***Abstract*—Loose tablets and capsules separated from their original packaging are difficult to identify because many pharmaceutical presentations share similar colors, shapes, and dimensions. This paper presents App My Pill, a low-data, reference-based computer vision prototype designed to rank possible matches for a loose solid oral dosage form from images of its two faces. The pipeline combines central-region segmentation, Lab color contrast, edge detection, morphological processing, GrabCut refinement, optional manual region selection, MobileNetV2 visual embeddings, imprint-text similarity, geometric descriptors, color features, and optional metric scale from an ArUco marker. A dynamic fusion strategy reduces the influence of physical descriptors when the crop heuristic is poor and applies a rule-based decision and abstention mechanism based on total compatibility, candidate margin, visual evidence, and the internal crop heuristic. The prototype intentionally reports a ranked hypothesis rather than a medical identification and abstains when the predefined criteria are not met. The current database contains two exact presentations: simethicone 40 mg, Neo Quimica, white tablet, and paracetamol 750 mg, Prati, each with 150 reference images per face. For each presentation and each face, 100 images were acquired under the same lighting setup and 50 additional images were acquired in different environments and lighting conditions. All reference and query images were acquired with a Samsung Galaxy A51, and the demonstrated simethicone query used files distinct from the reference images. In this two-class case demonstration, simethicone was ranked first with a compatibility index of 82.5%, compared with 65.3% for paracetamol. The internal crop heuristic was $Q_h = 0.977$. Because the no-imprint acceptance threshold was 86%, the system returned an unconfirmed hypothesis. This single case demonstrates execution of the proposed workflow but does not estimate accuracy, sensitivity, specificity, generalization, robustness, or clinical safety.**

***Index Terms*—computer vision, pill identification, medication safety, low-shot recognition, image segmentation, MobileNetV2, pharmaceutical informatics**

I. Introduction

Medication-related harm remains a major global patient-safety concern. The World Health Organization (WHO) updated its systematic review of preventable medication-related harm in 2024 and continues to promote system-level interventions through the Medication Without Harm initiative [1], [2]. Although medication errors span prescribing, dispensing, administration, monitoring, and transitions of care, one practical problem occurs when a tablet or capsule is separated from its labeled container. In this situation, patients, caregivers, pharmacists, and health professionals may need to distinguish among visually similar products without reliable contextual information.

The visual identification problem is intrinsically fine-grained. Numerous products may be white and round, while the same active ingredient may appear in different doses, manufacturers, colors, coatings, or imprint patterns. Conversely, different active ingredients may share nearly identical gross appearance. Regulations for solid oral dosage forms in the United States explicitly recognize that reliable identification depends on the combination of imprint, size, shape, and color, rather than on a single visual property [5]. Therefore, an automated system should treat each exact pharmaceutical presentation as a separate class and should integrate complementary evidence.

This U.S. regulatory context should not be directly generalized to Brazil. The Brazilian Health Regulatory Agency (Agencia Nacional de Vigilancia Sanitaria, Anvisa) establishes national medication-labeling requirements through RDC No. 768/2022 and provides official consultation resources for registered medicines, labels, and package inserts [3], [4].

Accordingly, visual features used by App My Pill are treated as retrieval cues only, and any practical identification must still be confirmed using original packaging, official regulatory information, manufacturer information, or a qualified health professional.

Computer vision has been applied to pill recognition through handcrafted descriptors, convolutional neural networks (CNNs), metric learning, retrieval systems, object detectors, and multimodal architectures [6]–[10], [13], [14]. However, real-world deployment remains challenging. Consumer photographs differ from curated reference images in illumination, viewpoint, background, scale, occlusion, reflections, device characteristics, and image quality. Low-shot benchmarks such as ePillID demonstrate the difficulty of distinguishing thousands of appearance classes with very few reference examples [10]. Recent work also emphasizes that segmentation quality and cross-domain distribution shift may remain limiting even when semantic classification appears strong [15], [16].

This study proposes App My Pill, a proof-of-concept system intended for low-data prototyping. Instead of training a new classifier for each medication class, the system builds a reference database from a small number of images and performs similarity-based retrieval. The current contribution is fourfold: 1) a two-sided reference-matching architecture combining deep visual embeddings with physical and textual cues; 2) a segmentation pipeline with both automatic and manual fallback modes; 3) an explicit abstention mechanism that separates a ranked hypothesis from a confirmed output; and 4) a transparent preliminary case demonstration in which all score components can be reproduced from the configured weights.

The prototype is not intended to authorize medication ingestion, replace a pharmacist, or provide a clinical diagnosis. Its current purpose is to investigate technical feasibility and define a validation pathway for a future assistive system.

II. Related Work

A. Pill Recognition and Retrieval

Early approaches relied on shape, color, texture, and imprint descriptors, whereas later studies adopted CNNs to learn discriminative representations. Wong *et al.* developed a fine-grained deep convolutional approach for unconstrained mobile images [7]. MobileDeepPill combined multiple CNN branches to capture pill shape, color, and imprint while reducing the model footprint for mobile use [8]. Delgado *et al.* demonstrated a medication-identification service based on reference and consumer images [9].

The ePillID benchmark formalized pill identification as a low-shot, fine-grained retrieval problem with two appearance classes per pill, corresponding to its two faces [10]. This formulation is directly relevant to loose pills because the two sides may contain different imprints or surface characteristics. Subsequent studies evaluated drug recognition in hospital workflows, retrieval systems, and multinational databases [11]–[14]. Across these studies, high reported performance is commonly associated with a particular dataset and acquisition protocol; it should not be assumed to transfer unchanged to a new population of products or consumer devices.

B. Segmentation and Domain Shift

Pill recognition requires both localization and classification. Background leakage, shadows, fingers, packaging, and fiducial markers can distort geometric and color measurements. GrabCut provides an iterative graph-cut method that combines edge and color information for foreground extraction with limited user interaction [18]. Fiducial markers such as ArUco provide a robust reference for scale and camera geometry [19].

A 2025 review identified dataset scarcity, visually confusing classes, imaging variability, and deployment robustness as continuing challenges in pill recognition [6]. The 2026 MEDISEG dataset expanded attention toward instance segmentation in cluttered and overlapping medication scenes [15], while deployment-oriented few-shot evaluation showed that localization and recall can deteriorate under domain shift even when class adaptation is rapid [16]. These findings motivate the explicit measurement of segmentation quality and the use of abstention in the present prototype.

III. Materials and Methods

A. System Overview

The system was implemented as a desktop proof of concept in Python 3.14 using OpenCV 5.0, NumPy, an ONNX version of MobileNetV2, and a Tkinter graphical interface. The processing pipeline is summarized in Fig. 1. The user may acquire images through a camera or select stored files. Two images are required, corresponding to face A and face B. The sides may be automatically matched in either direct or swapped order, reducing dependence on how the user labels the faces.

Each database class represents an exact presentation rather than only an active ingredient. The metadata structure includes a class identifier, display name, active ingredient, dose strength, manufacturer, dosage form, expected imprint on each face, expected color, and expected shape. This design follows the principle that product identification depends on the joint physical presentation [5], [20].

B. Reference Database and Image Acquisition

Reference images are organized by class and face. Multiple photographs of each face can be stored, allowing the reference representation to include modest variations in rotation and acquisition. The current preliminary database contains two exact presentations: Simethicone 40 mg—Neo Quimica, white tablet, and Paracetamol 750 mg—Prati, tablet. For both presentations, 150 reference images were acquired for face A and 150 for face B. For each presentation and each face, 100 images were obtained under the same lighting setup and 50 additional images were obtained in different environments and lighting conditions. All reference photographs and the demonstrated query were acquired with a Samsung Galaxy A51. The two simethicone query images were separate files and were not reused as reference images. However, acquisition and parameter development occurred iteratively, without prospectively separated

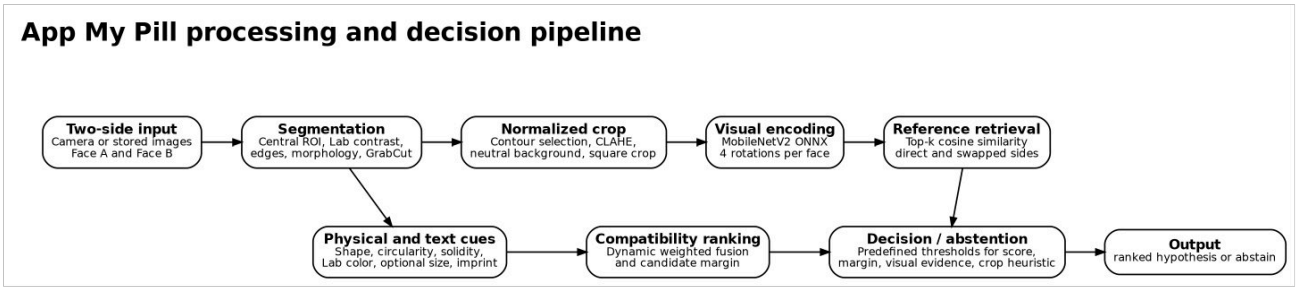

Fig. 1. Processing and decision pipeline. Two face images are segmented and normalized before visual embedding extraction. Deep visual similarity is fused with available physical and imprint evidence. A predefined decision and abstention rule returns either a ranked hypothesis or an abstention; it is not a clinically validated safety mechanism.

development, validation, and test sessions. Consequently, the demonstrated query is independent at the file level but cannot be considered an independent test set. Because data collection was still in progress, the reference set was intentionally treated as a proof-of-concept database rather than a statistically powered dataset.

Recommended acquisition conditions include a matte, uniform, high-contrast background; a perpendicular camera; limited glare; and one pill centered in the acquisition region. An ArUco marker from the DICT_4X4_50 dictionary, identifier 23, with a nominal printed side length of 20 mm, can be placed in the same plane as the pill. When detected, the mean marker-side length in pixels is divided by 20 mm to estimate pixels per millimeter. Size is omitted from the compatibility calculation when no valid scale is available.

C. Automatic and Manual Segmentation

The automatic pipeline first defines a central region of interest (ROI), corresponding to 76% of the image dimensions for still-image processing and 62% for the live camera guide. Marker polygons are expanded and masked so that the fiducial pattern does not compete with the pill contour.

The image is converted to the CIE Lab color space. Border pixels are used to estimate the median background color, and a per-pixel Euclidean distance from the background is calculated. Three candidate foreground signals are combined: 1) Otsu thresholding of the normalized Lab-distance image; 2) a robust threshold based on the median and median absolute deviation; and 3) Canny edges followed by region filling. Morphological opening, closing, and median filtering suppress isolated noise and bridge small contour gaps.

GrabCut refinement is initialized from the combined mask and the central ROI [18]. Candidate contours are rejected when their area is outside configured ROI-relative bounds. Remaining contours are scored using centrality, area plausibility, compactness, solidity, color contrast, and whether they touch the ROI boundary. The highest-scoring contour is filled and morphologically smoothed.

Automatic segmentation can fail when illumination is nonuniform, the object has low contrast, or the selected area contains a hand or large shadow. Therefore, the graphical interface includes manual ROI selection. In this mode, the user draws a rectangle around the pill; GrabCut is applied inside the selection, everything outside it is discarded, and the isolated object is placed on a uniform background before the normal processing pipeline resumes.

D. Internal Crop Heuristic

An internal crop heuristic $Q_h \in [0, 1]$ is calculated from contour centrality, solidity, compactness, foreground-background contrast, and boundary contact. This value is an engineering heuristic and not a percentage of segmentation quality, a Dice coefficient, or an intersection-over-union score because pixel-level ground-truth masks were not available. It serves two roles: warning the user about visibly poor crops and reducing the influence of physical descriptors when the segmentation is unreliable.

The quality modulation factor is

$$q = \mathrm{clip}\left(\frac{Q_h - 0.25}{0.65}, 0, 1\right). \tag{1}$$

Thus, physical measurements receive their full configured weight only when the internal crop heuristic is sufficiently high.

E. Crop Normalization and Visual Embeddings

The selected contour is cropped with a 16% margin around its bounding box, padded to a square, resized to 320×320 pixels, and placed on a neutral background. Contrast-limited adaptive histogram equalization is applied to the Lab lightness channel to reduce illumination variation while preserving chromatic channels.

Visual representations are extracted using MobileNetV2, a lightweight CNN based on inverted residuals and linear bottlenecks [17]. The ONNX network receives 224×224 RGB images normalized by ImageNet channel statistics. The output vector is flattened and L_2 normalized. Four embeddings are generated per face using rotations of $0°$, $90°$, $180°$, and $270°$, reducing sensitivity to in-plane orientation without training a new model.

For each query rotation, cosine similarity is calculated against the reference embeddings. The median of the strongest $k = 4$

reference similarities is retained. The two-face visual score for candidate c is

$$V_c = \max\left[\frac{v^{(c)}_{A,A} + v^{(c)}_{B,B}}{2}, \frac{v^{(c)}_{A,B} + v^{(c)}_{B,A}}{2}\right], \tag{2}$$

where the first term represents direct face correspondence and the second represents swapped correspondence.

F. Physical and Imprint Features

Shape is represented by aspect ratio, circularity, and solidity. Candidate similarity is calculated against the median and median absolute deviation of the reference class. Color is measured inside an eroded mask to reduce contamination from shadows and background pixels. The Lab a and b channels provide chromatic evidence, while relative lightness compares the pill interior with a local background ring. Optional width and height are estimated when the ArUco marker is available.

The physical score is a weighted mean over the available physical components,

$$P_c = \frac{\sum_{j\in\mathcal{A}} w_j s_{j,c}}{\sum_{j\in\mathcal{A}} w_j}, \tag{3}$$

where $\mathcal{A}$ contains only the available components and the nominal weights are 0.48 for shape, 0.42 for color, and 0.10 for size. Therefore, unavailable size is excluded from both numerator and denominator and does not impose an artificial 50% penalty.

Imprints are currently entered by the user rather than recognized automatically. Text is uppercased, accents and non-alphanumeric characters are removed, and visually confusable groups such as 0/O, 1/I/L, 2/Z, 5/S, and 8/B are normalized before fuzzy string comparison. The direct and swapped face assignments are evaluated, and the larger two-face imprint score is retained. If both the observed and expected imprints are blank, the interface may display agreement; however, the imprint component is not included in the total score unless the user actually enters an imprint. Automatic optical character recognition remains future work.

G. Dynamic Compatibility Index

The compatibility index for candidate c combines visual, imprint, and physical evidence:

$$S_c = w_v(Q_h)V_c + w_i I_c + w_p(Q_h)P_c. \tag{4}$$

When an imprint is supplied, the nominal weights are 0.55 for visual evidence, 0.30 for imprint, and 0.15 for physical evidence. The physical weight becomes $0.15q$, and its unused portion is transferred to the visual component. Without an imprint, the nominal weights are 0.78 visual and 0.22 physical; the physical weight becomes $0.22q$, and $w_v = 1 - w_p$. This design prevents uncertain contours from producing excessive influence through color or shape.

The fusion weights and decision thresholds used in the present prototype were selected heuristically during iterative engineering development. They were not optimized, calibrated, or statistically derived from an independent validation set, and complete independence between parameter selection and previously observed development behavior cannot be guaranteed. Accordingly, these values are operating rules for the prototype and must not be interpreted as clinically validated thresholds or as controlling a known false-accept rate.

