712 mm^{-1}; n = 6), followed by Control P4 (0.03638 ± 0.00447 mm^{-1}; n = 6), Control P8 (0.03318 ± 0.01825 mm^{-1}; n = 5), and Anoxia P8 (0.01971 ± 0.000668 mm^{-1}; n = 6). The approximate 95% confidence intervals for the mean μawere 0.0365–0.0515 mm^{-1} for Anoxia P4, 0.0317–0.0411 mm^{-1} for Control P4, 0.0105–0.0558 mm^{-1} for Control P8, and 0.0190–0.0204 mm^{-1} for Anoxia P8. These confidence intervals are presented as descriptive estimates of uncertainty around the group means and should be interpreted alongside the non-parametric statistical analysis.

Dunn's post hoc analysis with Benjamini–Hochberg correction showed that the principal significant difference occurred between the Anoxia P4 and Anoxia P8 groups. The Anoxia P4 group presented a significantly higher μathan the Anoxia P8 group (adjusted p = 0.00329). In contrast, no statistically significant differences were observed between control and anoxia groups at the same postnatal age. At P4, the difference between Anoxia P4 and Control P4 was not significant (adjusted p = 0.72834), despite the numerically higher mean observed in Anoxia P4. Similarly, Anoxia P8 and Control P8 did not differ significantly (adjusted p = 1.00000).

These results indicate that the main pairwise difference identified in the present experiment was between the two anoxia groups at different postnatal ages, rather than between anoxia and control animals at the same age. Therefore, the data do not demonstrate a statistically detectable difference in μaattributable to anoxia at either P4 or P8 when animals are compared within the same developmental stage.

The difference between Anoxia P4 and Anoxia P8 indicates that μavaried between the two postnatal ages within the anoxia condition. However, this finding cannot be interpreted as evidence of recovery, adaptation, or attenuation of the effects of the hypoxic-ischemic insult. Because the study has a cross-sectional design, the comparison between Anoxia P4 and Anoxia P8 simultaneously involves differences in postnatal age and experimental condition. Consequently, the observed difference may reflect developmental changes, effects associated with the hypoxic-ischemic condition, or a combination of both. Additional longitudinal measurements would be necessary to determine whether μachanges over time within the same animals.

The comparison between Anoxia P4 and Control P8 was also statistically significant (adjusted p = 0.027198). However, these groups differ in both experimental condition and postnatal age. Therefore, this comparison does not allow the independent contribution of anoxia to be distinguished from that of developmental stage. The remaining pairwise comparisons were not statistically significant, including Anoxia P4 versus Control P4 (adjusted p = 0.72834), Anoxia P8 versus Control P8 (adjusted p = 1.00000), and Control P4 versus Control P8 (adjusted p = 0.226556).

The confidence intervals provide additional information regarding the precision of the estimated group means. The relatively narrow interval observed for Anoxia P8 (0.0190–0.0204 mm^{-1}) contrasts with the substantially wider interval observed for Control P8 (0.0105–0.0558 mm^{-1}). This difference in interval width is consistent with the greater variability observed in the Control P8 group (SD = 0.01825 mm^{-1}) and its smaller sample size (n = 5). In comparison, the Anoxia P4, Anoxia P8, and Control P4 groups each included six animals. Thus, the small sample sizes, particularly in Control P8, introduce substantial uncertainty into the estimation of $\mu a$and may limit the statistical power to detect relatively small differences between groups.

Importantly, the absence of statistically significant differences between control and anoxia groups at the same postnatal age should therefore not be interpreted as evidence of equivalence between the groups. With only five to six animals per group, the study may have limited ability to detect subtle effects, particularly in the presence of biological variability. Conversely, the significant difference between Anoxia P4 and Anoxia P8 should not be interpreted independently of the sample size and variability of each group. Larger experimental groups would provide more precise estimates and greater statistical power to determine whether the observed differences are reproducible.

The biological interpretation of the observed differences should also remain restricted to the present SAMP8 mouse model. Changes in μamay potentially be associated with differences in tissue composition or in the concentration and distribution of absorbing chromophores, such as hemoglobin, water, and mitochondrial chromophores including cytochrome c oxidase [24,28]. However, these variables were not directly measured in the present experiment. Therefore, specific biological mechanisms cannot be established from the optical absorption measurements alone.

The observed differences in $\mu a$are relevant to the optical characterization of brain tissue in the SAMP8 model because absorption contributes to light attenuation within biological tissue. However, the present results do not establish whether the observed differences in μaresult in different biological responses to transcranial photobiomodulation, nor do they support the identification of a specific developmental stage as a more favorable therapeutic window. Such conclusions would require independent experimental measurements of treatment response and biological outcomes.

A further limitation is that $\mu a$is an integrative optical parameter and does not allow the individual contribution of specific chromophores to be determined. In addition, the present approach does not provide an independent simultaneous estimate of tissue scattering. Therefore, an important next step is to validate the estimated μausing an optical method specifically suited to turbid biological media. In particular, an integrating sphere combined with the Inverse Adding-Doubling (IAD) method would allow absorption and reduced scattering coefficients to be estimated simultaneously. Independent validation using this approach would strengthen the reliability of the optical characterization and determine whether the differences observed among the SAMP8 experimental groups are reproducible when both absorption and scattering are considered.

Future studies should therefore include larger sample sizes to improve statistical power and reduce the uncertainty of the estimated optical properties. Longitudinal experimental designs, when feasible, together with histological, immunohistochemical, or biochemical measurements, would also help distinguish developmental changes from alterations associated with the hypoxic-ischemic condition. These approaches would provide a stronger basis for interpreting the differences in optical absorption observed between P4 and P8 in the SAMP8 mouse model.

***Abstract*—High-density surface electromyography (HD-sEMG) decomposition provides a non-invasive approach to estimate motor unit spike trains, but algorithm comparisons can be influenced by method-specific post-processing and quality criteria. This study compared Gradient Convolution Kernel Compensation (gCKC), Fast Independent Component Analysis (FastICA), and Swarm Contrastive Decomposition (SCD) using the same recordings from eleven healthy participants performing trapezoidal isometric contractions for a broad range of intensities. A unified post-processing framework was applied to all methods, including CKC-based innervation pulse train (IPT) reconstruction, minimum discharge count, pulse-to-noise ratio (PNR), silhouette value (SIL), duplicate removal, and cross-method motor unit matching. Across visual-feedback trapezoidal tasks, FastICA identified a higher number of motor units, followed by gCKC and SCD. Accepted units showed high PNR and SIL values for all methods, with SCD presenting the highest average quality metrics after the common reconstruction procedure. Linear mixed-effects models showed significant force-level effects on MUAP amplitude and discharge rate, whereas neither measure differed significantly among decomposition methods. Overlap analysis showed that only a subset of recovered motor units was shared by all three approaches, indicating that algorithm choice can influence both motor unit yield and the motor unit sample recovered from the same HD-sEMG recordings.**

***Index Terms*—HD-sEMG, motor unit decomposition, Gradient Convolution Kernel Compensation, FastICA, Swarm Contrastive Decomposition**

Elias is a CNPq Research Productivity Fellow, process no. 316320/2023-4.

I. Introduction

High-density surface electromyography (HD-sEMG) decomposition has become one of the most powerful techniques for investigating the neural control of movement [1]. By separating interference EMG into the discharge times of individual motor units (MUs), HD-sEMG provides non-invasive access to the output of spinal motor neurons during voluntary contractions. This approach has supported detailed studies of motor unit recruitment, discharge behavior, neural drive, fatigue, aging, and neurological disorders [2].

Several computational approaches have been proposed for HD-sEMG decomposition, each relying on different mathematical principles to separate the contributions of individual motor units from multichannel EMG recordings. Among the most established methods are Gradient Convolution Kernel Compensation (gCKC) [5] and Fast Independent Component Analysis (FastICA) [8], both based on blind source separation but employing different optimization strategies [5], [9]. More recently, Swarm Contrastive Decomposition (SCD) was proposed as an adaptive source-separation approach that combines contrast-function optimization with a peel-off strategy. Using simulated data with excitation levels ranging from 10 to 100% MVC, the method was shown to improve the detection of small or deep motor units [10], [11].

The performance of HD-sEMG decomposition algorithms is traditionally assessed using the number of identified motor units, and, more directly, measures of the quality of the estimated sources, including the Pulse-to-Noise Ratio (PNR) and the Silhouette value (SIL) [6]–[8]. These metrics provide information about decomposition quality and reliability and can be used to compare algorithms. However, considerably less attention has been paid to investigating how different decomposition methods behave when applied to the same recordings acquired under varying contraction conditions.

This question is relevant for submaximal trapezoidal contractions performed at different force levels. As contraction intensity increases, interference EMG becomes progressively more complex because of additional motor unit recruitment, changes in discharge behavior, and greater action potential overlap [3]. Consequently, algorithms may exhibit different sensitivities to signal complexity, potentially affecting motor unit yield, decomposition quality, and agreement between methods.

Therefore, this study compared gCKC, FastICA, and SCD using the same HD-sEMG recordings collected during isometric trapezoidal contractions at different force levels. The methods were compared in terms of accepted motor units, PNR, SIL, and cross-method overlap. In addition, motor unit action potential (MUAP) amplitude and mean discharge rate were analyzed to investigate whether the choice of decomposition algorithm influenced the characteristics of the identified motor units. By using identical experimental conditions and acceptance criteria, this study aims to support the interpretation of HD-sEMG decomposition results across algorithms.

II. Materials and Methods

A. Participants

Eleven healthy volunteers (6 females and 5 males; age: 26.2 ± 4.5 years; body mass: 68.1 ± 11.3 kg; height: 1.67 ± 0.07 m) participated in this study. None of the participants reported a history of neurological or musculoskeletal disorders affecting the upper limbs. All participants provided written informed consent prior to participation. The experimental protocol was approved by the Research Ethics Committee of the University of Campinas (CEP/UNICAMP; CAAE: 88364525.6.0000.5404).

B. Experimental Protocol

Participants performed isometric trapezoidal contractions of the First Dorsal Interosseous (FDI) muscle at six force levels corresponding to 5, 15, 30, 45, 60, and 70 % of their maximum voluntary contraction (MVC). Each visual-feedback contraction began with a 2-s baseline period, followed by a linear increase in force at a constant rate of 5% MVC/s, a 15-s constant-force plateau, and a linear decrease at the same rate. Consequently, the total duration of each visual-feedback contraction was 21, 25, 31, 37, 43, and 47 s for the 5, 15, 30, 45, 60, and 70 %MVC conditions, respectively. Real-time visual feedback of the target force trajectory was displayed throughout these trials to assist participants in accurately following the desired force profile. A 90-s resting period was provided between consecutive visual-feedback contractions to minimize fatigue.

C. HD-sEMG Acquisition

HD-sEMG signals were acquired from the FDI muscle using a Muovi+ acquisition system (OT Bioelettronica, Turin, Italy) equipped with a HD08MM1305 high-density electrode array. The recordings consisted of 64 monopolar channels sampled at 2000 Hz. The same HD-sEMG recordings were independently processed by each decomposition algorithm, ensuring that all methods were evaluated using identical input signals.

D. HD-sEMG Decomposition

Three decomposition algorithms were evaluated: gCKC, FastICA, and SCD. The gCKC decomposition was performed using a MATLAB implementation based on the original gCKC formulation [5], [12]. The FastICA-based implementation followed the MUedit framework [9], whose algorithm is available at https://github.com/simonavrillon/MUedit2. The SCD implementation followed the particle swarm-optimized independence estimator and HD-sEMG SCD framework [10], [11], with code available at https://github.com/AgneGris/swarm-contrastive-decomposition.

All decomposition outputs were subjected to the same post-processing pipeline and motor unit acceptance criteria.

E. Motor Unit Acceptance Criteria

Identical acceptance criteria were applied to all detected motor units, regardless of method. Specifically, motor units were required to satisfy three quality criteria: a minimum number of detected discharges, a PNR above the predefined threshold, and a minimum SIL.

Motor units with fewer than 21 detected discharges were discarded. This operational threshold was used to exclude motor units that were active only briefly during the trapezoidal contraction, often near their recruitment or derecruitment thresholds, where discharge behavior tends to be more variable. Retaining only units with at least 21 discharges also provided a minimum number of interspike intervals (ISI) for estimating discharge rate and reduced the influence of unstable quality metrics and spike-triggered MUAP estimates derived from very short discharge trains. This criterion was considered complementary to PNR and SIL, since these metrics do not fully prevent the inclusion of motor units with irregular discharge behavior near activation thresholds.

The PNR was computed from the innervation pulse train (IPT) as the logarithmic ratio between the average energy of the IPT at the detected discharge instants and the average energy of the remaining signal after excluding a ±10-ms window around each discharge [6]. The PNR expression is shown in Equation (1).

$$PNR = 10\log_{10}\left(\frac{\frac{1}{N}\sum_{i=1}^{N} IPT^2(t_i)}{\frac{1}{M}\sum_{j=1}^{M} IPT^2(t_j)}\right), \tag{1}$$

where t_i denotes the detected discharge instants, t_j corresponds to the samples considered as noise, and N and M are the numbers of discharge and noise samples, respectively. Prior to the computation, the IPT was normalized by the maximum amplitude at the detected discharge instants.

The SIL was used to quantify the separation between spike and noise clusters. Let μ_s and μ_n denote the centroids of the spike and noise samples, respectively. The within-cluster and between-cluster distances are defined in (2).

$$W = \sum_{i=1}^{N} (s_i - \mu_s)^2, \qquad B = \sum_{i=1}^{N} (s_i - \mu_n)^2. \tag{2}$$

The silhouette value was then computed using (3).

$$SIL = \frac{B - W}{\max(B, W)}. \tag{3}$$

To avoid differences in the internal source representation of each decomposition algorithm influencing PNR and SIL, the IPT was reconstructed for every accepted candidate using a Convolution Kernel Compensation (CKC)-based formulation derived from the convolutive blind source separation framework [5]. This reconstruction used the common HD-sEMG input signal, rather than algorithm-specific source estimates. For each recording, the raw HD-sEMG was band-pass filtered using a Butterworth filter between 20 and 500 Hz, and a 60-Hz notch filter was applied. The filtered signal was then temporally extended and whitened to form $\mathbf{X}_e$. For motor unit j, the correlation vector was estimated from the detected discharge instants $\tau_i^{(j)}$ using (4)

$$\mathbf{c}_{\bar{y}t_j} = \frac{1}{N_j} \sum_{i=1}^{N_j} \mathbf{X}_e(\tau_i^{(j)}). \tag{4}$$

where N_j denotes the number of detected discharges of motor unit (j).

A separation vector was obtained from the inverse covariance matrix of the extended observations and normalized to unit norm, as shown in (5),

$$\mathbf{w}_j = \mathbf{C}_{yy}^{-1} \mathbf{c}_{\bar{y}t_j}, \qquad \mathbf{w}_j \leftarrow \frac{\mathbf{w}_j}{\|\mathbf{w}_j\|}. \tag{5}$$

The linear source estimate and CKC-based IPT were computed using (6).

$$\hat{t}_j = \mathbf{w}_j^T \mathbf{X}_e, \qquad \mathrm{IPT}_j = \hat{t}_j |\hat{t}_j|. \tag{6}$$

Finally, IPT_j was normalized by $\max(|IPT_j|)$ before PNR and SIL computation. This procedure was applied to gCKC, FastICA, and SCD using the discharge times detected by each method, so that quality metrics were computed from a common IPT representation.

A PNR threshold of 28 dB was adopted based on Holobar et al. [6], who associated values above 28 dB with discharge-identification sensitivities above approximately 85%. The SIL threshold was set to 0.90, consistent with prior EMG decomposition work [7]. Together with the minimum discharge count, these thresholds were used to retain reliable motor units while preserving yield.

This unified procedure reduced the influence of noisy or irregular sources and focused the comparison on motor units satisfying the same minimum quality criteria across algorithms.

F. Motor Unit Matching and Overlap Analysis

To evaluate overlap between methods and avoid counting the same underlying motor unit multiple times, all pairs of motor unit discharge trains were compared using spike-train cross-correlation.

For each motor unit pair, a coincidence histogram was computed within a temporal search window of ± 20 ms. A normalized spike-train similarity index was then calculated as

$$S = 100 \frac{\sum_{k=-L}^{L} C(k)}{\max(N_1, N_2)}, \tag{7}$$

where $C(k)$ denotes the number of coincident discharges at lag k, N_1 and N_2 correspond to the numbers of detected discharges in the two motor units, and L represents a tolerance window of ± 10 ms around zero lag.

Motor unit pairs with $S > 60\%$ were considered to correspond to the same underlying motor unit. When duplicates were identified, only the motor unit with the highest PNR was retained.

The same matching procedure was used to remove within-method duplicates and quantify cross-method overlap.

G. Outcome Measures

The decomposition methods were compared using the following outcome measures:

1) number of accepted motor units;
2) number of motor units excluded by the acceptance criteria;
3) PNR and SIL of the accepted motor units;
4) overlap between decomposition methods;
5) MUAP peak-to-peak amplitude;
6) mean discharge rate.

MUAP templates were estimated by spike-triggered averaging of the original HD-sEMG recordings using the discharge times identified by each decomposition method [4]. The channel exhibiting the largest peak-to-peak MUAP amplitude was selected to represent each motor unit. Mean discharge rate was calculated from the inter-spike intervals of each accepted motor unit [3], [4].

H. Statistical Analysis

MUAP peak-to-peak amplitude and mean discharge rate were quantified for each accepted motor unit. Descriptive analyses were performed at the motor-unit level. Statistical comparisons for MUAP amplitude and discharge rate were performed using linear mixed-effects models with decomposition method, force level (%MVC), and their interaction as fixed effects, while participant was included as random intercept. When a significant main effect of decomposition method was detected, pairwise contrasts between methods were conducted with Bonferroni correction.

Task-dependent changes in PNR and SIL were assessed within each algorithm using Friedman tests across force levels.

When significant differences were detected, pairwise comparisons were performed using the Wilcoxon signed-rank test with Bonferroni correction for multiple comparisons. To assess the robustness of cross-method matching, overlap analysis was repeated using similarity thresholds of 50%, 60%, and 70%. Statistical significance was established at $p < 0.05$.

III. Results

A. Motor Unit Yield

Across the six visual-feedback trapezoidal tasks, FastICA identified on average 7.42 accepted motor units per subject-task, followed by gCKC (5.09) and SCD (3.70) (Table I). FastICA also had the highest number of excluded units, indicating a larger initial candidate pool and a larger number of units that did not satisfy the unified quality thresholds.

TABLE I
MOTOR UNIT YIELD AND QUALITY AFTER UNIFIED ACCEPTANCE CRITERIA. VALUES ARE MEAN ± SD ACROSS VISUAL-FEEDBACK TRAPEZOIDAL TASKS. N_{MU} INDICATES THE TOTAL NUMBER OF ACCEPTED MOTOR UNITS ANALYZED FOR EACH METHOD.

Method (N_{MUs})	Accepted MUs	Excluded MUs	PNR (dB)	SIL
gCKC (336)	5.09 ± 1.42	11.03 ± 1.25	33.48 ± 1.12	0.942 ± 0.005
FastICA (490)	7.42 ± 1.30	46.03 ± 7.19	33.91 ± 0.60	0.930 ± 0.004
SCD (244)	3.70 ± 0.87	2.44 ± 0.63	36.21 ± 1.97	0.944 ± 0.006

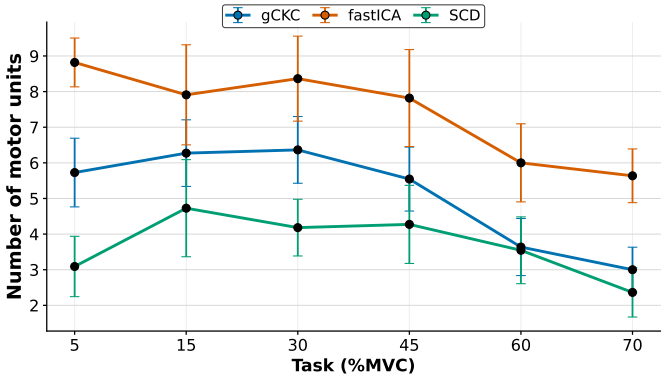

Fig. 1. Number of accepted motor units after applying the unified acceptance criteria and within-method duplicate removal. Error bars represent SEM across participants ($N = 11$).

B. Decomposition Quality

Mean PNR was highest for SCD, followed by FastICA and gCKC (Table I; Fig. 2). Mean SIL values were above the acceptance threshold for all methods, with SCD and gCKC showing slightly higher average SIL than FastICA (Fig. 3). Task-dependent changes in these quality metrics are reported in the next subsection.

C. Task-Dependent Quality Patterns

Task-dependent changes in quality metrics were assessed using Friedman tests performed separately within each decomposition method. For PNR, a significant force-level effect

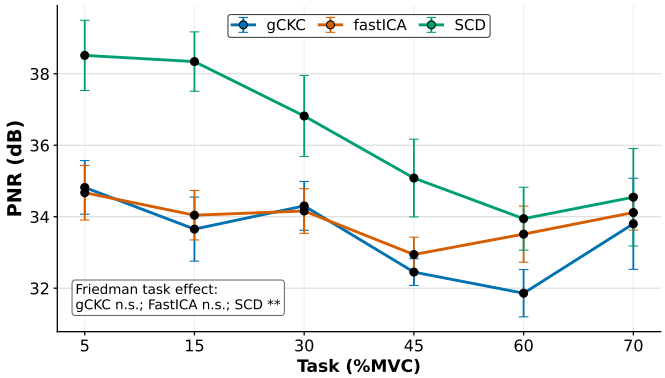

Fig. 2. Mean PNR of accepted motor units across trapezoidal tasks for each decomposition method. Error bars represent SEM across participants with accepted MUs; the number of contributing participants ranged from 9 to 11 across force levels and methods.

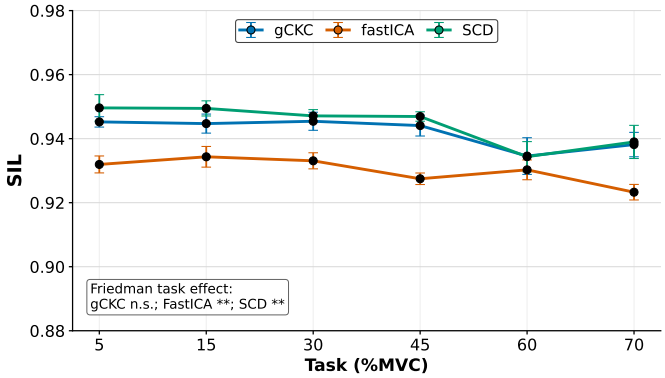

Fig. 3. Mean SIL of accepted motor units across trapezoidal tasks for each decomposition method. Error bars represent SEM across participants with accepted MUs; the number of contributing participants ranged from 9 to 11 across force levels and methods.

was observed for SCD ($\chi^2 = 16.76$, $p = 0.005$), but not for gCKC ($\chi^2 = 9.69$, $p = 0.085$) or FastICA ($\chi^2 = 4.83$, $p = 0.437$; Fig. 2). For SIL, significant force-level effects were observed for FastICA ($\chi^2 = 19.07$, $p = 0.002$) and SCD ($\chi^2 = 20.10$, $p = 0.001$), but not for gCKC ($\chi^2 = 3.49$, $p = 0.625$; Fig. 3). Because these tests were performed within each method, they describe method-specific task effects rather than a formal method-by-force-level interaction.

D. MUAP Amplitude and Discharge Rate

Accepted motor units were further characterized by best-channel MUAP peak-to-peak amplitude and mean discharge rate. MU-level median MUAP amplitudes were 0.56 for gCKC, 0.56 for FastICA, and 0.68 for SCD (Table II). The mixed-effects model indicated no significant effect of decomposition method ($F_{2,1043.24} = 0.15$, $p = 0.861$), but showed a significant force-level effect ($F_{5,1043.05} = 58.56$, $p < 0.001$) and no significant decomposition method-by-force-level interaction ($F_{10,1042.62} = 1.08$, $p = 0.375$).

Median MU-level discharge rates were 10.50 Hz for gCKC, 10.86 Hz for FastICA, and 10.54 Hz for SCD. The mixed-

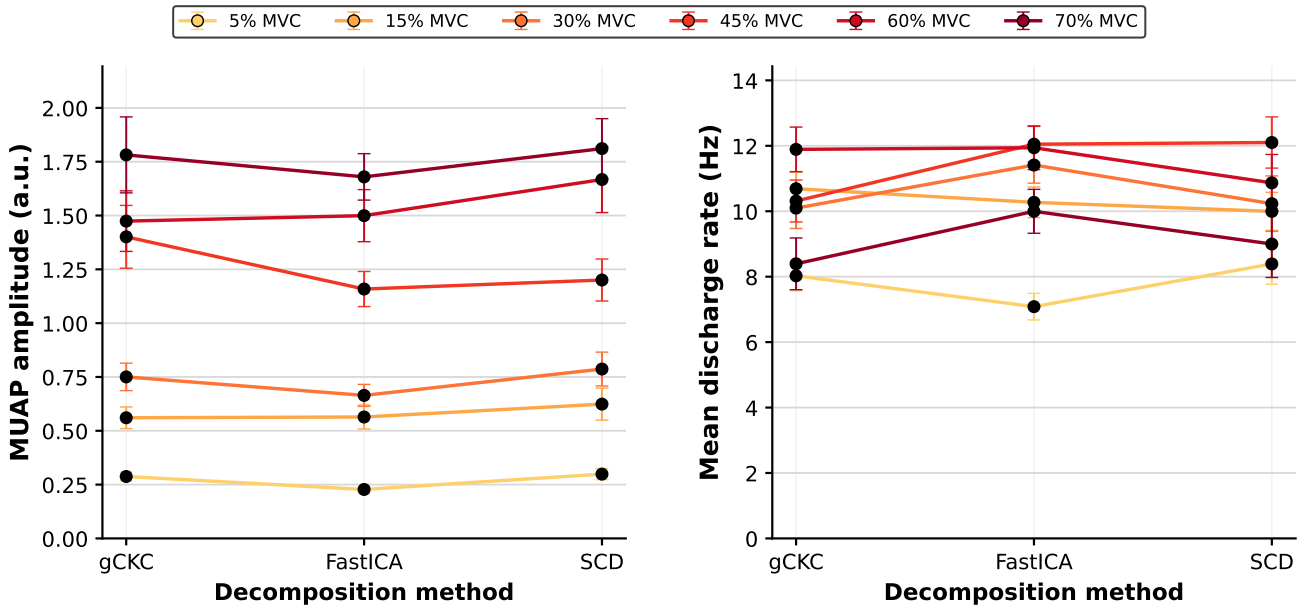

Fig. 4. MU-level MUAP peak-to-peak amplitude and mean discharge rate across decomposition methods for each force level. Values are MU-level means with SEM. Different lines represent force levels, and the x-axis shows the decomposition methods. Statistical comparisons were performed using linear mixed-effects models with decomposition method, and force level (%MVC), and their interaction as fixed effects and participant as a random intercept; no significant decomposition method-by-force-level interaction was observed for either variable.

effects model indicated no significant effect of decomposition method on discharge rate ($F_{2,1046.62} = 1.68$, $p = 0.187$), but showed a significant force-level effect ($F_{5,1045.62} = 3.81$, $p = 0.002$) and no significant decomposition method-by-force-level interaction ($F_{10,1044.25} = 1.40$, $p = 0.176$). The corresponding MU-level force-resolved summaries are shown in Fig. 4.

TABLE II
MUAP AMPLITUDE AND DISCHARGE-RATE CHARACTERISTICS OF ACCEPTED MOTOR UNITS. VALUES ARE MU-LEVEL MEDIANS WITH INTERQUARTILE RANGES.

Method	MUs	MUAP Amplitude	Mean DR (Hz)
gCKC	336	0.56 (0.32–1.30)	10.50 (5.94–13.63)
FastICA	490	0.56 (0.29–1.30)	10.86 (6.28–14.18)
SCD	244	0.68 (0.37–1.53)	10.54 (5.90–14.10)

E. Overlap Between Decomposition Methods

The three algorithms did not recover identical motor unit samples from the same recordings. Using the primary similarity threshold of 60%, an average of 2.61 motor units per subject-task were common to gCKC, FastICA, and SCD. Pairwise-only overlap was most pronounced between gCKC and FastICA (1.56 motor units per subject-task), whereas gCKC-SCD pairwise-only overlap was lower (0.14). Method-exclusive motor units were also observed, with gCKC-only, FastICA-only, and SCD-only components averaging 0.89, 2.56, and 0.28 motor units per subject-task, respectively (Fig. 5). Sensitivity analysis showed that the overall interpretation was stable when the similarity threshold was varied between 50% and 70%. Across these thresholds, the number of motor units shared by all three methods changed only modestly (2.66, 2.61, and 2.56 motor units per subject-task), while FastICA-only estimates remained the largest method-exclusive component (2.42, 2.56, and 2.72 motor units per subject-task).

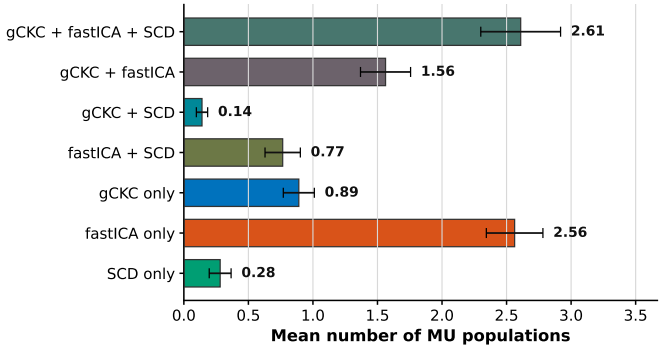

Fig. 5. Group-level overlap patterns among motor units identified by gCKC, FastICA, and SCD after applying the same acceptance and matching criteria.

IV. Discussion

This study compared gCKC, FastICA, and SCD using identical HD-sEMG recordings and a common CKC-based post-processing framework. HD-sEMG decomposition is widely used to estimate motor unit discharge behavior non-invasively, but algorithmic differences in source extraction and post-processing can affect the set of motor units available for

physiological interpretation [1], [4]. The main finding was that the algorithms produced partly overlapping but non-identical motor unit samples. FastICA yielded the largest number of accepted motor units after filtering and duplicate removal, gCKC showed an intermediate yield, and SCD yielded fewer accepted units under the present criteria. At the same time, accepted SCD units showed high PNR and SIL values, indicating that the lower SCD yield reflected the number of motor units passing the current acceptance pipeline rather than poor quality of the retained motor units.

The larger number of excluded FastICA candidate motor unit estimates indicates that the initial number of extracted sources should not be interpreted alone as decomposition performance. This is consistent with the use of signal-based quality metrics, such as PNR, and cluster-separation measures, such as SIL, to screen decomposition outputs before physiological analysis [6], [7]. In this context, the larger set of FastICA candidate motor unit estimates should be interpreted together with the number of motor units that remained after quality filtering and duplicate removal.

The MUAP and discharge-rate analyses indicate that method-related differences in accepted motor unit properties were modest compared with the differences observed in yield, quality metrics, and overlap structure. The mixed-effects models, which accounted for repeated observations within participants, did not identify a significant method effect for either MUAP amplitude or discharge rate, nor a significant decomposition method-by-force-level interaction. Both variables varied across force levels, which is expected because changes in contraction intensity are associated with motor unit recruitment, rate coding, and changes in the complexity of the interference EMG signal [3]. Thus, separating force levels in the analysis was important, but the present results do not indicate that the three algorithms sampled motor units with systematically different MUAP amplitudes or discharge rates.

Although MUAP amplitude is only an indirect proxy for motor unit size or depth, it was examined because SCD has been reported to improve the detection of small or deep motor units, particularly in simulated analyses [10], [11]. In the present data, however, the MUAP amplitude distribution of the units retained by SCD was not lower than those observed for gCKC or FastICA, and the mixed-effects model did not show a significant effect of decomposition method. In addition, SCD showed the lowest accepted-unit yield in the present results, which may indicate that, under the current acceptance criteria, this method behaved more selectively. This interpretation is consistent with the aim of the present pipeline, which prioritized the quality and reliability of the retained motor units over the total number of extracted sources.

The overlap results are particularly important for interpreting algorithm selection. If all methods recovered the same underlying motor units from the HD-sEMG recordings, differences in yield would mainly reflect missed detections, repeated estimates, or differences in quality filtering. Instead, the present results show that each method can contribute exclusive motor unit samples even after quality filtering and matching. This suggests that decomposition algorithms may be sensitive to different signal features or source characteristics, which is plausible given their different blind-source-separation strategies [5], [8]–[10]. The sensitivity analysis indicated that this interpretation was not strongly dependent on the specific 60% similarity threshold used for the primary overlap analysis. For studies that use motor unit samples to infer recruitment, discharge behavior, or neural drive, this finding emphasizes that algorithm choice can influence not only the number of accepted units but also which units are included in downstream analyses.

A. Limitations

This study has some limitations. First, the comparison was restricted to visual-feedback trapezoidal isometric contractions of the FDI muscle in healthy participants, and therefore the findings may not generalize to other muscles, contraction types, or clinical populations. Second, although MUAP amplitude and discharge rate were analyzed using mixed-effects models to account for repeated observations within participants, the yield and overlap analyses still depend on the accepted motor unit samples obtained under the selected quality criteria. Third, PNR and SIL provide signal-based and cluster-separation measures of decomposition quality, but they do not independently verify whether each detected discharge corresponds to the true activity of a motor unit [6], [7]. Validation using simulated signals with known motor unit activity or concurrent intramuscular recordings would provide a stronger independent reference. Finally, although the sensitivity analysis showed stable overlap patterns when the similarity threshold was varied from 50% to 70%, future work should also examine the influence of PNR and SIL thresholds on motor unit yield, quality, and cross-method agreement.