The compatibility index is a deterministic similarity score, not a calibrated posterior probability. Modern neural-network scores can be poorly calibrated even when classification performance is high [21]; consequently, percentages shown by the interface are explicitly labeled as compatibility rather than confidence or probability.

H. Decision and Abstention Rule and User Interface

Candidates are ordered by S_c. Let $\Delta = S_{(1)} - S_{(2)}$ denote the margin between the first and second candidates. Without an imprint, the current prototype accepts a possible match only when $S_{(1)} \geq 0.86$, $\Delta \geq 0.075$, $V_{(1)} \geq 0.82$, and $Q_h \geq 0.55$. With an imprint, the corresponding thresholds are 0.80, 0.045, 0.74, and 0.55. At least two classes must exist in the reference database before any result can be accepted. These configured thresholds implement the intended abstention behavior but have not been validated as a clinical safety mechanism.

When one or more conditions fail, the system still displays the highest-ranked candidate but labels it as an unconfirmed hypothesis. The graphical interface supports camera capture, stored images, face-specific manual cropping, optional imprint fields, ranked candidate details, an annotated image with contour and label, and text-to-speech output. Every output includes a warning not to use the result as the sole basis for medication ingestion. When metric size is unavailable, the revised interface displays "not evaluated" rather than the neutral 50% placeholder used in the development build shown in Fig. 2.

IV. Case Demonstration

A. Two-Class Query

A query was performed using two images of a Simethicone 40 mg—Neo Quimica white tablet. The two query files were distinct from the reference images. Manual cropping was applied to both faces. No imprint was entered. The system compared the query with the two presentations in the database and produced the results in Table I. The internal crop heuristic was $Q_h = 0.977$, corresponding to $q = 1$ after clipping in (1). This value is not a validated segmentation-accuracy percentage.

TABLE I
Two-Class Candidate Ranking in the Case Demonstration

Component	Simethicone 40 mg	Paracetamol 750 mg
Visual similarity V_c	0.860	0.728
Shape similarity H_c	0.719	0.214
Color similarity C_c	0.682	0.582
Size similarity Z_c	unavailable	unavailable
Internal crop heuristic Q_h	0.977	0.977
Compatibility index S_c	**0.825**	0.653
Rank	**1**	2

Because size was unavailable, the physical score was renormalized over shape and color. For simethicone,

$$P_{\text{sim}} = \frac{0.48(0.719) + 0.42(0.682)}{0.90} = 0.702, \tag{5}$$

and

$$S_{\text{sim}} = 0.78(0.860) + 0.22(0.702) = 0.825. \tag{6}$$

For paracetamol, the same calculation produced approximately 0.653. The first-to-second margin was 0.172, exceeding the no-imprint margin requirement of 0.075. The visual and internal-crop-heuristic requirements were also met. However, the winning total score remained below the no-imprint threshold of 0.86; therefore, the system correctly returned "principal hypothesis: Simethicone 40 mg—Neo Quimica" while retaining the "not confirmed" warning.

B. Interpretation of the Preliminary Scores

The visual embedding provided the strongest discriminatory signal, with an 86.0% visual similarity for simethicone versus 72.8% for paracetamol. The shape and color components also favored simethicone. The candidate margin shows that the expected class was ranked above the only alternative in this specific example. Nevertheless, this case cannot be interpreted as classification accuracy, sensitivity, specificity, or clinical performance. It is a single demonstration in a closed two-class database and does not assess unknown pills, additional manufacturers, damaged products, lighting variation, or independent users.

The abstention is therefore a desirable result rather than a failure. A system designed for medication support should avoid transforming a plausible match into an apparently definitive statement. This aligns with broader recommendations that health-related AI systems should prioritize safety, transparency, human oversight, and accountability [22].

V. Discussion

The preliminary experiment demonstrates that a hybrid, reference-based approach can provide a meaningful ranking with very limited class-specific data. This differs from a conventional supervised classifier that requires retraining when a new presentation is added. In the current design, a new class can be enrolled by adding metadata and reference images, after which embeddings and physical features are appended to the reference database.

The current reference set contains the same number of images for both enrolled presentations (300 images per class, 150 per face). Even with this balanced reference count, the present case does not quantify how reference density would affect performance as the database expands. In addition, no baseline or ablation experiments were performed; the contribution of two-face matching, physical cues, and crop-quality weighting therefore remains to be measured in an independent study.

The use of two faces is particularly important. Imprints, score lines, coatings, and logos may differ across sides, and a one-sided query can discard useful evidence. Direct and swapped matching also reduces user-interface error because the user does not need to know which side was labeled A during enrollment. This design is consistent with low-shot pill-recognition datasets that treat the two sides as separate appearance classes [10].

The case also illustrates why the compatibility value should not be described as a probability. The result is generated by a configured fusion rule, and its numerical scale depends on reference density, feature distributions, and threshold choices. Before deployment, the score would need calibration on a representative validation set, including known classes and unknown products. Calibration metrics and reliability diagrams should complement top-k classification results [21].

Segmentation remains the most immediate engineering limitation. The internal crop heuristic reached $Q_h = 0.977$ in the presented case, yet visual inspection still showed that the contour included some surrounding background. This discrepancy occurs because the indicator measures internal geometric and contrast heuristics rather than overlap with a human-annotated ground truth and therefore must not be interpreted as 97.7% segmentation accuracy. Future segmentation evaluation should use pixel-level masks and report intersection over union and Dice coefficient. The recent MEDISEG work is relevant because it provides instance masks under clutter, overlap, varied backgrounds, and reflective conditions [15].

The current physical features are interpretable and useful for error analysis. For example, the paracetamol candidate received a markedly lower shape similarity than simethicone. However, physical descriptors can also amplify acquisition bias: Lab color changes under illumination and white balance, apparent dimensions depend on perspective, and shape descriptors change when the contour includes shadows. The dynamic weighting mechanism mitigates but does not eliminate these risks.

The current system requires user-entered imprint text. This approach avoids premature dependence on OCR, but it limits usability. Pill imprints can be embossed, debossed, curved, partially occluded, low-contrast, or rotated. Future work should evaluate geometry-aware OCR and should preserve uncertainty rather than forcing a text string. The regulatory rationale for imprint use remains strong because the combination of imprint, size, shape, and color is designed to support unique identification [5].

For the Brazilian context, the FDA imprint framework is used only as international background. Anvisa regulations and official consultation systems govern Brazilian medication labeling and access to registered product information [3], [4]. Therefore, a future Brazilian deployment must preserve confirmation through packaging, official Anvisa information, manufacturer data, or a qualified health professional.

VI. Limitations and Risk Considerations

The present study has several important limitations.

First, the database includes only two enrolled presentations, with 300 reference images for each class. A two-class ranking is much easier than retrieval among hundreds or thousands of visually similar products. Second, the result is based on one

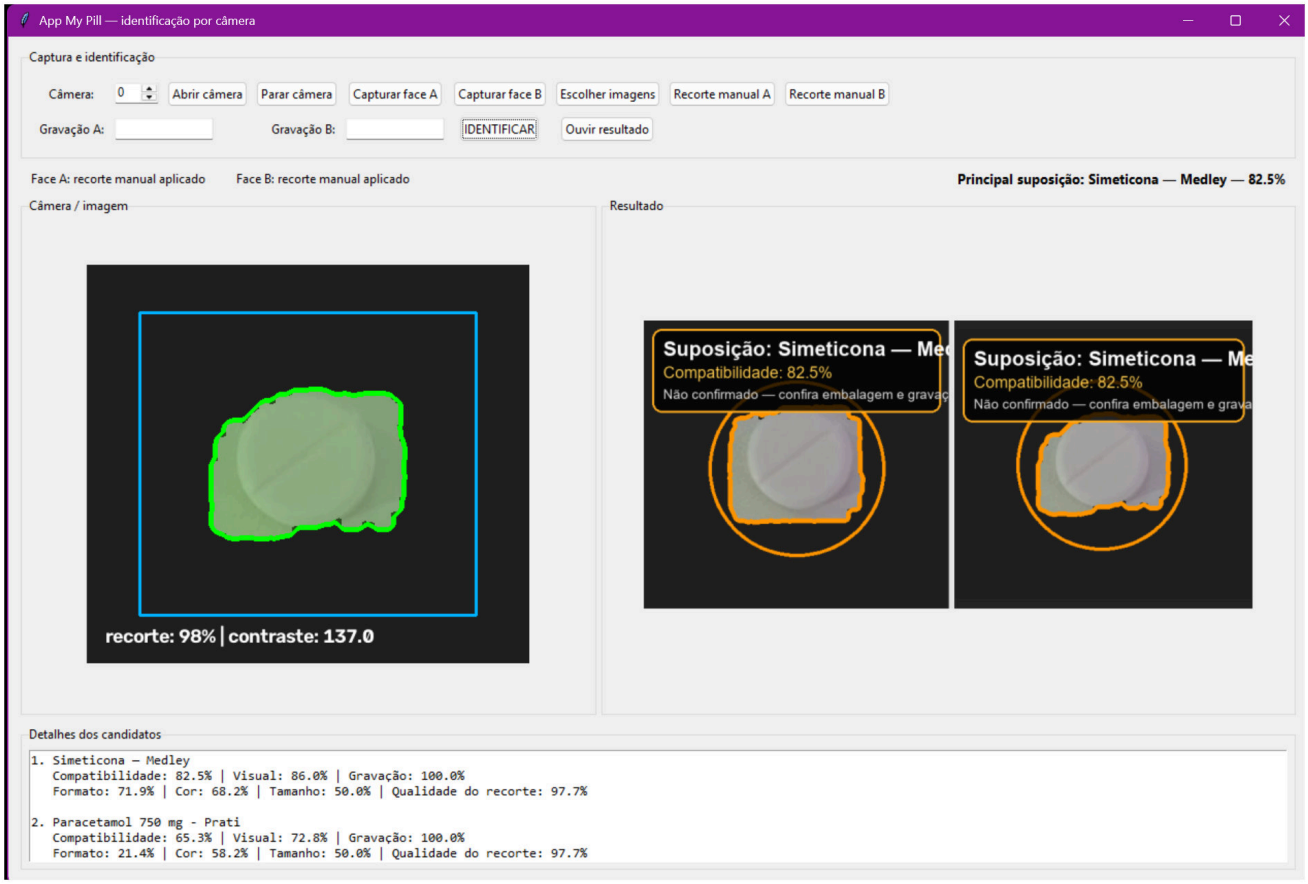

Fig. 2. Prototype interface during the simethicone case demonstration. The expected class was ranked first at 82.5%, but the result remained unconfirmed because the predefined no-imprint acceptance threshold was not reached. The interface is shown in Portuguese, the language used during prototype development. The screenshot corresponds to the development build, in which unavailable size was displayed as a neutral 50%; the revised interface displays this field as "not evaluated."

query case and cannot support any statistical performance claim. Third, all images were acquired with a Samsung Galaxy A51, and although the query files were distinct from the reference files, development, validation, and test acquisitions were not prospectively separated by session. Fourth, the internal crop heuristic has not been validated against annotated masks. Fifth, size information was unavailable in the demonstrated case; the neutral 50% placeholder visible in the development-build screenshot is not used in the compatibility calculation and has been replaced by "not evaluated" in the revised interface.

Sixth, the prototype operates in a closed-set manner: every query is ranked against enrolled classes, even when the true product is absent. Although threshold-based abstention reduces risk, robust open-set recognition requires dedicated unknown-class evaluation. Seventh, the MobileNetV2 representation was pretrained on natural images rather than pharmaceutical imagery and was not fine-tuned on a representative pill dataset. Eighth, color and shape alone cannot guarantee unique identification. Ninth, product appearance can change with manufacturer, market, dose, coating, storage, damage, or counterfeit status.

Finally, the software is a research prototype and has not undergone clinical evaluation, usability validation, cybersecurity assessment, regulatory classification, or quality-system development. WHO guidance emphasizes that AI for health should embed ethics and human rights throughout design and deployment [22]. Accordingly, any future practical version should remain an assistive tool, clearly communicate uncertainty, protect user data, preserve traceability, and require confirmation through original packaging, an authoritative database, or a qualified health professional.

VII. Proposed Validation Protocol

A subsequent study should separate enrollment, validation, and test images by acquisition session and, where possible, by device and user. The number of classes should be expanded to include visually confusable presentations, multiple manufacturers, multiple doses, and negative or unknown samples. Baselines should include visual-only, physical-only, and one-face retrieval, while ablations should remove two-face matching, physical cues, and crop-quality weighting one component at a time. Table II summarizes the proposed evaluation framework.

Thresholds should be chosen on the validation set according to a safety objective rather than maximum overall accuracy. For example, the system may prioritize a low false-accept

TABLE II
PROPOSED EVALUATION FRAMEWORK FOR THE NEXT DEVELOPMENT PHASE

Domain	Primary Measures	Recommended Stress Conditions
Segmentation	Intersection over union, Dice coefficient, boundary error, failure rate	Low contrast, hard shadows, reflective coatings, hands, clutter, partial occlusion, different backgrounds
Recognition	Top-1 and top-3 accuracy, macro precision, recall, F1 score, confusion matrix	Similar color/shape classes, different doses, manufacturers, front/back swaps, damaged imprints
Open-set safety	Unknown-detection AUROC, false-accept rate, false-reject rate, risk-coverage curve	Non-enrolled pills, vitamins, candy, fragments, counterfeit-like samples
Calibration	Expected calibration error, Brier score, reliability diagram	Device shift, illumination shift, background shift, reference-count variation
Robustness	Performance stratified by device, user, orientation, scale, and lighting	Independent smartphones, camera resolutions, indoor/outdoor illumination, motion blur
Baselines and ablations	Same recognition and risk-coverage measures	Visual-only, physical-only, one-face, two-face, full fusion; remove physical cues, swapped matching, or crop-quality weighting
Usability	Task completion, capture failure, time, comprehension of warnings, trust calibration	Patients, caregivers, pharmacists, older adults, users with visual or motor limitations
Efficiency	End-to-end latency, memory, CPU use, database growth	Offline CPU inference, increasing class count, mobile-device deployment

rate and tolerate more abstentions. External testing should then be conducted without changing the selected thresholds. Recent evidence on few-shot pill recognition under domain shift reinforces the need for deployment-oriented testing rather than only within-dataset evaluation [16].

Source code, YAML configuration files, model-identification information for MobileNetV2-10 ONNX, and reproducibility instructions are retained by the authors and can be provided with the research materials. The current image collection was produced during prototype development and is not presented as a public benchmark dataset.

VIII. FUTURE WORK

The next technical phase will focus on five areas. First, the reference database will be expanded and versioned with standardized metadata. Second, segmentation will be evaluated against human masks and may be replaced or augmented by a lightweight learned model. Third, automatic imprint extraction will be investigated using orientation-aware OCR. Fourth, the compatibility score will be calibrated and extended with explicit open-set detection. Fifth, the desktop proof of concept will be translated into a mobile architecture with offline inference, accessibility functions, and auditable result logs.

A clinically relevant study will require collaboration with pharmacists and medication-safety specialists. Ground-truth labels should originate from verified packaging, regulatory records, or manufacturer data. The evaluation should also consider the difference between identifying an active ingredient and uniquely identifying a presentation. The latter requires strength, manufacturer or distributor, and physical appearance information, as reflected in imprint regulation [5].