V. Conclusion

Using a unified CKC-based quality assessment framework, gCKC, FastICA, and SCD showed different motor unit yield, quality profiles, and overlap patterns when applied to the same HD-sEMG recordings. FastICA produced the largest number of accepted motor units, whereas SCD yielded fewer units but maintained high PNR and SIL values after the common post-processing procedure. MUAP amplitude and mean discharge rate varied across force levels, but mixed-effects models showed that neither variable differed significantly among decomposition methods, and no method-by-force-level interaction was observed. These findings indicate that, under the present acceptance criteria, differences among algorithms were mainly reflected in the number, quality, and overlap of the recovered motor unit samples rather than in MUAP amplitude or discharge-rate characteristics. Therefore, standardized post-processing and cross-method matching are important for interpreting comparisons among HD-sEMG decomposition algorithms.

***Abstract*—Abstract—Parkinson's disease (PD) is characterized by progressive degeneration of subcortical motor circuits, with direct implications for deep brain stimulation (DBS) planning. Two clinical features of PD are particularly relevant to individualized neuromodulation: the well-documented lateralization of motor symptoms and the sex-related differences in prevalence and disease progression. Structural correlates of both dimensions may constitute complementary biomarkers for surgical target selection. Objective: To investigate hemispheric asymmetry and sex-related differences in gray matter volume among DBS candidates with PD, to test whether these two dimensions interact, and to evaluate the influence of age at onset and disease duration on the resulting morphometric profile. Methods: Structural T1-weighted MRI scans from 38 individuals with PD (age: 60.3 ± 7.1 years; 25 men, 13 women; disease duration: 11.5 ± 3.9 years) were obtained from a public dataset and processed with voxel-based morphometry (CAT12). Hemispheric asymmetry was assessed with the paired Wilcoxon test; sex-related differences were assessed with the Mann-Whitney test, both before and after adjustment for total intracranial volume (TIV); a formal sex-by-hemisphere interaction was tested by comparing a per-subject asymmetry index between sexes; all comparisons were corrected for multiple testing (Benjamini-Hochberg). Results: Significant hemispheric asymmetries survived correction in the putamen (left dominance), supplementary motor cortex (left dominance), hippocampus (right dominance), and caudate nucleus (right dominance). Men showed larger unadjusted regional volumes than women across several regions, but TIV was itself 13.9% larger in men ($p<0.001$), and none of the regional sex differences remained significant after TIV adjustment. The formal asymmetry-index-based test found no significant sex-by-hemisphere interaction in any region. Age at onset correlated positively with right globus pallidus volume ($p=0.035$); no correlations were found with disease duration. Discussion: Hemispheric asymmetry is a robust structural feature of this cohort, distinguishable from global brain-size effects, whereas the apparent sex-related regional differences appear largely attributable to global brain-size scaling rather than PD-specific, region-level pathology. Conclusions: DBS candidates with PD present detectable, TIV-independent hemispheric asymmetry in motor and limbic structures, including the pallidum, a primary surgical target, and age at onset relates to pallidal volume. Sex-related regional differences and a sex-by-hemisphere interaction were not supported once appropriate covariate adjustment and formal interaction testing were applied, underscoring the importance of controlling for global brain size in morphometric studies of sex effects.**

***Index Terms*—Parkinson's Disease; Deep Brain Stimulation; Brain Asymmetry; Sex Dimorphism**

I. Introduction

Parkinson's disease (PD) is the second most prevalent neurodegenerative disorder, clinically characterized by resting tremor, rigidity, bradykinesia, and postural instability, arising from progressive degeneration of dopaminergic neurons in the substantia nigra pars compacta. Two clinical features of PD are especially relevant to the planning of individualized surgical treatment. The first is the marked asymmetry of motor symptoms: the majority of patients present with unilateral symptom predominance at disease onset, and this asymmetry tends to persist, albeit attenuated, throughout disease progression. This observation supports the hypothesis that nigrostriatal degeneration in PD does not occur symmetrically between hemispheres, and that this biochemical and functional asymmetry should be paralleled by measurable structural asymmetries on neuroimaging. The second feature is the well-established sex difference in PD: men are diagnosed roughly 1.5 times more often than women, and accumulating evidence points to distinct trajectories of motor and non-motor symptom progression between sexes, potentially reflecting differences in nigrostriatal dopaminergic density, hormonal neuroprotection, and genetic susceptibility.

Deep brain stimulation (DBS) is currently the primary surgical option for medication-refractory motor symptoms in PD, with the subthalamic nucleus (STN) and the internal globus pallidus (GPi) as the most commonly used targets. Target selection and lateralization, that is, the decision of which hemisphere to prioritize in unilateral implants, or how to asymmetrically adjust parameters in bilateral implants.

currently relies primarily on clinical criteria, such as the side of symptom predominance, complemented by stereotactic planning based on population atlases that do not typically account for individual variability in either hemispheric laterality or sex. In this context, individualized structural biomarkers capturing both dimensions have the potential to complement this decision-making process, particularly as voxel-based morphometry (VBM) becomes an increasingly accessible and reproducible tool in clinical neuroimaging workflows.

Prior structural neuroimaging studies in PD have demonstrated volumetric atrophy in basal ganglia nuclei, particularly the putamen, with magnitude associated with disease severity and progression [3,4]. More recent investigations combining functional and structural MRI have reinforced the existence of measurable interhemispheric asymmetry already in early-stage PD, both in functional connectivity metrics and regional volumetry [2]. In parallel, a growing body of literature has begun to characterize sex-specific gray matter correlates of PD, including sex differences in anxiety-related gray matter underpinnings in de novo PD [9] and longitudinal patterns of gray matter change that may differ by sex [10]. However, hemispheric asymmetry and sex dimorphism have generally been studied in isolation, and few studies have examined either dimension specifically in populations of DBS candidates — a clinically relevant subgroup, since these patients are already in an advanced disease stage and are precisely those for whom structural information would have the most direct practical application in surgical planning [6,7].

The present study addresses this gap by jointly investigating hemispheric asymmetry and sex-related differences in gray matter volume within the same cohort of DBS candidates with PD, with particular attention to motor structures (putamen, supplementary motor cortex), the surgical target structure (globus pallidus), and limbic structures (hippocampus, amygdala, caudate nucleus). Because both analyses were performed on the same sample, this design also allows a preliminary, exploratory look at whether the structures implicated by hemispheric laterality overlap with those implicated by sex, a question with direct relevance for how individualized these two axes of variability might need to be in DBS planning.

II. Objectives

The objectives of this study were:
(i) to investigate the presence of hemispheric asymmetry in the volume of gray matter among DBS candidates with PD;
(ii) to investigate differences related to sex in the volume of gray matter within the same cohort;
(iii) to evaluate the influence of age at the time of onset and duration of the disease on the resulting regional morphometric profile.

III. Methods

1) Sample: Structural T1-weighted MRI scans from 38 individuals with a clinical diagnosis of PD (age: 60.3 ± 7.1 years; 25 men, 13 women; disease duration: 11.5 ± 3.9 years) were obtained from the *London Health Sciences Centre Parkinson's Disease Dataset* (LHSCPD), a publicly available dataset hosted on OpenNeuro [1]. Men and women in the sample did not differ significantly in age (62.1 ± 5.6 vs. 59.1 ± 5.4 years), disease duration (12.1 ± 3.9 vs. 10.5 ± 4.1 years), or age at onset (all $p>0.05$), reducing the likelihood that these demographic variables confounded the sex comparisons reported below.

2) Image acquisition and preprocessing: Structural T1-weighted images were processed with the Computational Anatomy Toolbox (CAT12, version 26.0.rc3, revision 2874), running within a standalone SPM/MATLAB Runtime (R2023b) environment. Preprocessing followed the standard CAT12 pipeline: spatial adaptive non-local means (SANLM) denoising, bias-field correction, tissue segmentation into gray matter, white matter, and cerebrospinal fluid, and nonlinear spatial registration to the MNI152NLin2009cAsym template via Geodesic Shooting, resampled to 1.5 mm isotropic resolution. Regional gray matter volumes for the putamen, globus pallidus, caudate nucleus, hippocampus, amygdala, and supplementary motor cortex were extracted bilaterally in native space using the Neuromorphometrics atlas implemented in CAT12, which registers the atlas to each subject's native anatomy to yield absolute regional volumes. Total intracranial volume (TIV) was computed for each subject as the sum of gray matter, white matter, and cerebrospinal fluid volumes. Image quality was assessed automatically via CAT12's built-in quality metrics (noise-to-contrast ratio, inhomogeneity-to-contrast ratio, and the composite Image Quality Rating).

Statistical analysis:

Two complementary analyses were performed on the same cohort. First, hemispheric asymmetry was assessed by comparing homologous left and right ROI volumes using the paired Wilcoxon test, given the expected non-parametric distribution of regional volumes in a moderate-sized sample. Second, sex-related differences were assessed by comparing ROI volumes between men and women using the Mann-Whitney test, with effect size (r) reported alongside p-values to contextualize the magnitude of each difference beyond statistical significance alone. The relationship between regional volumes and the clinical variables age at onset and disease duration was evaluated by correlation analysis (Spearman) . Statistical significance was set at $p< 0.05$ throughout. .

IV. Results

1) Hemispheric asymmetry: Table I summarizes the hemispheric asymmetry findings across the sample as a whole.

Age at onset correlated positively with right globus pallidus volume ($p=0.035$), suggesting that patients with later disease onset present with greater volumetric preservation of this structure relative to those with earlier onset. No statistically significant correlations were observed between disease duration and volume in any of the regions assessed, including the DBS target structures.

TABLE I
HEMISPHERIC ASYMMETRY OF GRAY MATTER VOLUME

Region	**Direction of dominance**	**p-value**
Putamen	Left	0.002
Supplementary motor cortex	Left	0.008
Hippocampus	Right	<0.001
Caudate nucleus	Right	0.03

TABLE II
SEX-RELATED DIFFERENCES IN GRAY MATTER VOLUME (MEN VS. WOMEN), RAW AND TIV-ADJUSTED

Region	**Diff. (M>F)**	**Raw** p	r	**TIV-adj.** p
Putamen, left	+16.4%	0.012	0.51	0.62
Putamen, right	+17.0%	0.008	0.53	0.27
Hippocampus, left	+11.9%	0.002	0.64	1.00
Hippocampus, right	+11.1%	0.004	0.58	0.64
Amygdala, left	—	0.012	—	0.98
Amygdala, right	—	0.023	—	0.71
SMC, right	+11.0%	0.021	0.46	0.67
Caudate, right	+10.4%	0.049	0.40	0.34

2) Sex-related differences : Table II summarizes the unadjusted sex-related differences in gray matter volume observed within the same cohort. Across all regions in which a significant unadjusted difference was found, men presented with greater gray matter volume than women, with effect sizes ranging from small-to-moderate to large.

However, total intracranial volume (TIV) itself differed significantly by sex, with men presenting 13.9% larger TIV than women (1493 ± SD vs. 1311 ± SD cm³, p<0.001). Given that TIV was a strong predictor of regional volume across nearly all structures examined (p<0.001 for all regions except the pallidum), we re-tested each regional comparison after adjusting for TIV: for each region, gray matter volume was regressed on TIV, and the resulting TIV-independent residuals were compared between sexes with the Mann-Whitney test. Table II reports these TIV-adjusted comparisons. None of the twelve regional sex differences remained statistically significant after TIV adjustment, including after Benjamini-Hochberg correction for multiple comparisons; most adjusted p-values exceeded 0.6. A sensitivity analysis using a proportional (volume/TIV ratio) adjustment instead of residualization produced a consistent pattern, with no region showing a stable, method-independent effect. These findings indicate that the unadjusted sex differences reported in Table II are largely attributable to global brain-size scaling rather than to region-specific, PD-related structural divergence between sexes.

3) Formal test of sex-by-hemisphere interaction:: To directly test whether hemispheric asymmetry differs by sex, a per-subject, per-region asymmetry index was computed as AI = 100 × (Right Left)/[(Right + Left)/2], and compared between men and women with the Mann-Whitney test for each of the six regions examined. This approach respects the within-subject, paired structure of hemispheric data, which a conventional two-way ANOVA treating hemisphere as an independent factor would not. No region showed a significant sex-by-hemisphere interaction (all p>0.28; all p>0.77 after Benjamini-Hochberg correction), indicating that, in this cohort, the degree and direction of hemispheric asymmetry did not differ measurably between men and women. This formal result qualifies the descriptive observation that the putamen, hippocampus, and caudate nucleus appeared in both the asymmetry and (unadjusted) sex analyses: rather than reflecting a genuine interaction between these two clinical dimensions, this overlap is better interpreted as coincidental co-occurrence of two independently distributed sources of variability, one of which (the sex-related component) did not survive appropriate covariate adjustment.

V. DISCUSSION

The pattern of asymmetry observed in the putamen and supplementary motor cortex is compatible with the hypothesis of asymmetric nigrostriatal degeneration underlying the classic clinical lateralization of PD. The putamen, receiving the bulk of dopaminergic nigrostriatal projections related to motor control, is one of the structures most consistently associated with progressive atrophy in PD in prior VBM studies, and the magnitude of its atrophy has been proposed as a possible clinical evaluation index for the disease [4,5]. The left-hemisphere dominance observed here for the putamen and supplementary motor cortex is consistent with recent structural and functional asymmetry findings reported in early-stage PD [2], although the specific direction of asymmetry (left- versus right-predominant) varies across studies and populations, likely reflecting the distribution of the clinically predominant side in each cohort.

The right-hemisphere dominance observed in the hippocampus and caudate nucleus falls within a territory distinct from the primary motor circuit, aligning instead with the limbic and associative circuits of the basal ganglia. This finding is compatible with the literature describing non-motor involvement in PD, including cognitive and limbic dysfunction, as a process partially dissociated, in terms of laterality, from motor involvement per se.

The apparent sex-related differences observed in the unadjusted analysis initially seemed consistent with proposed sex differences in nigrostriatal dopaminergic density and disease progression rate reported elsewhere in the literature [10]. However, once total intracranial volume was accounted for, none of these regional differences remained statistically distinguishable from chance (Section IV.2). This pattern is consistent with the well-established observation that men have, on average, larger cranial and brain volumes than women, and it illustrates why covariate adjustment for global brain size is essential before attributing regional volumetric differences specifically to sex, rather than to global scaling. This does not rule out the existence of genuine, region-specific sex effects

in PD-related neurodegeneration; it indicates that this study, at its current sample size and with the covariate adjustment now applied, did not detect them.

The formal test of a sex-by-hemisphere interaction, based on a per-subject asymmetry index, was similarly negative across all regions examined (Section IV.3). This result argues against interpreting the overlap of the putamen, hippocampus, and caudate nucleus across the two analyses as evidence that hemispheric laterality and sex jointly shape structural variability in this cohort. Instead, the overlap is more parsimoniously explained as two separate axes of variability, one robust (hemispheric asymmetry) and one that did not survive proper covariate adjustment (sex), coincidentally implicating an overlapping set of regions. Consequently, the present data support individualizing DBS planning by hemispheric laterality, for which the evidence here is robust to TIV and survives multiple-comparisons correction, but do not currently support individualizing planning by sex on the basis of regional structural differences.

The most direct link to DBS planning practice remains the correlation between age at onset and right globus pallidus volume identified in the asymmetry analysis. As the GPi is one of the most frequently used surgical targets in PD, particularly in patients with prominent dyskinesia or in whom the STN is considered a higher-risk target [6,7], the existence of a systematic association between a readily available clinical variable (age at onset) and the volume of the target structure itself suggests that early- versus late-onset PD phenotypes may translate into measurable anatomical differences in the surgical target. Combined with the robust hemispheric asymmetry findings reported above, this reinforces the broader argument, already present in the DBS patient-and-target-selection literature, that target choice and fine-tuning should be individualized, and that preoperative structural neuroimaging, read jointly with clinical variables such as symptom laterality and age at onset, may add complementary information to the clinical criteria traditionally used [6,7]. The present data do not, however, support extending this individualization to sex on structural grounds, given the absence of TIV-independent regional sex differences reported above.

The absence of a correlation between disease duration and regional volume, including in the target structures, deserves careful discussion, as it may reflect either a genuine limitation in the sensitivity of the cross-sectional design employed or a real feature of the atrophy trajectory in PD, in which chronological disease duration is a weaker predictor of structural atrophy than motor severity or clinical subtype. Without longitudinal data or a concurrent measure of motor severity (e.g., MDS-UPDRS-III score at the time of acquisition), it is not possible to distinguish between these two explanations with the data currently reported.

1) A. Limitations: This study presents limitations that should be explicitly acknowledged. First, the overall sample size (n=38) is modest for voxel-based morphometry analyses, and the sex-comparison subgroup is particularly unbalanced (25 men vs. 13 women), which limits statistical power for the sex analysis and increases the instability of effect-size estimates; this imbalance is especially relevant to the null TIV-adjusted and interaction results reported above, since a modest, unbalanced sample has limited power to detect a genuine but smaller sex-related or interaction effect, were one present. Second, Benjamini-Hochberg false discovery rate correction was applied across the combined set of asymmetry, sex-related, and interaction tests reported above; this procedure is less conservative than family-wise approaches such as Bonferroni, under which the right caudate nucleus asymmetry finding (raw p=0.03) would not survive, and this discrepancy should be kept in mind when weighing the strength of individual findings. Third, the design is cross-sectional and does not include a healthy control group matched for age and sex, which prevents disentangling PD-specific asymmetries from those already described in the general population. Fourth, the absence of information on the clinically predominant side of motor symptoms limits the ability to directly test the central hypothesis of clinical-structural lateral- ization, leaving this association inferred only by analogy with the literature; similarly, no clinical motor subtype (tremor- dominant versus rigidity/bradykinesia-dominant) was available to contextualize the sex-related findings. Fifth, a formal test of the sex-by-hemisphere interaction, based on a per-subject asymmetry index compared between men and women, was performed and yielded no significant interaction in any region (Section IV.3); the modest and unbalanced sample nonetheless limits the power of this test to detect a genuine but smaller interaction effect, were one present. Sixth, in this reanalysis of a general-purpose public dataset, potentially relevant variables, such as medication state during image acquisition, could not be controlled. Finally, regional volumes were extracted via atlas-based parcellation in native space rather than a fully voxel-wise, smoothed analysis; because segmen- tation and registration relied on the asymmetric MNI152NLin2009cAsym template, template-driven left-right registration bias cannot be fully excluded as a contributor to the hemispheric asymmetry findings, and future replications should consider a symmetric template (e.g., MNI152NLin2009cSym) to isolate genuine anatomical asym- metry from registration artifact. Additionally, although TIV was incorporated as a covariate in the sex comparisons via both residualization and a proportional volume/TIV ratio (Section IV.2), this adjustment assumes a linear relationship between TIV and regional volume; nonlinear or region-specific scaling relationships, which residualization does not fully capture, cannot be excluded, and the absence of TIV-independent sex-related regional effects reported here should be interpreted with this caveat in mind.

VI. Conclusion

DBS candidates with Parkinson's disease present detectable, TIV-independent hemispheric asymmetry in motor structures (putamen, supplementary motor cortex) and limbic structures (hippocampus, caudate nucleus), with a left-motor/right-limbic pattern characterizing the sample as a whole; this asymmetry survived correction for multiple comparisons. Of particular

relevance to surgical practice, the volume of the right globus pallidus, one of the primary DBS target structures in PD, correlated with age at onset. In contrast, sex-related regional volume differences observed in unadjusted comparisons did not survive adjustment for total intracranial volume, and a formal test found no evidence of a sex-by-hemisphere interaction; taken together, these results suggest that the apparent sex effects in this cohort largely reflect global brain-size scaling rather than region-specific, PD-related structural divergence. These findings should still be interpreted as exploratory, given the sample size and the unbalanced sex distribution, which limits power to detect genuine region-specific sex effects were they present. Hemispheric asymmetry, robust to TIV adjustment and multiple-comparisons correction, remains a more directly actionable structural biomarker for individualized DBS planning at this stage than the sex-related dimension originally proposed; validation in larger, sex-balanced, TIV-matched cohorts is required before either dimension can be proposed as a clinically applicable biomarker.

***Abstract*—Hybrid EEG-EMG interfaces are promising for motor control applications because they combine cortical and peripheral information related to movement. However, it remains unclear whether hybrid models consistently outperform strong unimodal baselines when different fusion strategies are evaluated under the same subject-specific protocol. This study compared EEG-only, EMG-only, and hybrid EEG-EMG pipelines for the classification of seven executed upper-limb gestures using a public dataset with 11 subjects, 8 EEG channels, and 8 EMG channels. EEG was resampled to 200 Hz to match EMG, and the first 5 s of each segment were used as execution epochs. The evaluated approaches included feature-level fusion, decision-level fusion, corticomuscular coherence (CMC)-based features, and Riemannian covariance-based models. All pipelines were assessed using subject-specific six-fold grouped cross-validation, with macro F1-score, balanced accuracy, and classification time per epoch as the main metrics. The highest mean performance was obtained by the EMG Riemannian pipeline with an RBF SVM, achieving a macro F1-score of 0.925 ± 0.043 and balanced accuracy of 0.946 ± 0.030. However, planned post-hoc comparisons did not confirm a significant advantage over feature-level or decision-level fusion after correction for multiple comparisons. Feature-level and decision-level fusion were competitive, reaching macro F1-scores of 0.877 ± 0.072 and 0.863 ± 0.091, respectively, with lower offline classification time per epoch. In contrast, CMC-based models performed close to chance level, although this result should be interpreted with caution because coherence estimation is highly dependent on EEG-EMG temporal synchronization. These findings indicate that EEG-EMG fusion can be useful, but it is not automatically superior to unimodal models. For executed gesture classification, the benefit of hybridization depends strongly on the fusion strategy, feature representation, and computational cost.**

I. Introduction

Although prosthetic technologies have advanced substantially in both research and industry, many people living with limb amputation still abandon or use their devices only sporadically [1]. This limited adoption is associated with several factors, including cost, comfort, aesthetics, ergonomics, restricted functionality, and the difficulty of achieving intuitive control and neurocognitive embodiment [2], [3]. In this context, Human-Machine Interfaces (HMI) based on physiological signals have been investigated as a way to decode intended or executed movements more reliably. Among these signals, Electromyography (EMG) and Electroencephalography (EEG) are commonly investigated, as EMG directly reflects muscle activation [4] and EEG provides cortical information directly related to the intention of movement [5].

Despite promising results, using only one of these approaches has important limitations. EMG-based interfaces provide direct access to peripheral muscle activation, but their performance can be affected by electrode placement, muscle fatigue, crosstalk, and the availability of residual muscles, which may constrain intuitive control in amputees [6]. On the other hand, noninvasive EEG can provide information related to cortical motor processes, but it is typically noisy, nonstationary, and limited in the number of reliable control commands that can be decoded in real time [7]. In this context, hybrid Brain-Computer Interfaces (hBCIs) aim to combine multiple signals or control pathways to increase reliability, robustness and control dimensionality, thereby mitigating some limitations of single-signal HMIs [7], [8].

Hybrid EEG-EMG interfaces have been explored in motor-related applications, including direct EEG-EMG fusion, probabilistic fusion, and multimodal control of robotic devices [9]–[11]. Nevertheless, the feasibility of multimodal fusion does not guarantee that hybrid models consistently outperform strong unimodal baselines. The benefit of hybridization may depend on the fusion level, feature representation, and classifier architecture. Thus, a direct comparison of feature-level, decision-level, coherence-based, and Riemannian EEG-EMG pipelines under the same subject-specific validation protocol remains relevant [7], [12].

Therefore, this study compares unimodal and different EEG-EMG hybrid pipelines for subject-specific multiclass classification of executed upper-limb gestures using the public dataset *8-channel EMG, EEG upper limb gesture data* [13]. We evaluate EEG-only and EMG-only baselines, feature-level fusion, decision-level fusion, corticomuscular coherence-based

features, and Riemannian covariance-based models under the same grouped cross-validation protocol. In addition to classification performance, we also report classification time per epoch to assess the practical relevance of each approach for future online motor interfaces. By directly comparing multiple fusion strategies against strong unimodal baselines, this work aims to clarify when hybrid EEG-EMG models are actually beneficial for the executed gesture classification in a dataset of healthy participants. These findings may support future studies investigating hybrid approaches for prosthetic control in amputees.

II. Materials and Methods

A. Dataset

We conducted the experiments using the public *8-channel EMG, EEG upper limb gesture data* dataset [13]. The main characteristics of the dataset and the preprocessing decisions adopted in this study are summarized in Table I

TABLE I
MAIN CHARACTERISTICS OF THE EEG-EMG DATASET USED IN THIS STUDY

Characteristic	**Description**
Dataset	*8-channel EMG, EEG upper limb gesture data*
Subjects	11 (7 males, right-handed, 1 male, left-handed, and 3 females, right-handed; ages 25 $\pm$ 5.5 years)
Classes	7 executed upper-limb gestures
Repetitions per class	6
EEG channels	8 channels placed on F3, F4, C3, CZ, C4, P3, PZ and P4 with the earlobes as reference, originally sampled at 250 Hz
EMG channels	8 channels placed on the proximal part of the subject's forearm, originally sampled at 200 Hz
Preprocessing	EEG resampled to 200 Hz to match EMG
Epoch window	First 5 s of each segment
Epoch length	1000 samples at 200 Hz

Two EEG segments (S4_R3_G3, subject 4 at the third repetition of the third gesture, and S11_R6_G2, subject 11 at the sixth repetition of the second gesture) were excluded due to unexpected signal shapes. Since all analyses used paired EEG-EMG epochs, the corresponding EMG segments were also removed from the paired dataset. This resulted in 460 valid EEG-EMG pairs.

B. Classifiers

Three classifiers were adopted as base models: Support Vector Machine, with two types of kernels: linear and Radial Basis Function (RBF); and Multilayer Perceptron (MLP). These models were selected because they are commonly used in EEG and EMG-based classification tasks and represent different levels of model complexity, from linear decision boundaries to nonlinear kernel-based and neural network-based classifiers [4], [14], [15]. All models were implemented in Python using `scikit-learn` for conventional machine learning classifiers, feature selection, preprocessing, cross-validation, and performance metrics [16].

Since the evaluated task involves seven gesture classes, SVM-based models were implemented using a one-vs-rest multiclass strategy. Both SVM configurations used balanced class weights to compensate for small class imbalance caused by excluded segments. The linear SVM used $C = 1.0$ and a maximum of 20,000 iterations, while the RBF SVM used $C = 1.0$, $\gamma = \text{scale}$, and the same maximum number of iterations when applicable.

The MLP classifier was used as a lightweight nonlinear neural model. In the feature-based classification experiments, it consisted of a single hidden layer with 32 neurons, rectified linear unit (ReLU) activation, Adam optimization, L_2 regularization with $\alpha = 10^{-3}$, an initial learning rate of 10^{-3}, and a maximum of 500 training iterations. These hyperparameters were kept fixed across subjects to favor comparability between pipelines rather than extensive model-specific optimization.

The hyperparameters were selected as simple and commonly used configurations for SVM and MLP classifiers, with no subject-specific hyperparameter search. This choice was adopted to avoid introducing an additional optimization layer that could favor particular pipelines or subjects, especially considering the limited number of trials available per participant.

C. Unimodal Baseline Pipelines

Unimodal EEG-only and EMG-only pipelines were first implemented to provide reference performances for the hybrid approaches. Therefore, these baselines are essential because the advantage of multimodal fusion can only be interpreted when compared with strong single-modality models evaluated under the same protocol.

For the feature-based baselines, EEG and EMG epochs were represented by time and frequency-domain descriptors extracted independently from each channel. Time-domain features included mean value, standard deviation, root mean square (RMS), mean absolute value (MAV), variance, waveform length, and peak-to-peak amplitude. Frequency-domain information was calculated using Power Spectral Density (PSD) with Welch's method [17], [18] and then summarized through bandpower features. For EEG, bandpower was computed in the 4–8 Hz, 8–13 Hz, 13–30 Hz, and 30–45 Hz bands [19]. While for EMG, spectral information was summarized in three broad frequency ranges, 10–30 Hz, 30–60 Hz, and 60–90 Hz, to provide a compact representation of the low-to-mid frequency content of the surface EMG signal. Unlike EEG bands, these EMG ranges were not intended to represent canonical physiological rhythms, but rather frequency-domain descriptors for pattern recognition.

Furthermore, features were standardized before classification, and the same feature set was used across subjects and folds. No supervised feature selection was included in the official experiments. This conservative choice was adopted

because each subject had a limited number of trials, and feature selection could increase the risk of overfitting to subject-specific or fold-specific patterns.

A covariance-based Riemannian baseline was also implemented separately for EEG and EMG. In this pipeline, each epoch was represented by its channel covariance matrix, estimated with Oracle Approximating Shrinkage (OAS), and projected to the tangent space using the Riemannian metric. The resulting tangent-space features were standardized and classified using the same base classifiers. This approach was included as a stronger unimodal baseline because Riemannian methods are well established for classification of multichannel physiological signals [12].

D. Fusion Pipelines

After establishing the unimodal baselines, four EEG-EMG fusion strategies were evaluated: feature-level fusion, decision-level fusion, corticomuscular coherence (CMC)-based fusion, and Riemannian covariance-based fusion. All fusion pipelines used the same epochs, labels and classifiers adopted for the unimodal baselines.

- **Feature-level fusion** was implemented by concatenating EEG and EMG features vectors used on each unimodal classifier before classification. The resulting multimodal feature vector was standardized and classified using the same base classifiers described previously, representing an early fusion strategy [8]–[10].
- **Decision-level fusion** was implemented as a late fusion strategy. EEG and EMG classifiers were first trained independently, and their class-wise scores for the seven gestures were concatenated into a 14-dimensional decision vector. This vector was then classified by a meta-classifier, implemented either as logistic regression or MLP. To avoid information leakage, the meta-classifier was trained using out-of-fold predictions generated within the training data [7]–[9].
- **CMC-based fusion** was evaluated as a physiologically motivated representation of EEG-EMG coupling. Magnitude-squared coherence was computed between EEG and EMG channel pairs. Two representations were tested: average coherence in motor-related frequency bands (μ-band: 8–13 Hz and β-band: 13–30 Hz [19]) and the full coherence spectrum between 8 and 30 Hz [20]–[22]. The band-averaged representation provides a compact description of corticomuscular coupling, whereas the spectral representation preserves frequency-specific peaks at the cost of substantially higher dimensionality. Just raw EMG signals were considered, and CMC was computed using a combination taken pair by pair of all EEG and EMG channels.
- **Riemannian covariance-based fusion** was implemented by stacking EEG and EMG channels before covariance estimation. Before covariance estimation, each epoch was globally normalized by its Frobenius norm, as also adopted in the unimodal Riemannian pipelines. The resulting multimodal epochs were then processed with the same Riemannian pipeline used for the unimodal baselines, including OAS covariance estimation, tangent-space projection, standardization, and classification. No additional channel-wise normalization was applied before stacking EEG and EMG channels. [12].

E. Pipelines Validation

All experiments were performed in a subject-specific manner, i.e., models were trained and evaluated independently for each participant. This choice was adopted because EEG and EMG patterns are highly subject-dependent and because the intended hBCI approaches assumes an individual calibration stage for each user.

For each subject, a six-fold stratified grouped cross-validation was used. The repetition identifiers were used as grouping variables, so all gesture trials belonging to the same repetition were assigned either to the training set or to the test set, but never to both. This strategy prevents samples from the same repetition from appearing simultaneously in training and test sets, reducing optimistic bias due to repetition-specific patterns. Stratification was used to preserve the class distribution across folds whenever possible.

The same validation protocol was applied to all unimodal and hybrid pipelines. For feature-based models, all preprocessing steps that depended on the training data, including standardization, were fitted only on the training folds and then applied to the corresponding test fold. In decision-level fusion, the meta-classifier was trained using out-of-fold predictions from the base EEG and EMG classifiers to avoid information leakage.

Model performances were evaluated using macro-averaged F1-score, balanced accuracy, accuracy, Cohen's kappa, and one-vs-rest macro AUC. Macro F1-score and balanced accuracy were considered the main metrics because the task involved multiclass gesture classification and two segments were excluded from the original dataset. In addition, the average classification time per epoch was measured for each pipeline to compare the computational cost of the trained classifiers. This measurement considered offline prediction time in Python.

F. Statistical Analysis

For statistical analysis, each subject was treated as the experimental unit. Therefore, for each pipeline, cross-validation results were first averaged across folds within each subject, and group-level results were then reported as mean $\pm$ standard deviation across subjects. This procedure avoids treating folds from the same subject as independent observations.

Differences among pipelines were assessed using the Friedman test, since the same subjects were evaluated under all pipeline configurations. When a significant global effect was observed, planned pairwise comparisons were performed using the Wilcoxon signed-rank test with Holm-Bonferroni correction for multiple comparisons. These planned comparisons focused on the main methodological questions of the study: whether the best EMG-based unimodal model differed

from the strongest fusion strategies, whether feature-level and decision-level fusion differed from each other, whether band-averaged and full-spectrum CMC representations differed, and whether stacked Riemannian fusion improved over EMG-only Riemannian classification. Effect sizes for pairwise comparisons were reported using Cohen's d_z.

III. Results

Complete results for all classifier configurations were obtained under the same subject-specific validation protocol. Table II summarizes the best-performing model for each evaluated pipeline, reporting macro F1-score, balanced accuracy, and classification time per epoch. In addition, Fig. 1 provides a visual summary of these selected models by showing their overall performance across multiple metrics and the trade-off between macro F1-score and classification time. All values are reported as mean $\pm$ standard deviation across subjects, after averaging the cross-validation folds within each subject. Therefore, the reported variability reflects inter-subject variability, not independent trial-level variability.

A. Unimodal Baselines

Among the feature-based unimodal baselines, EMG-based features achieved higher mean performance than EEG-based features. The best EEG-only model was obtained with the MLP classifier, reaching a macro F1-score of 0.708 ± 0.059 and balanced accuracy of 0.767 ± 0.049. In contrast, the best EMG-only feature-based model was obtained with the RBF SVM, reaching a macro F1-score of 0.858 ± 0.099 and balanced accuracy of 0.889 ± 0.087.