IX. CONCLUSION

App My Pill demonstrates the feasibility of a low-data, reference-based pipeline for preliminary loose-pill matching. The system combines two-sided MobileNetV2 embeddings, physical descriptors, optional imprint evidence, internal-crop-heuristic-aware weighting, and a predefined decision and abstention rule. In the initial two-class case, simethicone was ranked above paracetamol with a 17.2 percentage-point margin, but the system abstained because the total compatibility did not meet the no-imprint threshold. This behavior illustrates the intended distinction between a useful hypothesis and an unsafe assertion.

The current case demonstration does not establish accuracy or clinical utility. The principal contribution is the transparent architecture and the definition of a validation pathway. Expansion to representative datasets, open-set evaluation, calibrated scores, ground-truth segmentation, device-shift testing, and professional confirmation will be essential before the approach can support real medication-safety workflows.

ACKNOWLEDGMENT

The authors acknowledge the institutional environments that support the development of interdisciplinary projects in biomedical engineering, computer vision, and pharmaceutical safety.

***Abstract*—Independent feeding is a fundamental activity of daily living associated with autonomy, dignity, and social participation. Motor and cognitive impairments may affect utensil handling and functional performance during meals, particularly in individuals with multiple disabilities. This study aimed to evaluate the interaction with assistive cutlery among institutionalized adults with multiple motor and cognitive disabilities during real-life feeding situations and to discuss the findings in relation to previous literature. A qualitative, descriptive, and observational study was conducted with 16 adults selected from an initial group of 30 individuals based on their ability to use the spoon independently, sufficiently understand the proposed activity, and agree to participate. Two assistive spoon models, with stainless-steel and polypropylene handles, were evaluated during usual meals. Observations included grasp patterns, food spillage, need for assistance, adaptation, sensory aspects, and material preferences. Most participants accepted using both assistive spoon models and showed different grasp and adaptation strategies. Some participants appeared to show better food control, although this was not quantitatively measured. Fourteen of the 16 participants (87.5%) preferred the polypropylene-handled spoon, mainly due to thermal and tactile comfort and familiarity. The findings highlight the importance of considering motor, cognitive, sensory, and contextual factors when evaluating assistive technologies under real-life conditions.**

***Index Terms*—Assistive technology, feeding, multiple disabilities, rehabilitation, user-centered design.**

I. Introduction

The ability to eat independently plays an important role in maintaining autonomy, dignity, and social participation in daily life. For individuals with motor impairments, tremor, rigidity, and coordination difficulties may affect utensil handling and compromise performance during meals.

In individuals with Parkinson's disease, Pagnussat et al. [1] identified difficulties related to food spillage and grasp instability, as well as preferences for specific utensil characteristics, including texture, weight, and shape. Other studies have proposed different solutions to support feeding, including intelligent systems and utensils designed for movement stabilization and tremor compensation [2-6].

Despite these advances, studies conducted during real-life feeding situations involving individuals with multiple disabilities remain less frequent. In this population, motor and cognitive impairments may coexist and influence utensil handling, acceptance, and adaptation. The institutional setting also presents specific characteristics related to feeding routines, different levels of assistance, and everyday interaction with support resources.

In this context, observing the use of assistive cutlery in the usual feeding environment may complement assessments performed under controlled conditions or based only on users' perceptions. In addition to performance during handling, grasp patterns, need for assistance, material preferences, and individual responses may contribute to understanding the interaction between the user and the product.

II. Methodology

This qualitative, descriptive, and observational study was conducted at the Pequeno Cotolengo Health Complex, a

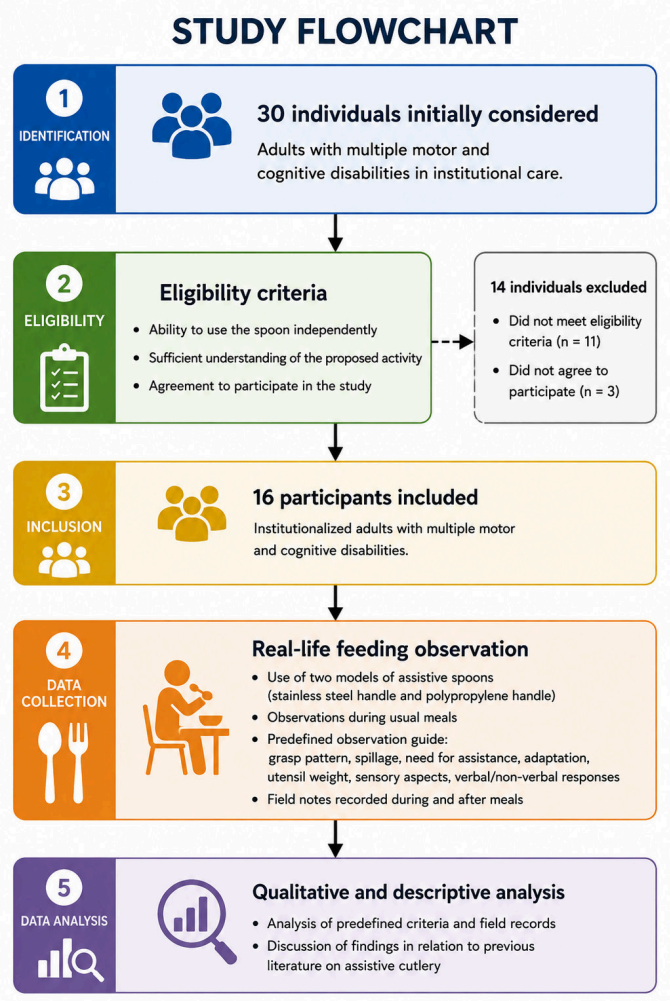

Fig. 1. Study flowchart.

long-term care institution for individuals with multiple disabilities. The study evaluated participants' interaction with assistive cutlery during real-life feeding situations in their usual environment. The study was approved by the Research Ethics Committee involving human subjects under protocol no. 7,752,165 and CAAE no. 90038025.2.0000.0177.

A. Participants and Procedures

Initially, 30 institutionalized adults with multiple motor and cognitive disabilities and different levels of functional impairment were considered for participation. The final sample included 16 participants who were able to use the spoon independently, sufficiently understand the proposed activity, and agreed to participate. The participants presented heterogeneous motor and cognitive conditions, including different degrees of upper-limb impairment, altered grasp patterns and, in some cases, dysphagia. Verbal communication was not required for participation. Given the heterogeneity of the sample, the study did not aim to establish associations between the findings and specific clinical diagnoses.

Fig. 2. Assistive spoon models evaluated in the study.

Two models of assistive spoons developed by a Brazilian company were evaluated: one made entirely of stainless steel with an adapted handle, and another consisting of a stainless-steel bowl and a polypropylene handle (Fig. 2). The spoon was selected because it can be used with different food consistencies commonly present in the institutional routine and provides greater food containment during transport to the mouth.

The utensils were presented as a new assistive cutlery option, without formal training for their use. Observations were conducted during usual meals in the participants' everyday environment and were performed by the same researcher. The use of a single observer resulted from the operational conditions of the study, in which including and training external observers was not feasible. Maintaining the same researcher allowed the same observation criteria to be applied throughout data collection, although it does not eliminate the subjectivity inherent to direct observation and prevented the assessment of inter-observer agreement.

A predefined observation guide included grasp pattern, preference between handle materials, food spillage and possible changes compared with usual feeding behavior, need for assistance, perception of utensil weight and, for participants able to communicate verbally, impressions and suggestions for product modifications. The main observational domains are summarized in Fig. 3.

Notes were recorded during the observations and completed immediately after each meal. Spontaneous manifestations were also documented, including individual adaptation strategies, behavioral and non-verbal responses, and preferences not initially included in the observation guide. Some observations were subsequently discussed with members of the multidisciplinary team and caregivers familiar with the participants' routines, helping to contextualize their usual feeding behavior.

B. Data Analysis

Data were analyzed qualitatively and descriptively, considering both the predefined observation criteria and aspects identified in the field records. The analysis focused on grasp patterns, food spillage, need for assistance, adaptation to motor

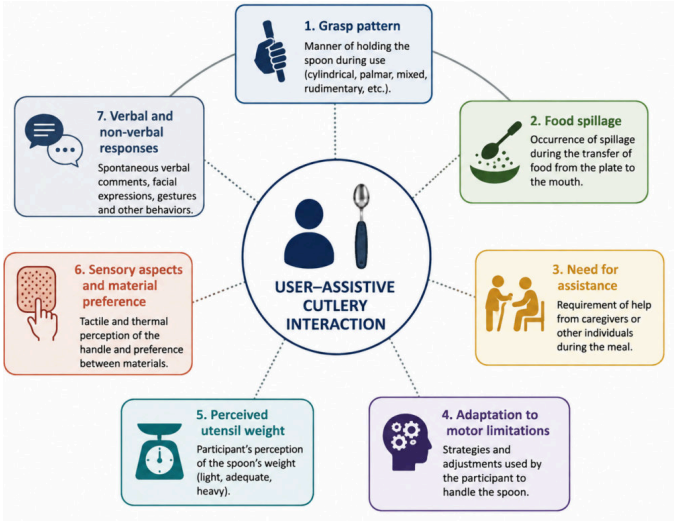

Fig. 3. User–assistive cutlery interaction model and main observational domains.

limitations, perception of utensil weight, material preferences, and individual responses during use.

The findings were discussed in relation to previous literature on assistive cutlery, including studies involving individuals with Parkinson's disease. However, differences in diagnosis, motor and cognitive impairment, functional independence, and context of use were considered in the interpretation. Therefore, the literature was used to identify points of convergence and contrast rather than as a direct comparison between equivalent populations.

III. Results and Discussion

Overall, most participants accepted using both assistive spoon models and showed different adaptation strategies during use. The heterogeneity of the sample was particularly evident in grasp patterns, sensory responses, and the way each participant interacted with the utensils during usual meals. The main observational findings and their relationship with aspects previously reported by Pagnussat et al. [1] are summarized in Table I.

Regarding food spillage, some participants who usually experienced food loss while moving the spoon from the plate to the mouth appeared to show better food control when using the assistive spoons. However, spillage episodes were not quantified, and no instruments were used to measure tremor or motor stability. Therefore, these findings should be interpreted as functional changes observed under real-life conditions and do not allow an objective reduction in food spillage or improvement in motor stability to be established. Previous studies have used different strategies to evaluate utensils designed to compensate for tremor during feeding [2]–[4], reinforcing the importance of objective measures in future assessments.

Variability in grasp patterns was also relevant. Participants with upper-limb impairments or deformities used different strategies to handle the spoons, including cylindrical and more

TABLE I
Observational Findings in Relation to Previous Literature

Aspect	**Pagnussat et al. [1]**	**Present Study**
Food spillage	Reported as a difficulty by users	Apparent improvement in food control in some participants; not quantitatively measured
Grasp	Difficulties in utensil handling	Different grasp and adaptation strategies, including cylindrical and rudimentary patterns
Motor aspects	Tremor affected utensil handling	Different motor limitations were observed; tremor and stability were not objectively measured
Assistance	Not the main focus	Generally similar to the assistance usually required during meals
Design and material	Texture, weight, size, and depth influenced preferences	14 of 16 participants (87.5%) preferred the polypropylene handle; thermal and tactile comfort and familiarity were relevant
User profile	Individuals with Parkinson's disease	Institutionalized adults with multiple motor and cognitive disabilities
Dysphagia	Not the study focus	Present in part of the sample; not evaluated as an outcome

rudimentary grasp patterns. These adaptations indicate that utensil use does not depend exclusively on a conventional grasp and reinforce the importance of considering individual characteristics when developing assistive technologies for neurologically heterogeneous populations [5].

Most participants maintained a level of assistance similar to that usually required during meals. Since this aspect was not assessed using a standardized scale, a quantitative gain in autonomy resulting from utensil use cannot be established.

Fourteen of the 16 participants (87.5%) preferred the spoon with the polypropylene handle. Perceived weight, handle shape, and ease of grasping may also have contributed to this preference. Pagnussat et al. [1] identified texture, size, weight, and utensil depth as relevant characteristics for individuals with Parkinson's disease, indicating that user experience is influenced by both functional and sensory characteristics of the product.

Cognitive factors also appeared to influence interaction. Although most participants accepted trying the utensils, one participant showed lower adherence, which, within the observed context, was associated with difficulty accepting changes in the usual feeding routine. Since no specific cognitive assessment instruments were applied, this relationship should be interpreted as a contextual observation rather than a demonstrated association.

The presence of dysphagia in some participants should also be considered. Feeding performance in this population involves factors beyond utensil manipulation, including eating pace, food consistency, swallowing safety, and need for super-

vision. Therefore, changes observed in grasp or food transport should not be interpreted as improvements in swallowing safety.

Comparison with Pagnussat et al. [1] requires caution because the two studies involved populations with different clinical and functional characteristics. While their study focused on individuals with Parkinson's disease, the present sample consisted of institutionalized adults with multiple motor and cognitive disabilities. The previous findings were therefore used to identify points of convergence and contrast rather than to establish direct equivalence between the populations.

Recent studies also illustrate the value of combining user perceptions with objective measures. Rosa et al. [6], for example, evaluated assistive cutlery using structured satisfaction assessment, video recordings, and kinematic analysis. In contrast, the present study prioritized spontaneous interaction under real-life institutional conditions. These approaches may be complementary: direct observation allowed individual adaptation strategies, non-verbal responses, and preferences to be identified, while standardized instruments and quantitative measures may improve the objectivity and comparability of future assessments.

A. Limitations, Lessons Learned, and Research Gaps

The main limitations of this study include the small and heterogeneous sample from a single institution, the use of a single observer, and the absence of standardized instruments and quantitative performance measures. Although maintaining the same observer provided a consistent observational perspective throughout data collection, inter-observer agreement could not be assessed. Meal duration, number of spillage episodes, grasp efficiency, and perceived effort were also not quantified. These limitations prevent conclusions regarding the clinical effectiveness of the utensils and restrict the generalizability of the findings.

Despite these limitations, the study provided relevant lessons from real-life use. Interaction with the utensils appeared to involve not only motor limitations but also cognitive and sensory factors, familiarity with the materials, and individual grasp strategies. Direct observation was particularly useful for participants with limited verbal communication, since spontaneous choices, behavioral responses, and individual adaptations complemented the predefined observation guide.

Future studies should include larger and multicenter samples, characterization according to motor and cognitive profiles, validated usability and satisfaction instruments, and quantitative performance measures. Longitudinal assessments and comparisons with other assistive cutlery models may also help determine whether acceptance and preferences are maintained over time. Combining real-life observation with objective measures, as demonstrated in recent assistive cutlery research [6], may improve the comparability of findings and support the development of solutions better suited to users' needs.

IV. Conclusion

This study evaluated the interaction of institutionalized adults with multiple motor and cognitive disabilities with two models of assistive spoons under real-life feeding conditions. Participants showed different grasp and adaptation strategies, and most accepted using both assistive spoon models. Fourteen of the 16 participants (87.5%) preferred the polypropylene-handled model, mainly in relation to thermal and tactile comfort and familiarity with the material.

The findings indicate that motor, cognitive, sensory, and contextual factors should be considered when evaluating and developing assistive technologies for feeding. Due to the qualitative and exploratory nature of the study, the results do not establish the clinical effectiveness of the utensils but provide information from real-life use that may support future studies using standardized instruments and objective performance measures.

Acknowledgment

The authors would like to thank the Universidade Tecnológica Federal do Paraná (UTFPR – Curitiba) for providing the resources necessary for the development of this project. The authors also acknowledge the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) for supporting the Junior Scientific Initiation Scholarship (PIBIC-EM), and Fundação Araucária and the Superintendência de Ciência, Tecnologia e Ensino Superior (SETI) for providing conference grants to H. C. C. and F. S. B. The assistive cutlery used in this study was donated by Tramontina S.A.

***Abstract*—Brazilian Sign Language (LIBRAS) is a vital means of communication for the Deaf community, with signed alphanumeric spelling serving as a fundamental resource for spelling out proper names, acronyms, and specific terms. However, few accessible assistive technology solutions are designed to physically reproduce the alphanumeric characters used in this context. This paper presents the development of an assistive upper-limb system for signed alphanumeric spelling, based on a 3D-printed robotic hand controlled by an ESP32 microcontroller and operated via a mobile app over Bluetooth. The system was developed using the open-source DexHand V1.0 platform, which was adapted to simplify the mechanics, reduce costs, and improve reproducibility. The results demonstrated the feasibility of reproducing signed alphanumeric spelling, highlighting the solution's potential as an assistive, educational, and research tool.**

***Index Terms*—Brazilian Sign Language - LIBRAS, assistive robotics, signed alphanumeric spelling, 3D printing, embedded systems.**

I. Introduction

Communication is a key element for social inclusion and access to knowledge. In this context, LIBRAS plays a fundamental role for the Brazilian Deaf community, as it is legally recognized as a means of communication and expression. Among its linguistic features, signed alphanumeric spelling stands out; it represents letters and numbers through specific hand configurations [1, 2].

LIBRAS is a full natural language rather than a simple gestural code: linguistic descriptions identify five parameters that combine to form each sign, namely hand configuration, place of articulation, movement, palm orientation, and non-manual markers such as facial expressions, all of which contribute to meaning [2]. Signed alphanumeric spelling relies mainly on hand configuration and is used chiefly to spell proper names, acronyms, and terms without a conventional sign [1]. Accordingly, the system presented here does not aim to replace LIBRAS communication or to reproduce the language in full; it targets a delimited, hand-configuration-based subset of the language, intended as a technological resource for teaching, demonstration, and research on signed alphanumeric spelling.

Visual aids, repetition, and imitation activities play a central role in instruction, helping the learner perceive hand configuration, articulation point, movement, and palm orientation—elements whose correct articulation defines the meaning of the sign [3, 4]. From a pedagogical standpoint, this approximates a multimodal reinforcement approach: the student observes, imitates, corrects, and repeats until the gesture is stabilized—a process particularly useful for signs that differ only by slight formal variations.

Although digital applications for teaching LIBRAS exist, solutions that can physically reproduce the gestures associated with signed alphanumeric spelling remain limited.

Tantum 1 [5] is an assistive robotic hand developed to support tactile sign interpretation for deafblind individuals. [6] details the specifications of the initial Tantum 1 prototype, featuring 15 servomotors controlled by an Arduino Mega microcontroller, along with a cloud service that converted text into movement instructions for the servomotors to reproduce American Sign Language signs.

The Sign-Representing Robotic Hand (MAR2S), developed by [7], is based on the open-source InMoov model and utilizes five servomotors controlled by a Raspberry Pi 3 Model B microcontroller.

Given this context, this study proposes developing a robotic assistive system capable of reproducing alphanumeric characters using the manual alphabet of LIBRAS, leveraging accessible technologies, an open architecture, and low implementation costs.

II. Materials and Methods

The developed system integrates three main subsystems: (1) a 3D-printed five-finger robotic upper limb based on the open-source DexHand V1.0 platform [8]; (2) an embedded control system based on the ESP32-WROOM-32D microcontroller with Bluetooth Low Energy (BLE); and (3) an iOS mobile

application developed in Flutter that communicates wirelessly with the microcontroller via the GATT protocol. Control flows from the mobile application to the microcontroller over BLE, which then drives all servomotors. Fig. 1 shows the system diagram, whereas Fig. 2 details system architecture.

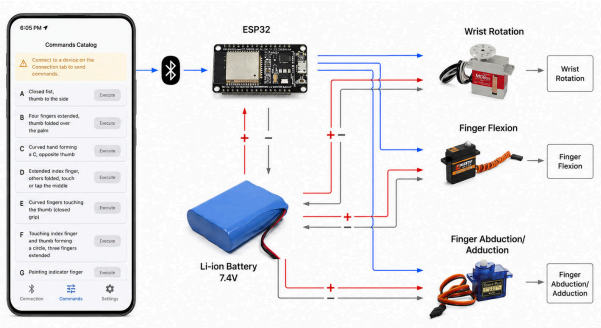

Fig. 1. System diagram.

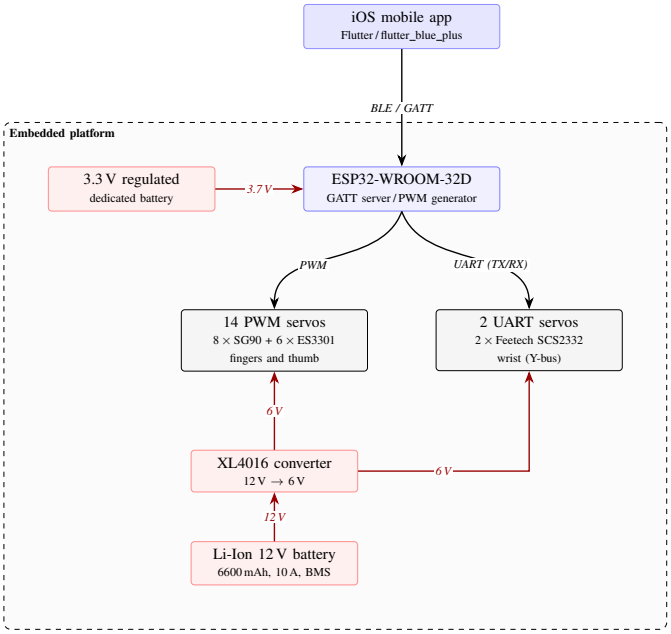

Fig. 2. System architecture.

A. Mechanical Platform: DexHand V1.0

The DexHand V1.0 [8] is an open-source, 3D-printed robotic hand employing up to 19 servomotors, nylon strings, and return springs distributed across five independent fingers and a wrist. Each main finger—index, middle, ring, and little—is driven by three servos: two TowerPro SG90 mounted at the metacarpal level for abduction/adduction, actuating a nylon string through a bearing in the proximal phalanx; and one Emax ES3301 housed in the forearm for flexion, via a string through internal channels across all three phalanges—extension is recovered by return springs. The thumb attaches to a support piece at the base of the middle finger and uses four ES3301s in the forearm for adduction, abduction, opposition, and flexion. Two Feetech SCS2332 in the forearm drive wrist flexion/extension and abduction/adduction. The overall mechanical structure is illustrated in Fig. 3 and the specifications and comparison of the three servo models are shown in Table I.

The body parts are fabricated using additive manufacturing (3D printing) with polylactic acid (PLA), the most common material for low-cost functional prototypes. Compared to acrylonitrile butadiene styrene (ABS), PLA offers better dimensional accuracy due to its lower coefficient of thermal expansion, which is critical for the tight tolerances required by finger joints and servo mounting cavities.

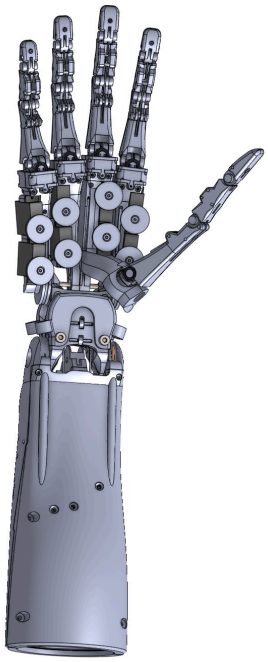

Fig. 3. CAD model: DexHand V 1.0 [8].

TABLE I
SERVO MOTOR SPECIFICATIONS.

Feature	SG90	ES3301	SCS2332
Type	Analog	Analog	Smart digital
Control	PWM	PWM	Serial
Torque	1.8kg·cm	2.2kg·cm	4.5kg·cm
Weight	9g	10.6g	20g
Gears	Plastic	Eng. plastic	Metal
Range	180°	180°	300°

B. Electronic Hardware

The hardware is based on the ESP32-WROOM-32D microcontroller, which simultaneously manages all actuators. Table II lists the main system components.

The servo power supply uses a 12V Li-Ion battery pack, stepped down to 6V by the XL4016 DC-DC converter, and is compatible with all three servo types. The ESP32 is

TABLE II
ELECTRONIC SYSTEM COMPONENTS.

Component	Qty.
ESP32-WROOM-32D microcontroller	1
TowerPro SG90	8
Emax ES3301	6
Feetech SCS2332	2
Li-Ion battery 12V, 6600mAh	1
XL4016 DC-DC step-down (12V → 6V)	1
3.7V battery (ESP32)	1
Custom PCB board	1
1 kΩ UART conditioning resistor	1
4700 μF electrolytic capacitor	1
100 nF electrolytic capacitor	5
AWG20 power wiring / AWG24 signal wiring	–

powered by a dedicated 3.7V rechargeable battery through its internal 3.3V regulator, isolating the logic supply from servo current transients. Of the 16 servomotors, 14 (8×SG90 and 6×ES3301) are controlled individually via PWM signals generated by ESP32 GPIO pins. The two Feetech SCS2332 wrist servos use half-duplex UART communication (GPIO16 RX, GPIO17 TX) on a shared Y-bus; each servo has a unique internal ID allowing independent addressing on the same bus. A 1kΩ resistor on the UART line limits current and improves signal integrity. A 4700μF bulk capacitor at the power input and five 100nF local capacitors distributed near the servo connectors reduce voltage drops and noise during simultaneous actuation.

Two changes distinguish this implementation from the original DexHand V1.0. First, motion commands in the original design are issued either by a radio receiver or by a computer running computer-vision hand tracking, relayed over serial to an Arduino Mega 2560 Pro; in this work, that microcontroller and its external vision/radio peripherals were replaced by a single ESP32-WROOM-32D, which provides native BLE connectivity and is driven directly by the mobile application (Section II-C). Second, the two ES3301 servos originally assigned to thumb abduction/adduction were removed: this motion can be reproduced through the combination of flexion, extension, and opposition without loss of the alphanumeric signs implemented, reducing the active actuator count from 19 to 16 while the 18-channel command protocol retains two reserved channels for compatibility with the complete architecture.

C. Firmware

The firmware (C++, Arduino framework) configures the ESP32 as a BLE GATT peripheral with a control service and a write characteristic, both of which share fixed UUIDs with the mobile application. The central concept of the command protocol is an 18-element array of joint angles (in degrees) that fully encodes a hand configuration. The array is structured in fixed groups: indices 0–11 encode the four fingers in triplets (pitch, yaw, and tip flexion for index, middle, ring, and little, respectively); indices 12–15 encode the thumb (pitch, yaw, tip, roll); indices 16–17 encode the wrist (pitch, yaw). This ordering is summarized in Table III.

TABLE III
DATA PACKET STRUCTURE AND ACTUATOR MAPPING.

Bytes	Group / DOF	Servos
0–2	Index: pitch, yaw, tip	2 SG90 + 1 ES3301
3–5	Middle: pitch, yaw, tip	2 SG90 + 1 ES3301
6–8	Ring: pitch, yaw, tip	2 SG90 + 1 ES3301
9–11	Little: pitch, yaw, tip	2 SG90 + 1 ES3301
12–15	Thumb: pitch, yaw, tip, roll	4 ES3301 (2 active)
16–17	Wrist: pitch, yaw	2 SCS2332
18	Checksum (mod-256 sum)	—

Table IV shows the configuration vectors for two sign examples. In vector **A**, all four finger triplets share `pitch = 25°` and `tip = 180°` (fully curled); index 12 sets thumb `pitch = 90°` (vertically extended); indices 16–17 keep the wrist neutral. Letter **B** contrasts with all fingers extended (`tip = 20°`) and the thumb repositioned (`yaw = 120°`, `tip = 100°`). Defining or modifying a sign requires only editing its array—no firmware changes are needed.

TABLE IV
CONFIGURATION VECTORS FOR TWO SIGN EXAMPLES.

Sign	18-angle vector (degrees)
A	`[25, 0, 180, 25, 0, 180, 25, 0, 180, 25, 0, 180, 90, 0, 0, 0, 0, 0]`
B	`[0, 0, 20, 0, 0, 20, 0, 0, 20, 0, 0, 20, 90, 120, 100, 0, 0, 0]`

Before transmission, each angle is encoded into a single byte to comply with the BLE MTU limit (Eq. 1), and a checksum byte is appended, resulting in a 19-byte BLE packet. Upon reception, the firmware validates the length and checksum, then decodes each byte.

The value 127 maps to 0°, enabling positive and negative angles. The decoded array is then distributed to `Finger`, `Thumb`, and `Wrist` objects, which apply per-joint angular limits—preventing out-of-range commands from mechanically overloading the structure—and direction correction before translating the target angles into PWM pulses (14 SG90/ES3301 servos) or UART position commands (2 SCS2332 wrist servos) via `updateHand()`. On disconnection or timeout, all joints return to the neutral reference posture, and BLE advertising resumes.

$$b = \mathrm{clamp}\left(\mathrm{round}\left(\theta \cdot \frac{256}{360} + 127\right), 0, 255\right) \qquad (1)$$

D. Command Catalog

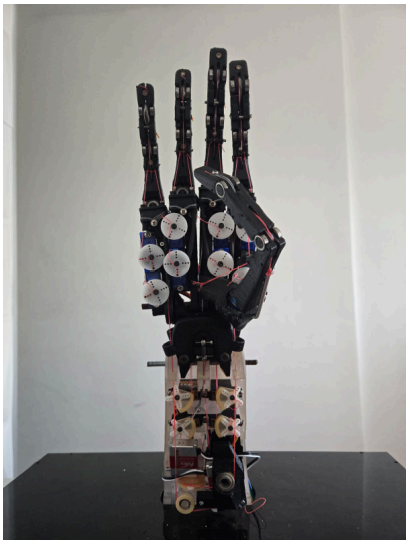
Static signs use a single 18-element array, whereas dynamic signs (H, J, K, X, Z) add a wrist waypoint sequence (pitch, yaw, dwell time) transmitted as successive packets after the handshape is set. The mobile application, developed in Flutter for iOS using the *flutter_blue_plus* BLE library, provides three

tabs: (1) connection management (BLE scan, device selection, status); (2) command catalog—36 signs (26 letters + digits 0–9) with one-tap execution, disabled when disconnected; and (3) settings (pairing, version info). Commands are dispatched as a timed packet sequence—fingers first, then wrist and thumb—to distribute the electrical demand.

III. Results and Discussion

A. Built Prototype

The constructed prototype (Fig. 4) integrates 16 servomotors (8 SG90, 6 ES3301, 2 SCS2332) within a PLA forearm shell and is controlled via BLE from an iOS device. The 18-channel protocol retains two reserved channels for the removed thumb servos, preserving future compatibility with the complete DexHand architecture. Electrical characterization at 6.6V revealed a resting draw of ≈300mA, ≈600mA during single-finger movements, and peaks of ≈6A under simultaneous multi-servo actuation—confirming the relevance of the bulk decoupling capacitor and the sequential actuation strategy. Given the 6600mAh servo battery capacity, these currents place the estimated autonomy between ≈11h of continuous single-finger actuation (≈600mA) and ≈22h of idle operation at the neutral posture (≈300mA); the 6A peaks are transient and therefore do not represent a sustained draw, but they set the instantaneous demand that the power stage must support.