The Riemannian representation further improved the EMG-only performance. The EMG Riemannian pipeline with an RBF SVM achieved the highest mean performance among all evaluated pipelines, with a macro F1-score of 0.925 ± 0.043 and balanced accuracy of 0.946 ± 0.030. Conversely, the EEG Riemannian pipeline remained close to the EEG feature-based baseline, reaching a macro F1-score of 0.711 ± 0.096 and balanced accuracy of 0.768 ± 0.085. These results suggest that, for executed upper-limb gesture classification, the covariance structure of multichannel EMG contains highly discriminative information.

B. Hybrid Fusion Performance

Feature-level and decision-level fusion achieved competitive performance when compared with the feature-based unimodal baselines. Feature-level fusion achieved the best hybrid performance among the non-Riemannian fusion pipelines. The best model was the MLP classifier, with a macro F1-score of 0.877 ± 0.072 and balanced accuracy of 0.904 ± 0.058.

Decision-level fusion also performed well, but slightly below feature-level fusion. The best configuration combined an EEG RBF SVM, an EMG MLP, and an MLP meta-classifier, reaching a macro F1-score of 0.863 ± 0.091 and balanced accuracy of 0.898 ± 0.072. Although both hybrid strategies improved over the EEG-only baselines and were comparable to the EMG-only feature-based model, neither exceeded the mean performance of the EMG Riemannian baseline.

C. Coherence-Based Fusion

CMC-based fusion showed substantially lower performance than the other evaluated pipelines. The band-averaged CMC representation, computed from the average coherence in the μ and β bands, achieved its best result with a linear SVM, reaching a macro F1-score of 0.168 ± 0.056 and balanced accuracy of 0.214 ± 0.071. The full-spectrum CMC representation between 8 and 30 Hz performed even worse, with a macro F1-score of 0.102 ± 0.029 and balanced accuracy of 0.143 ± 0.046.

The planned comparison between both CMC representations indicated that the band-averaged representation achieved higher macro F1-score than the full-spectrum representation after nonparametric correction. However, both approaches remained close to chance level. Therefore, preserving the full coherence spectrum did not compensate for the low discriminative capacity of CMC in this dataset. This suggests that the poor CMC performance was unlikely to be explained only by the loss of narrowband peaks caused by band averaging, but may also reflect a mismatch between CMC as a physiological coupling marker and the multiclass gesture identification problem evaluated here.

D. Riemannian Covariance-Based Fusion

The best stacked Riemannian model was obtained with an RBF SVM, reaching a macro F1-score of 0.804 ± 0.092 and balanced accuracy of 0.846 ± 0.082. Although this result was higher than the EEG-only Riemannian baseline, it remained below the EMG-only Riemannian model.

This finding suggests that simply stacking EEG and EMG channels before covariance estimation did not provide additional discriminative information beyond the EMG covariance structure alone. Although joint covariance matrices can theoretically capture cross-modal relationships, EEG and EMG have different physiological origins, amplitude ranges, and signal-to-noise ratios. Therefore, when EMG is already highly discriminative, adding EEG channels may introduce structured variability into the covariance matrix rather than useful complementary information. This may explain why Riemannian methods were highly effective for EMG-only classification, but stacked EEG-EMG covariance was not the most effective fusion strategy in this dataset.

E. Statistical Comparison and Class-wise Analysis

The statistical analysis supported the existence of differences among pipelines for macro F1-score, balanced accuracy, and classification time (Friedman test, $p < 0.001$ for all metrics). However, planned post-hoc comparisons showed that the EMG Riemannian pipeline, despite achieving the highest mean macro F1-score and balanced accuracy, was not significantly superior to feature-level fusion, decision-level fusion, or EMG-only features after correction for multiple comparisons. In contrast, classification time differed more consistently across pipelines. Feature-level fusion was significantly faster than EMG Riemannian, decision-level fusion, and EMG-only features. For the coherence-based approaches, band-averaged

TABLE II

BEST PERFORMANCE OBTAINED BY EACH EVALUATED PIPELINE. F1: MACRO-AVERAGED F1-SCORE; BACC: BALANCED ACCURACY. VALUES ARE REPORTED AS MEAN ± STANDARD DEVIATION ACROSS SUBJECTS.

Pipeline	Best model	F1	BAcc	Time (ms/epoch)
EEG-only features	MLP	0.708 ± 0.059	0.767 ± 0.049	0.042 ± 0.003
EMG-only features	RBF SVM	0.858 ± 0.099	0.889 ± 0.087	0.280 ± 0.014
EEG Riemannian	RBF SVM	0.711 ± 0.096	0.768 ± 0.085	2.079 ± 0.899
EMG Riemannian	RBF SVM	0.925 ± 0.043	0.946 ± 0.030	1.987 ± 0.771
Feature-level fusion	MLP	0.877 ± 0.072	0.904 ± 0.058	0.073 ± 0.012
Decision-level fusion	EEG RBF SVM + EMG MLP + meta-MLP	0.863 ± 0.091	0.898 ± 0.072	0.338 ± 0.045
CMC band mean	Linear SVM	0.168 ± 0.056	0.214 ± 0.071	54.138 ± 2.236
CMC spectrum	Linear SVM	0.102 ± 0.029	0.143 ± 0.046	53.612 ± 7.318
Riemannian fusion	RBF SVM	0.804 ± 0.092	0.846 ± 0.082	2.782 ± 1.363

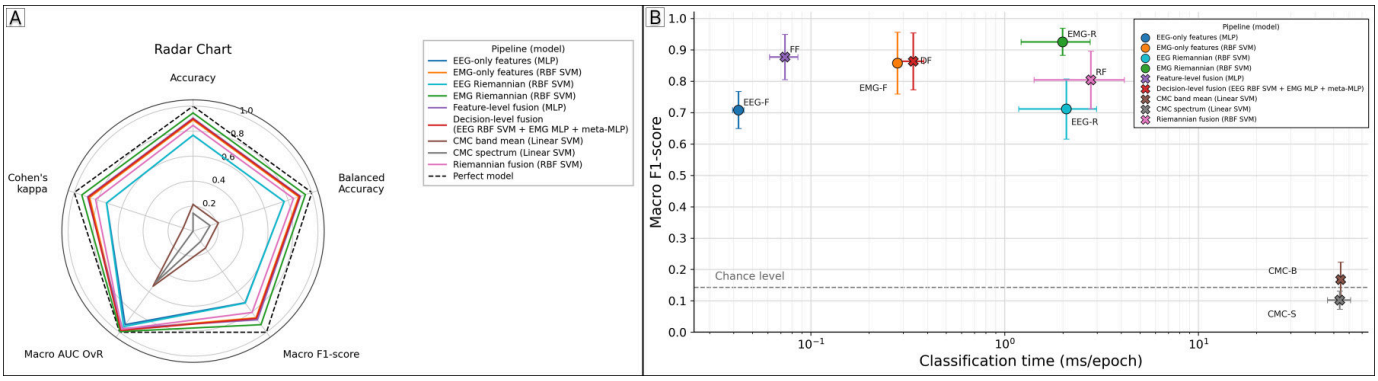

Fig. 1. Summary of the best-performing configuration for each evaluated pipeline. (A) Radar chart showing the mean performance across subjects for accuracy, balanced accuracy, macro F1-score, macro one-vs-rest AUC, and Cohen's kappa. The dashed line represents the ideal value for all metrics. (B) Macro F1-score versus classification time per epoch for the best model in each evaluated pipeline. The unimodal baselines are represented by circles and the hybrid models are represented by x-shaped markers. Error bars indicate one standard deviation across subjects, after averaging cross-validation folds within each subject. Vertical bars were clipped to the valid macro F1-score range [0, 1]. Overall, the results indicate that EMG provided stronger discriminative information than EEG for executed gesture classification, and that hybrid fusion strategies were competitive but did not necessarily outperform the best unimodal baseline.

CMC achieved significantly higher macro F1-score than full-spectrum CMC, although both remained close to chance level.

The class-wise recall analysis in Fig. 2 showed that the strongest EMG-based and hybrid pipelines maintained high recall across most gestures, whereas EEG-only and EEG Riemannian models showed more variable class-dependent performance. For the EMG Riemannian model, recall remained high for all gestures, with comparatively lower values for G3 and G4. In contrast, CMC-based models showed low recall across nearly all gesture classes, indicating that their poor performance was not restricted to a single movement, but reflected a broader limitation of the CMC representations for this multiclass task.

IV. DISCUSSION

Overall the results presented, they suggest that fusion can improve some unimodal feature-based models, but it does not automatically outperform a strong unimodal baseline configuration. Both feature-level and decision-level fusion achieved high mean performance and improved over the EEG-only baselines. However, although the EMG Riemannian pipeline achieved the highest mean macro F1-score and balanced accuracy, planned statistical comparisons did not confirm a significant advantage over feature-level fusion, decision-level fusion, or EMG-only features after correction for multiple comparisons. This finding is important because hybrid BCIs are often motivated by the complementarity between cortical and peripheral signals, with the expectation of improved robustness, reliability, or number of control commands [7], [8], [23]. Our results support this rationale only partially: EEG-EMG fusion was competitive and computationally attractive, especially in the feature-level and decision-level pipelines, but its benefit depended strongly on the representation and classifier architecture. Thus, the advantage of hybridization should not be assumed from the use of multiple modalities alone; it must be demonstrated against strong unimodal models evaluated under the same validation protocol.

The highest mean performance was obtained with the EMG Riemannian pipeline. A possible explanation is that the Riemannian representation captures the covariance structure among EMG channels, rather than treating each extracted feature independently. For multichannel physiological recordings, covariance-based representations can encode spatial relationships between sensors and have been shown to be effective in BCI classification problems [12]. In the present task, these channel relationships may reflect coordinated activation patterns across the forearm electrodes, which are highly

Fig. 2. Class-wise recall for the best-performing model of each evaluated pipeline. The heatmap summarizes how performance varied across gesture classes and pipelines, allowing the identification of movements that were more difficult to classify without requiring one confusion matrix for each model.

informative for distinguishing executed gestures. This may also explain why the same approach was less effective for EEG alone and for stacked EEG-EMG fusion. In EEG, the covariance structure may be less directly tied to the final gesture class, whereas stacking EEG and EMG channels before covariance estimation combines signals with different physiological origins, signal-to-noise ratios, and amplitude structures. Moreover, no channel-wise normalization was applied before stacking EEG and EMG channels. Thus, the joint covariance representation may still have been affected by differences in signal-to-noise ratio and discriminative strength between modalities. In this context, adding EEG channels to an already highly discriminative EMG covariance structure may have introduced structured noise rather than complementary information, which may partly explain why Riemannian fusion did not outperform the EMG-only Riemannian pipeline.

Although the hybrid models were not the best overall classifiers, their results should not be dismissed. Feature-level fusion achieved one of the best performance-time trade-offs, reaching high macro F1-score with very low classification time per epoch. Decision-level fusion also performed close to the EMG feature-based baseline while preserving a modular structure in which EEG and EMG classifiers are trained separately before being combined by a meta-classifier. This is relevant for future online interfaces. In this sense, the results suggest that feature-level and decision-level fusion remain promising strategies, especially if future systems are designed to exploit EEG as complementary information when EMG reliability decreases due to fatigue, electrode displacement, or changes in residual muscle condition [6], [7], [9].

The coherence-based pipelines showed substantially lower performance than the other approaches. This result does not imply that corticomuscular coherence is physiologically irrelevant. On the contrary, CMC is a well-established measure of coupling between sensorimotor cortical activity and peripheral muscle activation, especially during sustained contraction and motor control tasks [20], [21]. Moreover, CMC-based hBCIs have shown promising results in rehabilitation-oriented paradigms. For example, de Seta et al. used CMC features in a pseudo-online hBCI to discriminate hand movements from rest in healthy and stroke participants, reporting high detection performance and clinically relevant delays [24]. However, their objective was movement detection relative to rest, whereas the present study evaluated seven-class gesture identification during executed movements. Therefore, the two findings are not contradictory. Instead, they suggest that CMC may be more suitable for detecting motor engagement, task-related corticomuscular coupling, or movement onset than for encoding the fine identity of multiple executed gestures.

This interpretation is also consistent with studies that use CMC or corticomuscular networks as markers of motor control, rehabilitation state, or hybrid BCI activation rather than as direct multiclass gesture descriptors [22], [25]. In the present study, the comparison between band-averaged and full-spectrum CMC also suggests that the low performance was not caused only by the loss of narrow spectral peaks through band averaging. Although the full-spectrum representation preserved more frequency-specific information, it did not improve performance over the compact band-averaged representation. Thus, the poor CMC performance may also reflect physiological and methodological constraints of coherence estimation in this dataset, including the absence of a specific task-versus-rest contrast, the limited number of trials, possible EEG-EMG synchronization uncertainty, and the need for sufficiently stable time windows to estimate corticomuscular coupling [26], [27]. These aspects are particularly relevant for hBCI design,

because protocols that use CMC as a control feature may require adequate contraction duration, temporal alignment, and coupling stabilization before classification. Therefore, the low CMC performance observed here should not be interpreted as evidence against CMC as a physiological marker or as an hBCI activation feature, but rather as evidence that these simple CMC representations were not competitive for multiclass gesture classification in this dataset.

In addition, it is important to highlight that this study has some limitations when it comes to generalizing the results obtained here to real-time BCI or hBCI. First, all analyses were performed offline, using previously segmented EEG and EMG recordings, and therefore do not fully reproduce the constraints of online signal acquisition, continuous preprocessing, decision updating, and feedback delivery. Second, although the subject-specific design is coherent with individual calibration scenarios, the dataset included only 11 subjects with a limited number of trials per class, which restricts the generalization of the observed performances and increases the importance of validating these findings in larger datasets. The small sample size also limits the statistical power of the comparisons among pipelines. Therefore, the absence of statistically significant differences between the strongest models should not be interpreted as evidence that these models are equivalent. Third, because the EEG and EMG signals were provided as segmented files and were originally sampled at different frequencies, it is not possible to guarantee that the two modalities were perfectly synchronized at the sample level. This is a critical point for multimodal EEG-EMG analyses, especially for coherence-based approaches, since CMC estimation depends directly on the temporal relationship between cortical and muscular activity [27], [28]. Therefore, synchronization uncertainty may have contributed directly to the low performance of the CMC-based models, in addition to being a general limitation for multimodal interpretation. Finally, classification time was measured in a Python/offline environment rather than on embedded real-time hardware. Thus, the reported time per epoch should be interpreted as a comparative estimate of computational cost across pipelines, and not as a final measure of real-time system latency.

Taken together, for the specific analysis of the specific dataset showed here, the present results indicate that EEG-EMG fusion is useful, but not universally superior. For executed upper-limb gesture classification, EMG carried the strongest discriminative information, especially when represented through Riemannian covariance features. However, the lack of statistically confirmed superiority over the strongest feature-level and decision-level fusion pipelines suggests that computational cost and implementation simplicity should also guide model selection for future online systems. CMC, despite its physiological relevance, was not suitable as a direct multiclass gesture feature in this dataset. These findings reinforce that hybrid motor interfaces should be evaluated not only by whether they combine EEG and EMG, but by how the signals are represented, fused, validated, and ultimately translated into computationally feasible control decisions.

V. Conclusion

This study provided a comparative analysis between unimodal models and different hybrid EEG-EMG fusion strategies for the classification of seven executed upper-limb gestures. Overall, the results showed that hybrid EEG-EMG models are not automatically superior to unimodal models, since their benefit depends directly on the adopted fusion strategy. Although the highest mean performance was achieved by the unimodal EMG Riemannian pipeline, this advantage was not statistically confirmed over the strongest feature-level and decision-level fusion pipelines after correction for multiple comparisons. Since these fusion approaches achieved competitive performance with lower offline classification time per epoch, they provide relevant insights for future online evaluations of EEG-EMG architectures.

An important negative finding was the substantially lower performance of the CMC-based models. Nevertheless, CMC-based approaches should not be automatically discarded, since corticomuscular coupling has a well-established physiological basis. Instead, the present results suggest that CMC may not be the most suitable feature for distinguishing different executed gestures in a multiclass problem. Rather, it may be more informative as a marker of motor engagement, attention, or task-related corticomuscular interaction during motor activity.

Therefore, although further studies with larger datasets, improved EEG-EMG synchronization, real-time validation, and complete real-time pipeline validation are still necessary, the results obtained in this analysis may help guide future hBCI applications. In particular, they indicate which fusion strategies and unimodal baselines should be prioritized in future online tests for EEG-EMG-based motor interfaces.

VI. Declaration of AI use

The authors declare that AI tools were used exclusively for language editing and proofreading, under strict human oversight. AI was not used to generate scientific hypotheses, define the methodology, perform data analysis, or interpret the results. After using these tools, the authors carefully reviewed and edited the manuscript to ensure accuracy, coherence, and scientific responsibility.

***Abstract*—Parkinson's disease compromises cervicofacial mobility, affecting swallowing dynamics and phonatory functions. This work presents a proof-of-concept study of a computer vision system for the non-invasive tracking of cervical anatomical landmarks from conventional video. Using the DeepLabCut tool with transfer learning (ResNet-50), a network was trained to locate 17 cervical anatomical landmarks from 24 publicly accessible videos, obtaining a Mean Radial Error (MRE) of 3.86 pixels on the test set after 100,000 iterations. It should be stressed that the 95/5 partition was performed at the frame level rather than at the video level, which implies possible information leakage between training and test and makes this value an optimistic estimate. From the estimated trajectories, the automatic detection of the swallowing reflex onset was evaluated through a benchmark among four classifiers (Random Forest, XGBoost, SVM, and KNN); the dataset for this stage contains only 182 sampled frames, of which 27 (14.8%) correspond to onset. Only Random Forest detected any event, with 25% recall and an F1 of 0.08, meaning that roughly three out of every four onsets went undetected; no class-balancing strategy was applied. The results demonstrate the technical feasibility of markerless cervical tracking, but event-detection performance is insufficient for clinical use. Importantly, the dataset does not include individuals with a confirmed diagnosis of Parkinson's disease, so no conclusion regarding clinical applicability to parkinsonian dysphagia can be drawn at this stage.**

***Index Terms*—DeepLabCut, transfer learning, swallowing, Parkinson's disease, computer vision, proof of concept**

I. Introduction

Parkinson's disease (PD) is a chronic and progressive neurodegenerative condition of the central nervous system, resulting primarily from the loss of dopaminergic neurons in the substantia nigra pars compacta [1]. Clinically, it manifests through motor disorders such as resting tremor, muscle rigidity, postural instability, and bradykinesia. In the speech-language domain, bradykinesia and rigidity affect the orofacial and cervical musculature, culminating in facial hypomimia, dysphonia, and oropharyngeal dysphagia, the latter being directly associated with an elevated risk of aspiration pneumonia and malnutrition [1], [2].

Preserving phonatory and swallowing functions depends on systematic speech-language interventions. In this context, there arises a need to track and map specific anatomical landmarks on the face and neck in order to quantify the patient's mobility and movement patterns. In response to this demand, at least two viable approaches stand out: networks with transfer learning focused on the cervical region, and consolidated tracking solutions such as MediaPipe [3], aimed at facial dynamics.

Systems based on computer vision and deep learning enable the non-invasive extraction of biomechanical metrics using conventional cameras. Although the detection of anatomical landmarks by deep networks is well established in the literature [4], the mapping of the external cervical region from conventional video remains little explored. The focus on the cervical region is justified by its importance in swallowing biomechanics, specifically in monitoring the vertical excursion of the hyolaryngeal complex and in following suprahyoid and stabilizing muscle dynamics. To address this demand, the markerless pose estimation tool DeepLabCut stands out [5], [6].

Modeling through DeepLabCut employs architectures based on adapted Residual Networks (ResNet) [7] coupled with spatial probability decoders (*scoremaps*). Training such networks from scratch requires thousands of annotated images, a scarce resource in the biomedical domain. Transfer learning [8] mitigates this bottleneck by reusing weights previously optimized on generic databases (ImageNet [9], ResNet-50 architecture) and fine-tuning them for cervical anatomy.

Works applying deep learning to swallowing kinematics concentrate on instrumented modalities. Videofluoroscopy (VFSS) remains the gold standard and has already been combined with deep networks for automatic hyoid bone detection [10], but it depends on hospital infrastructure, ionizing radiation, and specialized professionals. Non-invasive alternatives include high-resolution cervical auscultation with deep learning [11] and wearable accelerometry sensors [12], which dispense with radiation but require instrumentation attached to the patient. Conventional video tracking, by contrast, requires neither radiation nor attached sensors, yet it has been little investigated for the external cervical region. The present work is positioned in this gap and is explicitly characterized as a technical proof-of-concept study: it evaluates whether markerless pose estimation is able to track cervical structures in conventional video, without claiming, at this stage, clinical validation in a parkinsonian population.

II. Objectives

A. General Objective

To evaluate, as a proof of concept, the technical feasibility of a computer vision-based system for the markerless tracking of cervical anatomical landmarks relevant to swallowing biomechanics.

B. Specific Objectives

- To optimize the training of the neural network via DeepLabCut using transfer learning for the identification and marking of cervical anatomical landmarks critical to swallowing, based on a public video database.
- To evaluate the feasibility of automatically detecting the onset instant of the swallowing reflex from the spatial trajectories estimated by the network, through a comparative benchmark among supervised machine learning classifiers.
- To analyze the model's performance quantitatively and qualitatively, comparing it with reference values from the literature, so as to delimit its methodological limitations and support guidelines for future work.

III. Methodology

A. Dataset Characterization

To assemble the database, searches for videos of the cervical region were carried out in search engines, restricted to publicly accessible material. The set comprised 24 videos depicting the frontal positioning characteristic of the intended use of the application, a size consistent with recommendations for exploratory pilot studies [13].

The following characteristics and limitations of the dataset should be made explicit, given the exploratory nature of this work:

- **Absence of a clinical population:** the videos depict individuals with no known or confirmed PD diagnosis, and no clinical metadata are available (age, sex, Hoehn and Yahr stage, presence or degree of dysphagia). The dataset therefore does *not* represent the target clinical population, and the performance reported here cannot be extrapolated to parkinsonian patients, who present precisely a reduction in the amplitude and velocity of cervical movements.
- **Acquisition heterogeneity:** the videos were obtained from independent public sources, with no control over camera distance, lighting, or resolution, and with acquisition parameters that were not recorded at collection time. Frame rates were in the region of 30 fps, but spatial resolution varied across the set and was not documented per video. This heterogeneity carries a direct methodological consequence that compounds the interpretability problem discussed in Section IV-A: because a pixel corresponds to a different physical distance in each video, the MRE aggregated over the dataset is not expressed in a single consistent physical unit. Recording resolution and frame rate per clip, and reporting the error stratified by acquisition condition, is a required step in any follow-up study.
- **Absence of spatial calibration:** no physical referent of known scale is present in the videos, which prevents converting errors and displacements from pixels to millimeters.

To avoid computational redundancy, the *K-means* clustering algorithm (integrated into DeepLabCut [5]) was used to automatically select, on average, 20 representative frames per video, covering rest, onset of the reflex, peak of laryngeal excursion, and return to the basal position. This amounted to approximately 480 annotated frames. Python 3.8 was used with DeepLabCut in a Conda environment with TensorFlow, on a Linux (Ubuntu) operating system.

B. Anatomical Landmark Selection Criteria

The elevation and anteriorization of the hyolaryngeal complex constitute the primary biomechanical mechanisms of airway protection during swallowing, and hyoid and laryngeal displacement is a consolidated parameter in the instrumental assessment of dysphagia, with normative values described in the literature [14]. The taxonomy adopted therefore sought to cover three functional domains: (i) the vertical excursion of the hyolaryngeal complex, the primary target of the analysis; (ii) the activity of the suprahyoid musculature, responsible for hyoid traction; and (iii) stable references for displacement normalization.

A protocol of 17 landmarks distributed across the cervical region and the upper thoracic boundary was defined: lateral borders of the neck (superior, medial, and inferior; right and left sides), sternocleidomastoid muscle (SCM) (superior, medial, and inferior; right and left sides), suprahyoid musculature (digastric, mylohyoid, and geniohyoid), larynx (thyroid prominence), and sternum (jugular notch), shown in Fig. 1.

One conceptual distinction must be recorded: the landmarks tracked here are *cutaneous surface landmarks*, not the bony or cartilaginous structures themselves. The "larynx" point corresponds to the cutaneous projection of the thyroid prominence, not to the hyoid bone visualized in VFSS. These are

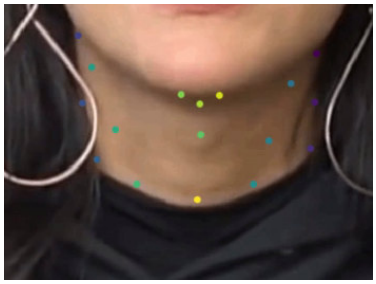

Figure 1. Anatomical landmarks.

therefore indirect measures (*proxies*) whose correlation with actual hyoid displacement has not been established in this work, which constitutes a validation step required before any clinical use.

C. Annotation and Data Partitioning

Manual annotation (*ground truth*) was performed frame by frame in the DeepLabCut Graphical User Interface, defining the Cartesian coordinates (x, y) of each landmark. The marking was carried out **independently** by two specialized speech-language pathologists, neither having access to the other's annotations. It is recorded, however, that **no quantitative measure of inter-rater agreement was computed** (for example, intraclass correlation coefficient or mean pixel error between annotators). Consequently, the variability inherent to the *ground truth* itself remains unknown, which makes it impossible to determine which portion of the reported MRE is attributable to the model and which to imprecision in the reference. Quantifying this agreement is a necessary step in future work.

Since the study exclusively involved public-domain videos, with no recruitment, intervention, or collection of identifiable data, it did not involve procedures subject to review by a Research Ethics Committee under the applicable national regulation [15].

The annotated set was partitioned according to DeepLabCut's *Shuffle* 4, allocating 95% of the frames to training and 5% to testing. It must be stressed, as the central methodological limitation of this work, that **this partition operates at the frame level and not at the video or subject level**. As a consequence, frames from the same video (and therefore from the same individual, with the same anatomy, lighting, and framing) may be simultaneously present in the training and test sets. This information leakage makes the reported error an optimistic estimate of the actual capacity to generalize to new individuals, rather than a measure of between-subject generalization.

D. Network Training

The base model was a residual network pre-trained on ImageNet (ResNet-50), adapted with deconvolutional layers for the generation of *scoremaps*. The main parameters are summarized in Table I.

Performance was quantified by the Mean Radial Error (MRE), the Euclidean distance in pixels between predicted coordinates and the *ground truth*. A spatial probability threshold (*p-cutoff* = 0.1) was additionally applied, restricting the computation to predictions with confidence equal to or greater than 10%.

E. Swallowing Onset Detection Pipeline

Once trained, the network was used to automatically generate the coordinates of the 17 landmarks in every frame of three new swallowing videos, producing, for each one, a CSV file with the spatiotemporal trajectories. Specialized speech-language pathologists performed the manual marking of the onset instant of the reflex. This marking was not performed frame by frame, but every 3 frames, an interval sufficient for visual perception of the difference between rest and onset. It should be noted that this 3-frame labeling resolution establishes a floor for the attainable temporal precision: the maximum label granularity is, by construction, three times coarser than that of the video.

From these markings, a binary column (*onset*) was created and incorporated into the coordinate CSV. The *pipeline* adopted was as follows:

- **Feature vector:** the Cartesian coordinates (x, y) of the 17 anatomical landmarks estimated by the network, augmented with variation/velocity features obtained by first-order differencing between consecutive frames of the sampled series, totaling 54 columns in the final dataset. The spatial probabilities (*likelihood*) produced by DeepLabCut were **not** incorporated into the feature vector.
- **Temporal resolution and windowing:** classification was performed independently on each sampled frame, **with no sliding window** and no aggregation of temporal context. The only dynamic information available to the models is that contained in the first-order variation features, which corresponds to an effective context of two sampled frames.
- **Pre-processing:** no spatial normalization of the coordinates relative to a reference point, no feature scaling, no temporal filtering, and no explicit handling of missing values were applied.
- **Class imbalance handling: no balancing strategy was adopted**. All classifiers were trained on the original class distribution, without class weighting, oversampling, or synthetic example generation. As discussed in Section IV-B, this is a determining factor for the degenerate behavior observed in three of the four models.

Table II presents the composition of the dataset used in this stage. The final set contains 182 sampled frames, of which only 27 (14.8%) correspond to the "onset" class. Note the marked heterogeneity across videos: the proportion of onset frames ranges from 3.9% (*video_2*) to 29.4% (*video_3*), so that the difficulty of the task and the degree of imbalance depend strongly on which video is held out for testing.

Table I
TRAINING PARAMETERS ADOPTED

Parameter	**Specification**
Optimizer	Stochastic gradient descent (SGD) with momentum and learning rate decay.
Learning Rate	*Multi-step* schedule: 0.005 (0 to 10,000 iterations) and 0.02 (10,000 to 100,000 iterations).
Batch Size	`batch_size: 1`
Data Split	Shuffle 4, with a partition of 95% for training and 5% for testing, **at the frame level**.
Total Iterations	100,000 iterations, with *snapshots* every 1,000 iterations.
Processing	Conda environment (`dlc_gui`), Python 3.8, TensorFlow *backend*, Linux (Ubuntu), executed on a central processing unit (CPU).

Table II
DATASET COMPOSITION FOR ONSET DETECTION (FRAMES SAMPLED EVERY 3 FRAMES OF THE ORIGINAL VIDEO)

Video	**Rest**	**Onset**	**Total**	**% Onset**
video_1	21	8	29	27.6%
video_2	98	4	102	3.9%
video_3	36	15	51	29.4%
Total	**155**	**27**	**182**	**14.8%**

Table III
QUANTITATIVE PERFORMANCE OF THE DEEPLABCUT MODEL (RESNET-50, SHUFFLE 4) AT 100,000 ITERATIONS

Metric	**Training**	**Test**
MRE, without *p-cutoff*	4.03 px	3.86 px
MRE with *p-cutoff* = 0.1	4.03 px	3.86 px

A comparative benchmark was conducted among Random Forest [16], XGBoost [17], *Support Vector Machine* (SVM) with a radial basis function (RBF) *kernel* [18], and *K-Nearest Neighbors* (KNN), all subjected to the same decision probability threshold ($p = 0.35$). Of the three videos, two were allocated to training and one was reserved exclusively for testing, so that the evaluation rests on a single video not observed during fitting. Given the distribution in Table II, this implies that the test set contains at most a handful of positive frames, making the minority-class metrics extremely sensitive to individual hits or misses [19].

IV. RESULTS AND DISCUSSION

A. Anatomical Mapping Performance

The evaluation was conducted upon reaching 100,000 iterations in *Shuffle* 4. Table III summarizes the MRE obtained.

Fig. 2 visually illustrates the spatial proximity between the manual markers (circles) and the network predictions (crosses). The frame shown belongs to the **training** set; the result observed there is therefore more optimistic than performance on unseen frames and serves only as a qualitative check.

As a technical reference point, the founding DeepLabCut literature reports that with as few as approximately 200 labeled frames the network attains tracking performance on test frames comparable to human accuracy, and further documents that the trial-to-trial labeling variability of a single expert annotator is itself mostly below 5 pixels [5]. Against that benchmark,

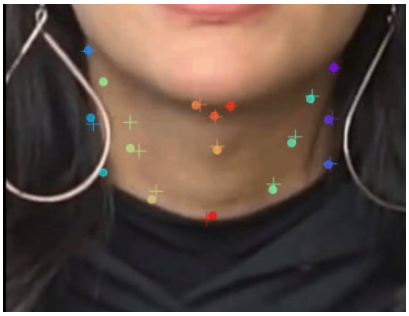

Figure 2. Comparison between the manual markers (*ground truth*, circles) and the neural network predictions (crosses) in a frame from the training set.

the MRE of 3.86 pixels obtained here from approximately 480 annotated frames falls within the range expected for the tool. The comparison is nonetheless only indicative, since those reference figures were obtained on datasets with different image scales and different target-structure sizes.

This value, moreover, requires three qualifications before any interpretation of merit:

1) **Leakage from frame-level partitioning:** as detailed in Section III-C, the 3.86 px error was measured on frames sharing video and individual with the training set. It measures within-video consistency, not between-subject generalization, and should be read as an optimistic upper bound.
2) **Absence of absolute metric meaning:** an error in pixels is not biomechanically interpretable without spatial calibration. To gauge the problem: the measurement error for hyoid and laryngeal displacement in VFSS, the reference modality, lies between 2.48 and 3.06 mm [20]. Without a physical referent in the videos, it is not possible to state whether 3.86 px corresponds to a fraction or a multiple of that range and, consequently, **no clinical meaning can be assigned to the value obtained**.
3) **Aggregated error:** the reported MRE is the mean across the 17 landmarks. As the qualitative analysis below indicates, the dispersion across landmarks is substantial, so the mean masks the poor performance of specific markers. Per-landmark errors were not computed at this stage.

The numerical equivalence of the errors with and without the confidence filter (*p-cutoff* = 0.1) indicates that the network

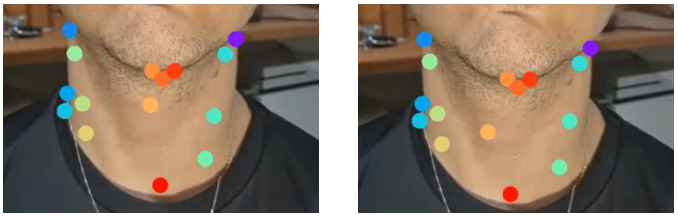

Figure 3. Examples of automatic tracking of the laryngeal point by the network, in the same video: (a) anatomically coherent marking, anchored on the thyroid prominence; (b) marking with deviation relative to the anatomical structure. Visual classification validated by two specialized speech-language pathologists.

kept its spatial probability above the threshold in virtually all estimates. It is worth noting that a threshold of 0.1 is permissive, so this stability should not be read as an indicator of high confidence.