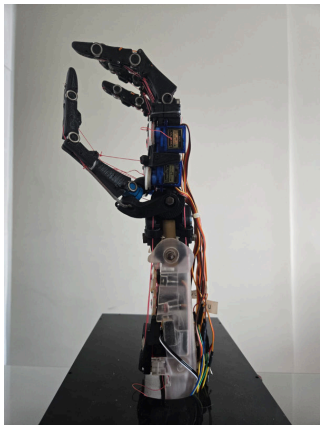


Fig. 4. Prototype developed for LIBRAS alphanumeric character reproduction.

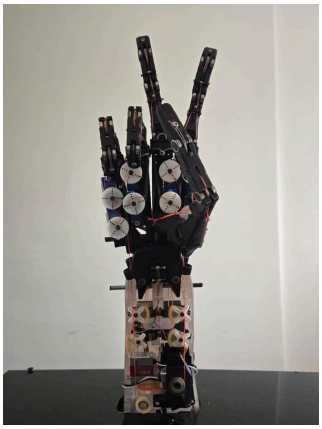
B. Implemented Signed Alphanumeric Spelling



All 36 signed alphanumeric spelling (26 letters + digits 0–9) were implemented and evaluated by visual inspection against the expected manual alphabet configuration. Table V summarizes the results; Fig. 5 illustrates two examples—letter C (arc formed by all fingers with the thumb opposing) and letter V (index and middle extended and separated)—demonstrating the system's ability to produce distinct hand configurations.

TABLE V
Signed alphanumeric spelling reproduction quality.

Quality	Signs
Excellent	A, B, C, E, O, U, V; digits 1–4
Good	D, F, G, I, L, P, R, S, T, W, Y; digit 0; digits 5–9; H, J, K, X, Z
Limited	M, N, Q (require forearm rotation)

(a) Letter C

(b) Letter V

Fig. 5. Examples of signed alphanumeric spelling reproduction.

Dynamic signs (H, J, K, X, Z) were implemented via the multi-waypoint wrist-trajectory approach, yielding recognizable letter strokes within 0.5–1.2 s after handshape stabilization. The checksum mechanism ensured communication reliability: every command applied to the hardware matched exactly what the application sent, so all observed deviations between intended and reproduced postures are attributable to mechanical factors.

C. Mobile Application

The application (Fig. 6) performed reliably across all testing sessions: BLE scanning and connection were stable, and the command catalog provided immediate one-tap access to all 36 signs while correctly disabling execution when disconnected. Static postures are assumed in 2–4 s; the sequential packet dispatch (fingers → wrist → thumb, with configurable inter-step delays) attenuated current peaks and maintained system stability. All timing parameters are software-defined, enabling speed adjustment without hardware modifications.

D. Limitations

Primary constraints are mechanical: nylon-string friction limits effective torque delivery to the finger joints, and string breakage occurred recurrently in the little finger, ring finger, and thumb during testing. Progressive loosening of string tension requires session-by-session recalibration, compromising repeatability. The SG90 servos' limited torque amplifies these effects. Signs M, N, and Q additionally require forearm pronation, which the static forearm shell cannot reproduce: because the forearm is fixed, the fingertips would instead face

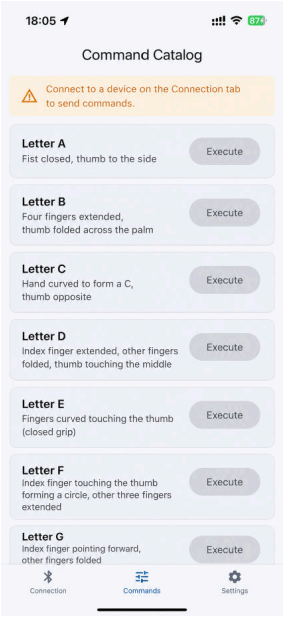


Fig. 6. Mobile application — command catalog tab.

downward, so these three signs could only be approximated in a static posture. Weight and dimensions, while compatible with the demonstrator scope, reduce portability for prolonged interaction scenarios. Future work should address string routing, lower-friction guides, higher-tensile strings, and user studies with the target population.

IV. Conclusion

This work presented the development of an upper-limb assistive system for communicational education, based on a low-cost, 3D-printed robotic platform. The integration of the mechanical structure, embedded system, and mobile application enabled the reproduction of signs corresponding to signed alphanumeric spelling, demonstrating the technical feasibility of the proposal.

The results indicate that open-architecture assistive devices can contribute to future research in accessibility, rehabilitation, and assistive communication, expanding the possibilities for interaction between users and robotic systems.

Beyond its technological contribution, the project highlights the potential of assistive technologies applied to communication and social inclusion. The concepts regarding LIBRAS and human-machine interfaces provide a foundation for future system enhancements, including myoelectric control, movement customization, and an expanded sign repertoire.

***Abstract*—Braille music notation allows people with visual impairment to read and study music autonomously. However, its production depends almost exclusively on manual transcription or on tools that require an already-digitized score, excluding musicians who learn by ear – such as the recorder students at the Instituto de Cegos do Ceará. This work develops and evaluates a pipeline for automatic transcription of monophonic soprano recorder melodies, from audio directly to braille music notation following the New International Manual of Braille Music Notation (NIMBN) standard, without any supervised training stage, combining pitch detection via pYIN, rhythmic segmentation and quantization based on MIDI discretization, and symbolic conversion to braille cells. Evaluation was conducted on 30 synthetic melodies (613 notes) with ground truth (GT) derived from MIDI files and eight real recorder recordings (329 notes), comparing performance against Basic Pitch, a lightweight neural transcription model, as a baseline. The proposed system achieved an onset F1-score of 94.6% on the synthetic dataset and 93.6% on the real recordings; a calibrated Basic Pitch baseline reached a higher onset F1 (96.8%) but a substantially worse Symbol Error Rate (SER) on the resulting braille output (36.4% vs. 8.6%). These values were obtained without a validation set independent of the test set; the comparison should be read as a measure of fit on the evaluated sets, not of generalization. The braille encoding table was verified cell by cell against the official manual, achieving 100% conformance for notes and rests. For this niche instrument, the results indicate that a classical, signal-driven approach is a viable alternative to a generic neural model when no large-scale annotated data is available, addressing a gap between automatic music transcription and braille music notation identified by a systematic literature review (Section II).**

***Index Terms*—automatic music transcription, braille music notation, recorder, pYIN, accessibility**

I. Introduction

Braille music notation is the tactile music notation system created by Louis Braille as a natural extension of his reading system [1], standardized internationally by the *New International Manual of Braille Music Notation* (NIMBN) [1]. It allows people with visual impairment to read, write and study music autonomously. In Brazil, institutions such as the Instituto Benjamin Constant and the Instituto de Cegos do Ceará (ICC) use braille music notation as their main tool for musical inclusion [2] [3].

Despite its importance, producing braille scores faces a persistent bottleneck: the conversion of music to this format is mostly a manual process, requiring professionals with dual expertise in conventional notation and braille music notation. Available tools such as Goodfeel, BrailleMUSE and Musibraille automate only the final conversion step and require a digitized score in MusicXML as input [4] [5], which presupposes that the music already exists in visual notation, transcribed by a sighted person. For visually impaired musicians who learn by ear or work without digitized scores, this conversion chain never closes.

Automatic Music Transcription (AMT) is the research area that investigates computational methods to convert audio signals into symbolic music representations, such as scores or MIDI files [6]. The field has advanced markedly for polyphonic instruments such as the piano, driven by deep learning architectures [7]. To assess whether an audio-to-braille system already exists, we conducted a systematic literature review across IEEE Xplore, Scopus and ACM Digital Library, combining terms for "automatic music transcription"/"audio-to-score" with terms for the target instruments and for braille music notation. Of 1,020 papers identified, 198 were accepted after title/abstract and full-text screening against explicit inclusion criteria (peer-reviewed AMT systems with a working implementation) and exclusion criteria (surveys without a proposed method, non-audio symbolic-to-symbolic conversion only). None of the 198 accepted papers performs the complete chain from musical audio to braille music notation, and none addresses the recorder specifically. This gap represents a concrete research opportunity with potential impact on the musical accessibility of people with visual impairment.

The contribution of this paper is threefold: (i) a training-free, audio-to-braille transcription pipeline for a niche monophonic instrument, the first, to the authors' knowledge, to close the chain from raw audio to symbolic braille output without an in-

This paper is a condensed, English-language derivation of the first author's undergraduate thesis (Trabalho de Conclusão de Curso), Department of Teleinformatics Engineering, Federal University of Ceará (UFC), 2026, advised by the second author.

termediate digitized-score step; (ii) an end-to-end quantitative evaluation, including a symbol-level metric (SER) computed on the actual braille output rather than only on an intermediate MIDI representation; and (iii) a cell-by-cell verification of the braille encoder against the official NIMBN manual, with 100% conformance for notes and rests.

A. Motivation

The soprano recorder is widely adopted in Brazilian music education, present in both elementary schools and specialized conservatories [8] [9]. Its popularity stems from its low cost, the absence of mechanical parts, and fingering that can be learned within a few classes. At the ICC, founded in Fortaleza in 1943 and a pioneer in the education of visually impaired people in the state [3], the recorder is taught regularly, making the demand for braille material for this instrument concrete and immediate.

From a technical standpoint, the recorder combines favorable characteristics for an AMT system. Being monophonic, it eliminates the multi-pitch separation problem that is the main difficulty of transcription systems for piano and ensemble instruments [6]. Its signal also has a well-defined fundamental frequency and a fixed melodic range (C5 to D7 on the soprano recorder), which restricts the pitch detector's search space and simplifies note quantization.

The literature review found AMT work for other monophonic, niche wind instruments – the sopele, a traditional Croatian flute [10], and the diatonic harmonica [11] – showing that instrument-adapted classical approaches are viable and competitive even without large annotated datasets. However, no identified work addresses the recorder specifically, and none proposes braille music notation as the transcription system's output. This work positions itself at that intersection.

B. Objectives

The general objective is to develop and evaluate a system for automatic transcription of soprano recorder melodies, from audio, to braille music notation. The system implements a classical signal-processing pipeline – pitch detection via pYIN, segmentation and rhythmic quantization, and symbolic conversion to braille – without any supervised training stage, and its technical feasibility is verified through quantitative metrics on synthetic and real recordings. Specific objectives are: (1) a systematic literature review on the AMT state of the art; (2) a pitch detection and note segmentation module based on pYIN [12]; (3) a converter from note sequences to braille music notation following the NIMBN standard [1]; (4) an evaluation set of 30 synthetic melodies with automatic ground truth and real recorder recordings provided by the ICC; (5) a quantitative evaluation against the Basic Pitch neural model [13] as a baseline.

II. Related Work

The AMT literature is dominated by deep neural systems developed and evaluated mostly for piano, with datasets of hundreds of hours of annotated audio [7] [6]. This concentration motivates the empirical comparison, in this work, with a general-purpose neural model (Basic Pitch [13]) as a direct test of a domain-mismatch hypothesis.

For niche, monophonic wind instruments, Skoki et al. [10] transcribed the sopele using a supervised model trained on a small, purpose-built dataset, while Lins et al. [11] transcribed the diatonic harmonica using a classical approach without large-scale training. Marták, Hu and Widmer [14] systematically show that general-purpose neural transcription models degrade when recording conditions or musical style diverge from their training corpus, a domain-mismatch hypothesis tested empirically in Section IV.

On the braille side, existing tools (Goodfeel, BrailleMUSE, Musibraille, FreeDots) and academic systems such as Goto et al. [5] all convert from an already-digitized score (MusicXML) to braille notation; none starts from raw audio. The gap between audio-based AMT and braille music notation output, identified by the systematic review underlying this work, remains, to the authors' knowledge, unaddressed in the literature.

TABLE I
pYIN Parameters

Parameter	Value
`fmin` / `fmax`	523.3 Hz (C5) / 2,349 Hz (D7)
`frame_length`	2048 samples ($\sim$93 ms)
`hop_length`	512 samples ($\sim$23 ms)
`voiced_threshold`	0.10
Sample rate	22,050 Hz

III. Methodology

The proposed system is a modular AMT pipeline for soprano recorder with braille music notation output (Fig. 1), composed of three sequential modules, implemented in Python 3.11 using `librosa` [15] and `pretty_midi` [16].

A. Module 1: Pitch Detection (pYIN)

Fundamental frequency (f_0) is estimated frame-by-frame with the pYIN algorithm [12] via `librosa.pyin`. Key parameters, calibrated to the recorder's physical range, are listed in Table I. Audio is pre-processed by resampling to 22,050 Hz, trimming silence at the edges (-30 dB threshold), and amplitude normalization.

B. Module 2: Note Segmentation and Rhythmic Quantization

f_0 is discretized to the nearest integer MIDI number per voiced frame, after 3-frame median smoothing. A new note starts on an *unvoiced→voiced* transition or on a confirmed MIDI change (persisting for $\geq$ 2 frames), which avoids false onsets from attack transients. Since sustained repeated notes of equal pitch produce no MIDI change and no voiced/unvoiced transition, a dedicated onset-detection step is applied to segments longer than 1.3 beats: an onset novelty

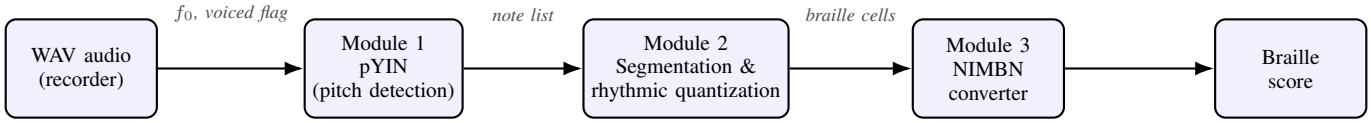

Fig. 1. Overview of the proposed pipeline: pitch detection (pYIN), note segmentation and rhythmic quantization, and conversion to braille music notation (NIMBN standard).

function (`librosa`) is peak-picked with a calibrated threshold ($\delta = 0.55$), and candidates are validated against rhythmic-grid proximity and energy-drop criteria before a segment is split. Note durations are quantized to $\{0.5, 1.0, 2.0, 4.0\}$ beats (eighth, quarter, half, whole note) using tempo estimated by `librosa.beat_track` [15].

C. Module 3: Braille Music Notation Converter

The converter implements the subset of the NIMBN standard [1] sufficient to represent diatonic monophonic melodies with basic rhythm: notes C5–D7, the four durations above and their rests, octave signs, treble clef, and 4/4 and 3/4 time signatures. The cell-encoding table was verified cell-by-cell against the official manual, reaching 100% conformance for notes and rests after correcting an initial implementation error. Output is a Unicode string using the Braille Patterns block (U+2800–U+28FF). This conformance check verifies that the encoder correctly implements the programmed NIMBN rules for the supported elements; it does not, by itself, demonstrate that the resulting score is musically correct, legible, or usable by a visually impaired reader – a distinct question this work does not evaluate and leaves to the formal legibility validation with braille music readers proposed in Section V.

D. Evaluation Set and Baseline

The evaluation set combines two subsets. The *synthetic subset* comprises 30 monophonic soprano recorder melodies (613 notes) – scales, technical exercises, and folk/classical pieces – synthesized via FluidSynth with a General MIDI *Recorder* soundfont; ground truth (GT) was extracted automatically from the source MIDI files. The *real subset* comprises 8 recordings (329 notes) made by ICC students with a smartphone in an untreated acoustic environment; ground truth was derived from reference scores and pYIN-based spectral analysis. Note identity in all eight real-subset ground truths has since been independently verified by a music teacher at the ICC, who transcribed each recording by ear from the printed score without access to the pipeline's output; this cross-check corrected two notes omitted from one recording.

As a baseline, Basic Pitch [13] is a lightweight, instrument-agnostic neural AMT model whose documented training corpus does not include wind instruments. It was evaluated in three configurations – default parameters, frequency range restricted to the recorder's register, and a grid-search-calibrated configuration (`onset_threshold`, `frame_threshold`; 16 combinations) – giving both methods a broadly comparable degree of calibration effort. A third Basic Pitch parameter controlling note-length granularity (`minimum_note_length`) was left at its library default and not included in the grid search, so this comparison should be read as approximately, not strictly, equivalent in calibration effort.

TABLE II
CONSOLIDATED METRICS – SYNTHETIC DATASET ($n = 30$ MELODIES, 613 NOTES)

Metric	Value
Onset F1 (mir_eval, 50 ms tol.)	**94.6%**
Temporal pitch accuracy	94.0%
Positional pitch accuracy	80.6%
Note Error Rate (NER)	5.4%
Symbol Error Rate (SER)	**8.6%**
Notes detected / ground truth	593 / 613

Four metrics were used: onset F1-score (`mir_eval` [17], 50 ms / $\pm$50-cent tolerance), positional pitch accuracy (index-aligned, more demanding for braille readability), Note Error Rate (NER $= 1 - F_1$), and Symbol Error Rate (SER), the edit distance between predicted and reference braille cell sequences, adopted as the most relevant metric since it directly reflects the pipeline's final product.

IV. RESULTS AND DISCUSSION

A. Synthetic Dataset

Table II summarizes results on the 30 synthetic melodies. The pipeline detected 593 of 613 expected notes, with onset F1 of 94.6% and SER of 8.6%. Ten melodies (mostly scales and stepwise-motion pieces) reached F1 = 100%; the worst case, *jingle_bells_frag* (F1 = 64.9%), contains long runs of fast repeated notes.

Failure analysis converges on a single root cause: the difficulty of delimiting consecutive notes of equal pitch, which surfaces both as under-segmentation (merged repeated notes, e.g. *parabéns*: 25→22 notes) and over-segmentation (a single sustained note split in two, e.g. *intervalo_oitava*: 9→11 notes) – both visible in the Δ column of Table III. This explains the gap between temporal (94.0%) and positional (80.6%) pitch accuracy: any count mismatch shifts every subsequent note's index, cascading the penalty through the rest of the sequence.

Fig. 2 shows the full distribution: melodies with exclusively stepwise motion cluster at F1 = 100%, while the worst performers share long runs of repeated notes at moderate-to-fast tempo. The dashed line in Fig. 2 marks the unweighted mean across the 30 melodies (94.6%), consistent with the note-weighted onset F1 reported in Table II.

TABLE III
PER-MELODY RESULTS ($n = 30$ MELODIES; EXCERPT: 3 BEST, 4 WORST BY ONSET F1)

Melody	GT	Pred	Δ	F1	SER
escala_do_maior	16	16	0	100.0%	0.0%
london_bridge	24	24	0	100.0%	0.0%
minueto_sol_bach	30	30	0	100.0%	0.0%
intervalo_segunda	16	16	0	87.5%	0.0%
mary_had_a_little_lamb	26	22	−4	87.5%	25.9%
intervalo_oitava	9	11	+2	80.0%	22.2%
jingle_bells_frag	24	13	−11	64.9%	64.0%

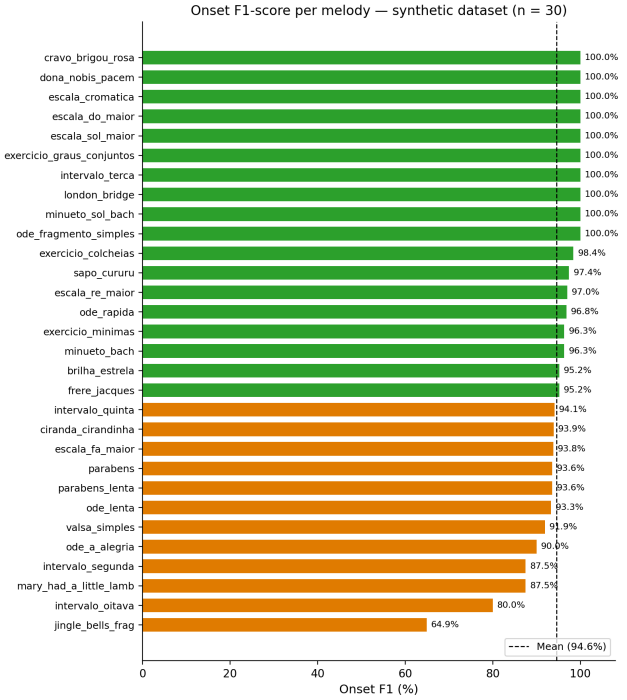

Fig. 2. Onset F1-score per melody, synthetic dataset, sorted in descending order.

B. Comparison with Basic Pitch

Table IV compares the two methods. In its default configuration, Basic Pitch detected 1,111 notes for 613 expected (1.81×). Restricting only the frequency range barely changed this (1,109 notes), ruling out simple out-of-range detections as the cause. Grid-search calibration of confidence thresholds corrected most of the excess (644 notes, 1.05×) and raised onset F1 to 96.8%, above the proposed pipeline (94.6%) on that single metric. However, SER tells a different story: even calibrated, Basic Pitch's SER (36.4%) remains over four times worse than pYIN's (8.6%), showing that domain mismatch persists at a finer transcription layer not captured by onset F1 – more than a third of the resulting braille cells would still require manual correction, against 8.6% for the proposed pipeline. This is consistent with Marták, Hu and Widmer's [14] observation that general-purpose neural models degrade when recording conditions or instrument diverge from their training

TABLE IV
PYIN (PROPOSED) VS. BASIC PITCH (BASELINE) – SYNTHETIC DATASET ($n = 30$ MELODIES, GT = 613 NOTES)

Method	Onset F1	SER	Notes	Notes/GT
pYIN (proposed)	94.6%	**8.6%**	593	0.97×
Basic Pitch – default	71.7%	107.7%	1,111	1.81×
Basic Pitch – restr. range	71.6%	107.7%	1,109	1.81×
Basic Pitch – calibrated	**96.8%**	36.4%	644	1.05×

TABLE V
CONSOLIDATED METRICS – REAL RECORDINGS ($n = 8$, 329 NOTES)

Metric	Value
Onset F1	**93.6%**
Temporal pitch accuracy	99.2%
Positional pitch accuracy	40.8%
Note Error Rate (NER)	6.4%
Symbol Error Rate (SER)	17.3%
Notes detected / ground truth	369 / 329 (1.12×)

corpus, and supports the choice of a classical, instrument-adapted approach for niche instruments lacking large annotated datasets. We note that SER is also the metric on which pYIN's advantage over calibrated Basic Pitch is most pronounced among those reported in Table IV; we treat SER as the most relevant metric because it corresponds directly to the pipeline's final output (Section III-D), not because of this coincidence, but the coincidence itself is a limitation to bear in mind when interpreting the comparison (see Section IV-E).

C. Real Recordings

On real recordings (Table V), onset F1 (93.6%) is close to the synthetic result (94.6%), indicating consistent behavior once the synthetic dataset's register was corrected to match the recorder's real range. This correction was informed by comparing the synthetic dataset's pitch range against the real recordings' observed range, which revealed a register mismatch in the original synthetic set. Positional pitch accuracy drops markedly (40.8% vs. 80.6%), driven by systematic over-segmentation present in all eight recordings (6.5%–25.0% extra notes, Table VI) combined with longer average sequences, which amplifies the cascading-index-error effect described above. SER (17.3%) is adopted as the most informative metric for practical readability, since it captures both pitch and count errors proportionally rather than under an all-or-nothing criterion. The best individual result was *serra_serrador_fl2* (F1 = 96.3%, SER = 11.1%), a rhythmically simple piece; the worst was *trem_maluco_fl1* (F1 = 88.9%, SER = 29.2%), composed entirely of long notes, which are more prone to the over-segmentation described above.

D. Positioning Relative to the Literature

The obtained F1 (94.6%/93.6%) is in the same order of magnitude as prior work on training-free transcription of niche wind instruments. Mauch and Dixon [12], evaluating pYIN on synthesized singing from the RWC Music Database, report recall/precision between 97.7% and 98.7%, but computed

TABLE VI
PER-RECORDING RESULTS – REAL AUDIO ($n = 8$)

Recording	GT	Pred	F1	SER
asa_branca	104	120	91.1%	18.4%
cancao_ninar	46	49	92.6%	18.2%
morgen_kommt	48	54	94.1%	18.4%
trem_maluco_fl1	16	20	88.9%	29.2%
trem_maluco_fl2	17	19	94.4%	16.7%
ode_a_alegria	49	54	95.1%	17.7%
serra_serrador_fl1	23	25	95.8%	8.6%
serra_serrador_fl2	26	28	96.3%	11.1%

frame-by-frame (5.8 ms windows, one-semitone tolerance) rather than at note/onset level. Lins et al. [11], transcribing diatonic harmonica, reported a mean F-measure of 68.1% for multi-pitch detection, also frame-based (9.5 ms grid). In both cases the unit of analysis is more permissive than the note-level, 50 ms-tolerance onset F1 used here, since a frame can be counted correct even when note-level segmentation is wrong. None of the three evaluations share metric, dataset, or tolerance, so these figures indicate that the proposed pipeline's performance sits within the same magnitude range as the niche-instrument literature, not evidence of superiority.

E. Threats to Validity

The following limitations are grouped by validity type, following standard practice for empirical evaluations of signal-processing systems.

Statistical conclusion validity. The two thresholds calibrated empirically (`voiced_threshold`, onset-detection δ) were tuned on the same 30 melodies later reported as the final synthetic result, without an independent holdout set. A symmetric limitation applies to the calibrated Basic Pitch baseline, whose grid search used the same 30 melodies. Table VII shows that `voiced_threshold` degrades smoothly across a $6\times$ wider range than typically tested (F1: 94.6%→93.4% from 0.05 to 0.30), and δ varies within 3 percentage points of F1 across its tested range; the pipeline does not depend on a narrow, fragile optimum. Reported metrics are unweighted means (30 melodies / 8 recordings) with no significance test or confidence interval. The real subset (329 notes across only six distinct pieces, two contributing two voices each) is too small to support claims of variance beyond the sample evaluated. The comparison in Section IV-B also rests on a single neural baseline (Basic Pitch); the claim that the proposed classical approach is more reliable than general-purpose neural models for this niche instrument should not be read as established beyond that one baseline, evaluated on the calibration-leakage-affected sample described above.

Construct validity. Real-recording ground truth was derived via pYIN-based spectral analysis, the same algorithm under evaluation, calibrated to the audio's estimated BPM. Note identity in all eight ground truths has since been independently verified by a music teacher at the ICC, who transcribed each recording by ear from the printed reference score without access to the pipeline's output; this cross-check

TABLE VII
THRESHOLD SENSITIVITY (ONSET F1 / SER), SYNTHETIC DATASET

`voiced_thr.`	F1 / SER	δ (onset)	F1 / SER
0.05	94.6% / 8.6%	0.45	93.3% / 12.9%
0.10	**94.6% / 8.6%**	**0.55**	**94.6% / 8.6%**
0.20	94.3% / 9.4%	0.60	95.4% / 6.5%
0.30	93.4% / 10.3%	0.70	95.1% / 7.5%

corrected two notes omitted from one recording (previously undercounted in *Canção de Ninar*). Onset/offset instants were not independently re-measured in any of the eight recordings – the reported values remain pYIN-derived in all cases. The same teacher did informally confirm, while listening to each recording alongside her transcription, that the rhythmic pacing sounded consistent with the audio; this is a qualitative, ear-based impression, not a precise, sample-level independent annotation of onset/offset instants, so it attenuates but does not eliminate the circularity described above for timing information, and the real-audio evaluation still cannot be treated as fully independent of the evaluated technique on that dimension. Tempo (BPM) was also supplied from ground truth rather than estimated autonomously in every reported result, which directly affects rhythmic quantization and therefore SER. A fully autonomous deployment – the work's actual motivating use case, where no reference score exists – may yield different SER values. NER and SER are also reported only in aggregate; we did not decompose either metric into insertion, deletion, substitution, duration-specific, and rhythm-specific error components. Such a decomposition would isolate the contribution of the repeated-note segmentation bottleneck (Section IV-A) from other error sources more precisely than the aggregate figures allow, and is left to future work.

External validity. Both datasets cover mostly elementary didactic repertoire (scales, exercises, simple folk melodies), performed by students rather than professional musicians, reflecting the proficiency level at the partner institution at collection time rather than a deliberate sampling of difficulty levels. The pipeline was not tested on intermediate/advanced repertoire, other recorder registers (alto, tenor, bass), or other instruments, and performer skill is confounded with pipeline error in the reported real-audio results.

V. CONCLUSION

This work developed and evaluated a training-free pipeline combining pYIN-based pitch detection, MIDI-discretization segmentation with localized repeated-note detection, and NIMBN-standard braille conversion, achieving onset F1 of 94.6% (synthetic) and 93.6% (real recordings), and outperforming a calibrated general-purpose neural baseline on SER (8.6% vs. 36.4%, Section IV-B). The braille cell-encoding module reached full conformance with the official manual, as detailed in Section III-C. The main remaining limitation is delimiting consecutive notes of equal pitch, particularly in fast passages with repeated eighth notes.

These results support the three contributions outlined in Section I. For this niche instrument, our results suggest that a classical, instrument-adapted method remains competitive with – and in symbol-level accuracy, more reliable than – the single general-purpose neural baseline tested here, even after calibration; whether this pattern generalizes to other niche instruments or other neural baselines is left to future work. From an engineering standpoint, integrating braille conversion directly into the transcription pipeline eliminates the intermediate MusicXML digitization step required by existing tools (Goodfeel, BrailleMUSE, Musibraille), directly addressing the literature gap identified in Section II.

Addressing the repeated-note segmentation bottleneck is prioritized ahead of extending the pipeline to other instruments. Two directions appear most promising, both preserving the pipeline's training-free character by refining decision rules within the existing signal-processing framework rather than introducing a supervised model: (a) replacing the current hard energy-drop threshold with a probabilistic decision – e.g., a duration-aware Hidden Markov Model over inter-onset intervals, conditioned on estimated tempo, so a split is accepted only when jointly consistent with the rhythmic grid and a learned prior over note-duration sequences, rather than by a single onset-novelty peak; and (b) combining multiple onset-detection functions (spectral flux, phase deviation, and the energy-envelope criterion already used) to reduce dependence on any single acoustic cue, since the failure mode identified in Section IV-A suggests the energy-drop criterion alone under- or over-triggers depending on tempo and dynamics.