The qualitative analysis indicates heterogeneous adherence of the markers to the underlying structures:

1) **Larynx and suprahyoid region:** the central laryngeal point and the suprahyoid region showed good fidelity in most frames. Oscillation and occasional deviation of the laryngeal marker were nevertheless observed in certain frames, probably associated with moments of higher displacement velocity or with contrast variations at the thyroid prominence. The distinction between coherent frames and frames with deviation was made by visual analysis, validated by two specialized speech-language pathologists, as exemplified in Fig. 3. Since the laryngeal marker is precisely the primary target of the biomechanical analysis, this instability is the most consequential of the tracking limitations observed.
2) **Sternocleidomastoid and lateral borders:** the chains of SCM points maintained adequate alignment. The lateral border points, however, did not remain stable throughout the video, an instability attributed to image noise and to the poor contour definition in that region.
3) **Lower anchoring point:** the sternum marker remained stable, providing a baseline for computing relative vertical elevation distances.

A demonstration video of the tracking in operation was made publicly available[1], allowing direct visual inspection of marker adherence throughout the movement.

B. Swallowing Onset Detection: Classifier Benchmark

Table IV summarizes the overall accuracy and the metrics for the class of interest ("onset").

The results highlight the difficulty of the task under severe class imbalance. The XGBoost, SVM, and KNN models failed to generalize to the rare class, obtaining null *recall* (0.00). In the confusion matrices of Fig. 4, rows represent the actual class and columns the predicted class; for these three classifiers, the entire column corresponding to the predicted "Onset" class remains empty, showing that no frame was classified as onset.

[1]Video available at: https://youtu.be/dnU-ldg7EPM

Table IV
COMPARATIVE BENCHMARK OF THE SWALLOWING ONSET DETECTION CLASSIFIERS (THRESHOLD = 0.35)

Model	Acc.	Prec.	Rec.	F1
Random Forest	77.5%	0.05	0.25	0.08
XGBoost	63.7%	0.00	0.00	0.00
SVM (RBF)	95.1%	0.00	0.00	0.00
KNN ($K = 5$)	76.5%	0.00	0.00	0.00

Prec., Rec., and F1 refer to the "Onset" class.

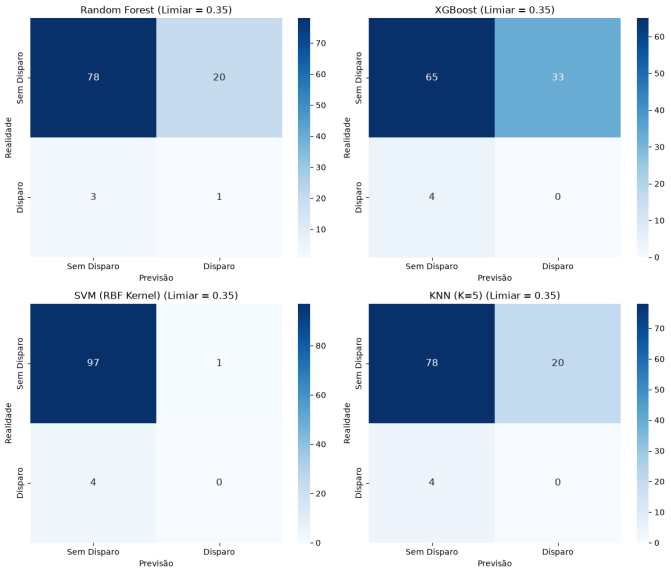

Figure 4. Confusion matrices of the four classifiers.

The SVM, despite achieving the highest nominal accuracy of the experiment (95.1%), classified the entire test video as rest: this is a false accuracy peak, explained solely by the imbalance [19], and it illustrates why overall accuracy is an inadequate metric in this scenario.

Random Forest was the only classifier to overcome the majority-class bias, with 25% *recall* and an overall accuracy of 77.5%. In the corresponding subplot of Fig. 4, this translates into at least one true positive in the "Onset" (actual) × "Onset" (predicted) cell.

Interpreting this result requires candour about its operational meaning. A *recall* of 25% means that **three out of every four swallowing onsets went undetected**. A precision of 0.05 means that, among the frames flagged as onset, approximately 95% were false positives. The resulting F1 of 0.08 is very close to what random flagging would yield under this degree of imbalance. In a dysphagia screening context, the false negative is the more consequential error: failing to detect a swallowing event may mean missing precisely the altered episode one intended to identify, with a risk of false clinical reassurance. For this reason, Random Forest should be understood here only as the most promising baseline classifier among those tested, and **not as a usable detector**. No inference regarding applicability to clinical screening or monitoring is supported

at this performance level.

Contributing to this result, cumulatively and now quantifiable from Table II: (i) the very small absolute number of positive examples, with only 27 onset frames in the entire dataset and a single test video containing just a few of them; (ii) the absence of any class-imbalance handling, which makes constant prediction of the majority class the lowest-cost solution for the models and directly explains the null *recall* of XGBoost, SVM, and KNN; (iii) the independent per-frame classification, which discards the sequential structure of the event and reduces the available temporal context to a first-order difference between two frames; and (iv) the 3-frame labeling granularity, which limits the attainable temporal precision by construction.

One further note of methodological transparency is warranted: the overall accuracy values in Table IV are not fully reconcilable with the per-video partition described in Table II, which suggests a possible divergence between the subsets actually evaluated by each classifier. This verification, together with the inclusion of the specificity requested by the reviewers, is under way and does not alter the qualitative conclusion of this section: detection performance remains well below what clinical use would require.

C. Comparison with Existing Approaches

Comparison with the literature on automatic swallowing event detection situates the present work clearly. In high-resolution cervical auscultation with deep networks, detection accuracies above 95% have been reported, validated on more than 3,000 swallows from 248 patients labeled by experienced speech-language pathologists [11]. Wearable accelerometry approaches have likewise demonstrated hyoid displacement tracking without videofluoroscopy [12], and VFSS combined with deep learning achieves robust automatic hyoid detection [10].

Against these works, the approach presented here is, on the axis of event-detection performance, inferior by a wide margin, explained above all by a difference of two to three orders of magnitude in the volume of annotated events. Its potential contribution lies on a different axis: the barrier to access. Cervical auscultation and accelerometry require sensors attached to the patient and dedicated hardware; VFSS requires a hospital environment and radiation. Conventional video tracking dispenses with all three. The open question, which this work does not answer, is whether the information available at the cervical skin surface is sufficient to support event detection at a clinically useful level.

D. Limitations

The following limitations are consolidated:

1) **Mismatch between motivation and validation:** the motivation is dysphagia in PD, but the dataset contains neither individuals with confirmed PD nor clinical metadata. No conclusion about the target population is supportable.
2) **Frame-level partitioning:** the MRE of 3.86 px is optimistic owing to within-video leakage and does not measure between-subject generalization.
3) **Absence of spatial calibration and undocumented acquisition parameters:** errors in pixels are not convertible to millimeters and are therefore not biomechanically interpretable. Because per-video resolution was not recorded, the aggregated MRE also mixes pixels of differing physical size.
4) **Insufficient event-detection performance:** 25% *recall* and an F1 of 0.08 rule out any clinical use.
5) **Sample size:** 24 videos for tracking and three videos (two for training, one for testing) for event detection, with only 27 positive frames out of 182.
6) **No class-imbalance handling:** the classifiers were trained on the original distribution (14.8% positives), without class weighting or resampling.
7) **No temporal modeling:** independent per-frame classification disregards the sequential nature of the swallowing event.
8) **Inter-rater agreement not quantified:** annotation was independent, but the variability of the *ground truth* was not measured.
9) **Surface *proxies*:** the markers track the skin surface, and their correlation with actual hyoid displacement has not been established.
10) **Aggregated error metrics:** per-landmark errors were not computed.

V. Final Considerations and Future Work

This work demonstrated the technical feasibility of using markerless pose estimation to track external cervical structures in conventional video, with an MRE of 3.86 pixels consistent with the range expected for the tool. This is a proof-of-concept contribution: it establishes that tracking is technically feasible with scarce annotated data, and it delimits precisely what still separates this result from a clinically usable tool.

The swallowing onset detection stage, by contrast, did not reach usable performance, and the evidence obtained does not support application to dysphagia screening or monitoring in any population.

Future work follows directly from the limitations identified:

1) **Independent validation protocol:** adopt partitioning strictly at the video or subject level and *leave-one-subject-out* cross-validation, so as to obtain an unbiased estimate of between-subject generalization.
2) **Spatial calibration:** incorporate a physical referent of known scale into the acquisition protocol, allowing errors and displacements to be reported in millimeters and compared against the error ranges of the reference instrumental assessment [20]. Standardize camera distance and positioning, and compute the individual error of each of the 17 landmarks.
3) **Temporal modeling:** replace per-frame classification with models operating over sequences (e.g., long short-term memory (LSTM), temporal convolutional net-

works (TCN), or *Transformers*), explicitly incorporating marker velocity and acceleration, and substantially increase the number of annotated swallowing events, in addition to adopting explicit class-imbalance strategies (class weighting, resampling, or synthetic example generation), absent in the present configuration.

4) **Validation in a clinical population:** assemble a cohort of patients with confirmed PD, with documented staging and speech-language assessment, and validate the extracted metrics against the instrumental gold standard before any proposal of clinical use.
5) **Quantification of the reference:** compute inter-rater agreement between the annotators, so as to separate model error from the variability of the *ground truth* itself.
6) **Tracking improvements:** expand the dataset, apply temporal smoothing, and use automatic cropping of the region of interest (ROI) to mitigate the instability observed in the laryngeal and lateral-border markers.

***Abstract*—Theta-gamma coupling (TGC) is a neural mechanism associated with the integration of cognitive processes and has been proposed as a potential biomarker of psychopathological vulnerability. This study investigated the relationship between TGC and the p-factor during a sequence learning task using data from the Healthy Brain Network (HBN). The sample consisted of 141 participants aged 8–16 years. TGC was quantified in the central, frontal, frontopolar, and parietal regions using the Modulation Index between theta (4–8 Hz) and gamma (30–50 Hz) oscillations. Spearman correlations, ANOVA, multiple linear regression, and receiver operating characteristic (ROC) analyses were performed. No statistically significant associations were observed between TGC metrics and the p-factor, and the regression models and ROC analyses showed no significant effects and limited discriminative performance. Exploratory analyses identified weak correlations between PAC_slope and the p-factor, with the largest association in the central region ($\rho = 0.129$), and between Delta_PAC and Attention, also in the central region ($\rho = -0.147$); however, neither association reached statistical significance. Overall, the findings provide limited evidence of an association between TGC and transdiagnostic psychopathological vulnerability. Future studies with larger samples, longitudinal designs, and cognitive tasks targeting specific domains may help clarify the potential of TGC as a neurophysiological marker.**

***Index Terms*—theta-gamma phase-amplitude coupling, p-factor, electroencephalography, visual sequential learning.**

I. Introduction

Understanding the neurobiological architecture of psychopathology has advanced through transdiagnostic approaches, particularly with the introduction of the p-factor, a general construct that represents the shared vulnerability across different mental disorders and consistently emerges in bifactor models applied to the Child Behavior Checklist (CBCL) [1]. Evidence indicates that the p-factor is associated with alterations in the connectivity of brain networks involved in cognitive control, including the default mode network (DMN) and frontoparietal networks, and is further linked to genetic influences and the development of functional brain networks [2]–[4].

Electroencephalography (EEG) is a promising tool for investigating neural biomarkers of psychopathology because of its high temporal resolution [5], [6]. In this context, the Healthy Brain Network (HBN) provides a large multimodal dataset, including high-density EEG recordings and transdiagnostic measures such as the p-factor, enabling the investigation of the relationship between neural activity and vulnerability to psychopathology [7].

Among the tasks available in the HBN dataset, the sequence learning task is particularly relevant because it engages attention, working memory, and executive control processes [8], [9]. These cognitive processes rely on the interaction between theta (4–8 Hz) and gamma (30–80 Hz) oscillations, with theta–gamma phase-amplitude coupling (PAC) being considered a key neural mechanism for the temporal integration of information and learning [10], [11].

Based on the association between the p-factor and alterations in cognitive control networks, we hypothesized that individuals with higher p-factor scores would exhibit distinct patterns of oscillatory power and theta–gamma coupling during sequence learning. Therefore, this study investigated the relationship between the p-factor and neural activity during this task using data from the HBN cohort. Specifically, we aimed to (1) characterize differences in theta and gamma band power and theta–gamma coupling among participants with different levels of the p-factor and (2) evaluate the potential of these neurophysiological markers to predict the general dimension of psychopathology.

II. Theta-Gamma Coupling as an Integrative Mechanism of Cognitive Processes and Psychopathology

Theta-gamma coupling (TGC) has been proposed as a fundamental neural mechanism underlying the integration of higher-order cognitive processes by linking neural oscillations at different frequencies to coordinate communication across distributed brain regions [12]. Theta oscillations (4–8 Hz) are associated with the temporal organization of sequential information and the maintenance of working memory, whereas gamma oscillations (30–80 Hz) reflect local neuronal activity and information integration within specific neural

networks [10]. TGC refers to the modulation of gamma-band amplitude by the phase of theta oscillations, enabling information from multiple sources to be integrated within a common temporal framework [13].

This mechanism has been implicated in cognitive processes such as working memory, selective attention, sequence learning, and executive control—functions (particularly within frontoparietal networks) that are frequently impaired across psychiatric disorders [14]. In this context, TGC represents a unifying mechanism that may account for the shared vulnerability across different forms of psychopathology, as disruptions in this coupling could impair the temporal coordination required for efficient cognitive processing. Previous studies have reported reduced TGC in conditions such as schizophrenia, attention-deficit/hyperactivity disorder (ADHD), and autism spectrum disorder (ASD), suggesting that it may serve as a transdiagnostic marker of neural dysfunction [15], [16].

Likewise, the p-factor represents a general dimension of psychopathology that captures the shared vulnerability across multiple mental disorders and has been linked to alterations in neural circuits underlying cognitive control and emotion regulation. Consequently, alterations in TGC may reflect the functional integrity of these neural systems, supporting its potential as a neurophysiological marker of vulnerability to psychopathology [17], [18].

Previous studies have also demonstrated that TGC is sensitive to individual differences in cognitive performance and can be modulated by interventions such as cognitive training and transcranial direct current stimulation (tDCS), highlighting its potential as a biomarker of neural plasticity and as a therapeutic target in clinical populations [12], [19]. However, the relationship between TGC and psychopathology remains largely unexplored in pediatric populations, particularly in relation to the p-factor. Moreover, few studies have examined this relationship using sequence learning tasks, which rely on the integration of attentional, mnemonic, and executive processes mediated by TGC within frontoparietal networks. The present study addresses this gap by investigating the relationship between TGC and the p-factor in a sample of children and adolescents using an eight-target sequence learning task, with the aim of determining whether neural coupling during the acquisition of motor and cognitive sequences reflects general vulnerability to psychopathology.

III. Methodology

A. Dataset and Study Cohort

This study used data from the Healthy Brain Network (HBN) dataset published by [7], a large-scale pediatric and adolescent biobank collected in New York, USA, including participants aged 5–21 years and containing neurophysiological, behavioral, cognitive, and clinical measures. Participants were included if they: (i) were 8–16 years old; (ii) had available EEG recordings from the Sequence Learning 8 Targets task; and (iii) had available p-factor, attention, externalizing, and internalizing scores. Participants who did not meet these criteria or had insufficient EEG data for phase-amplitude coupling analyses were excluded. After eligibility and EEG quality-control procedures, the final sample comprised **141 participants**, consistently used across the central, frontal, frontopolar, and parietal analyses. The 8–16-year age range was selected to reduce developmental heterogeneity, given the substantial structural and functional brain maturation occurring during childhood and adolescence [20]. Although variability remains within this interval, restricting the age range was intended to reduce broader developmental differences.

The Sequence Learning 8 Targets task was selected because sequential learning involves attention, working memory, performance monitoring, and the formation of learned representations, processes associated with theta-gamma interactions [21]. Participants observed and learned a sequence of eight stimuli repeated across five learning blocks [22], [23]. As the study relied on a single sequential learning paradigm, the task was not considered to capture all cognitive processes potentially associated with psychopathological vulnerability.

The primary transdiagnostic measure was the p-factor, which reflects shared vulnerability across different psychopathological symptoms [24]. Higher scores were interpreted as indicating greater overall psychopathological burden. Attention, externalizing, and internalizing scores were additionally examined to assess more specific cognitive and psychopathological dimensions. Attention reflects attentional and inhibitory-control processes [25], whereas externalizing and internalizing dimensions broadly reflect behavioral dysregulation and symptoms related to anxiety, fear, and emotional distress, respectively [26], [27]. Continuous scores were used as the primary variables in association analyses, while group-based analyses derived from the p-factor and attention scores were treated as complementary exploratory analyses, with categorization procedures described in the statistical analysis subsection.

B. EEG Data Acquisition and Preprocessing

1) Data Acquisition: EEG data were acquired using a high-density 128-channel EGI HydroCel Geodesic Sensor Net (GSN) system, following the standardized Healthy Brain Network (HBN) acquisition protocol [7].

The central region was defined as the primary region of interest (ROI) for theta-gamma phase-amplitude coupling analyses. Complementary analyses were conducted in the frontal (E11, E12, E13, E19, E20, E24, and E124), frontopolar (E8, E21, and E25), and parietal (E61, E62, E67, E68, E77, E78, E83, and E84) regions.

These regions were selected based on their relevance to cognitive processes involved in sequential learning and theta-gamma interactions. The central region was treated as the primary ROI, whereas the frontal, frontopolar, and parietal regions were included as complementary regional analyses. For each multi-electrode ROI, the same predefined electrode sets were applied consistently across participants and analyses.

2) Preprocessing: EEG signal preprocessing was performed using the MNE-Python library. The continuous EEG

signals were band-pass filtered between 1 and 100 Hz to attenuate low-frequency drifts and high-frequency components. A 60 Hz notch filter was subsequently applied to reduce power-line interference. The signals were then re-referenced using the average reference across the available EEG channels.

Experimental events were identified using the `mne.events_from_annotations()` function. Events corresponding to the *learningBlock* markers were used to segment the recordings into five consecutive learning blocks associated with the Sequence Learning 8 Targets task.

Segments shorter than 3 s were excluded from subsequent analyses to ensure that only epochs with sufficient duration for the planned phase-amplitude coupling calculations were retained.

C. Phase-Amplitude Coupling Calculation

Phase-amplitude coupling (PAC) is a neurophysiological measure that quantifies the relationship between the phase of a low-frequency brain oscillation and the amplitude of a higher-frequency oscillation. In the present study, theta oscillations (4–8 Hz) were used as the phase-providing signal, whereas gamma oscillations (30–50 Hz) were used as the amplitude-providing signal.

PAC was computed using the TensorPAC library. The coupling method was defined using the parameter `idpac=(2,0,0)`, in which the first value specifies the PAC estimation method. Thus, the Modulation Index (MI) proposed by [28] was used to quantify theta-gamma coupling. The second value indicates that no surrogate-based computation was applied, whereas the third value indicates that no statistical correction was applied within the PAC computation.

PAC was calculated separately for each participant, brain region, and learning block. The Sequence Learning 8 Targets task was divided into five consecutive learning blocks, allowing the temporal evolution of theta-gamma coupling throughout the task to be examined.

From these values, PAC-derived measures were calculated to characterize the magnitude and temporal evolution of coupling. These measures included: (i) PAC values for each task block (*PAC_block1–PAC_block5*); (ii) the overall mean PAC value (*PAC_mean*); (iii) between-block variability (*PAC_std*); (iv) the temporal trend estimated by the slope coefficient of a linear regression across the five blocks (*PAC_slope*); (v) the difference between the last and first blocks (*Delta_PAC*); and (vi) a normalized learning index (*Learning_Index*), calculated as:

$$Learning_Index = \frac{PAC_5 - PAC_1}{PAC_1} \tag{1}$$

The flowchart presented in Figure 1 summarizes the main stages of the methodology, from EEG preprocessing to the calculation of the PAC-derived measures used in the subsequent analyses.

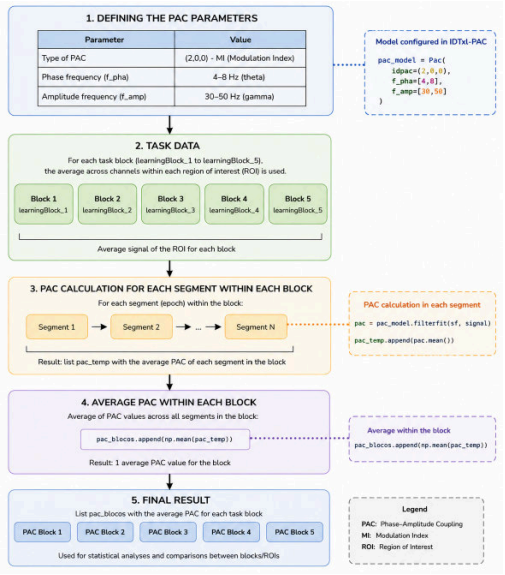

Fig. 1. Flowchart illustrating the main stages of EEG preprocessing and theta-gamma phase-amplitude coupling calculation.

IV. RESULTS

A. Sample Characterization

The final sample comprised 141 participants aged 8-16 years (mean = 11.52 years, SD = 2.09), including 85 males and 56 females. According to the predefined p-factor thresholds, participants were categorized into low (p-factor < -0.5; $n = 46$), intermediate ($-0.5 \leq$ p-factor ≤ 0.5; $n = 47$), and high (p-factor > 0.5; $n = 46$) groups. Table I summarizes the demographic and psychopathological characteristics of the sample.

TABLE I
DEMOGRAPHIC AND PSYCHOPATHOLOGICAL CHARACTERISTICS OF THE SAMPLE ($N = 141$).

Variable	Mean (SD)
Age (years)	11.18 (1.89)
Sex (M/F)	85/56
p-factor	-0.003 (0.92)
Attention	0.02 (0.85)
Internalizing	0.11 (0.76)
Externalizing	-0.08 (0.67)

B. Correlational Analyses

To investigate the relationship between theta-gamma coupling and psychopathological dimensions, Spearman correlation analyses were performed between *PAC_mean* and the p-factor, Attention, Internalizing, and Externalizing scores separately for the central, frontal, frontopolar, and parietal regions.

As shown in Figure 2, correlations between *PAC_mean* and psychopathological measures were consistently weak across all regions, with Spearman coefficients ranging from $\rho = -0.093$ to $\rho = 0.084$. The largest negative association was observed between *PAC_mean* and Attention in the frontopolar

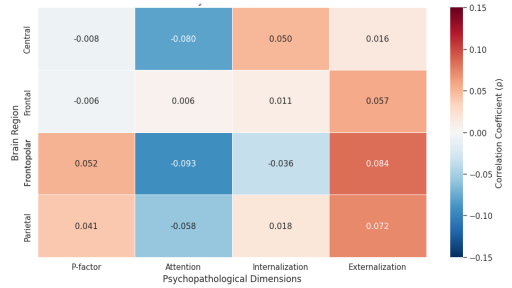

Fig. 2. Correlations between *PAC_mean* and psychopathological dimensions across brain regions.

region ($\rho = -0.093$, $p = 0.274$), whereas the largest positive association was observed between *PAC_mean* and Externalizing in the same region ($\rho = 0.084$, $p = 0.322$). Neither association was statistically significant.

After correction for multiple comparisons, none of the correlations reached statistical significance. Overall, these results indicate that mean theta-gamma phase-amplitude coupling was not significantly associated with general psychopathological vulnerability or with Attention, Internalizing, and Externalizing dimensions in the present sample.

Exploratory analyses involving additional PAC-derived measures also yielded no statistically significant associations. In the central region, *PAC_slope* showed a weak positive correlation with the p-factor ($\rho = 0.129$, $p = 0.126$), whereas *Delta_PAC* showed a weak negative correlation with Attention ($\rho = -0.147$, $p = 0.082$). Because these associations were small and did not reach statistical significance, they were not interpreted as evidence of specific neurophysiological or compensatory mechanisms.

C. Comparison Between p-factor Groups

Participants were divided into three groups according to the predefined p-factor thresholds. Table II presents the mean and standard deviation of *PAC_mean* for each group and brain region, together with the results of the one-way ANOVA and corresponding effect sizes.

TABLE II
MEANS AND STANDARD DEVIATIONS (IN PARENTHESES) OF PAC_MEAN FOR THE P-FACTOR GROUPS IN EACH BRAIN REGION, ALONG WITH THE UNIVARIATE ANOVA RESULTS (F, p, AND η^2) ($N = 141$).

Region	**Low**	**Inter.**	**High**	$F(2, 138)$	p	η^2
Central	0.00204 ± 0.0043	0.00189 ±0.0034	0.00512 ±0.0102	1.67	0.192	0.024
Frontal	0.00158 ±0.0041	0.00171 ±0.0035	0.00325 ±0.0055	1.32	0.270	0.019
Frontopolar	0.00121 ±0.0029	0.00124 ±0.0025	0.00219 ±0.0040	0.98	0.379	0.014
Parietal	0.00130 ±0.0027	0.00113 ±0.0020	0.00229 ±0.0040	1.12	0.329	0.016

As shown in Table II, no statistically significant differences in *PAC_mean* were observed among the p-factor groups in any of the four brain regions analyzed. Effect sizes were small across all regions ($\eta^2 < 0.03$), indicating that group membership accounted for only a limited proportion of the variability in *PAC_mean*.

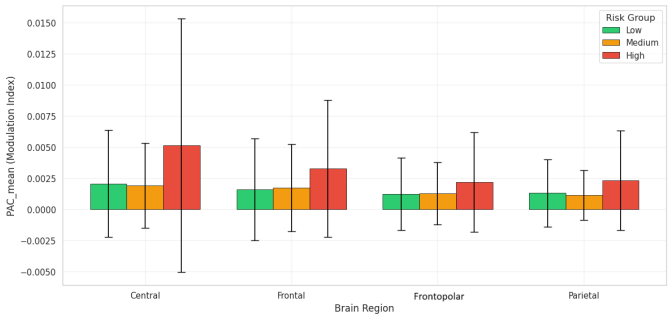

Fig. 3. Theta-gamma coupling (*PAC_mean*) across p-factor groups and brain regions.

Figure 3 shows the descriptive distribution of *PAC_mean* across the three groups. Numerically, the high p-factor group presented higher mean *PAC_mean* values than the low and intermediate groups across all regions. The largest numerical difference was observed in the central region, where mean *PAC_mean* values were 0.00512, 0.00204, and 0.00189 for the high, low, and intermediate groups, respectively.

The high p-factor group also showed larger standard deviations, particularly in the central region. However, because the group differences were not statistically significant and effect sizes were small, these descriptive differences were not interpreted as evidence of distinct neurophysiological mechanisms or greater neurophysiological heterogeneity.

D. Analysis of Temporal Dynamics of Coupling

The sequential learning task consisted of eight stimuli repeated across five consecutive blocks. For each block (*PAC_block1* to *PAC_block5*), theta-gamma phase-amplitude coupling was estimated, allowing the temporal dynamics of PAC to be examined throughout the task. A mixed repeated-measures ANOVA was performed with block (1–5) as the within-subjects factor and p-factor group as the between-subjects factor. Figure 4 presents the PAC trajectories across the five blocks for each brain region.

No statistically significant main effect of block was observed in any of the regions analyzed. Likewise, no significant block-by-group interaction was found, indicating no evidence that the temporal evolution of PAC differed among the p-factor groups.

As shown in Figure 4, descriptive differences in PAC trajectories were observed across regions and groups. In particular, the high p-factor group showed an increasing numerical pattern in the parietal region and a decreasing pattern in the frontopolar region. However, these variations were not statistically significant and were therefore interpreted only as descriptive patterns.

Figure 5 presents the distribution of *PAC_slope*, which summarizes the direction of PAC change across the five learning blocks. Descriptively, the high p-factor group showed

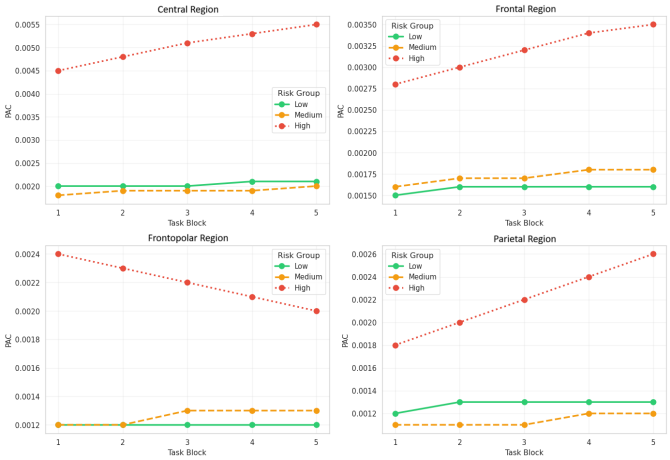

Fig. 4. Evolution of theta-gamma phase-amplitude coupling across the five task blocks.

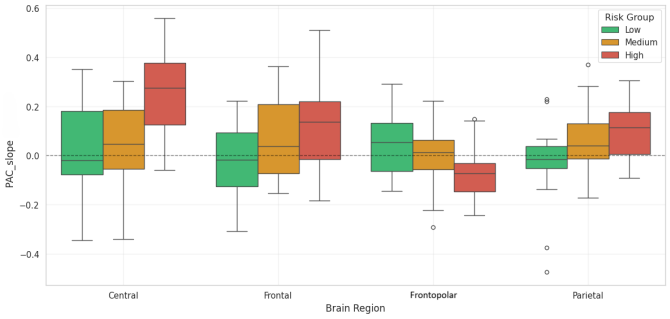

Fig. 5. Temporal slope of theta-gamma coupling (*PAC_slope*) across p-factor groups and brain regions.

positive PAC slopes in the parietal region and negative slopes in the frontopolar region, whereas the low and intermediate groups showed less pronounced changes.

Because these patterns did not reach statistical significance, they were not interpreted as evidence of differential neural recruitment, cognitive impairment, or specific neurophysiological mechanisms. Overall, the temporal analyses provided no statistically significant evidence of systematic changes in theta-gamma coupling across the task or of differences in PAC trajectories among p-factor groups.

E. Multiple Linear Regression Analyses

Multiple linear regression models were fitted to examine whether *PAC_slope* was associated with the p-factor after controlling for age and sex. Separate models were estimated for the central, frontal, frontopolar, and parietal regions. Table III presents the standardized regression coefficients (β), standard errors, t-statistics, p-values, AIC, and adjusted R^2 for each model.

Across all regions, *PAC_slope* was not significantly associated with the p-factor after adjustment for age and sex. The largest standardized coefficient was observed in the central region ($\beta = 0.128$, $p = 0.126$), although this association

TABLE III
LINEAR REGRESSION RESULTS FOR EACH CORTICAL REGION.

Region	**Predictors**	β	**Std. Error**	**t**	p	**AIC**	**Adjusted** R^2
Central	PAC_slope	0.128	0.083	1.54	0.126	412.3	0.015
	Age	-0.045	0.082	-0.55	0.583		
	Sex	0.062	0.082	0.76	0.449		
Frontal	PAC_slope	0.073	0.083	0.88	0.379	415.1	0.005
	Age	-0.048	0.083	-0.58	0.563		
	Sex	0.065	0.083	0.78	0.436		
Frontopolar	PAC_slope	0.052	0.084	0.62	0.539	416.7	0.003
	Age	-0.042	0.084	-0.50	0.618		
	Sex	0.058	0.084	0.69	0.491		
Parietal	PAC_slope	0.069	0.084	0.82	0.414	415.8	0.004
	Age	-0.046	0.084	-0.55	0.583		
	Sex	0.061	0.084	0.73	0.467		

was not statistically significant. Age and sex were also not significant predictors in any of the regional models.

The adjusted R^2 values were consistently low (< 0.02), ranging from 0.003 to 0.015, indicating that the models explained only a small proportion of the variability in the p-factor. Overall, these findings provide little evidence that *PAC_slope*, when considered together with age and sex, has substantial explanatory value for general psychopathological vulnerability in the present sample.

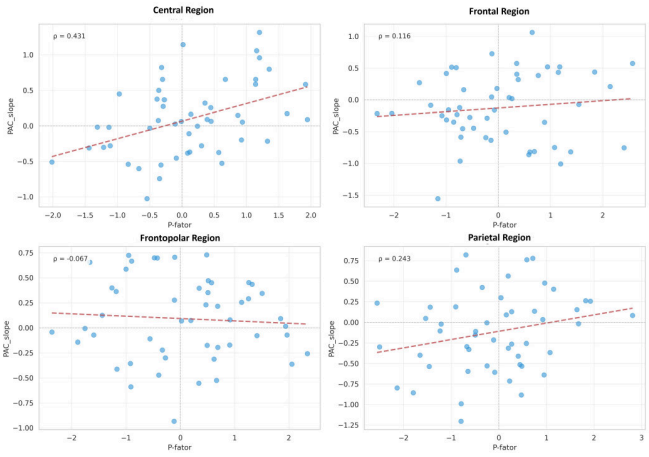

Fig. 6. Relationship between the p-factor and *PAC_slope* across brain regions.

As illustrated in Figure 6, the associations between the p-factor and *PAC_slope* were weak across all brain regions. Small positive associations were observed descriptively in the central and parietal regions, whereas the frontopolar region showed a near-zero association. However, none of these relationships reached statistical significance.

Accordingly, the observed regional differences were not interpreted as evidence of compensatory neural recruitment, altered cognitive efficiency, or region-specific neurophysiological mechanisms. Instead, the regression results indicate that temporal changes in theta-gamma coupling showed limited association with the p-factor when examined in isolation and after adjustment for age and sex.

F. ROC Curve Analysis

As illustrated in Table IV, the ROC curves for all brain regions display trajectories very close to the diagonal line representing a random classifier (AUC = 0.50). This visual pattern indicates that *PAC_mean* does not possess discriminative ability to distinguish between individuals with low and high psychopathological vulnerability. The area under the curve (AUC) values, unsurprisingly, corroborate this behavior.

TABLE IV
DISCRIMINATIVE PERFORMANCE OF *PAC_mean* BETWEEN LOW- AND HIGH-RISK GROUPS ($n = 92$).

Region	AUC	95% CI	Cutoff Point	Sensitivity	Specificity	Youden's Index
Central	0.52	[0.41; 0.63]	0.0012	0.52	0.54	0.06
Frontal	0.51	[0.40; 0.62]	0.0009	0.50	0.52	0.02
Frontopolar	0.55	[0.44; 0.66]	0.0007	0.57	0.53	0.10
Parietal	0.54	[0.43; 0.65]	0.0008	0.54	0.54	0.08

All 95% confidence intervals include the value 0.50, reinforcing the conclusion that the performance of *PAC_mean* as a classifier is not statistically superior to chance. The cutoff points ranged from 0.0007 to 0.0012, depending on the region. However, the overall low accuracy renders these values of little practical utility. The sensitivity (0.50 to 0.57) and specificity (0.52 to 0.54) values were equally low, indicating that *PAC_mean* fails to adequately identify either high-risk or low-risk individuals. Youden's index values were very low (0.02 to 0.10), confirming the reduced accuracy of *PAC_mean* as a discriminative marker.

G. Exploratory Correlation Patterns

Two descriptive correlation patterns were further examined: *PAC_slope* versus the p-factor and *Delta_PAC* versus Attention.

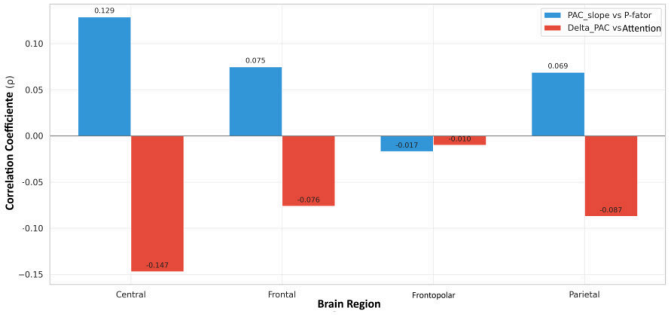

Fig. 7. Spearman correlation coefficients for *PAC_slope* versus the p-factor and *Delta_PAC* versus Attention across brain regions.

1) PAC_slope vs. p-factor: As shown in Figure 7, the largest positive correlation between *PAC_slope* and the p-factor was observed in the central region ($\rho = 0.129$). Smaller positive correlations were observed in the frontal ($\rho = 0.075$) and parietal ($\rho = 0.069$) regions, whereas the frontopolar region showed a near-zero negative correlation ($\rho = -0.017$).

Although these coefficients differed in direction and magnitude across regions, all associations were weak and did not reach statistical significance. Therefore, these regional patterns were interpreted descriptively and were not considered evidence of compensatory neural recruitment, neural desynchronization, or region-specific modulation by psychopathological vulnerability. Overall, the results provide limited evidence for an association between temporal changes in theta-gamma coupling and the p-factor in the present sample.

2) Delta_PAC vs. Attention: The same figure shows that the correlations between *Delta_PAC* and Attention were negative across all four regions. The largest negative correlation was observed in the central region ($\rho = -0.147$), followed by the parietal ($\rho = -0.087$) and frontal ($\rho = -0.076$) regions. The frontopolar region showed a near-zero negative correlation ($\rho = -0.010$).

Despite the similar direction of these coefficients, all associations were weak and did not reach statistical significance. Therefore, the observed pattern was considered descriptive and does not provide evidence that attentional difficulties are associated with reduced temporal variation in theta-gamma coupling. Likewise, the present findings do not support the conclusion that *Delta_PAC* is more sensitive to attentional processes than to general psychopathological vulnerability. Further studies are required to determine whether this pattern can be replicated in independent samples.

V. CONCLUSION

The present study examined how the general dimension of psychopathology, captured by the p-factor, is reflected in neural dynamics during a sequence learning task.

The present findings did not provide evidence of significant associations between theta-gamma coupling metrics and the psychopathological dimensions assessed across the brain regions analyzed. Correlational analyses, group comparisons, regression models, and ROC curve analyses consistently showed small effects, low explained variance, and limited discriminative performance. Taken together, these results indicate that theta-gamma coupling, when assessed in isolation during the sequential learning task, has limited utility as a neurophysiological marker of transdiagnostic psychopathological vulnerability.

The absence of robust associations also highlights the importance of considering psychopathological vulnerability as a complex and multidimensional phenomenon that may not be adequately characterized by a single electrophysiological measure. Therefore, the present findings establish a boundary on the use of theta-gamma coupling as a standalone biomarker in this experimental context rather than supporting specific neurophysiological mechanisms.

Future studies should investigate larger and longitudinal cohorts, employ cognitive paradigms more specifically targeted to relevant cognitive domains, and integrate complementary EEG measures, such as spectral power, functional connectivity, event-related potentials, and network-level features. Multimodal and multivariate approaches may provide a more comprehensive characterization of the neurophysiological mechanisms associated with psychopathological vulnerability.

***Abstract*—Motor imagery brain–computer interface (MI-BCI) performance is commonly summarized by a scalar output that does not describe the evolution of the neural path. This longitudinal within-participant pilot study evaluates candidate markers derived from electroencephalographic (EEG) covariance trajectories on the manifold of symmetric positive definite (SPD) matrices. Eight sessions from a healthy 24-year-old man, collected over 30 days, were analyzed using a 16-channel EEG-cap and continuous pneumatic-glove feedback. Successive covariances in the 8–30 Hz band were compared with the affine-invariant Riemannian metric. Dispersion quantified compaction between the first and third training blocks, as well as persistence between the feedback-free periods before (PRE) and after (POST) training; length, curvature, and straightness complemented the description. Six sessions showed compaction, with a median reduction of 0.119 and a rank-biserial effect size of -0.611, although the result has been inconclusive (p = 0.148). Four sessions showed lower dispersion in POST, without consistent persistence (p = 0.844). In an exploratory analysis, mean controller target aperture was not associated with compaction (Spearman's rho = 0.024, p = 0.977). The results support Riemannian trajectories as complementary descriptors of neural dynamics during the protocol and provide an auditable framework for larger studies.**

***Index Terms*—brain–computer interface, motor imagery, neural manifolds, neural trajectories, Riemannian geometry.**

I. Introduction

Motor imagery brain–computer interfaces (MI-BCIs) convert voluntary modulations of brain activity into external commands [1]. During MI, changes in sensorimotor mu and beta rhythms can be observed with electroencephalography (EEG), particularly over frontocentral and centroparietal regions [2]. Training seeks to produce these patterns voluntarily, stably, and reproducibly, involving adaptation by both the user and the system [3], [4]. Visual feedback or feedback delivered through robotic effectors adds a sensorimotor consequence to practice, which is relevant to neurorehabilitation [5]–[7].

Classification accuracy is frequently used to quantify learning in MI-BCIs [3], [8], although it represents the joint performance of the user and the algorithm and depends on calibration, model choice, decision threshold, and EEG nonstationarity [8]. Decoder adaptation can increase accuracy without a consistent neural change, whereas neural reorganization may not alter a binary decision. Within-class Riemannian changes can accompany skill acquisition and stabilization even when recalibration is infrequent [9]. Classifier-independent stability and separability metrics have therefore been proposed to assess user evolution rather than only the machine decision [10]–[12].

In multichannel EEG, each window describes a joint configuration across the electrodes; ordering these configurations forms a path between states and allows for analysis of both the state reached and the transitions throughout the task. Intracortical studies show that population evolution contains sensorimotor information absent from isolated observations [13], whereas latent-state models represent motor activity as low-dimensional trajectories [14]–[16]. Dynamic mode decomposition also extracts coherent spatiotemporal patterns [17]. These findings do not establish equivalence between intracortical populations and scalp EEG, but support the methodological principle of jointly preserving the spatial organization and temporal ordering of the signals. Explicit descriptors also favor the balance between flexibility and interpretability recommended for data-driven modeling in neuroengineering [18].

Motor learning can reorganize variability within pre-existing neural subspaces [19], [20], and MI-BCI studies have identified low-dimensional representations that are sensitive to training and rehabilitation [21], [22]. In EEG, a covariance matrix represents the multichannel configuration and lies on the manifold of symmetric positive definite (SPD) matrices [23], [24]. Riemannian methods assign one covariance matrix to each data segment for classification [25], [26] or user-stability assessment [11], [12], whereas manifold analyses emphasize state embeddings [21], [22]. Here, successive covariance matrices are linked into a trajectory, preserving both geometry and temporal order.

This study characterizes neural trajectories at three scales: during training, after feedback withdrawal, and across sessions. Each temporal segment is represented as a trajectory on the SPD manifold; dispersion quantifies reproducibility, whereas length, curvature, straightness, geodesic progress, and orthogonal deviation describe path shape and direction. The primary

This work was supported by the Fundação de Amparo à Pesquisa e Inovação do Espírito Santo (FAPES), Brazil, through research funding and a scholarship.

hypothesis is that greater stabilization of MI corresponds to more compact trajectories. As a complementary hypothesis, trajectories oriented toward the target state should exhibit lower curvature and orthogonal deviation, together with greater straightness and geodesic progress.

A. EEG representation on the SPD manifold

Let a multichannel EEG window be $\boldsymbol{X}_t \in \mathbb{R}^{C\times N}$, with C channels and N samples. After centering, its sample covariance $\boldsymbol{S}_t$ is shrinkage-regularized:

$$\boldsymbol{C}_t = (1-\lambda)\boldsymbol{S}_t + \lambda\frac{\mathrm{tr}(\boldsymbol{S}_t)}{C}\boldsymbol{I}, \qquad \boldsymbol{C}_t \in \mathcal{S}_{++}^{C}. \tag{1}$$

Here, $\boldsymbol{I}$ is the identity matrix, $\mathrm{tr}(\cdot)$ denotes the trace, and $\lambda \in [0,1]$ is the shrinkage intensity, which preserves positive definiteness and numerical stability. Because the SPD cone is not a vector space, Euclidean differences between covariance matrices can distort its structure. We therefore used the affine-invariant Riemannian metric (AIRM) [24], [27]:

$$d_{\mathrm{R}}(\boldsymbol{P},\boldsymbol{Q}) = \left\|\log\!\left(\boldsymbol{P}^{-1/2}\boldsymbol{Q}\boldsymbol{P}^{-1/2}\right)\right\|_{\mathrm{F}}, \tag{2}$$

for $\boldsymbol{P},\boldsymbol{Q} \in \mathcal{S}_{++}^{C}$, where $\log(\cdot)$ is the matrix logarithm and $\|\cdot\|_{\mathrm{F}}$ is the Frobenius norm. This metric preserves distances under invertible congruence transformations. A set of covariance matrices can be summarized by a geometric mean, defined as the minimizer of the sum of squared distances,

$$\bar{\boldsymbol{C}} = \arg\min_{\boldsymbol{C}\in\mathcal{S}_{++}^{C}} \sum_{i=1}^{n} d_{\mathrm{R}}^{2}(\boldsymbol{C},\boldsymbol{C}_i), \tag{3}$$

where n is the number of matrices in the set. This construction yields a centroid consistent with the geometry of the space.

B. Trajectories and geometric markers

The temporal sequence of covariance matrices for segment i is denoted by $\mathcal{T}_i$. For two trajectories aligned across their T windows, we defined

$$d_{\mathrm{T}}(\mathcal{T}_i,\mathcal{T}_j) = \frac{1}{T}\sum_{t=1}^{T} d_{\mathrm{R}}(\boldsymbol{C}_{i,t},\boldsymbol{C}_{j,t}). \tag{4}$$

The dispersion of a block B with n_B segments is the mean distance over all pairs,

$$D_B = \frac{2}{n_B(n_B-1)}\sum_{i<j} d_{\mathrm{T}}(\mathcal{T}_i,\mathcal{T}_j). \tag{5}$$

The three feedback training blocks are denoted B1, B2, and B3, and the feedback-free periods before and after training are denoted PRE and POST. Thus, $\Delta D_{\mathrm{train}} = D_{\mathrm{B3}} - D_{\mathrm{B1}} < 0$ characterizes within-session compaction, whereas $\Delta D_{\mathrm{persist}} = D_{\mathrm{POST}} - D_{\mathrm{PRE}} < 0$ indicates persistence of greater consistency after feedback withdrawal.

To describe path shape, each covariance matrix is projected onto the tangent space at a reference $\boldsymbol{R}$ as $\boldsymbol{z}_t = \mathrm{vec}_{\mathrm{sym}}\big[\log(\boldsymbol{R}^{-1/2}\boldsymbol{C}_t\boldsymbol{R}^{-1/2})\big]$, where $\mathrm{vec}_{\mathrm{sym}}$ denotes the isometric vectorization of the independent elements of a symmetric matrix. Length L and straightness S are

$$L = \sum_{t=1}^{T-1}\|\boldsymbol{z}_{t+1}-\boldsymbol{z}_t\|_2, \qquad S = \frac{\|\boldsymbol{z}_T-\boldsymbol{z}_1\|_2}{L}. \tag{6}$$

With $\Delta\boldsymbol{z}_t = \boldsymbol{z}_{t+1}-\boldsymbol{z}_t$, curvature was defined as the mean, in radians, of the angles between $\Delta\boldsymbol{z}_t$ and $\Delta\boldsymbol{z}_{t+1}$, computed from the normalized cosine. For an expected direction $\boldsymbol{v}$ from the reference to the MI target state, progress and orthogonal deviation are

$$p_t = \frac{\langle\boldsymbol{z}_t,\boldsymbol{v}\rangle}{\|\boldsymbol{v}\|_2^2}, \qquad o_t = \left\|\boldsymbol{z}_t - \frac{\langle\boldsymbol{z}_t,\boldsymbol{v}\rangle}{\|\boldsymbol{v}\|_2^2}\boldsymbol{v}\right\|_2. \tag{7}$$

To visualize the local direction of neural movement, the plane formed by the first two tangent components was divided into a grid. In each cell g, the number of states n_g and the sum $\boldsymbol{s}_g$ of consecutive displacements were accumulated. After discrete Gaussian smoothing G_σ, we defined

$$\widehat{\boldsymbol{f}}(\boldsymbol{x}_g) = \frac{G_\sigma(\boldsymbol{s})_g}{\max[G_\sigma(\boldsymbol{n})_g,\varepsilon]}. \tag{8}$$

Here, $\boldsymbol{x}_g$ is the center of cell g, and $\varepsilon > 0$ is a numerical stabilization constant. The field estimates mean displacement in visited regions without assuming an autonomous system or attractors. Together, these measures separate consistency, path efficiency, and the direction of reorganization.

A second visualization summarizes occupancy through an empirical potential,

$$V(\boldsymbol{x}) = -\log[\widehat{p}(\boldsymbol{x})+\varepsilon] - \min_{\boldsymbol{u}}\{-\log[\widehat{p}(\boldsymbol{u})+\varepsilon]\}, \tag{9}$$

where $\widehat{p}$ is a kernel density estimate and $\boldsymbol{u}$ ranges over the domain points used to define the minimum. Lower values indicate more frequently visited regions, not physiological energy. This deliberately descriptive interpretation distinguishes these representations from methods intended to identify operators, delay models, or governing equations [17], [28]. The protocol sequence, EEG montage, and analytical trajectory pipeline are shown in Figs. 1, 2, and 3, respectively.

II. Materials and Methods

A. Study design and protocol

A longitudinal within-participant pilot study was conducted with a healthy 24-year-old man. Eight sessions (S1–S8) performed over 30 days were analyzed. In every session, the participant received standardized instructions to kinesthetically imagine opening his right hand without executing a voluntary movement, while a pneumatic glove assisted hand opening during feedback. The study was conducted under a protocol approved by the Research Ethics Committee of the Federal University of Espírito Santo, Brazil, under Certificate of Presentation for Ethical Review (CAAE) 91161425.6.0000.5060. The procedures complied with the Declaration of Helsinki, and written informed consent was obtained from the participant before any study-related procedure.

Each session began with 180 s of rest, followed by a 70-s PRE period of motor imagery without feedback. After a short preparation interval, three 70-s training blocks with continuous feedback, B1, B2, and B3, were performed. A 90-s rest interval separated B1 from B2 and B2 from B3. Following B3, a 3–5-min rest period preceded POST, which comprised 70 s of MI without feedback, as shown in Fig. 1.

Before training, a session-specific calibration related sensorimotor changes in the 8–30 Hz band to MI evidence. During B1–B3, this evidence was continuously converted into a target spanning 0–80% of the glove's safe range of motion; stronger evidence produced a larger target aperture, and pneumatic motion provided visual and kinesthetic feedback. The control logic evolved from an adaptive configuration in S1 to an anti-saturation ramp in S2–S6 and a geodesic gate in S7–S8. These changes did not enter the offline geometric computation, but limited direct comparison of controller outputs. PRE and POST retained the same instruction, without glove movement or decoder output. Contrasts between B1 and B3, PRE and POST, and across sessions defined within-session adaptation, feedback-free persistence, and longitudinal evolution, respectively.

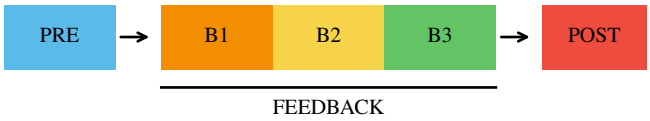

Fig. 1. Analytical block sequence. PRE and POST were performed without feedback, whereas B1–B3 used proportional pneumatic-glove feedback. Rest intervals are omitted from the diagram and described in the text.

B. EEG acquisition

EEG was acquired with an OpenBCI Cyton+Daisy system using 16 channels at a sampling rate of 125 samples/s. FCz was connected to the common SRB2 input: in the referential mode of the ADS1299 converter each channel was digitized directly as a potential difference relative to FCz. AFz was connected to the BIAS input, which was used for common-mode stabilization and interference reduction rather than as a second reference subtracted offline [29]. The montage comprised FC3, FC1, FC2, FC4, C5, C3, C1, Cz, C2, C4, C6, CP3, CP1, CPz, CP2, and CP4. Geometric analysis used ten frontocentroparietal channels: FC3, FC1, FC2, FC4, C3, Cz, C4, CP3, CPz, and CP4 (Fig. 2).

C. Preprocessing and trajectory construction

Temporal integrity was verified from the sample index and effective sampling rate. A 60-Hz notch filter with quality factor $Q = 30$ and a fourth-order, zero-phase 1–40 Hz Butterworth bandpass filter were applied. For geometric analysis, the ten selected channels were filtered between 8 and 30 Hz. The first 5 s of each 70-s phase were discarded; 64 s of the remaining 65 s were divided into eight contiguous 8-s temporal segments. These segments were standardized analysis units within PRE, B1, B2, B3, and POST rather than independent behavioral trials.

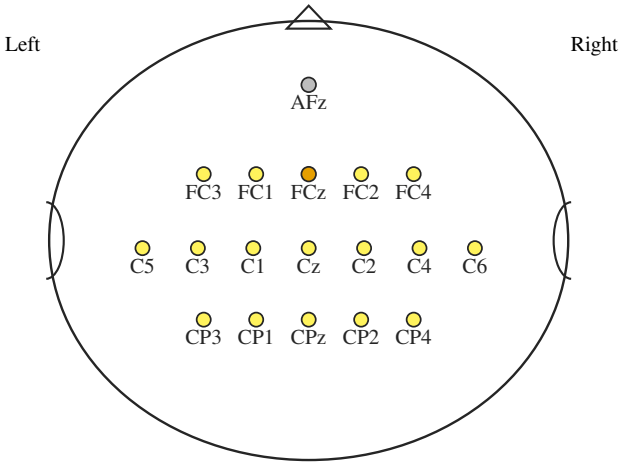

Fig. 2. EEG montage used in the study, redrawn as a vector diagram. The labeled yellow markers indicate the 16 acquisition sites; FCz was the physical reference and AFz the ground electrode.

Channels were evaluated for flatness, extreme amplitude, line-noise content, and derivative peaks. Each temporal segment was checked for robust amplitude, power ratios in the 1–4 and 30–40 Hz bands, nonfinite values, and covariance conditioning. The primary thresholds were a robust peak amplitude of 200 μV, a maximum robust score of 3.5, and a condition number below 10^6. PRE and POST were required to retain at least seven of the eight valid segments.

Each temporal segment was decomposed into 2-s windows with a 1-s step. Covariance matrices were regularized with $\lambda = 0.10$ and compared using the AIRM. Trajectory distance was computed after alignment by temporal index. For visualization and shape markers, the matrices were mapped to the tangent space at a reference estimated from B1–B3 and reduced to three principal components. When computing the distance from one segment to its phase centroid, the centroid was estimated using only the remaining segments from that phase, preventing the segment from contributing to its own reference. On the plane of the first two components, occupancy counts and consecutive displacements were accumulated on a 28×28 grid and smoothed with a Gaussian filter of $\sigma = 1.25$ cells. The occupancy and field defined in (8) were used as descriptive representations.

To obtain a common three-dimensional visualization across all eight sessions, the 2,170 tangent states were first subjected to principal component analysis (PCA), retaining at least 95% of the variance; 33 components preserved 95.3%. Diffusion maps with 25 neighbors were then applied [30], and the first three nontrivial coordinates, ψ_1, ψ_2, and ψ_3, defined the embedding. A principal surface $\psi_3 = f(\psi_1, \psi_2)$ was fitted with radial basis functions, and its color encoded kernel-estimated local density. For each phase of S8, the observed trajectory with the smallest mean distance to the other trajectories in that phase was selected. This representative trajectory was projected onto the surface while preserving temporal order. The colored ribbons follow

the local tangent plane only to aid depth perception; they do not represent geodesics or introduce a new metric.

The stability of this construction was assessed by varying PCA retention from 90% to 98% and the number of neighbors from 15 to 45. We also performed 200 bootstrap resamples stratified by session and phase while preserving complete temporal trajectories, eight leave-one-session-out reconstructions, and three levels of surface smoothing. Comparisons used Procrustes alignment, Spearman correlation between paired distances, and overlap among the ten nearest neighbors.

To compare centroids across sessions, a common log-Euclidean tangent reference and PCA were estimated from B1–B3 in all eight sessions; each session was then centered by its own training centroid. PRE, B1, B2, B3, and POST centroids were computed in this global system. Ninety-five-percent ellipses for the means were obtained from 4,000 bootstrap resamples; the first two axes explained 77.1% of the tangent-space training variance. The pipeline used to construct each trajectory is summarized in Fig. 3.

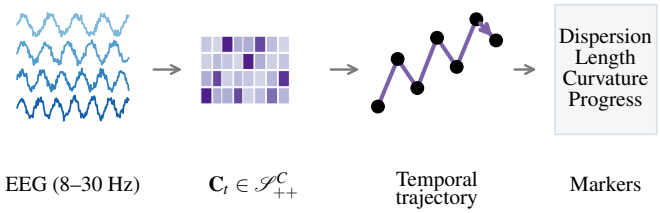

Fig. 3. Schematic representation of a temporal segment. Multichannel EEG is divided into windows; each window yields an SPD covariance matrix, and the ordered sequence preserves the trajectory used to compute the markers.

D. Markers and statistical analysis

The primary marker of within-session adaptation was $\Delta D_{\text{train}} = D_{\text{B3}} - D_{\text{B1}}$; negative values indicated greater compaction by the end of training. Feedback-free persistence was assessed by $\Delta D_{\text{persist}} = D_{\text{POST}} - D_{\text{PRE}}$, likewise oriented toward negative values. POST dispersion across session order described longitudinal evolution. In offline analysis of the acquired data, length, straightness, and curvature were computed as complementary descriptors of trajectory shape. Geodesic progress and orthogonal deviation were formalized as candidate directional markers but were not included in the primary longitudinal contrasts. Event-related desynchronization/synchronization (ERD/ERS) in the mu (8–12 Hz) and beta (18–24 Hz) bands relative to rest was also computed offline as a physiological control.

The session was retained as the inferential unit because temporal segments were nested within each phase. Paired contrasts used the exact two-sided Wilcoxon signed-rank test; the median, paired rank-biserial effect size (r_{rb}), mean, and 95% confidence interval (95% CI) were reported. Trends over session order were evaluated using Spearman correlation with exact permutation and the Theil–Sen slope. Spectral trends and the relationship between compaction and mean controller target aperture were treated as exploratory rather than confirmatory analyses.

III. Results

A. Session integrity

All eight sessions contained the required phases. Out of the 320 expected temporal segments, 310 were valid (96.9%). All 16 channels passed the post-filtering criteria in every session, and the effective sampling rate remained 125 samples/s without breaks in the sample index. In PRE and POST, every session retained at least seven of the eight temporal segments.

B. Within-session compaction and persistence

Six of the eight sessions ended B3 with lower dispersion than B1 (Table I). The difference had a median of -0.119, a mean of -0.088 (95% CI: -0.191 to 0.015), and $r_{\text{rb}} = -0.611$. The pattern was directionally consistent in most sessions but inconclusive (Wilcoxon $p = 0.148$). The largest relative compactions occurred in S8 (13.9%), S1 (13.7%), and S5 (13.4%).

In the PRE–POST contrast, four sessions showed lower dispersion, with a median of -0.021, a mean of -0.008 (95% CI: -0.176 to 0.160), and $r_{\text{rb}} = -0.111$ ($p = 0.844$; Table II). S3 and S8 showed the largest individual reductions, 19.0% and 11.8%, respectively; no consistent persistence after feedback withdrawal was detected.

Table I
WITHIN-SESSION COMPACTION ACROSS THE EIGHT SESSIONS

Session	B1	B3	$\Delta_{\text{B3}-\text{B1}}$

Median Δ; 4/8 decreased			-0.021
Exact two-sided Wilcoxon			$p = 0.844$

C. Trajectories across multiple scales

To relate within-phase dispersion, across-session organization, and trajectory shape, the data were examined at three complementary scales. Session S8 is presented as an illustrative,

rather than inferential, case because it combined substantial B1–B3 compaction with a PRE–POST reduction; all inferential contrasts remained based on the eight sessions.

At the first scale, 38 out of the 40 temporal segments from S8 were valid, with 13.9% B1–B3 compaction and an 11.8% PRE–POST reduction. The distance to the phase centroid, estimated without the segment itself, decreased in B3 (Fig. 4); the pairwise distance matrix likewise showed phase organization and greater homogeneity in B3 (Fig. 5). These summaries capture related but nonidentical properties: centroid distance quantifies concentration around a phase-specific reference, whereas the full matrix reveals the relative organization of all trajectories without reducing each phase to a single center. Their agreement indicates that the S8 pattern was not dependent on only one descriptive summary.

At the second scale, the global projection placed the mean B1–B3 centroids in a region distinct from the feedback-free periods, whereas PRE and POST remained close (Fig. 6). Within-session lines and bootstrap intervals indicated heterogeneity around the mean path. The proximity of PRE and POST is consistent with the small PRE–POST effect, whereas the displacement of the feedback blocks suggests a context-dependent organization during glove use. This projection summarizes relationships across sessions, but it does not replace the paired AIRM contrasts or establish a retained physiological state.

At the third scale, trajectories in the common embedding traversed contiguous regions while differing in extent and orientation (Fig. 7). In S8, B3 extended beyond the region shared with B1, whereas POST followed a longer path than PRE. Because temporal order is preserved, this view distinguishes two paths that may occupy nearby regions yet traverse them differently. It therefore complements dispersion by showing how the sequence evolves, without treating visual separation as an inferential result.

The global configuration remained stable in the sensitivity analyses. Median Spearman correlations of the global distances were 0.997 when varying the parameters, 0.986 under bootstrap resampling, and 0.997 when excluding one session. In contrast, local neighborhoods were less stable, with median Jaccard indices of 0.210, 0.125, and 0.244, respectively. Thus, the large-scale ordering was reproducible, whereas the identity of individual nearest neighbors was sensitive to analytical perturbations.

Across the eight sessions, the four PRE–POST reductions occurred among the six sessions that compacted during feedback. However, S4 and S6 compacted between B1 and B3 without retaining lower dispersion in POST. Within-session adaptation and feedback-free persistence were therefore related in this sample but were not equivalent outcomes.

The embedding surface should consequently be read as a descriptive map rather than a mechanistic model. The ribbons preserve temporal order and permit comparison of path extent and orientation, but do not represent geodesics, attractors, or physiological boundaries. Conclusions about fine surface details remain limited by local instability, and the paired AIRM contrasts across all eight sessions remain the primary evidence.

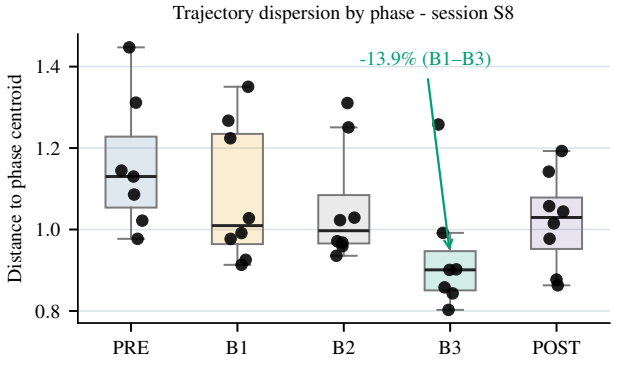

Fig. 4. Distance from each temporal segment to the estimated phase centroid in S8. Boxes show the median and interquartile range.

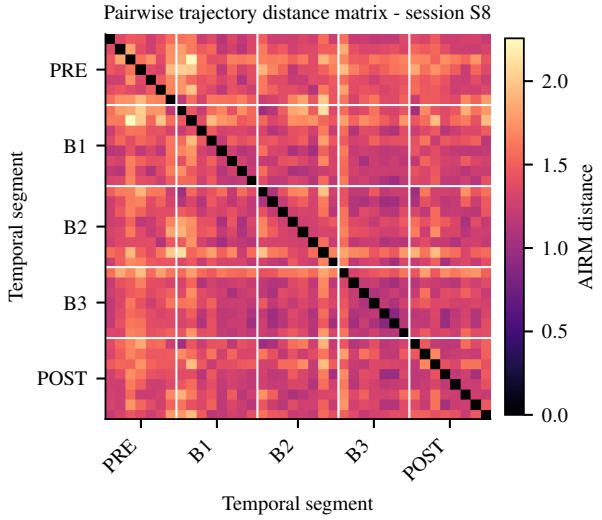

Fig. 5. AIRM distance matrix among the 38 valid trajectories from S8. White lines delimit PRE, B1, B2, B3, and POST.

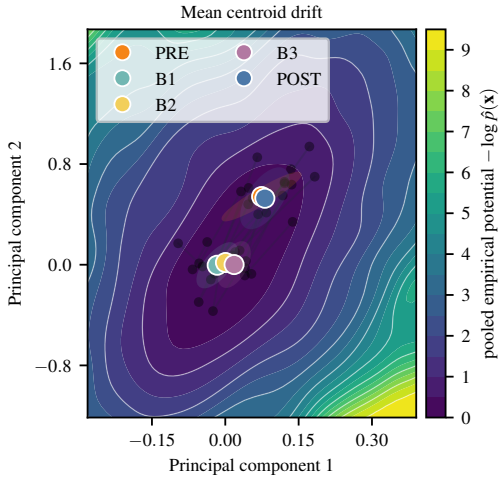

Fig. 6. Centroid drift across the eight sessions after global tangent referencing and PCA. Lines: sessions; points: phase means; ellipses: 95% bootstrap CIs.

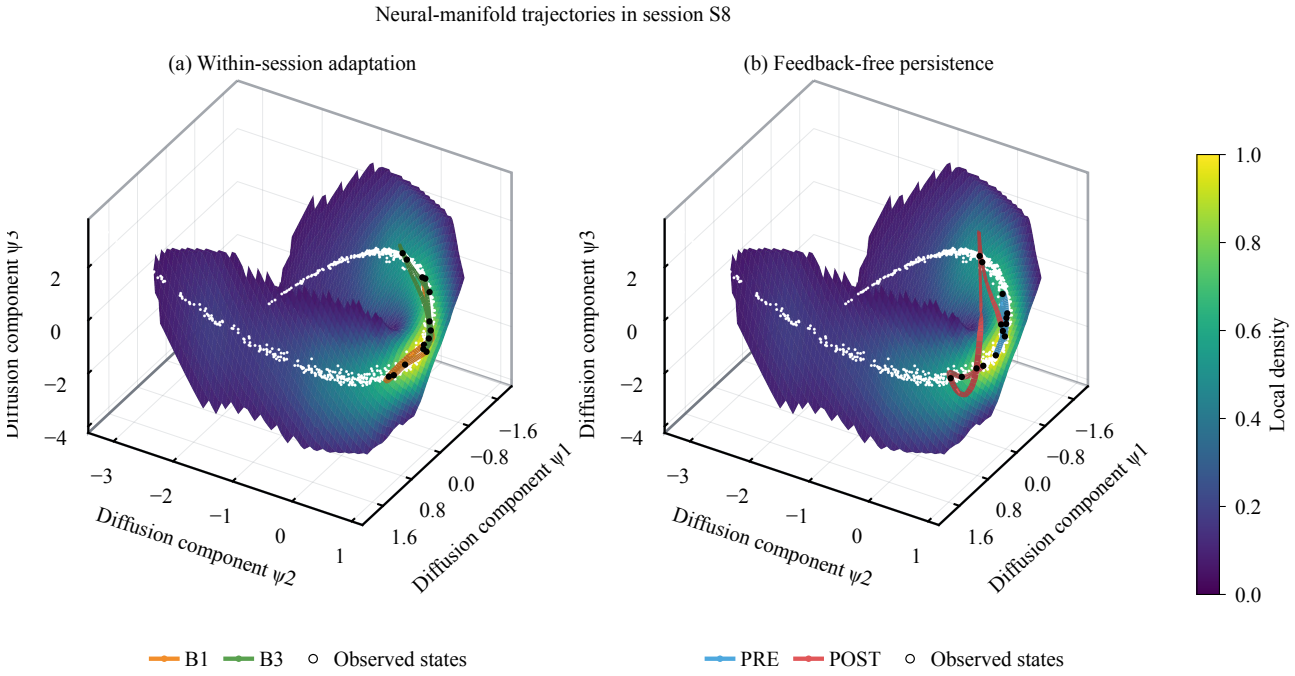

Fig. 7. S8 trajectories on the principal surface estimated in the common embedding of all eight sessions. (a) B1 and B3: within-session adaptation; (b) PRE and POST: feedback-free persistence. Color encodes local density; white points indicate observed states; colored ribbons show medoid-selected trajectories projected onto the surface. Temporal order is preserved, but the paths do not represent geodesics.