Future work includes: (1) the segmentation refinements above, together with dynamic calibration of the energy-drop threshold conditioned on estimated tempo; (2) extension to other monophonic instruments and recorder registers; (3) expansion of the real dataset with professional performers, extending the independent verification described in Section IV-E from note identity to onset/offset instants (not yet covered), and applying a development/test split or music-level cross-validation to obtain generalization estimates free of the calibration leakage also disclosed in Section IV-E; (4) comparison against additional AMT baselines beyond Basic Pitch, checking whether the SER advantage reported in Section IV-B holds on a fully independent test set; (5) formal validation with visually impaired users of the ICC, assessing braille-score legibility, the number of manual corrections required, time to understand or perform the transcribed melody, and perceived usefulness – since the 100% NIMBN conformance reported in Section III-C establishes only that the encoder is correctly implemented, not that its output is musically legible or useful in practice; and (6) public release of the dataset, source code, and evaluation scripts.

Acknowledgment

The authors thank the Instituto de Cegos do Ceará for providing the recordings and reference scores that made the real-audio evaluation possible.

***Abstract*—Objective monitoring of upper-limb rehabilitation after stroke typically relies on expensive motion-capture systems confined to laboratories. This work describes the operation of a low-cost inertial capture system, composed of an ESP32 microcontroller and BNO085 sensors, that acquires the orientation of the limb segments, transmits the data over Wi-Fi, and processes them through a biomechanical modeling pipeline in OpenSim. The system reproduces the patient's pose in three dimensions and simultaneously estimates the shoulder, elbow, and forearm joint angles during functional movements, making it possible to measure joint range of motion objectively and replay the same movement as many times as needed, for educational and therapeutic purposes. Using only two sensors, placed on the arm and forearm, the prototype, with a materials-only cost of approximately BRL 255, demonstrates the technical feasibility of an affordable tool for kinematic assessment in rehabilitation; the accuracy of the estimated angles against a reference and the clinical validity with patients remain to be established.**

***Index Terms*—motion capture, inertial sensors, IMU, functional movements, assistive technologies, rehabilitation, stroke, biomechanics, OpenSim**

I. Introduction

Stroke is one of the leading causes of motor disability worldwide, frequently impairing upper-limb function [1]. Recovery is a prolonged process involving many physical-therapy sessions based on movement repetition. This process imposes a physical burden on the healthcare professional and, when the frequency of care is low, may delay the patient's return to functional independence.

There is, therefore, room for systems that increase the frequency of exercises and provide objective movement measurements without adding to the therapist's physical burden. Motion capture with inertial sensors (IMUs) is well suited to this context, as it does not require cameras, is not affected by occlusion, and uses portable, inexpensive sensors. Established commercial inertial systems [2], however, are costly, which makes their routine use in public health services unfeasible.

Moreover, there is still no consensus in the literature on the use of IMUs for analyzing upper-limb functionality, particularly regarding the number of sensors required and the anatomical locations where they should be positioned. This work therefore also aims to contribute to that debate.

The clinical focus is on capturing functional movements, that is, task-oriented gestures from daily life, such as bringing a cup to the mouth. By reproducing these movements in three dimensions and quantifying their joint angles, the system allows the physical therapist to visualize and replay a recording repeatedly, measure joint range of motion without a goniometer, and objectively track the patient's progress. These characteristics place this work within the scope of assistive rehabilitation technologies and were outlined in collaboration with a physical-therapy research group.

This work describes the operation of this low-cost inertial capture system for the upper limbs, from data acquisition by the sensors to the estimation of joint angles through biomechanical modeling, with an emphasis on its application to rehabilitation.

II. Related Work

Beyond its acute impact, stroke is a leading cause of long-term disability, imposing a major burden on patients, families, and society [1]. Rehabilitation after a stroke is an iterative process involving specialized physical-therapy assessment and training, which are often limited by the scarce resources of health and rehabilitation centers. Low-cost IMUs have the potential to assess and monitor patients both inside and outside

clinical settings, allowing a more detailed evaluation of the impairment and enabling the individualization of rehabilitation therapies [3].

Reference motion-capture systems are based on multiple cameras or infrared tracking with markers. Although they offer high accuracy, they are costly and require a controlled environment, falling outside the scope of routine use in public physical-therapy services. For this reason, the state of the art considered here is restricted to low-cost, low-complexity solutions compatible with the project's budget.

Within this scope, two approaches stand out. The first is capture with inertial sensors (IMUs), in which segment orientation is estimated by fusing accelerometer, gyroscope, and magnetometer data; it is portable, is not affected by occlusion, and requires no cameras. The second is vision-based pose estimation with a single camera, in which algorithms extract body posture directly from images [4]; it is affordable and requires no instrumentation on the patient, but it depends on lighting and framing conditions and suffers from occlusions.

The proposed system falls under the first approach, prioritizing portability and freedom from occlusion. Vision-based pose estimation is considered a complementary resource for future work, and not a direct competitor, given the adopted low-cost scope.

Regarding validation, IMU-based upper-limb systems are usually assessed against optical motion capture [3], [5]. For single-joint shoulder and elbow tasks, root-mean-square errors below 4° have been reported for the angles mainly involved in each movement [5], with larger errors in the remaining degrees of freedom, which are more sensitive to soft-tissue artifacts and magnetic disturbances. The present work does not yet include such a comparison, which is discussed as a limitation in Section IV.

III. The Proposed System

As an assistive technology, the system was designed for a simple usage flow by the physical therapist: the professional attaches two sensors to the patient's limb, performs a brief calibration, and asks the patient to perform the functional movement; the system then records the execution and, at the end, provides the three-dimensional animation and the joint angles. No step requires technical knowledge of instrumentation, and the digital record makes it possible to revisit the capture at any time.

Technically, the system is organized into three stages: embedded inertial acquisition, wireless transmission, and biomechanical processing. The ESP32 reads the sensors, preprocesses the orientations, and sends them over Wi-Fi to a server, which applies them to a musculoskeletal model in OpenSim to reproduce the patient's pose and compute joint kinematics. Fig. 1 shows the embedded unit of the prototype.

A. Acquisition: ESP32 and BNO085 Sensors

The embedded unit uses an ESP32 microcontroller, chosen for its low cost, native Wi-Fi connectivity, and dual-core processor running at about 240 MHz, capable of reading multiple sensors in real time. Its role in the project is to acquire, preprocess, and transmit the IMU data.

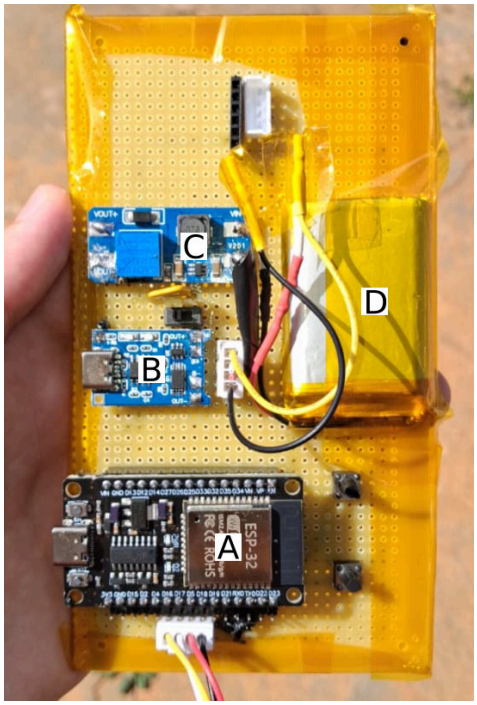

Figure 1. Prototype of the embedded unit, on perfboard: ESP32 (A), TP4056 charging module (B), MT3608 boost converter (C), and 3.7 V LiPo battery (D).

Segment orientation is measured by BNO085 sensors, which integrate an accelerometer, a gyroscope, and a magnetometer. The readings from these sensors are processed by a proprietary on-chip sensor-fusion algorithm, which directly provides the orientation of each segment as a quaternion. Communication with the ESP32 is carried out over an I^2C bus. Two sensors are used, attached with velcro straps to the right upper limb: one on the forearm and one on the arm, associated with the two I^2C addresses available on the component (Fig. 2). This limit of two addresses is the main challenge for scaling up the number of sensors, and it can be circumvented by signal routing (an I^2C multiplexer or multiple buses).

B. Firmware and Communication

The ESP32 firmware continuously reads the two sensors and converts the sensor's orientation reference frame to the frame adopted by OpenSim. At the start of the capture, the system performs a calibration that zeroes the initial horizontal orientation (yaw), removing the dependence on cardinal direction without altering the sensor's operating mode. During the capture, the orientations are stored on the device in a standardized file, while a live summary is streamed over Wi-Fi (UDP) to the server for monitoring; at the end of the capture, the file is uploaded to the server for processing. The nominal sampling rate is 50 Hz; the measured effective rate ranged from 30 to 36 Hz, because the firmware schedules each sample with a non-blocking 20 ms timer and, whenever an iteration

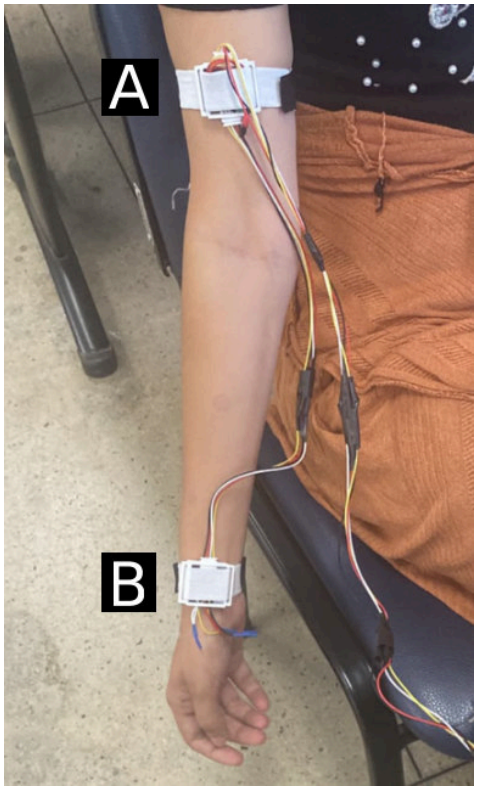

Figure 2. Wearable system positioned on the right upper limb, with the sensors attached with velcro straps to the arm (A) and the forearm (B).

of the main loop takes longer than that — I^2C polling of the two sensors, writing to the flash file system, and servicing the Wi-Fi stack — the missed interval is not recovered. For the wrist during activities of daily living, the dominant frequency is about 1 Hz and most of the spectral energy lies below 5 Hz [6], and 6 Hz is the usual upper bound adopted for voluntary human movement [7]; an effective rate of 30 Hz is therefore still 2.5 times the Nyquist rate for a 6 Hz bandwidth. Each sample is stamped with the ESP32 clock at the moment of acquisition and stored on the device, so the actual, irregular intervals are preserved in the recorded file and used by the inverse-kinematics step rather than a uniform 50 Hz being assumed.

C. Biomechanical Modeling in OpenSim

OpenSim is free software for biomechanical simulation of human movement; it relies on musculoskeletal models composed of bones, joints, and anatomical degrees of freedom [8]. The processing pipeline occurs in three steps. First, a calibration aligns the user's initial posture with the virtual skeletal model, registering the sensors to their respective segments. Next, orientation-based inverse kinematics [9] estimates, for each sample, the joint angles that best explain the measured orientations, mirroring the patient's pose. Finally, the resulting angles are exported in standardized biomechanical-analysis formats and visualized in three dimensions. The coordinates analyzed were shoulder flexion, adduction, and rotation; elbow flexion; and forearm pronation–supination. The functional movements evaluated — bringing a cup to the mouth, combing the hair, and waving — are relevant to activities of daily living, particularly in the context of post-stroke upper-limb rehabilitation. Fig. 3 illustrates the musculoskeletal model reproducing the captured pose, with the right upper-limb segments highlighted.

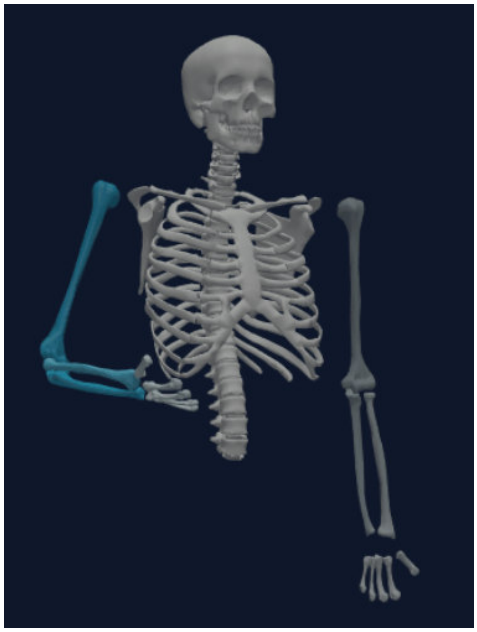

Figure 3. Musculoskeletal model in OpenSim reproducing the captured pose; the arm and forearm segments of the right upper limb tracked by the sensors are highlighted.

D. Web Interface

A web interface, served by the same server, provides the physical therapist with a single screen to operate the system and monitor the capture in real time. The data relayed by the server reach the browser through Server-Sent Events (SSE), so no software installation is required on the client side.

Each capture is stored as a session, listed in the interface together with the files produced by the pipeline — the calibrated model, the calibration and motion files, the inverse-kinematics results and orientation errors, and the plot and animation of the movement — which can be revisited at any time (Fig. 4). This organization keeps a persistent record of every acquisition, supporting the objective follow-up of the patient across sessions.

The interface also displays the connection status of the device and, for each of the two IMUs, the current roll, pitch, and yaw angles, an anatomical pose indicator with a qualitative fit score, and live plots of the three angles over time (Fig. 5, top). A control panel (Fig. 5, bottom) exposes the operations of the workflow — calibrate, record, and stop — together with the configuration of the OpenSim model, the heading axis, the sensor-to-OpenSim rotation, the inverse-kinematics weight, and the arm and forearm segment lengths. A real-time log reports each step, from the calibration pose to the

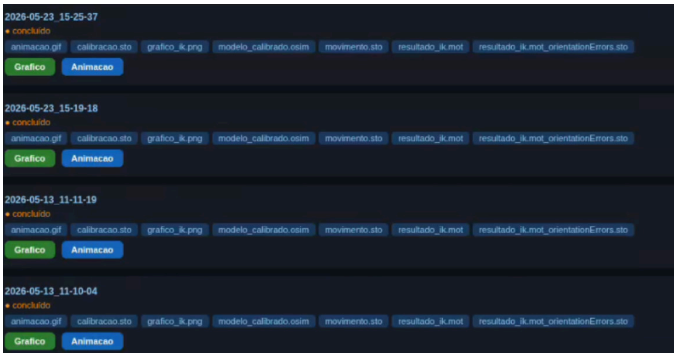

Figure 4. Session list in the web interface: each completed capture keeps the files produced by the OpenSim pipeline (calibrated model, calibration and motion files, inverse-kinematics results and orientation errors, plot, and animation).

triggering of the OpenSim pipeline on the server. This interface consolidates the acquisition, calibration, and processing steps into a workflow that requires no technical knowledge of instrumentation from the operator.