D. Physiological drift and specificity controls

There was no monotonic trend in POST dispersion across the eight sessions ($\rho = -0.024$; $p = 0.977$). In an exploratory analysis, beta ERD decreased with session order ($\rho = -0.905$; $p = 0.0046$; Fig. 8), suggesting that compaction, persistence, and physiological drift may operate on different scales and require independent confirmation.

Mean controller target aperture during B1–B3 ranged from 0.161 to 0.416, with no detectable monotonic association with within-session compaction ($\rho = 0.024$; $p = 0.977$; Fig. 9). Thus, a larger scalar controller output did not necessarily correspond to greater neural compaction. This comparison is exploratory and does not evaluate classifier accuracy.

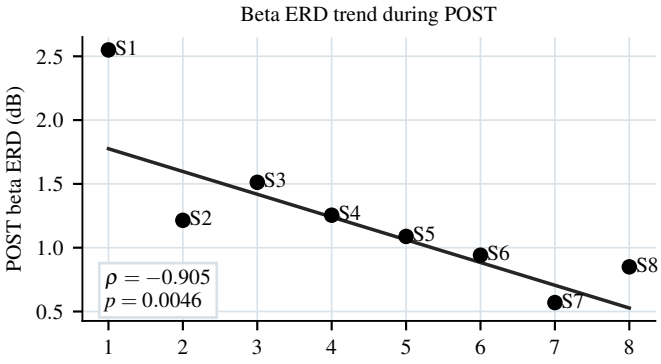

Fig. 8. Beta ERD during POST and its robust trend over session order. The line represents the Theil–Sen slope.

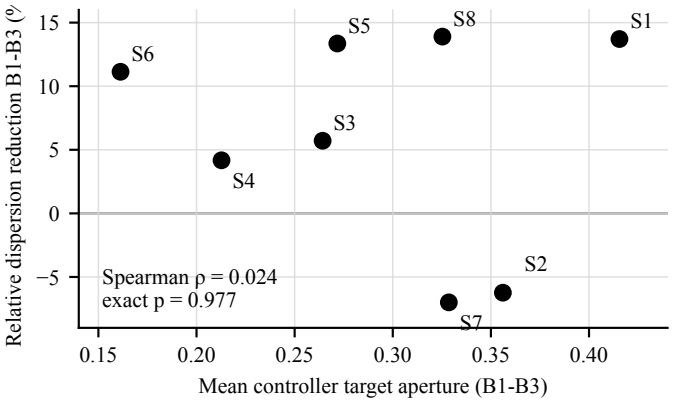

Fig. 9. Exploratory relationship between mean controller target aperture during B1–B3 and within-session compaction. Each point represents one session; positive vertical-axis values indicate lower dispersion in B3. No monotonic association was detected ($\rho = 0.024$; $p = 0.977$).

IV. Discussion

This study examines MI-BCI training through the temporal geometry of neural responses. The main observation was recurrent within-session compaction: six out of the eight sessions showed lower dispersion in B3 than in B1. The repeated direction and moderate rank-biserial effect support trajectory dispersion as a candidate marker for future validation, although the primary contrast remains nonconfirmatory. The central contribution is not a new classifier, but measures that separate practice consistency, feedback-free persistence, and longitudinal drift.

A. Compaction as a candidate marker

Paired dispersion directly measures the reproducibility of the neural path. Two blocks may produce the same scalar output, yet differ in how consistently the user traverses the MI state space. The absence of a detectable association between mean target aperture and compaction (Fig. 9) is compatible with this complementarity, but it does not demonstrate independence or superiority of the geometric metrics. This distinction extends classifier-independent stability metrics [10], [11]: instead of summarizing each segment by a single covariance matrix, the definition in (4) preserves the sequence of states. In longitudinal training, Tortora *et al.* found that within-class Riemannian changes tracked skill acquisition and stabilization better than conventional metrics [9]; the present result extends this principle from covariance distributions to the reproducibility of complete trajectories.

This formulation brings macroscopic EEG analysis closer to the population-dynamics perspective, according to which the temporal evolution of joint activity and latent factors carries relevant motor information [13]–[15], [31]. The extension is conceptual rather than an equivalence of scale: EEG covariances do not directly recover intracortical neural states. Nevertheless, the compaction observed in several sessions is compatible with stabilization during practice and with the hypothesis of manifold-constrained learning [19], [20]. The term *candidate marker* remains necessary because habituation or a nonspecific reduction in variability could also produce consistency.

B. Learning as a multiscale phenomenon

The B1–B3 contrast captures adaptation during feedback; PRE–POST asks whether the change persists without the effector; and session order tests longitudinal stabilization. The lack of equivalence among these contrasts is informative. One session may compact during training and return to its previous regime in POST, suggesting a context-dependent effect, whereas another may preserve the reorganization. The mean proximity of PRE and POST in Fig. 6, together with the displacement of the trained blocks, reinforces this multiscale interpretation. In Fig. 7, both contrasts are visualized on the same data-estimated surface, allowing path extent and orientation to be compared without confusing them with the primary inferential measure. The proposed framework prevents within-session improvement from being labeled automatically as retention or consolidation.

Length, curvature, and straightness add a second interpretive dimension. Lower dispersion indicates that repetitions became closer; it does not establish whether the path became more direct, shorter, or better oriented toward the target. Geodesic progress and orthogonal deviation allow these properties to be tested relative to an a priori direction. Differential geometry and delay models provide related tools for organizing observed trajectories and dynamics [28], whereas modal decomposition methods seek coherent spatiotemporal patterns [17]. Here, flow, potential, and surface were kept descriptive: the contribution is to quantify and visualize the path, not to claim recovery of governing equations.

C. Nonstationarity as part of the phenomenon

The longitudinal beta trend was stronger than the across-session geometric trend, although its exploratory nature requires replication. This contrast illustrates why separation across scales and physiological controls are necessary. Changes in fatigue, attention, strategy, posture, or baseline state can alter covariance structure and spectral power. At another observational scale, Raut *et al.* showed that arousal can organize the evolution of spatiotemporal brain measures [32]; the relevant inference is that global states should be measured rather than conflated with learning. A robust marker should therefore combine geometric consistency, feedback-free persistence, physiological specificity, and stability under global changes in brain state.

D. Limitations

The within-participant design provides longitudinal resolution but does not support population-level generalization. The fixed order does not separate training, habituation, and fatigue. Daily recalibration accommodated EEG nonstationarity; nevertheless, the three controller configurations limit absolute comparisons of controller output and causal attribution of the geometric pattern to feedback. Low-density EEG and the absence of surface electromyography (sEMG) or synchronized video restrict separation among cortical activity, muscle tension, and subtle movement. The session was retained as the inferential unit because segments were nested within blocks. Although the global embedding geometry was stable, the lower stability of exact neighborhoods argues against interpreting surface details as physiological states or attractors.

V. Conclusion

Riemannian covariance trajectories enable neural dynamics to be tracked during MI-BCI training while separating within-session compaction, feedback-free persistence, and longitudinal drift. Lower dispersion from B1 to B3 in six out of the eight sessions, with a moderate directional effect, identifies a promising but still nonconfirmatory candidate marker. Consistent PRE–POST persistence was not detected, and compaction showed no monotonic correspondence with mean controller target aperture. Together, geometric measures, shape descriptors, and ERD/ERS provide a characterization complementary to the system's scalar output and an auditable basis for larger studies using a frozen protocol.

***Abstract*—Chronic extracellular electrophysiological recordings in freely moving animals require implantable systems that integrate mechanical stability, compact design, adjustable electrode positioning, and compatibility with electrophysiological acquisition systems. In this work, we describe the fabrication and stereotaxic implantation of a shuttle-drive microdrive designed for chronic extracellular recordings in the dorsal hippocampus of adult Wistar rats. The device accommodates up to eight independently movable tetrodes connected to a 32-channel electrode interface board. The fabrication workflow comprises the assembly of the microdrive body and movable shuttles, preparation of the adjustment screws, construction of a silica guide-tube matrix, fabrication of nickel-chromium tetrodes, integration of the electrodes with the interface board, and stereotaxic implantation. The surgical procedure and postoperative management required for device implantation are also described. The resulting system provides a modular and adjustable platform for the implantation of multiple tetrodes in a compact configuration. By detailing the materials, fabrication procedures, component assembly, electrode organization, and implantation steps, this work provides a reproducible methodological framework for the construction and implementation of microdrive-based systems for chronic extracellular electrophysiological recordings in freely moving rats.**

***Index Terms*—microdrive, electrophysiology, hippocampus, Wistar rats.**

I. Introduction

Chronic extracellular electrophysiological recordings in freely moving animals require implantable systems that combine mechanical stability, compact dimensions, reliable electrical connections, and the possibility of maintaining or adjusting electrode position after surgery. The performance of these systems therefore depends not only on the recording electronics, but also on the mechanical design of the implant, the materials used in its construction, the organization of the electrodes, and the surgical procedures required for implantation [1], [2].

The dorsal hippocampus is a frequent target for chronic electrophysiological recordings because of its involvement in learning, memory, and spatial processing. Recordings from this structure require accurate stereotaxic placement and, in many experimental configurations, the ability to advance the electrodes after implantation. Movable tetrode systems are well suited to this purpose because the depth of individual recording elements can be adjusted independently while the animal remains implanted.

Several microdrive architectures have been developed to improve the accessibility and adaptability of chronic electrophysiological implants. These systems include lightweight and open-source designs, recoverable components, 3D-printed structures, modular head-mounted assemblies, and configurations capable of supporting independently movable electrodes [3]–[7]. Other designs have emphasized the integration between implant construction, surgical implantation, and multichannel electrophysiological acquisition [8]–[11]. These developments provide different solutions to common technical requirements, including electrode positioning, mechanical protection, component organization, and adaptation to different experimental configurations.

Among these approaches, the shuttle-drive architecture described by Voigts et al. provides independent mechanical control of multiple tetrodes through movable shuttles coupled to adjustment screws [12]. This arrangement allows individual electrodes to be advanced after implantation while maintaining multiple recording channels within a compact assembly. Reproducing such a system, however, requires coordination of several fabrication steps, including preparation of the drive body, assembly of the movement mechanism, construction of the guide-tube matrix, tetrode fabrication, connection to the electrode interface board, and stereotaxic implantation.

Detailed documentation of these procedures is important because changes in component dimensions, guide-tube organization, electrode routing, or implantation strategy can affect the final configuration and usability of the device. Methodological descriptions that integrate mechanical assembly, electrode preparation, surgical implantation, and electrophysiological acquisition can therefore facilitate reproduction and adaptation of microdrive systems under different laboratory conditions.

In the present study, we describe the construction and stereotaxic implantation of a shuttle-drive microdrive based on the architecture reported by Voigts et al. [12]. The device was configured to accommodate eight independently movable tetrodes connected to a 32-channel electrode interface board and was implanted targeting the dorsal hippocampus of an

adult Wistar rat. The workflow includes microdrive assembly, preparation of the adjustment mechanism, construction of the silica guide-tube matrix, fabrication and organization of nickel–chromium tetrodes, connection to the electrode interface board, and surgical implantation. The functionality of the implanted system was further assessed through multichannel extracellular signal acquisition and local field potential spectral characterization. The aim was to provide a technically detailed and reproducible description of the construction and implementation of this recording system while defining the electrophysiological validation within the scope of the data obtained in the present experiment.

II. Materials and Methods

A. Experimental Design

This study describes the fabrication and stereotaxic implantation of a shuttle-drive microdrive for chronic extracellular electrophysiological recordings in freely moving rats, followed by electrophysiological data acquisition and offline LFP analysis. The experimental procedures included microdrive fabrication and assembly, tetrode preparation, stereotaxic implantation, electrophysiological recording, electrode impedance assessment, and LFP signal processing.

One adult Wistar rat (*Rattus norvegicus*; $n = 1$) was used in the present study. The microdrive was designed to accommodate eight independently movable tetrodes, providing a total of 32 recording channels [12]. The main stages of device assembly and stereotaxic implantation are illustrated in Fig. 1.

B. Animals

One adult male Wistar rat (*Rattus norvegicus*), aged 5–7 months and weighing approximately 480 g, was used in the present study. The animal was housed in a high-ceiling cage under controlled environmental conditions, with temperature maintained between 22 and 26 °C and a 12-h light/dark cycle. Food and water were provided according to the experimental protocol.All procedures were performed by trained personnel and approved by the local Ethics Committee for Animal Use, following institutional and national guidelines for animal experimentation. High-ceiling cages were used after implantation to reduce the risk of mechanical contact between the implant and the cage lid. The animal were monitored daily during the postoperative period for body weight, grooming, locomotor activity, wound healing, and signs of discomfort.

C. Microdrive Assembly

We used a microdrive originally described by [12]. The device was designed to accommodate up to eight independently movable tetrodes, corresponding to 32 recording channels, in small rodents. Its fabrication followed the main steps described in the original protocol, including assembly of the microdrive body, construction of the silica matrix, tetrode fabrication, connection to the electrode interface board, and stereotaxic implantation. Initially, the microdrive body was positioned on an assembly support to ensure mechanical stability and safe handling. The shuttles, which are the movable components responsible for the independent displacement of each tetrode, were inserted into the guide channels of the device. Custom M0.6 screws were then coupled to the corresponding shuttles. The upper portion of each screw was secured with light-curable dental resin, forming a mechanism that allowed controlled and independent vertical displacement of each tetrode. The silica matrix was constructed using polyimide-coated fused-silica tubing (Molex Polymicro TSP100170). Twelve tube segments were arranged into a matrix approximately 4 mm in length and bonded together with epoxy resin. After the matrix had been assembled, eight silica guide tubes were inserted to establish the connection between the shuttles and the matrix. At the end of this stage, a correspondence map was created to document the position of each tube within the matrix, as well as its associated shuttle and screw. This mapping allowed each tetrode to be individually identified during post-implantation adjustments.

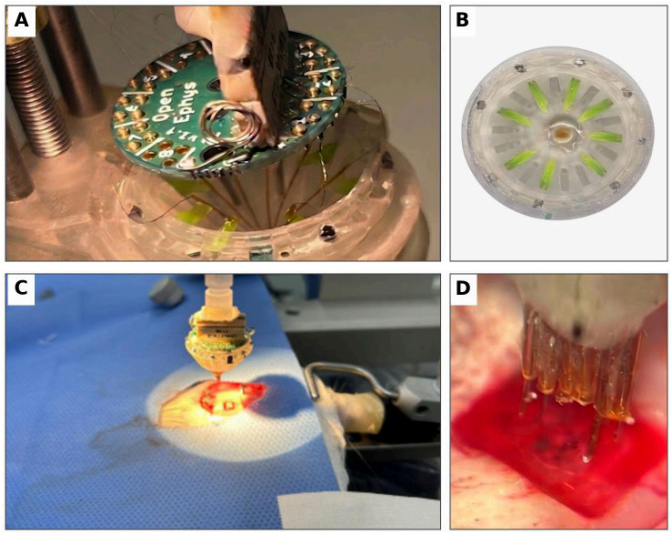

Fig. 1. Assembly and stereotaxic implantation of the shuttle-drive microdrive. (A) Connection of the tetrode wires to the 32-channel electrode interface board. (B) Top view of the assembled microdrive, showing the radial arrangement of the movable shuttles. (C) Stereotaxic positioning of the microdrive above the craniotomy. (D) Magnified view of the guide-tube matrix and tetrode tips aligned with the implantation site.

The tetrodes were fabricated using nickel-chromium alloy wire (Sandvik), with a diameter of approximately 0.012 mm, and coated with polyimide insulation. For each tetrode, four wires were aligned and placed in a high-speed tetrode twister operating at 200 revolutions per minute. After twisting, the tetrodes had a final length ranging from 3.5 to 4.0 cm. Each tetrode was inserted into its corresponding movable guide tube under stereomicroscopic visualization and subsequently secured with epoxy resin. The tetrode wires were connected to a custom 32-channel electrode interface board equipped with an Omnetics connector. The board was positioned on the upper portion of the microdrive and rotated between 90° and 180°, as needed, to accommodate the wires and reduce mechanical tension on the tetrodes. After appropriate positioning, the

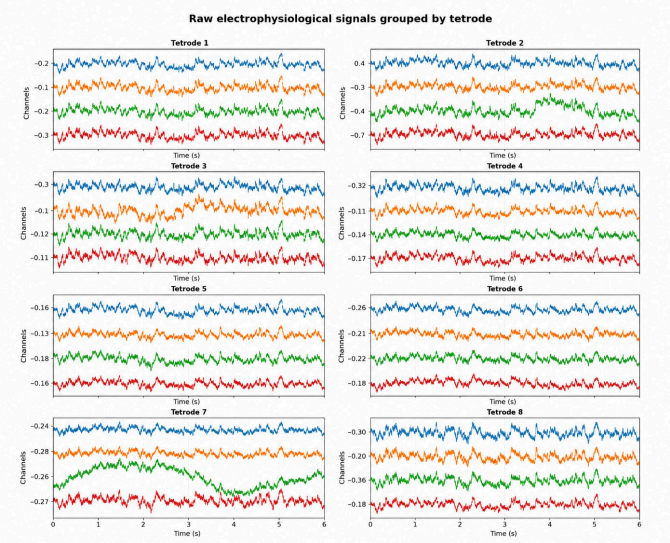

Fig. 2. Representative raw electrophysiological signals acquired from the 32 recording channels. Signals are grouped into eight tetrodes, with four simultaneously recorded channels per tetrode. A representative 6-s recording segment is displayed, and the traces were vertically offset within each panel to improve visualization.

electrode interface board was secured to the microdrive body with epoxy resin. During this stage, the wires were inspected to ensure that they remained properly organized and did not interfere with shuttle movement. For surgical implantation, the animals were anesthetized with isoflurane delivered in oxygen, using a concentration of 4% for induction and 1.5–2% for maintenance. Following the shaving of the cranial region and the antiseptic preparation of the surgical field, the animals were positioned in a stereotaxic apparatus. The skull was exposed and leveled using the bregma and lambda as anatomical reference points. A unilateral craniotomy was performed over the right dorsal hippocampus using the following stereotaxic coordinates relative to bregma: anteroposterior, -4.2 mm; mediolateral, +2.5 mm; and dorsoventral, -2.4 mm relative to the skull surface. During implantation, the tetrodes remained fully retracted in their uppermost position to minimize the risk of mechanical damage to the brain tissue. The microdrive was positioned over the craniotomy and secured to the skull using stainless-steel screws and methyl methacrylate-based dental cement. At the end of the implantation procedure, the tetrode tips were positioned approximately 1 mm above the cortical surface, allowing their gradual advancement toward the target region during the postoperative period. Following surgery, the animal received meloxicam at a dose of 1 mg/kg, administered subcutaneously, for postoperative analgesia. They were then individually housed in high-ceiling cages to prevent mechanical contact between the implant and the cage lid and to allow adequate postoperative recovery.

D. Electrode Impedance

Prior to implantation,electrode impedance was assessed for all 32 recording channels before electrophysiological analysis using the impedance-measurement function of the acquisition system. Impedance magnitude was recorded individually for each channel.

E. Electrophysiological Acquisition

Neural signals were acquired using an Open Ephys acquisition system connected to the implanted 32-channel electrode interface board. The recording configuration comprised eight tetrodes, with four channels assigned to each tetrode. Electrophysiological activity was continuously recorded during the experimental sessions and subsequently exported for offline signal processing.Signal quality was initially assessed through visual inspection of the raw electrophysiological traces.A channel was considered functional when a continuous electrophysiological signal without saturation or loss of acquisition was present during the analyzed interval. The power spectral density was then estimated for all recording channels to characterize the distribution of signal power across frequencies and to assess possible contamination by 60-Hz power-line noise and its 120-Hz harmonic. Time-frequency representations were also calculated for selected channels to examine changes in spectral power throughout the recording interval. Signal processing and visualization were performed in Python using NumPy, SciPy, and Matplotlib. When digital filtering was required, zero-phase filtering was applied to minimize phase distortion and preserve the temporal structure of the electrophysiological signals.

III. Results

A. Electrophysiological Recording

Electrophysiological signals were successfully acquired from all 32 recording channels connected to the implanted microdrive, corresponding to a functional-channel yield of 32/32 channels (100%) during the analyzed recording session. A channel was considered functional when a continuous electrophysiological signal without saturation or loss of acquisition was present during the analyzed interval. Fig. 2. Each tetrode comprised four simultaneously recorded channels. Continuous voltage fluctuations were observed across the analyzed 6-s segment, with channel-dependent differences in signal amplitude and waveform characteristics. The traces were vertically offset within each panel to facilitate comparison among the channels of the same tetrode.

B. Electrode Impedance

Impedance measurements were obtained from all 32 recording channels. Across channels, impedance magnitude ranged from 0.277 to 18.40 MΩ, with a median of 1.12 MΩ. Most channels showed impedance values below 3 MΩ; however, Channel 5 exhibited a markedly higher impedance of 18.40 MΩ. When this channel was considered separately as an extreme high-impedance channel, the remaining 31 channels showed a mean impedance of 1.29 ± 0.73 MΩ, ranging from 0.277 to 2.99 MΩ.

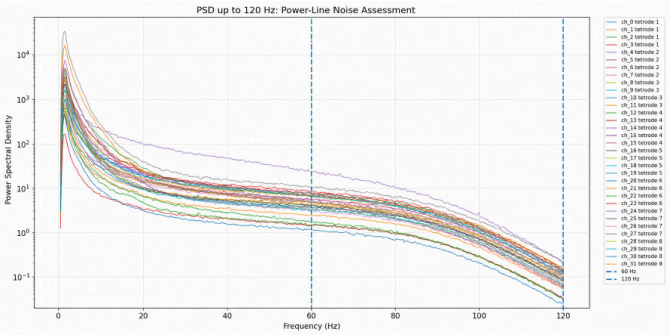

Fig. 3. Power spectral density estimates for the 32 extracellular electrophysiological recording channels from 0 to 120 Hz. Dashed vertical lines indicate the 60-Hz power-line frequency and its 120-Hz harmonic. Spectral power was predominantly concentrated at lower frequencies and decreased toward the higher-frequency range.

C. Power Spectral Density

The frequency-domain characteristics of the recordings were evaluated by estimating the power spectral density of all 32 channels. As shown in Fig. 3, spectral power was predominantly concentrated at lower frequencies and progressively decreased as frequency increased. Although differences in absolute power were observed among channels, the overall spectral profiles were comparable. Visual inspection did not reveal a dominant narrowband peak at the 60-Hz power-line frequency or at its 120-Hz harmonic, indicating that power-line interference did not dominate the analyzed recording segment.

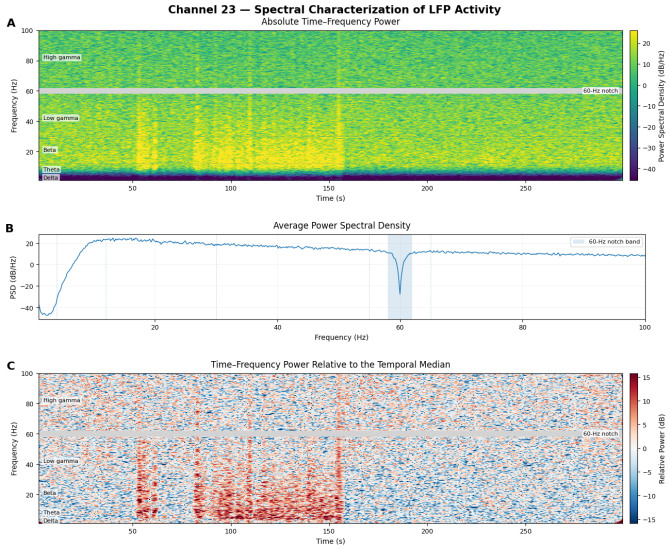

Fig. 4. Spectral characterization of local field potential activity from Channel 23, shown as an illustrative example of the time–frequency analysis. (A) Absolute time–frequency power over an approximately 300-s recording interval. (B) Average power spectral density from 0 to 100 Hz. (C) Time–frequency power expressed relative to the temporal median.

D. Representative LFP Spectral Characterization

A detailed spectral characterization was performed for Channel 23, selected as a representative recording channel. During the recording session, the animal was observed alternating between spontaneous locomotion and immobility. As shown in Fig. 4, the recorded activity remained continuous throughout the approximately 300-s interval and exhibited a structured distribution of spectral power. The absolute time–frequency representation showed greater power at low and intermediate frequencies, with a progressive reduction toward higher frequencies (Fig. 4A). The average power spectral density displayed a broadband profile and a marked attenuation centered at 60 Hz, resulting from the notch filter applied to suppress power-line interference (Fig. 4B). After normalization relative to the temporal median, transient increases in spectral power became more evident, particularly below approximately 30–40 Hz and between approximately 50 and 160 s (Fig. 4C). These variations indicate that the spectral composition of the signal was not temporally uniform and may reflect changes in the functional state of the recorded neural network. These results demonstrate that the spectral composition of the recorded signal varied over the analyzed interval. Because behavioral events were not temporally synchronized with the electrophysiological recording, the physiological origin of these variations was not determined.

IV. Discussion

The present study describes the fabrication and implantation of a shuttle-drive microdrive configured for eight independently movable tetrodes and 32 recording channels. The use of independently movable tetrodes is an important feature of the device because electrode depth can be adjusted after implantation. This configuration is advantageous when gradual electrode advancement is required and is consistent with the mechanical principles of the shuttle-drive architecture described by Voigts et al. [12]. The present implementation further demonstrates that this architecture can be assembled using the materials and procedures described here and coupled to a 32-channel Open Ephys acquisition system. The electrophysiological validation presented in this study should,however, be interpreted within its methodological scope. Recordings were obtained from a single animal ($n = 1$), and the 32 channels therefore represent recording sites within the same experimental subject rather than independent biological replicates. In addition, the detailed time–frequency characterization was performed on one representative channel. Consequently, the present results provide a technical proof-of-principle rather than an assessment of between-animal reproducibility. A further limitation is the absence of histological verification of the final tetrode positions. Therefore, anatomical localization in the present study is based on the stereotaxic implantation coordinates and electrode advancement procedure rather than postmortem confirmation of individual recording sites.

V. Conclusion

This article describes the fabrication and surgical implantation of a shuttle-drive microdrive for chronic extracellular electrophysiological recordings in freely moving rats. The device enables independent adjustment of multiple tetrodes

and is suitable for targeting the dorsal hippocampus during behavioral and resting-state recordings. This methodological framework may support reproducible studies of hippocampal oscillations, neuronal activity, and spatial memory in rodents.

***Resumo*— Modelos animais, em especial os modelos *in vitro* de fatias de cérebro e hipocampo, são fundamentais para a pesquisa em neurociências, pois permitem elucidar mecanismos neuronais e suas bases patológicas em condições controladas. Contudo, é essencial desenvolver estratégias que reduzam o número de animais utilizados, em conformidade com os princípios dos 3Rs (*Replacement, Reduction, Refinement* - Substituição, Redução, Refinamento). Neste estudo, apresentamos um método que combina a perfusão transcardíaca utilizando fluido cerebrospinal artificial protetor modificado contendo sacarose (SP-mACSF) à ressecção de fatias de hipocampo. O sucesso dessa abordagem reside na capacidade do SP-mACSF em promover uma lavagem vascular eficiente, permitindo tanto a viabilidade tecidual para a realização de gravações eletrofisiológicas quanto a obtenção de imagens de imunofluorescência de alta qualidade para análises de histologia, a partir do mesmo tecido. Para o desenvolvimento e validação desse método, foram utilizadas fatias de 400 µm de espessura obtidas de ratos machos da linhagem *Wistar*. As fatias provenientes de animais perfundidos com SP-mACSF exibiram atividades epileptiformes não-sinápticas no giro dentado indistinguíveis das dos controles em todos os aspectos avaliados. As ressecções de 40 µm produzidas a partir das fatias de 400 µm, após fixação em paraformaldeído proporcionaram marcações anti-GFAP bem definidas, isentas de artefatos e com baixa autofluorescência no grupo SP-mACSF quando comparadas às do grupo Controle. Este método inovador representa um avanço significativo para a neurociência, consolidando a aplicação dos princípios dos 3Rs ao permitir a correlação direta entre dados funcionais e estruturais, com a extração de dados multifatoriais de um único animal, promovendo uma prática científica mais sustentável, ética e metodologicamente integrada.**

Palavras-chave — fatias de hipocampo, atividade epileptiforme, imunofluorescência, autofluorescência, 3Rs

I. INTRODUÇÃO

A epilepsia é uma condição neurológica crônica e complexa, caracterizada por descargas neuronais excessivas e hiperssincronizadas recorrentes, conhecidas como crises epilépticas espontâneas. Estima-se que aproximadamente 1 em cada 10 indivíduos apresentará ao menos uma crise epiléptica ao longo da vida, enquanto cerca de 1 em cada 6 desenvolverá epilepsia [1]. Com aproximadamente 50 milhões de pessoas afetadas no mundo, a epilepsia destaca-se como uma das doenças neurológicas mais prevalentes no planeta [2]. Apesar dos avanços no desenvolvimento de fármacos anticrise, aproximadamente um terço dos pacientes apresenta epilepsia refratária ao tratamento medicamentoso [3], evidenciando a necessidade de uma compreensão mais profunda dos mecanismos fisiopatológicos subjacentes à doença. Essa eficácia limitada da terapia medicamentosa [4] sugere que a origem dessas descargas ultrapassa as conexões puramente sinápticas, envolvendo também o fluido iônico, a matriz extracelular e as comunicações não-sinápticas da rede neuronal. A relevância da modulação não-sináptica na epilepsia foi confirmada experimentalmente nos anos 1980, quando estudos pioneiros demonstraram a viabilidade de induzir atividades epileptiformes *in vitro*, em fatias de hipocampo, apenas pela alteração das concentrações extracelulares de cálcio e potássio [5, 6]. Tais interações não-sinápticas exercem profundos efeitos fisiológicos no tecido neuronal, sendo categorizadas em quatro mecanismos principais [7]: o acoplamento eletrotônico, o efeito de campo elétrico, o acoplamento efáptico e as flutuações iônicas extracelulares.

Diante da elevada prevalência global e do elevado índice de pacientes refratários aos tratamentos farmacológicos

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

atuais, a compreensão dos mecanismos fisiopatológicos da epilepsia torna-se imperativa para o desenvolvimento de novas terapias. As preparações de fatias de cérebro e, particularmente, de hipocampo preservam aspectos essenciais da organização neuronal e da circuitaria sináptica, tornando-se ferramentas amplamente empregadas para investigar mecanismos celulares e de rede em condições experimentais rigorosamente controladas [8, 9]. Em fatias de hipocampo, modelos *in vitro* de atividade epileptiforme permitem investigar, com elevada resolução temporal e espacial, os mecanismos envolvidos na geração, propagação e modulação das descargas neuronais, constituindo uma plataforma consolidada para estudos fisiopatológicos e farmacológicos [10]. Contudo, as implicações éticas constituem um fator significativo de complexidade no emprego de tecido humano vivo para estudos de natureza eletrofisiológica [11].

Em decorrência disso, ao longo dos anos, o uso de fatias de cérebro e de hipocampo obtidas a partir de modelos animais tornou-se uma abordagem bem estabelecida na pesquisa em neurociências [9, 12, 13, 14]. Nesse contexto, modelos animais *in vitro* são amplamente utilizados em investigações experimentais de atividades epileptiformes, reforçando sua relevância na pesquisa translacional em epilepsia [15, 16, 17]. Na pesquisa em epilepsia, essa preparação é particularmente valiosa, pois permite a investigação detalhada dos mecanismos celulares e de rede subjacentes à geração, propagação e modulação da atividade epileptiforme sob condições mais acessíveis à manipulação eletrofisiológica e farmacológica do que em modelos *in vivo* [18].

Paralelamente aos estudos eletrofisiológicos com fatias de hipocampo, a análise histológica e a marcação por imunofluorescência de roedores são ferramentas fundamentais na neurociência, pois permitem a identificação de alterações celulares, de astrogliose reativa e de remodelação sináptica dentro de redes epileptogênicas [19]. Contudo, para realizar adequadamente essas avaliações microscópicas, é mandatório fixar quimicamente o tecido cerebral, geralmente com paraformaldeído. Esse processo de fixação promove a reticulação de proteínas e interrompe a degradação tecidual, preservando a citoarquitetura das fatias e garantindo a retenção espacial precisa dos marcadores moleculares necessários para investigar a fisiopatologia das crises [20].

A integração entre abordagens eletrofisiológicas, histológicas e de imunofluorescência constitui um dos pilares da neurociência experimental contemporânea, permitindo correlacionar alterações funcionais e estruturais envolvidas em processos fisiológicos e patológicos do sistema nervoso. No entanto, apesar da relevância complementar das gravações eletrofisiológicas e das análises histológicas e de imunofluorescência em neurociência, essas abordagens geralmente não são aplicadas ao preparado tecidual do mesmo animal. A presença de sangue residual no tecido constitui uma importante fonte de autofluorescência [21, 22]. Essa autofluorescência constitui um fator de interferência conhecido na marcação por imunofluorescência, podendo comprometer a especificidade e a qualidade das imagens obtidas por microscopia confocal [21, 22]. Por esse motivo, a análise de histologia com imunofluorescência utiliza, rotineiramente, a perfusão transcardíaca com PBS, seguido de paraformaldeído, para fixação química com vistas a preservar a arquitetura tecidual por meio da estabilização estrutural [13, 18, 20]. Mas, uma vez que o tecido nervoso tenha sido fixado com paraformaldeído, a atividade neuronal se torna ausente, uma vez que o tecido e as células neuronais não são mais viáveis, o que os torna inadequados para investigações eletrofisiológicas da excitabilidade neuronal ou da atividade epileptiforme, pois gravações eletrofisiológicas requerem tecido nervoso vivo com células neuronais viáveis [8, 23].

Assim, embora registros eletrofisiológicos e análises histológicas sejam complementares, essas abordagens permanecem, na maioria dos protocolos experimentais, habitualmente dissociadas. Enquanto a eletrofisiologia depende da manutenção da viabilidade neuronal em tecido vivo, a imunofluorescência requer fixação química para preservar a arquitetura tecidual e os antígenos de interesse. Isso torna as duas abordagens, em grande parte dos desenhos experimentais, mutuamente exclusivas para o mesmo animal [13, 18, 20]. Como consequência, avaliações funcionais e estruturais costumam ser realizadas em animais distintos, impedindo a correlação direta entre os achados experimentais, aumentando a variabilidade biológica e ampliando o número de animais necessários para responder à mesma hipótese científica.

Diante desse cenário, o presente estudo propôs desenvolver e validar uma estratégia metodológica baseada na perfusão transcardíaca com fluido cerebrospinal artificial modificado contendo sacarose (SP-mACSF), combinada à preparação de fatias de hipocampo. O método foi concebido para permitir a realização de registros eletrofisiológicos e análises por imunofluorescência utilizando tecido proveniente do mesmo animal, preservando a funcionalidade neuronal e reduzindo a autofluorescência decorrente de resíduos sanguíneos. Dessa forma, a nossa abordagem buscou ampliar a integração entre análises estruturais e funcionais, ao mesmo tempo em que otimiza o aproveitamento experimental de cada animal em conformidade com os princípios dos 3Rs. O método desenvolvido e testado neste estudo foi adaptado como uma combinação modificada que integra duas abordagens previamente descritas. A primeira foi descrita por [24], que empregou uma solução à base de sacarose para lavar o sangue do tecido antes da dissecção cerebral, preservando a viabilidade tecidual e minimizando artefatos para visualização em um microscópio confocal de disco giratório BX51WI *Olympus*, destinado a experimentos simultâneos de fluorescência e eletrofisiologia. A segunda foi descrita por [25], na qual fatias utilizadas para registrar atividade epileptiforme não sináptica em câmara de interface foram pós-fixadas em paraformaldeído, embutidas em gel de ágar e resseccionadas em vibrátomo para coloração por meio do método de *Nissl*. A Figura 1 mostra um resumo gráfico esquemático do método desenvolvido e validado.

II. MÉTODOS

A. Animais

Neste trabalho, foram utilizados 10 ratos *Wistar* machos com 4 semanas de idade, com um tamanho amostral de 5 animais por grupo. O estudo foi conduzido de acordo com os procedimentos aprovados pelo Comitê de Ética no Uso de Animais da Universidade Federal de São João del Rei (CEUA/UFSJ), sob o protocolo 8518220426/2026, em conformidade com a legislação brasileira vigente e com as diretrizes do CONCEA para experimentação animal.

B. Perfusão transcardíaca e preparação de fatias de hipocampo

Para a coleta de tecido, os animais do grupo SP-mACSF foram anestesiados por meio de injeção intraperitoneal de ketamina (100 mg/kg) e xilazina (10 mg/kg). Após a indução anestésica, foi realizada uma incisão horizontal mediana abdominal, estendendo-se da região genital e subindo verticalmente de ambos os lados, a fim de acessar a cavidade torácica e o coração. A seguir, o diafragma foi seccionado, as costelas de ambos os lados foram bissectadas até o nível axilar e o esterno foi elevado e preso nessa posição por meio de uma pinça hemostática para expor o coração. Uma vez realizada a exposição cardíaca, uma agulha hipodérmica (0,6 x 25 mm) conectada por meio de um tubo extensor a uma bomba de perfusão, foi inserida no ventrículo esquerdo (Figura 1). Em seguida, os animais foram perfundidos com 100 ml de SP-mACSF para depurar o sistema circulatório e garantir a remoção dos resíduos de sangue tecidual. Previamente ao início da perfusão, realizou-se uma incisão na artéria renal esquerda para permitir a drenagem sanguínea, sendo a bomba de perfusão conFigurada para uma taxa de fluxo de um litro por hora. Utilizou-se um volume total de 200 ml de SP-mACSF por animal, dos quais 100 ml foram destinados à perfusão transcardíaca propriamente dita, 50 ml para o preenchimento do sistema de alimentação da bomba de perfusão e 50 ml para o armazenamento e transporte do encéfalo, bem como para a posterior dissecação e seccionamento dos hipocampos.

A solução de perfusão SP-mACSF consistiu em um fluido cerebrospinal artificial com baixas concentrações de sódio, potássio e cálcio, combinadas com concentrações elevadas de magnésio e glicose, modificado a partir da formulação empregada por [24]. Assim como no protocolo original descrito por [24], o cloreto de sódio foi integralmente substituído por uma concentração equimolar de sacarose. Essa substituição tem como objetivo inibir a atividade neuronal e, consequentemente, limitar a excitotoxicidade, sem, contudo, alterar a osmolaridade do mACSF. A elevação da concentração de magnésio foi empregada para reduzir a ativação glutamatérgica de receptores NMDA, amplificando as propriedades neuroprotetoras do SP-mACSF. As concentrações reduzidas de potássio e cálcio foram utilizadas com o objetivo de diminuir a excitabilidade neuronal e a liberação de neurotransmissores, respectivamente, reduzindo os danos excitotóxicos durante a preparação do tecido. Adicionalmente, com o intuito de atenuar lesões induzidas por hipóxia e otimizar o fluido cerebrospinal artificial (ACSF) proposto por [24], a concentração de glicose no SP-mACSF foi ajustada para 20 mM. Essa concentração, superior aos 10 mM empregados por [24], fundamenta-se em evidências de que valores mais elevados de glicose atenuam os danos isquêmicos associados a condições hipóxicas [26]. Assim, a composição do SP-mACSF utilizado para perfusão transcardíaca neste estudo foi (em mM): 210 sacarose, 26 $NaHCO_3$, 2.5 KCl, 1 $CaCl_2$, 4 $MgCl_2$, 1.25 NaH_2PO_4 e 20 glicose. A solução SP-mACSF foi preparada em volume estoque de 2 litros, borbulhada com mistura carbogênica (95% O_2, 5% CO_2) por 30 minutos e congelada em tubos *falcon* de 50 ml para armazenamento. Para a perfusão transcardíaca, o SP-mACSF foi descongelado e mantido em 2 a 4 °C até o momento de início da perfusão. Após o descongelamento, o SP-mACSF destinado ao armazenamento do encéfalo e à dissecção e fatiamento dos hipocampos foi resfriado novamente até atingir uma consistência semissólida.

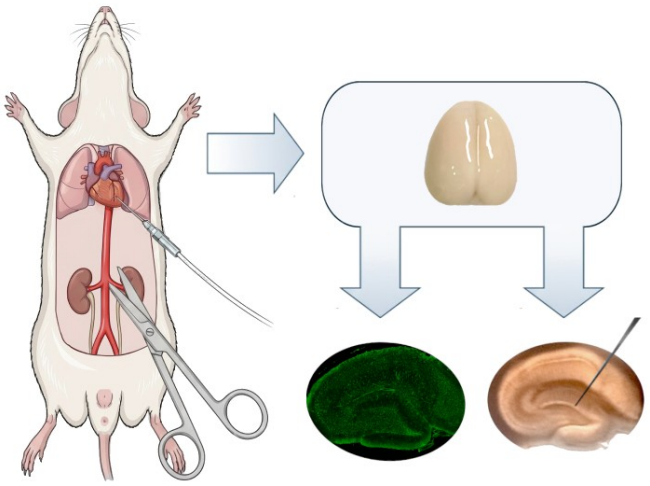

Figura 1. Resumo gráfico do método descrito no artigo. Detalhe metodológico da técnica de perfusão modificada evidenciando a secção da artéria renal esquerda e o uso de agulha hipodérmica inserida no ventrículo esquerdo. Esse método de perfusão, desenvolvido originalmente em nosso laboratório para utilização em gerbils da Mongólia, é uma alternativa à tradicional canulação da aorta com incisão no átrio direito.

Concluída a perfusão transcardíaca, procedeu-se a decapitação com guilhotina de aço inoxidável para roedores (*INSIGHT*) para facilitar o manuseio. O crânio foi então aberto e o encéfalo cuidadosamente removido. Após a dissecção, o encéfalo foi armazenado em SP-mACSF semicongelado por cerca de um minuto. Em seguida, os hipocampos foram isolados e fatiados em 400 µm utilizando um fatiador do tipo *chopper*. Para isso, após separar os hemisférios cerebrais com bisturi, enquanto um hemisfério foi dissecado para separar o primeiro hipocampo para fatiamento, o segundo hemisfério permaneceu submerso em SP-mACSF resfriado a 2 a 4 °C, aguardando a conclusão do processo de fatiamento do primeiro hipocampo. Uma vez concluído o primeiro fatiamento procedeu-se à dissecção e fatiamento do hipocampo do hemisfério contralateral. Cada hipocampo produziu de 10 a 12 fatias, sendo metade da quantidade de seções (5 a 6 fatias por hipocampo) fixada em paraformaldeído e a outra metade reservada para registros eletrofisiológicos.

No grupo Controle, os animais foram decapitados sem anestesia e tiveram o encéfalo removido e armazenado em ACSF semicongelado. A seguir, a dissecção e o fatiamento dos hipocampos foram realizados com ACSF resfriado a 2 a 4 °C. Além disso, o período de recuperação na câmara de perfusão das fatias do grupo Controle, foi de 60 minutos. Todos os procedimentos subsequentes foram idênticos ao grupo SP-mACSF.

C. Registro dos Potenciais de Campo durante Atividade Epileptiforme no Giro Dentado

Previamente às gravações eletrofisiológicas, as fatias foram mantidas submersas a 30 °C em uma câmara de perfusão preenchida com fluido cerebrospinal artificial normal oxigenado (*Ringer* ACSF) por 120 a 150 minutos, permitindo a recuperação de traumas decorrentes do preparo e a eliminação dos agentes anestésicos. Após esse período inicial de recuperação, as fatias foram transferidas para uma câmara de interface e mantidas em repouso por 60 minutos adicionais antes da exposição à solução de modificada de ACSF (mACSF) indutora de atividade epileptiforme. A composição do *Ringer*-ACSF normal foi (em mM): 127 NaCl,

2 KCl, 1.5 $MgSO_4$, 1.1 KH_2PO_4, 26 $NaHCO_3$, 2 $CaCl_2$ e 10 glicose [27]. A composição do mACSF utilizado para induzir atividade epileptiforme no giro dentado foi (em mM): 127 NaCl, 7 KCl, 1.5 $MgSO_4$, 1.1 KH_2PO_4, 26 $NaHCO_3$ e 10 glicose (sem cálcio adicionado) [27]. Todas as soluções foram continuamente borbulhadas com carbogênio (95% O_2 5% CO_2), mantendo o pH em 7.4. A temperatura da câmara de interface foi mantida constante em 32 °C durante todo o período de repouso das fatias e também durante a indução das atividades epileptiformes.

Na câmara de interface, as fatias foram mantidas sobre uma membrana microporosa, submetida a uma perfusão contínua de solução *Ringer*-ACSF/mACSF por baixo, aquecida em banho-maria a temperatura de 32 °C. A mistura de carbogênio (95% O_2, 5% CO_2), após ser borbulhada na água destilada do banho-maria, portanto sendo umidificada e aquecida, foi continuamente liberada na parte superior da membrana, formando a interface gás/líquido da câmara, onde as fatias foram mantidas. Durante a indução de atividades epileptiformes, as fatias foram visualizadas utilizando um estereomicroscópio *Nikon* SMZ1500.

Os registros dos potenciais de campo foram realizados utilizando eletrodos de prata cloretados e inseridos em micropipetas de vidro preenchidas com a solução mACSF indutora de atividades epileptiformes. As micropipetas foram fabricadas a partir de capilares de vidro com paredes finas, estiradas em um puxador universal. Os eletrodos foram conectados a um *headstage* de baixo ruído, ligado a um amplificador conFigurado para ganho total de 500x e filtro passa-baixa com corte de 1600 Hz. Os sinais amplificados foram digitalizados em frequência de amostragem de 5 kHz via plataforma desenvolvida em *LabVIEW*. Os eletrodos de registro foram posicionados na camada granular do giro dentado, precisamente na região de transição entre o ápice e a lâmina supra piramidal (Figura 2. D). As gravações eletrofisiológicas foram obtidas de duas fatias por animal, totalizando 20 gravações (10 para cada grupo), e as marcações de imunofluorescência foram realizadas utilizando o mesmo número de fatias dos mesmos animais. As fatias foram escolhidas aleatoriamente, tanto para o registro eletrofisiológico quanto para a histologia.

D. Obtenção dos valores de parâmetros do Potencial de Campo (FP)

Os parâmetros duração do evento (DE), eventos por minuto (Ev/min) e amplitude média de *population spikes* (Amp Med) foram obtidos, para cada um dos eventos epileptiformes analisados, utilizando-se um *script* desenvolvido em plataforma MATLAB®. A Transformada Discreta de Fourier (DFT) foi utilizada para decompor o sinal nos componentes da corrente contínua (DC) e o sinal contendo os PS. A partir do cálculo da DFT do sinal registrado, foi realizado o corte da frequência baixa abaixo de 10 Hz e que corresponde à componente DC separando-a da frequência alta, que corresponde aos *population spikes* (PS). A seguir, através da Transformada Inversa de Fourier, foi obtido o sinal contendo apenas a componente DC (sem os PS). Uma vez obtida a componente DC, a linha de base foi determinada como a média de um trecho do potencial elétrico antes do evento. Assim, a amplitude da componente DC foi obtida como sendo a variação máxima do sinal em relação à linha de base. O parâmetro DE foi obtido por meio da fórmula: DE(s) = Tfinal (s) - Tinicial (s). O instante de tempo "Tinicial" foi considerado como quando a componente DC do sinal atingiu

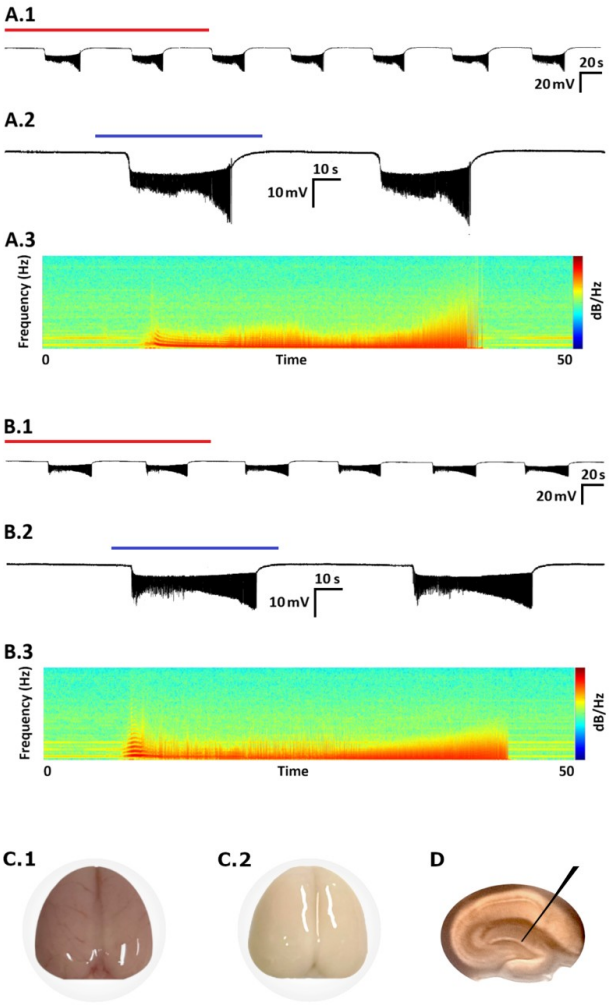

Figura 2. (A, B) Morfologias das atividades epileptiformes registradas na camada granular do giro dentado dos grupos Controle e SP-mACSF. (A1) Traços brutos de eventos epileptiformes: a linha vermelha indica o segmento do traço expandido em A2. (A2) Detalhe temporal do evento: a linha azul indica o período de registro utilizado para calcular o espectro de potência apresentado em A3. (A3) Espectro de potência do segmento destacado, com escala de frequência (*Frequency)* de 0 a 1600 Hz e escala de potência de –30 a 30 dB/Hz. (B) Gravações correspondentes de uma fatia obtida de um animal perfundido com SP-mACSF (B1–B3), seguindo a mesma sequência e parâmetros de escala de A1-A3). Figura gerada em MATLAB®. (C) Encéfalos obtidos de animais do grupo controle (C.1) e SP-mACSF (C.2). (D) Local de posicionamento do eletrodo para registro das

uma variação de 20% da amplitude máxima em relação à linha de base e o instante de tempo "Tfinal", quando esta retornou a 20% da amplitude máxima em relação à linha de base. O parâmetro Ev/min foi obtido por meio da fórmula: Ev/min = total de eventos registrados/tempo total de registro (min). A Amp Med corresponde ao componente de alta frequência dos eventos epileptiformes e também foi separada do sinal do PE utilizando-se o cálculo da DFT do sinal elétrico, eliminando frequências inferiores a 10 Hz (componente DC), restando um sinal cujas componentes em alta frequência (acima de 10 Hz) correspondem aos PS. O valor do parâmetro Amp Med foi obtido pela valor médio das amplitudes dessas variações de alta frequência. A Figura 2 ilustra exemplos típicos de eventos epileptiformes registrados nos dois grupos, bem como o aspecto dos encéfalos dos grupos Controle e SP-mACSF e o local de registro das atividades epileptiformes não-sinápticas na camada granular do giro dentado.

E. Histologia

Após o corte em fatiador do tipo *chopper*, as fatias de tecido provenientes de ambos os grupos experimentais destinadas à análise de histologia foram coletadas e armazenadas temporariamente em solução ACSF (Controle) ou SP-mACSF, resfriada (2 a 4 °C) pelo tempo necessário para realizar o fatiamento dos hipocampos. Imediatamente após a conclusão do fatiamento, as fatias foram coletadas da solução ACSF (Controle) ou SP-mACSF resfriada (utilizando-se um conta gotas plástico descartável com diâmetro de 5 mm) e fixadas por imersão em solução de paraformaldeído a 2% resfriada (2 a 4 °C), onde foram mantidas (resfriadas em 2 a 4 °C) por 5 a 7 dias para pós-fixação. Em seguida, as fatias fixadas pelo paraformaldeído foram embutidas em gelatina ágar e resseccionadas em 6 a 8 seções seriadas, de 40 µm de espessura, utilizando vibrátomo *Leica* e armazenadas em solução crioprotetora anticongelante (solução *antifreeze*) no congelador. A solução crioprotetora anticongelante foi composta por 300 g de sacarose, 500 ml de tampão fosfato (PBS) e 300 ml de monoetileno glicol, ajustada ao volume final de 1 litro com PBS. Para a realização das marcações de imunofluorescência, as secções permaneceram *overnight* a 4 °C em uma solução de soro albumina bovina (BSA), contendo 0,1% de Triton X-100, 10% de BSA em PBS 0,1 M. Em seguida, as secções foram incubadas por 48 horas, a 4 °C, em solução (2% de BSA em PBS 0,1M e 0,1% Triton X-100) contendo o anticorpo primário anti-GFAP (glial fibrillary acidic protein - proteína do citoesqueleto de astrócitos – *Abcam*, produzido em coelho, na concentração 1:1000). Após o processo com os anticorpos primários, as secções foram incubadas por duas horas, em temperatura ambiente, em solução com o anticorpo secundário anti-IgG de coelho (anticorpo policlonal, produzido em cabra, conjugado com *DyLight*® 488; 1:250, Abcam).

Eritrócitos exibem autofluorescência endógena em múltiplos comprimentos de onda, que promove sobreposição direta com os espectros de excitação e emissão de fluoróforos comumente empregados, interferindo no sinal específico da marcação [31, 32, 34]. Nesse contexto, a imunomarcação fluorescente anti-GFAP foi utilizada neste estudo tanto para a evidenciação da autofluorescência de fundo quanto por sua relevância anatômica, uma vez que os astrócitos, mesmo estando presentes em toda a fatia hipocampal, se distribuem de forma peculiar ao redor dos vasos sanguíneos no hipocampo. Essa característica anatômica dos astrócitos torna particularmente evidentes, na marcação para GFAP, os artefatos decorrentes de sangue residual no interior dos capilares. A marcação por imunofluorescência foi realizada segundo protocolos padrão descritos em estudos anteriores, com aquisição de imagens em microscopia confocal utilizando um sistema confocal *Zeiss* LSM710 acoplado a um microscópio invertido *Observer* Z1, conforme descrito previamente por [28, 29].

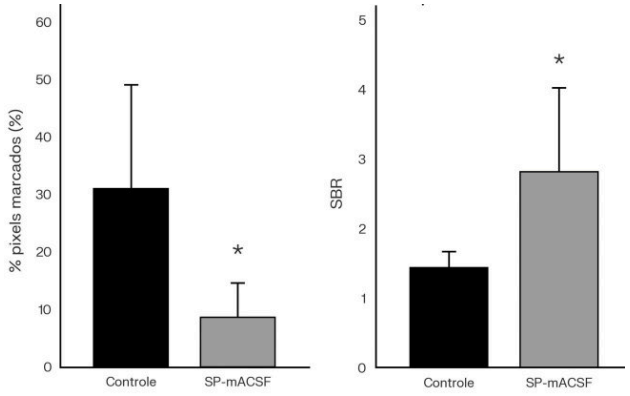

Figura 3. Marcação imunofluorescente anti-GFAP utilizado limiar fixo. Valor de % de pixels marcados significativamente menor no grupo SP-mACSF quando comparado ao controle, em decorrência de identificação de marcação inespecífica por autofluorescência e elevado *background* no grupo controle. Valor de SBR significativamente maior no grupo SP-mACSF.

Para a quantificação do % de pixels marcados, as micrografias confocais foram binarizadas aplicando-se um limiar fixo de detecção com intensidade de brilho igual a 75 (em uma escala de 0 a 255), calculando-se a proporção de pixels com intensidade acima desse corte em relação à área total da micrografia. A intensidade corrigida (BCI) foi calculada pela diferença entre a intensidade média da região de interesse de sinal (IS) e a intensidade média da região de fundo (IB): BCI = IS - IB. A razão sinal/fundo (SBR) foi calculada pela razão entre a IS da região de interesse (ROI) e a intensidade média da ROI de fundo (IB): SBR = IS / IB. A SBR normalizada (SBRN) foi calculada como: SBRN = (IS - IB) / IB. Essa medida foi utilizada como uma forma complementar para facilitar a interpretação do contraste relativo entre sinal e fundo.

F. Análise estatística

Para a análise estatística dos registros de potencial de campo, foram avaliados os parâmetros DE, Ev/min e AmpMed. Nas imagens de microscopia confocal, foram avaliados % de pixels marcados, IC, SBR e a SBRN. As fatias foram mantidas como unidades observacionais individuais. Como duas fatias de cada animal foram utilizadas para cada análise, a dependência entre observações provenientes do mesmo animal foi considerada por meio de modelos lineares de efeitos mistos. Para cada variável, o grupo experimental foi incluído como efeito fixo, enquanto o animal foi incluído como intercepto aleatório. Foram estimadas as diferenças entre os grupos, os intervalos de confiança de 95% e os valores de *p* associados ao efeito do grupo. Os tamanhos de efeito corrigidos de *Hedges* foram calculados como medida complementar da magnitude das diferenças. A normalidade dos dados foi avaliada pelo teste de *Shapiro–Wilk*. O nível de significância adotado foi de 5%, e as análises foram realizadas no software JAMOVI [30], utilizando o módulo GAMLj para os modelos lineares de efeitos mistos.

III. Resultados

A. Viabilidade eletrofisiológica após perfusão com a solução SP-mACSF

Todos os experimentos de indução de atividade epileptiforme no giro dentado utilizando fatias do grupo perfundido com SP-mACSF geraram eventos epileptiformes de forma consistente, assim como no grupo controle. Os registros das atividades epileptiformes foram realizados simultaneamente em duas fatias por experimento, escolhidas aleatoriamente dentre as 10 a 12 dispostas na câmara de interface, respeitando os critérios de viabilidade tais como: regularidade dos eventos e nível de shift DC no entorno de 5 mV e PS no entorno de 10 mV. A Figura 2 mostra sinais típicos registrados em experimentos do grupo controle e do grupo perfundido com SP-mACSF. A comparação qualitativa dos sinais mostra padrões morfológicos similares entre os grupos, confirmando a preservação da viabilidade eletrofisiológica após perfusão com SP-mACSF.

A análise quantitativa dos parâmetros do FP confirma a compatibilidade entre os registros realizados em fatias provenientes de ambas as preparações. Os valores do parâmetro DE foram semelhantes entre os grupos. O grupo Controle apresentou média de 41,46 ± 6,38 s, enquanto o grupo SP-mACSF apresentou 41,20 ± 5,97 s. A diferença estimada entre Controle e SP-mACSF foi de -0,262 s, com IC95% de -6,264 a 5,740 e p=0,932. O tamanho de efeito foi desprezível, com *Hedges' g*=-0,041. Ev/min também foi semelhante entre os grupos, sendo os valores médios 0,772 ± 0,087 no grupo Controle e 0,803 ± 0,196 no grupo SP-mACSF. A diferença estimada entre Controle e SP-mACSF foi de 0,031 evento/min, com IC95% de -0,141 a 0,204 e p = 0,720. O tamanho de efeito foi pequeno, com *Hedges' g* = 0,199. O valor médio de Amp Med foi de 0,911 ± 0,196 mV no grupo Controle e 0,903 ± 0,362 mV no grupo SP-mACSF. A diferença estimada entre os grupos Controle e SP-mACSF foi de -0,008 mV, com IC95% de -0,272 a 0,256 e p = 0,952. O tamanho de efeito foi desprezível, com *Hedges' g* = -0,026. Em conjunto, os modelos mistos não indicaram diferenças estatisticamente significativas entre os grupos para os parâmetros do FP avaliados.

B. Qualidade do Sinal de Imunofluorescência

A análise qualitativa de imunofluorescência revelou que as secções histológicas do grupo Controle apresentaram elevado nível de marcação decorrente da autofluorescência, o que resultou em uma marcação inespecífica acentuada. Na Figura 3, ilustra-se a análise quantitativa da porcentagem de área marcada, obtida mediante a aplicação de um limiar (*threshold*) de intensidade de fluorescência fixo para ambos os grupos. O grupo SP-mACSF exibiu um valor médio significativamente menor em comparação ao Controle. Entretanto, astrócitos são um tipo celular de formato característico e expressam GFAP de uma forma que possibilita facilmente a identificação qualitativa de marcação inespecífica, o que propiciou a avaliação das micrografias (Figura 4) e confirmou que os índices de marcação elevados no grupo Controle correspondiam a marcação inespecífica gerada por autofluorescência e não o resultado de uma ligação genuína do complexo anticorpo primário secundário direcionado à proteína glial fibrilar ácida GFAP (Figura 3). Assim, realizamos a quantificação da relação sinal / ruído (SBR) e constatamos quantitativamente o ganho de qualidade de marcação nas fatias do grupo SP-mACSF.

A análise estatística dos dados quantitativos da histologia apontou que a porcentagem de pixels marcados foi maior no grupo Controle do que no grupo SP-mACSF. A média foi de 31,00 ± 18,10% no grupo Controle e 8,61 ± 6,02% no grupo SP-mACSF. A diferença estimada entre Controle e SP-mACSF foi de -22,396 pontos percentuais, com IC95% de -37,706 a -7,086 e p = 0,004. O tamanho de efeito foi grande, com *Hedges' g* = -1,590. A BCI foi menor no grupo Controle do que no grupo SP-mACSF. Os valores médios foram 38,56 ± 15,48 no grupo Controle e 77,76 ± 22,69 no grupo SP-mACSF. A diferença estimada entre Controle e SP-mACSF foi de 39,200 unidades, com IC95% de 22,176 a 56,224 e p < 0,001. O tamanho de efeito foi grande, com *Hedges' g* = 1,933. A SBR foi menor no grupo Controle do que no grupo SP-mACSF. A média foi de 1,44 ± 0,23 no grupo Controle e 2,82 ± 1,21 no grupo SP-mACSF. A diferença estimada entre Controle e SP-mACSF foi de 1,380, com IC95% de 0,617 a 2,142 e p < 0,001. O tamanho de efeito foi grande, com *Hedges' g* = 1,519. A SBRN apresentou média de 0,44 ± 0,23 no grupo Controle e 1,82 ± 1,21 no grupo SP-mACSF. A diferença estimada entre Controle e SP-mACSF foi de 1,380, com IC95% de 0,617 a 2,142 e p < 0,001, com *Hedges' g* = 1,519. Sendo a SBRN matematicamente equivalente à SBR -

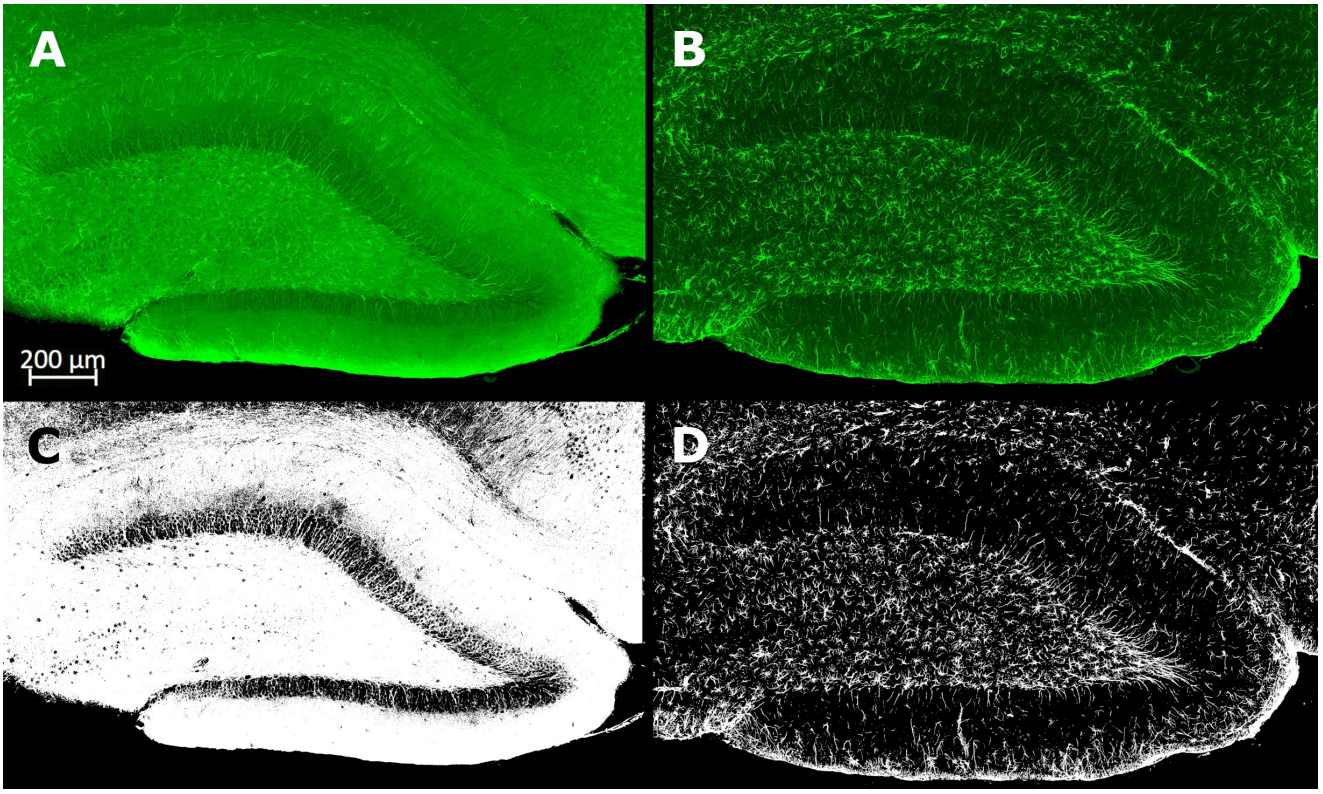

Figura 4. Micrografias representativas da marcação anti-GFAP no giro dentado de fatias de hipocampo: Grupo Controle (A) e grupo SP-mACSF (B). (C, D) Imagens binarizadas para quantificação com limiar fixo em fatia do grupo Controle (C) e fatia do grupo SP-mACSF (D). Identificação de marcação inespecífica causada pela autofluorescencia de *background* nas imagens do grupo Controle (A, C).

1, os valores de diferença, IC95%, *p* e tamanho de efeito foram iguais aos observados para a SBR.

Os modelos lineares de efeitos mistos indicaram que os grupos Controle e SP-mACSF apresentaram parâmetros eletrofisiológicos semelhantes, sem diferenças detectáveis em DE, Ev/min ou Amp Med. Em contraste, o grupo Controle apresentou maior % de pixels marcados, enquanto o grupo SP-mACSF apresentou maiores BCI, SBR e SBRN. Esse conjunto de resultados sugere que a perfusão com SP-mACSF preservou a viabilidade funcional das fatias e, simultaneamente, melhorou a qualidade relativa da marcação por imunofluorescência. A maior porcentagem de pixels marcados no grupo Controle, quando acompanhada de menor BCI, menor SBR e SBRN, é compatível com maior contribuição de fluorescência inespecífica e autofluorescência de fundo. Assim, o grupo SP-mACSF apresentou menor área acima do limiar, mas maior contraste relativo entre o sinal da ROI e o fundo.

IV. Discussão

O principal achado deste estudo foi demonstrar que a perfusão transcardíaca com SP-mACSF, associada ao método de preparação de fatias de hipocampo desenvolvido, permite realizar, de forma eficiente, análises eletrofisiológicas e morfológicas utilizando tecido proveniente do mesmo animal, sem comprometer a viabilidade funcional das fatias e, ao mesmo tempo, melhorar a qualidade das marcações por imunofluorescência. Mais do que uma adaptação técnica, essa estratégia representa um avanço metodológico ao proporcionar a possibilidade de correlação direta entre propriedades funcionais e estruturais do tecido nervoso.

Nesse contexto, a análise histológica demonstrou que, em contraste com as secções do grupo Controle, que exibiram acentuada autofluorescência de fundo, o tecido submetido à perfusão com SP-mACSF demonstrou uma marcação imuno-fluorescente nítida. A análise das micrografias confocais corroborou essas observações qualitativas, revelando uma proporção significativamente menor de área marcada no grupo perfundido quando aplicado um limiar fixo de detecção. Tendo em vista que o valor médio elevado de % de pixels marcados no grupo Controle derivou predominantemente de fluorescência inespecífica, o que ficou evidenciado pelos valores médios de IC, SBR e SBRN, conclui-se que o uso do SP-mACSF foi eficaz em eliminar a autofluorescência reduzindo a quantificação de artefatos, permitindo a detecção fidedigna dos fluoróforos secundários efetivamente acoplados à proteína-alvo, a GFAP. Nesse sentido, a literatura estabelece amplamente que os eritrócitos retidos na microvasculatura são importantes fontes de autofluorescência endógena no tecido nervoso [31, 32, 33, 34]. Dessa forma, os resultados evidenciam que o protocolo de perfusão transcardíaca com SP-mACSF foi eficaz na lavagem vascular, mitigando a autofluorescência de forma considerável e garantindo uma detecção mais precisa e confiável dos antígenos-alvo.

No aspecto eletrofisiológico, não é possível afirmar, a partir dos dados obtidos no nosso estudo, se a glicose aumentada (de 10 mM para 20 mM) em relação ao protocolo original de [24], exerceu, de fato, efeito protetor contra danos hipóxicos, conforme demonstrado por [26]. Entretanto, as fatias obtidas de animais submetidos à perfusão com SP-mACSF apresentaram viabilidade equivalente para indução de atividade epileptiforme não sináptica no giro dentado quando comparadas a fatias controle não perfundidas com SP-mACSF. Assim, apesar da variabilidade na morfologia dos eventos entre fatias, comum na indução de atividades epileptiformes não-sinápticas [27, 35, 36, 37] a análise qualitativa das gravações de FP revelou padrões morfológicos de atividade epileptiforme indistinguíveis entre os grupos Controle e SP-mACSF. A semelhança entre os registros é evidenciada por traços brutos sobrepostos e ilustrada pela densidade espectral de potência, apresentadas na Figura 2. Além disso, a análise e a comparação dos parâmetros quantitativos Ev/min, DE e Amp Med dos eventos não demonstrou diferença estatisticamente significativa nos valores obtidos para o grupo Controle e para o grupo SP-mACSF, corroborando o que foi constatado por meio da análise qualitativa dos registros do FP. Esses resultados indicam que a perfusão transcardíaca com SP-mACSF foi capaz de preservar a função neuronal mantendo as fatias de hipocampo em um estado de viabilidade capaz de deflagrar e sustentar eventos epileptiformes, mesmo diante do procedimento invasivo de lavagem vascular, corroborando os achados de [24].

Além disso, a equivalência qualitativa e quantitativa em termos dos parâmetros avaliados no FP, entre as gravações eletrofisiológicas obtidas em fatias perfundidas e fatias não perfundidas sugere que o período prolongado de equilíbrio na câmara de perfusão (120-150 min), somado ao tempo de descanso na câmara de interface (60 minutos), ambos sob perfusão de solução Ringer-ACSF normal, foi capaz de promover a extração completa (*washout*) dos anestésicos residuais do tecido, impedindo qualquer interferência na indução da atividade epileptiforme. Esse tempo é compatível com o tempo de 4 a 5 horas utilizado para tecido de hipocampo humano proveniente de ressecção cirúrgica de pacientes com epilepsia [38].

Em conjunto, os dados apresentados evidenciam que o método desenvolvido e validado neste estudo constitui um avanço metodológico significativo para a neurociência integrativa. A técnica viabiliza, a partir de um mesmo espécime animal, a obtenção de registros eletrofisiológicos de alta fidelidade e ensaios de imunofluorescência que produzem imagens de alta qualidade. Ao promover a lavagem vascular com SP-mACSF, a abordagem garante a preservação da integridade e excitabilidade neuronal, eliminando a autofluorescência inerente às células sanguíneas retidas no tecido. Desse modo, o método atinge uma dupla funcionalidade: sustenta a viabilidade tecidual necessária para a indução e o registro da atividade epileptiforme, além de assegurar a preservação estrutural para análises microscópicas de alta resolução.

V. Conclusão

Os resultados demonstram que a perfusão transcardíaca com SP-mACSF preserva a viabilidade eletrofisiológica das fatias de hipocampo, ao mesmo tempo em que reduz significativamente a autofluorescência e melhora a qualidade das análises por imunofluorescência. Dessa forma, o método permite a integração confiável de avaliações funcionais e morfológicas, utilizando tecido proveniente do mesmo animal e superando uma limitação metodológica recorrente na neurociência experimental. Além das vantagens técnicas, a estratégia proposta maximiza o aproveitamento científico de cada animal experimental e tem potencial para reduzir a variabilidade entre indivíduos e fortalecer a correlação entre alterações estruturais e funcionais, em consonância com os princípios dos 3Rs. Embora validado neste estudo em um

modelo de atividade epileptiforme não sináptica, o protocolo apresenta potencial para aplicação em diferentes paradigmas eletrofisiológicos e modelos experimentais, constituindo uma plataforma metodológica promissora para pesquisas integrativas em neurociência.

AGRADECIMENTOS

Os autores agradecem à Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), ao Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), à Fundação de Amparo à Pesquisa do Estado de Minas Gerais (FAPEMIG), ao Instituto Federal de Educação, Ciência e Tecnologia de Minas Gerais (IFMG), ao Instituto Federal de Educação, Ciência e Tecnologia do Sudeste de Minas Gerais (IF Sudeste MG), à Universidade Federal de São João del Rei (UFSJ) e à Universidade Federal de São Paulo (UNIFESP) pelo apoio financeiro e institucional.

Abstract* — Parkinson's Disease (PD) is a neurodegenerative condition characterized by progressive motor impairment, with tremor being one of its most disabling manifestations. Transcranial Photobiomodulation (tPBM) has been investigated as a non-invasive therapeutic strategy with potential neuromodulatory effects on neural activity. The aim of this study was to describe the clinical response observed after the isolated application of tPBM on tremors in a patient with PD, using the MDS-UPDRS scale as a clinical outcome measure. This was a prospective longitudinal case study conducted in a home-based setting. The participant underwent a tPBM protocol five times per week for 12 weeks, totaling 60 sessions. The intervention was performed using a near-infrared light-emitting device (808 nm) applied for 20 minutes per session. Motor assessment was conducted before and after the intervention using the MDS-UPDRS scale. A reduction in the total score from 35 to 17 points was observed, corresponding to an approximate 51% reduction in the evaluated motor scores, in addition to a consistent decrease in resting, postural, and kinetic tremor scores, as well as rigidity. Functional improvements in activities of daily living, especially fine motor coordination, were also observed. The findings describe a clinical response temporally associated with tPBM in this participant. However, due to the case study design, the results should be interpreted with caution, without allowing inferences of efficacy or causality, and controlled studies are required to confirm these findings.

Keywords — Parkinson's Disease; Tremor; Neurorehabilitation; MDS-UPDRS.

I. INTRODUCTION

Parkinson's Disease (PD) is the second most prevalent neurodegenerative disorder associated with aging and is characterized by progressive and disabling motor alterations, including resting tremor, rigidity, bradykinesia, and postural instability. Among these manifestations, tremor stands out as one of the most disabling symptoms, significantly impairing functionality and life quality. Despite advances in pharmacological and surgical therapies, limitations related to sustained efficacy and adverse effects reinforce the need for complementary therapeutic approaches [1–2].

In this context, Transcranial Photobiomodulation (tPBM) has emerged as a promising strategy for modulating neural activity. This approach is based on the application of light at specific wavelengths capable of interacting with intracellular chromophores, particularly cytochrome c oxidase, potentially promoting increased ATP production and improving neuronal bioenergetic efficiency. Additionally, studies suggest that tPBM may be associated with reduced oxidative stress and modulation of inflammatory processes, mechanisms directly involved in the pathophysiology of PD [1–5].

From a functional perspective, these effects may contribute to the reorganization of neural circuits and improvements in the dynamics of systems responsible for motor control. Experimental and clinical studies suggest potential neuroprotective effects of tPBM and a possible enhancement of neuroplasticity, with observed associations between the intervention and reductions in motor symptoms, including tremor [2–5].

However, despite promising findings, important gaps remain in the literature, especially regarding the isolated application of tPBM and its ability to specifically modulate motor parameters assessed by standardized clinical scales. Most available studies combine the technique with other interventions, making it difficult to understand its direct effects.

Therefore, the present study aimed to describe the clinical response observed after the isolated application of tPBM on tremors in a patient with PD, using the MDS-UPDRS as the primary outcome measure, thereby contributing to the understanding of the clinical and functional effects of this intervention.

II. MATERIALS AND METHODS

A. Ethical Considerations

This study was approved by the Research Ethics Committee of Centro Universitário de Itajubá – FEPI (CAAE 73135023.5.0000.5094). The participant was properly informed about the objectives and procedures of the study and signed an informed consent form prior to the beginning of treatment.

This was a prospective, descriptive, and longitudinal case study conducted in the participant's home environment.

B. Clinical Description of the Patient

The present study was conducted with a 62-year-old male participant diagnosed with PD who was under regular clinical follow-up and on regular use of the medication Prolopa® BD 100/25 mg, at a dose of one tablet at 6:00 AM, 11:30 AM, and 5:00 PM. The medication regimen remained stable during the 12 weeks of the protocol. The patient presented predominant tremor in the Right Upper Limb (RUL), with functional impairment in activities requiring fine motor control.

Eligibility criteria for inclusion in this case study included a clinical diagnosis of PD, the presence of motor

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

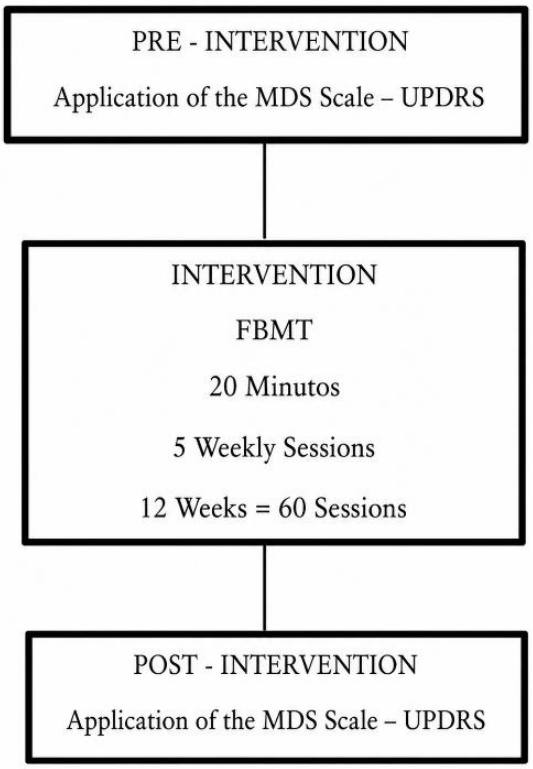
tremor, and stable medication use. Exclusion criteria included the presence of other associated neurological diseases, a history of recent neurosurgical procedures, photosensitivity disorders, or clinical conditions that could interfere with tPBM application.

An initial evaluation was performed, including the collection of personal, anthropometric, and clinical data, such as a body weight of 86 kg, a height of 1.72 m, and a Body Mass Index (BMI) of 29.1 kg/m².

Motor function assessment was performed using the MDS-UPDRS (Movement Disorder Society–Unified Parkinson's Disease Rating Scale), applied before and after the intervention period. The analysis focused primarily on items related to resting tremor, postural tremor, kinetic tremor, and rigidity, allowing comparison of the participant's clinical progression throughout the treatment. The pre- and post-intervention evaluations were performed in the ON state, approximately 60 minutes after the administration of Prolopa®, maintaining the relative timing of medication.

C. Motor Function Assessment

The MDS-UPDRS is a widely used scale for assessing the severity and progression of PD, encompassing both motor and non-motor aspects of the disease. In the present study, the analysis focused primarily on motor function items, with emphasis on resting tremor, postural tremor, kinetic tremor, and rigidity.



The scale was administered by another author of the study, who was previously trained and distinct from the researcher responsible for the intervention sessions, in a controlled environment, with the patient under standardized resting conditions and during the execution of specific motor tasks. During the assessment, the participant was instructed to remain seated for resting tremor evaluation and subsequently perform voluntary upper limb movements to assess action tremors and motor control. Scores were assigned according to the intensity and frequency of the observed clinical signs, ranging from 0 (no impairment) to 4 (severe impairment). The evaluator was aware of the pre- or post-intervention timing, with no blinding. The scale was applied at two distinct time points: before the intervention and after completion of the tPBM protocol, allowing comparison of clinical findings before and after the treatment period.

D. Intervention Protocol

As this was a case study, no group allocation was performed, and an individualized approach was adopted to analyze the effects of the intervention. The participant underwent exclusive tPBM application, without association with other therapeutic interventions, allowing the isolated evaluation of the effects of the technique. However, the absence of a control group or Sham condition prevents attributing the observed changes exclusively to tPBM.

The protocol was conducted five times per week for 12 consecutive weeks, totaling 60 sessions. tPBM was applied using a device positioned over the cranial region containing light-emitting diodes (LEDs) operating in the near-infrared range (808 nm), with a duration of 20 minutes per session. The application was performed with the patient in a comfortable position, with the helmet covering the entire cranial region, without targeting specific cortical regions.

Figure 1 – Experimental design of the case study.

Source: Personal Archive

E. tPBM Protocol in PD

The tPBM intervention was performed using a helmet composed of gallium-aluminum-arsenide (GaAlAs) LED emitters arranged to cover the entire cranial region, without selective targeting of a specific cortical target. The device was designed to provide homogeneous distribution of light radiation over the scalp, favoring light penetration into encephalic structures.

The helmet emitted near-infrared radiation at a wavelength of 808 nm, a value widely described in the literature for its tissue penetration capacity and interaction with cytochrome c oxidase, favoring cellular bioenergetic effects. The device featured an acrylic encapsulation with an approximate diameter of 5 mm per emitter. The system presented a total optical power of 6 W and a power density of 3.41 mW/cm², allowing application for 1200 seconds per session, corresponding to 20 minutes, with an approximate energy density of 4.09 J/cm² per session.

During application, the participant remained in a comfortable position with the helmet properly adjusted to the cranial region, ensuring adequate contact and uniform distribution of light. No additional anatomical landmarks were used for cortical targeting, and the same fitting procedure was repeated across sessions. To ensure

appropriate biosafety conditions, the device was disinfected with 70% alcohol after each session.

F. Statistical Analysis

As this was a case study, no inferential statistical analyses were performed. Data analysis was conducted descriptively, comparing pre- and post-intervention findings. The analysis focused primarily on MDS-UPDRS scores related to resting tremor, postural tremor, kinetic tremor, and rigidity, allowing the evaluation of the participant's clinical progression throughout the tPBM protocol. No intermediate or follow-up assessments were conducted, making it impossible to characterize the trajectory or persistence of the observed changes.

Results were presented using absolute values and graphical representations, enabling visualization of the changes observed after the intervention period. Data analysis was conducted in an integrated manner, considering both quantitative changes and the clinical relevance of the observed findings.

III. RESULTS

After completion of the 60 tPBM sessions, a descriptive reduction in the total MDS-UPDRS score was observed, decreasing from 35 to 17 points, representing an approximate 51% reduction in the evaluated motor parameters. Descriptive improvement was observed in resting tremor, kinetic tremor, and articular rigidity.

The present study involved a single participant diagnosed with PD presenting predominant tremor in the RUL. During the initial MDS-UPDRS assessment, the participant presented a total score of 35 points, indicating mild-to-moderate motor impairment, with emphasis on the presence of resting, postural, and kinetic tremor in the RUL, as well as rigidity in the same segment and cervical spine.

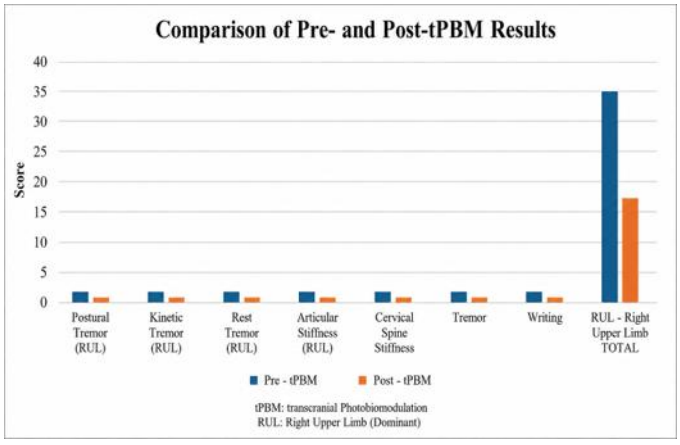
Regarding specific items, reductions were observed in scores related to resting tremor, postural tremor, and kinetic tremor, in addition to decreased articular rigidity and improvement in functional tasks such as handwriting, which is associated with fine motor control. Parameters related to gait and postural stability remained stable throughout the intervention period.

Table 1 presents the comparison of scale scores in the pre- and post-intervention periods, while Figure 2 graphically illustrates the reduction in the evaluated motor parameters.

In the MDS-UPDRS, scores range from 0 (no impairment) to 4 (severe impairment), representing increasing levels of motor symptom severity. A score of 2 corresponds to mild-to-moderate impairment, characterized by evident clinical manifestations already interfering with movement quality and precision, whereas a score of 1 indicates mild impairment, with subtle signs and lower functional impact.

In this patient, the reduction from 2 to 1 suggests a transition from a motor pattern with noticeable impairment to a milder condition in which symptoms remained present but with lower intensity and reduced interference in motor task execution. Since accelerometry or IMUs were not used, it was not possible to objectively quantify the amplitude or frequency of the tremor.

Table 1 – Comparison of MDS-UPDRS Scores Pre- and Post-tPBM Intervention.



Variable	Pre-tPBM	Post-tPBM
Postural Tremor (RUL)	2	1
Kinetic Tremor (RUL)	2	1
Resting Tremor (RUL)	2	1
Articular Rigidity (RUL)	2	1
Cervical Spine - Articular Rigidity	2	1
Tremor	2	1
Handwriting	2	1
Total Score	**35**	**17**

From a clinical perspective, this change may be associated with improved motor control, greater movement fluidity, and reduced tremor amplitude observed in the participant, potentially contributing positively to functional capacity. Furthermore, although numerically representing only a one-point difference on the scale, this variation has important clinical relevance, especially in patients with PD, in whom small score changes may be associated with meaningful functional gains in activities of daily living, particularly those requiring coordination and manual dexterity, such as handwriting. However, a minimal clinically important difference (MCID) has not been defined for these items, and the absence of instrumental measures limits the interpretation of clinical relevance.

Figure 2 presents the comparison of MDS-UPDRS scores before and after the intervention, demonstrating a descriptive reduction across all evaluated motor parameters.

Figure **2** – Scores Pre- and Post-tPBM Intervention.

Source: Personal Archive

A homogeneous reduction pattern was observed in the items related to tremor (postural, kinetic, and resting) and rigidity, with scores decreasing from 2 to 1 in all these domains. Since this is an ordinal clinical scale applied at only two distinct time points, this pattern does not allow demonstrating response stability or low intra-individual variability.

Additionally, functional items such as tremor and handwriting also showed score reductions, suggesting a possible association between the intervention and improvement in fine motor task execution. This finding reinforces the potential relationship between improvements in clinical parameters and participant functionality.

A reduction in the total scale score from 35 to 17 points was also observed, representing an approximate decrease of 51%. This magnitude of change suggests a potential association between tPBM and improvement in the participant's global motor performance. In the absence of EEG, neuroimaging, or other neurophysiological measures, it is not possible to assert that these changes resulted from the modulation of neural circuits.

IV. DISCUSSION

The results observed in the present study, assessed through the MDS-UPDRS, were accompanied by consistent reduction in motor scores following tPBM application. An approximate 51% decrease in the total scale score was observed, from 35 to 17 points, suggesting a potential association between the intervention and improvement in the evaluated motor parameters. This pattern was accompanied by a homogeneous reduction in scores related to resting tremor, postural tremor, kinetic tremor, and rigidity, in addition to improvements in functional tasks associated with fine motor control, such as handwriting. These findings describe a change between two time points, without allowing the determination of its trajectory, persistence, or causal relationship with tPBM.

The findings observed in the present study are consistent with results described in the literature. Liebert et al. (2021) reported improvements in motor parameters in patients with PD undergoing tPBM, including reductions in tremor-related manifestations and functional improvement. Similarly, Ahrabi et al. (2022) described a potential neuroprotective effect of tPBM on motor circuits involved in movement control, suggesting an association between neuronal bioenergetic modulation and functional improvement observed in neurodegenerative diseases [1,5].

From a clinical perspective, tremor represents one of the most disabling motor manifestations of PD and is frequently associated with functional limitation, loss of independence, and impaired quality of life. According to Abusrair, Elsekaily, and Bohlega (2022), tremor-related motor alterations may significantly impact activities of daily living dependent on fine motor coordination, such as handwriting, eating, and object manipulation. In this context, the reduction observed in tremor-related scores may suggest important functional relevance, even with small variations of the clinical scale. However, the absence of an objective measure of tremor and of additional functional evaluations limits this interpretation.

From a physiological and biophysical perspective, tPBM may act as an energetic stimulus potentially capable of modulating cellular processes related to neuronal activity. The application of near-infrared light (808 nm) allows greater tissue penetration, reaching cortical structures and potentially influencing neuronal activity [11]. The interaction of light with intracellular chromophores, especially cytochrome c oxidase, may promote increased mitochondrial activity and ATP production, resulting in possible improvement in neuronal bioenergetic efficiency [5–6]. These mechanisms are hypotheses proposed by the literature and were not measured in the present study.

Additionally, the reduction in rigidity identified in the present study may be associated with modulation of neural pathways related to muscle tone, possibly influenced by reduced central inflammatory processes. Experimental studies suggest that tPBM may reduce microglial activation and pro-inflammatory cytokine release, potentially contributing to improved neuronal function and motor control [5,12].

Regarding functional items of the scale, such as tremor and handwriting, the observed improvement suggests a possible alteration in the execution of fine motor tasks. Although the literature presents hypotheses related to the integration between motor planning and execution, the present study did not directly evaluate the signal-to-noise ratio or the activity of motor circuits. Therefore, it is not possible to confirm neurophysiological mechanisms from the clinical outcomes obtained [5,10].

From a biophysical standpoint, the observed effects may also be related to the irradiation parameters used, such as wavelength, energy density, and exposure time. However, as this is a single case and there is no comparison between different doses, it is not possible to establish a dose-dependent behavior of the response to tPBM.

Although the identified findings are promising, it should be considered that case studies present important limitations regarding generalization of the results, since they do not allow control of external variables or comparison with a control group. In addition, factors such as individual clinical variability, placebo effects, and possible natural disease fluctuations may influence the reported findings. Therefore, the results should be interpreted with caution, reinforcing the need for controlled studies with greater methodological robustness to confirm the effects of tPBM [3].

Another relevant aspect is that the intervention was applied in isolation, which allows a possible association between the identified clinical response and isolated tPBM application without interference from other therapeutic variables [4,10]. However, the absence of a control group does not allow attributing the clinical response exclusively to tPBM [4,10]. Furthermore, the inclusion of only a single participant limits the analyses of interindividual variability. Electrophysiological or imaging parameters that could provide greater support for interpretation of the involved mechanisms were not evaluated [10].

Therefore, the results of the present study describe clinical changes temporally associated with the tPBM protocol in this participant. However, the data do not allow demonstrating modulation of neural circuits, therapeutic efficacy, or a causal relationship. Future studies with greater methodological robustness are necessary to confirm these findings.

V. CONCLUSION

Near-infrared tPBM applied in isolation in the present case report was associated with a reduction in the motor scores assessed by the MDS-UPDRS in a patient with PD. Decreases in tremor and rigidity-related parameters were observed, in addition to improvements in functional tasks related to fine motor control, such as handwriting.

The observed findings suggest a potential association between the application of tPBM and the observed clinical changes. However, the study does not allow asserting functional modulation of neural circuits, clinical efficacy, or a causal relationship.

Although the results are limited by the case study design, the clinical response observed justifies further investigations of tPBM as a non-invasive strategy in the rehabilitation of patients with PD. However, future controlled studies with a larger sample size, blinded evaluators, serial assessments, a follow-up period, and objective instrumental measures are necessary before conclusions regarding its clinical efficacy can be supported.

***Abstract*—Neurodegenerative disorders have been increasingly associated with the neurological complications observed following Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) infection, particularly those related to the neurotoxic effects of the Spike protein. Although photobiomodulation (PBM) has emerged as a promising neuroprotective strategy, its effects in neuroglial co-culture models exposed to the Spike protein remain poorly understood. This study evaluated the neuroprotective potential of PBM in an *in vitro* SH-SY5Y/U87MG neuroglial co-culture challenged with the SARS-CoV-2 Spike protein. Cell metabolic activity was assessed using the Alamar Blue assay at 2 and 24 h after irradiation, while brightfield microscopy and Congo Red staining were used to evaluate the structural organization of the neuroglial network and protein aggregation, respectively. Spike exposure reduced metabolic activity and disrupted the structural organization of the neuroglial network, accompanied by alterations in the distribution of Congo Red-positive material. PBM attenuated the metabolic impairment induced by Spike, preserved neurite-like intercellular connections, and modified the distribution pattern of Congo Red-positive protein aggregates. These findings suggest that PBM exerts neuroprotective effects by preserving cellular metabolism and maintaining the structural integrity of neuroglial networks following Spike-induced injury, supporting its potential as a therapeutic strategy for neuroinflammatory and neurodegenerative conditions.**

I. INTRODUCTION

Neurodegenerative disorders represent one of the greatest global public health challenges nowadays. These pathologies are characterized by the progressive loss of neuronal functions and, classically, by the accumulation of abnormal protein aggregates in brain tissue, with a particular emphasis on amyloid-β (Aβ) peptides.

Recently, the scientific literature has increasingly investigated the correlation between systemic viral infections and the onset or acceleration of central nervous system (CNS) dysfunctions. In the context of the Coronavirus Disease 2019 (COVID-19) pandemic, SARS-CoV-2 has demonstrated neurotropic potential and has been associated with persistent neurological manifestations. Pioneering studies indicate that the isolated Spike protein of SARS-CoV-2 can compromise cellular homeostasis, induce oxidative stress, and activate inflammatory pathways in brain parenchyma cells, thereby mimicking the early stages of neurodegenerative processes [1]. Furthermore, mitochondrial dysfunction has emerged as one of the earliest events associated with Spike-induced neurotoxicity, resulting in impaired Adenosine Triphosphate (ATP) production, increased Reactive Oxygen Species (ROS) generation, and disruption of neuronal bioenergetics, all of which contribute to the loss of cellular homeostasis and viability [2].

A thorough investigation of these neurotoxic mechanisms and the screening of new therapeutic strategies require *in vitro* models that more faithfully reproduce the brain microenvironment. While monocellular models provide valuable data, they fail to mimic the complex bidirectional communication between neurons and glial cells. In this context, the co-culture of neuron-like and astrocyte-like cells serves as a robust tool for simulating neuroglial interactions. Astrocytes-like cells play a critical role in metabolic support and inflammatory response, directly modulating neuronal viability and vulnerability in the face of toxic insults such as exposure to the Spike protein. Beyond their metabolic role, astrocytes actively regulate neurotransmitter recycling, antioxidant defenses, synaptic homeostasis, and neuronal survival through continuous bidirectional communication with neurons. Consequently, alterations in neuron–glia interactions have been recognized as key events during the

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

development and progression of several neurodegenerative disorders, making neuroglial co-culture models more physiologically relevant than conventional neuronal monocultures [3-6].

In addition to direct cellular damage, evidence suggests that the Spike protein can interact with proteins prone to misfolding, accelerating fibrillization and deposition of Aβ aggregates [7]. To evaluate the amyloidogenic profile and the formation of these β-sheet-rich structures in the co-culture model, the histological dye Congo Red is widely used, serving as a classical and reliable biomarker for the detection and quantification of these protein aggregates [8]. Moreover, alterations in protein aggregation are frequently accompanied by cytoskeletal remodeling and disruption of the neuroglial network, reinforcing the importance of simultaneously evaluating metabolic activity, cellular organization and amyloidogenic responses following Spike exposure.

Given the neurotoxic potential of the Spike protein, the search for non-invasive and bioenergetic therapies becomes a priority. Photobiomodulation (PBM), using light-emitting diodes (LEDs), stands out for its neuroprotective properties. Acting predominantly in the red to near-infrared range, PBM is absorbed by the mitochondrial chromophore cytochrome c oxidase, optimizing the electron transport chain, increasing ATP synthesis, and modulating ROS [9]. In addition to improving mitochondrial bioenergetics, previous studies have demonstrated that PBM contributes to the preservation of neuronal morphology, maintenance of neurite integrity, modulation of oxidative stress, and regulation of protein homeostasis, highlighting its potential as a therapeutic strategy for neurodegenerative disorders [10-13]. However, the effectiveness of PBM in mitigating stress and the amyloidogenic profile, specifically in co-culture models challenged with the SARS-CoV-2 Spike protein, still needs to be thoroughly elucidated.

Considering the above, the objective of this study is to evaluate the neuroprotective effects of PBM in an *in vitro* SH-SY5Y/U87MG neuroglial co-culture model exposed to the SARS-CoV-2 Spike protein. Specifically, metabolic activity, structural organization of the neuroglial network, and protein aggregation assessed by Congo Red staining were investigated to determine whether PBM attenuates the early cellular alterations induced by Spike exposure.

II. METHODOLOGY

A. Cell Culture and Establishment of Co-culture

The human neuroblastoma (SH-SY5Y) and human glioblastoma (U87MG) cell lines were cultured individually in flasks under controlled incubation conditions (37°C and 5% CO_2). SH-SY5Y cells were maintained in Dulbecco's modified Eagle's medium/nutrient mixture F-12 (DMEM/F12), while U87 cells were maintained in DMEM, both supplemented with 10% Fetal Bovine Serum (FBS) and 1% Antibiotic-Antimycotic (AA).

After reaching appropriate cell confluence, both cell lines were trypsinized, centrifuged, and resuspended in DMEM. For the establishment of co-culture, the cells were seeded in 96-well plates at a final density of $1x10^5$ cells/mL, with a cell ratio of 70:30, consisting of $7x10^4$ cells/mL of SH-SY5Y and $3x10^4$ cells/mL of U87.

B. Cell Differentiation and Experimental Design

After 24 h of initial seeding, the culture medium for all experimental conditions was replaced with a differentiation medium composed of DMEM supplemented with 0.5% FBS, 1% AA, and 0.1% retinoic acid (RA). Cellular differentiation and maturation were maintained for five days.

Following the differentiation period, the cultures were assigned to four experimental groups to evaluate the effects of Spike protein challenge and PBM: Control, maintained in differentiation medium without intervention; Spike, exposed to the recombinant SARS-CoV-2 Spike protein (0.5 µg/mL) for 1 h; LED Control, subjected only to the LED irradiation protocol (660 nm, 3 J/cm²); and LED + Spike, which received PBM in combination with Spike protein exposure.

The recombinant SARS-CoV-2 Spike protein used in this study was the full-length glycoprotein (amino acids 1-1208) produced by the Cell Culture Engineering Laboratory (LECC, COPPE/UFRJ, Rio de Janeiro, Brazil; batch 0151021). The protein was expressed in HEK293 cells cultured in chemically defined medium, purified by affinity chromatography, and characterized by SDS-PAGE and Western blot. The stock solution (0.25 mg/mL) was supplied in phosphate-buffered saline (PBS) containing biotin and 0.02% sodium azide and stored at -80 °C until use. The working concentration of 0.5 µg/mL was selected based on previous studies demonstrating biologically relevant effects of the recombinant Spike protein in central nervous system-derived *in vitro* models [1], [14].

PBM was performed using a custom-built red LED system (660 nm) housed in a dedicated irradiation chamber (Biotable). Before each experiment, the device was calibrated with a power meter to ensure reproducible irradiation conditions. The irradiation parameters consisted of an irradiance of 36.8 mW/cm², a total output power of 115.34 mW, and a fluence of 3 J/cm², delivered over 82 s. Culture plates were positioned at a fixed distance of 4 cm from source to ensure homogeneous light distribution. Temperature monitoring confirmed that thermal variation remained below 0.5 °C throughout irradiation, excluding photothermal effects.

C. Cell Viability Assay

Cellular metabolic activity was quantified 2h and 24 h post-treatment using the Resazurin-based Alamar Blue® assay (Sigma-Aldrich, USA). First, the incubation media were replaced with a working solution composed of differentiation medium and 10% Alamar Blue reagent.