IV. Results and Discussion

The results reported in this section correspond to a functional demonstration of the instrument, in which the authors themselves operated the prototype to exercise the complete acquisition-to-visualization pipeline; no study with participants was conducted, and the estimated angles were not compared with a reference measurement. The system reconstructs the movement in three dimensions and provides the joint angles simultaneously (Figs. 3 and 6). Because the capture is recorded digitally, the same movement can be replayed as many times as needed, which favors educational use, training, and therapeutic purposes, while the direct reading of the joint angles dispenses with the manual goniometer and yields an objective record of the patient's progress without adding to the therapist's physical burden. Unlike the manual goniometer, which provides single-joint measurements, the system quantifies multiple joints simultaneously. Whether these measurements can support the assessment of movement quality or the detection of compensations is a question of clinical validity that is not answered by the present results, which establish the technical feasibility of the low-cost pipeline but not its measurement accuracy.

The estimates are sensitive to error sources inherent to inertial technology, especially magnetic disturbances and sensor-to-segment misalignment. In addition, because no sensor is placed on the chest, the shoulder angles are computed assuming a stationary chest, so any chest motion or compensation is reflected as error in these angles; an additional sensor would be required. In patients, who frequently recruit trunk compensations, this error is expected to be larger than in the demonstration captures, which were performed seated with the back supported. The anatomical constraints of the musculoskeletal model help keep the angles within physiologically plausible ranges, but they do not eliminate the cause of the error. Moreover, the OpenSim model must be appropriately customized for each patient. For assistive use, this reinforces the need for a standardized collection protocol that fixes the initial posture, the positioning of the limbs, and the placement of the sensors; even small postural variations affect the captured movement and, therefore, the repeatability of the measurements. The definition of this protocol is being carried out together with the partner physical-therapy group, so as to ensure that the measurements are clinically useful and comparable across sessions.

A. Limitations

The main limitation of the present results is the absence of a quantitative accuracy assessment: the angles estimated by the system were not compared with a reference such as a universal goniometer, calibrated video, or optical motion capture, and the repeatability across executions was not quantified. The internal orientation error reported by the inverse-kinematics solver (Fig. 4) indicates how well the model fits the measured orientations, but it is not a measure of accuracy against the true joint angle. Root-mean-square errors below 4° against optical motion capture have been reported for commercial inertial systems in single-joint shoulder and elbow tasks [5], but these values cannot be assumed for the present low-cost prototype. This assessment, using MAE and RMSE per joint and the variability of the range-of-motion peaks across repetitions, is the immediate next step, and until it is completed the system should be regarded as a technically feasible low-cost pipeline rather than a validated measurement instrument.

B. Cost

The total cost of the prototype, considering only the materials (components) and excluding labor or development, was approximately BRL 255, a value considerably lower than that of commercial inertial systems, which cost between 4 and 31 times more per sensor. This is, however, a simplified comparison, since dividing the resale price by the number of sensors is not entirely fair; moreover, many commercial systems require recurring license payments. The comparison therefore reveals only the order of magnitude of the cost difference. The low cost and the use of the open-source OpenSim API and GUI package, as well as commercial off-the-shelf (COTS) components, are central to the proposal, since they enable the local and large-scale use and maintenance of the tool in physical therapy.

V. Conclusion

This work described the operation of a low-cost inertial motion-capture system for the upper limbs, from acquisition with the BNO085 sensors and the ESP32 to the estimation of joint angles through biomechanical modeling in OpenSim. The system reproduces the patient's pose in three dimensions and provides objective, simultaneous measurements of the shoulder, elbow, and forearm, with the potential to support rehabilitation monitoring without adding to the therapist's physical burden.

Figure 5. Web interface for capture control and real-time monitoring. Top: monitoring dashboard with connection status, current roll/pitch/yaw angles of the two IMUs, anatomical pose indicators, and live angle plots. Bottom: control and calibration panel, with the calibrate/record/stop operations, OpenSim model and parameter configuration, and the real-time log.

The results demonstrate the technical feasibility of the proposed approach: with only two sensors and a total material cost of approximately BRL 255, based on commercial off-the-shelf components and the open-source OpenSim package, it provides a kinematic assessment tool aimed at the same purpose as systems costing several times more. The complete pipeline was exercised by the authors operating the prototype, confirming its end-to-end functionality. These results do not establish measurement accuracy or clinical validity: the angles were not compared with a reference and the captures assumed a stationary thorax. Quantitative validation against a goniometer or calibrated video, followed by validation with patients in a real clinical scenario, is planned as future work, to be conducted upon approval by a research ethics committee.

The results presented are preliminary and restricted to what was actually observed in the captures performed. Future work includes the definition of a unified collection protocol, covering posture, limb positioning, sensor attachment, and the number of sensors. Regarding this last point, reported configurations range from two to ten sensors, and establishing the number that is sufficient for functional assessment remains an open question that we intend to investigate. In particular, we intend to evaluate the addition of a third sensor on the scapular girdle so as to jointly assess scapular, shoulder, and elbow motion and thus better cover the dynamics of the upper limb, removing the stationary-thorax assumption. Future work

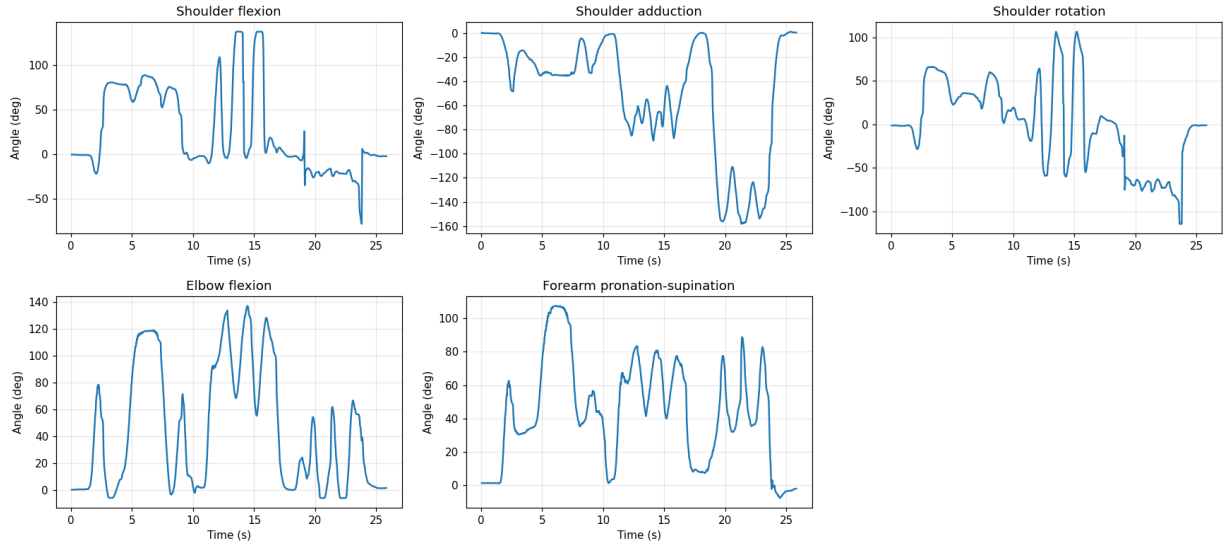

Figure 6. Joint angles estimated over three functional movements performed in sequence: bringing a cup to the mouth, combing the hair, and waving.

also includes the segmentation of movements into phases and the temporal normalization of the series to a common time base by resampling/interpolation [10], to allow comparison between executions of different durations. Finally, it includes comparison with quality-assessment methods from the literature, the use of complementary means such as computer vision, and the application of movement clustering and classification methods, such as K-means, to organize and compare large sets of recorded functional movements. A key next step is to validate the estimates against reference techniques, such as a universal goniometer and calibrated video in a first stage, and marker-based optical motion capture (the gold standard) and established inertial systems (e.g., Xsens MVN [2]) subsequently, quantifying the estimation error (MAE/RMSE per joint) and the repeatability between executions; the use of digital twins is envisioned as a future application of the tool, not as a comparison reference.

***Abstract*—Aging is associated with progressive changes in functional capacity, particularly in balance, mobility, and muscle strength, increasing the risk of falls and dependency. In this context, wearable sensors, such as accelerometers, have emerged as a promising alternative for the objective assessment of human movement. The aim of this study was to analyze the clinical applicability of these devices in the functional assessment of older adults in a home environment. This was a pilot, observational, and cross-sectional study involving individuals aged 60 years or older. Clinical tests, including the Timed Up and Go (TUG) test and the Medical Research Council (MRC) scale, were administered for screening purposes, and accelerometer data were analyzed during the performance of functional tasks. The wearable accelerometers successfully acquired kinematic signals during all functional tasks, allowing the identification of differences in movement symmetry, oscillatory patterns, and motor strategies among participants. It is concluded that wearable sensors have potential clinical applicability in the functional assessment of older adults in a home environment.**

Keywords— rehabilitation; physical therapy; older adults; monitoring; accelerometer data; functional assessment

I. Introduction

Population aging represents one of the major contemporary challenges in public health, particularly due to the increasing prevalence of chronic conditions and functional decline [1], [2]. Among the most common changes observed in older adults are balance deficits, reduced muscle strength, slower gait, and impaired functional mobility, all of which are directly associated with an increased risk of falls, hospitalizations, and loss of independence [3].

Home-based assessment has become increasingly relevant because it allows the evaluation of older adults under their habitual environmental conditions, potentially providing greater ecological validity than assessments performed exclusively in clinical settings.

In physical therapy practice, functional assessment represents a fundamental step in identifying limitations, establishing therapeutic interventions, and monitoring clinical progress. Traditionally, this assessment is performed using validated clinical instruments, such as the Timed Up and Go (TUG) test and muscle strength scales, which are widely used due to their practicality and low cost [4]. However, these methods have limitations, as they rely partly on the examiner's subjective observation and provide limited information regarding the quality of the movement performed [5].

In this context, the incorporation of technologies such as portable devices has expanded the possibilities for functional assessment [6]. Wearable sensors, particularly accelerometers, enable the real-time measurement of quantitative variables related to human movement, providing objective data on acceleration, symmetry, body sway, and motor performance during functional tasks such as upper limb elevation, cycling on a cycle ergometer, and gait. Thus, these technologies may contribute to more accurate, sensitive, and reproducible assessments in the older adult population [6], [4], [7] [8].

Despite the growing use of wearable sensors in human movement analysis, studies investigating the clinical applicability of accelerometer-based assessment in older adults assessed in a home environment remain scarce. Therefore, the present study aimed to analyze the clinical applicability of wearable sensors in the functional assessment of older adults in a home environment.

II. Materials and Methods

A. Study Design

This was a pilot study of technological applicability with a cross-sectional design and an observational approach applied to functional analysis using wearable sensors. The study was approved by the Human Research Ethics Committee of the Health Sciences Center at the Federal University of Pernambuco under approval number 5.135.351.

B. Volunteers

The sample consisted of five older adults aged 60 years or older, recruited by convenience sampling. The inclusion criteria comprised individuals of both sexes, aged 60 years or older, with preserved cognitive function as assessed by the Mini-Mental State Examination (MMSE), and with internet access at home. Individuals younger than 60 years, those with cognitive impairment identified by an MMSE score below 24 points, those with uncontrolled hypertension, and those who.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

used assistive walking devices that could interfere with locomotion and the use of the accelerometers were excluded.

C. Assessment Procedures

Data collection was conducted in the participants' homes to reproduce habitual functional conditions and enhance the clinical applicability of the assessment, in the city of Recife, Pernambuco, and its metropolitan region.

Initially, participants underwent sociodemographic and clinical characterization. Subsequently, functional assessment was performed using the Timed Up and Go (TUG) test to evaluate mobility and fall risk, the Medical Research Council (MRC) scale to assess muscle strength, and the Mini-Mental State Examination (MMSE).

Five wearable sensor modules equipped with MPU-9052 accelerometers were used. One sensor was secured on the dorsal surface of the right wrist and one on the dorsal surface of the left wrist. One sensor was positioned over the right lateral malleolus and one over the left lateral malleolus. The fifth sensor was placed on the anterior midline of the trunk, immediately inferior to the sternum. Each accelerometer recorded three orthogonal acceleration signals (X, Y, and Z), corresponding to the anteroposterior, mediolateral, and vertical directions, respectively. The acceleration signals were acquired at a sampling frequency of 50 Hz using an accelerometer measurement range of ±2 g.

Participants performed stationary walking, upper limb abduction, and cycling on a cycle ergometer for 30 seconds to 1 minute at a comfortable, self-selected pace. During these activities, accelerometer signals were continuously acquired. The accelerometers were positioned on the participants' ankles, wrists, and trunk, as shown in Fig. 1.

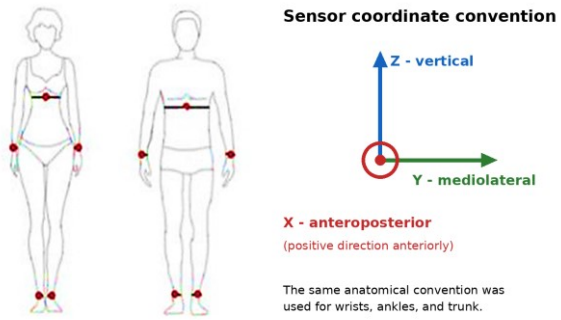

Fig. 1. Anatomical placement of the five wearable modules: dorsal surface of each wrist, over each lateral malleolus, and on the anterior midline of the trunk immediately inferior to the sternum. The anatomical coordinate convention was X = anteroposterior, Y = mediolateral, and Z = vertical.

D. Data Acquisition System and Signal Transmission

The data acquisition system was developed by the Biomedical Engineering Research Group (GPEB) at the Human-Machine Interface Laboratory (LIHOM), Federal University of Pernambuco (UFPE). It comprised five wearable inertial measurement modules, a fixed acquisition module based on a Raspberry Pi 4 Model B 8GB, and a web-based portal for data storage and monitoring.

Each wearable module incorporated an MPU-9052 inertial sensor with a triaxial accelerometer and a triaxial gyroscope. The accelerometer measurement range was configured to ±2 g and the gyroscope range to ±250°/s. Acceleration and angular velocity signals were sampled at 50 Hz, corresponding to a sampling interval of 20 ms.

Data transmission from the wearable modules was performed over a Wi-Fi network using the Message Queuing Telemetry Transport (MQTT) protocol. Each module published its inertial measurements within the same MQTT communication infrastructure. Acquisition of the five modules was initiated by a common trigger: a command published by the web-based portal to a dedicated MQTT topic and received by all modules. Upon receipt of this command, the modules initiated data acquisition, establishing a common temporal reference for the beginning of each recording. The acquired measurements were then transmitted to the remote server for real-time visualization and storage through the web portal.

E. Analyzed Variables

The acceleration signals obtained from the accelerometers during the execution of the proposed functional tasks were analyzed. Based on the collected data, the extraction of kinematic parameters related to linear acceleration, directions, and movement patterns was performed. The analyzed axes corresponded to anteroposterior (X), lateral (Y), and vertical (Z) displacements.

The signals were stored in the cloud for subsequent processing and analysis. Video recordings were also used as a complementary resource to verify movement execution and correlate it with the obtained kinematic data.

Although all participants completed the full functional protocol, a random selection procedure was used solely to determine the participant, functional task, and accelerometer axis to be presented as representative examples in the manuscript. All eligible participants, exercises, and axes were included in the selection process, and the final examples were determined by random draw to minimize selection bias.

No filtering was applied to the acceleration or angular velocity signals during the acquisition process. The signals were retained in their original acquired form to avoid introducing additional signal-processing effects that could modify their temporal or amplitude characteristics.

F. Statistical Analyses

The data were analyzed using descriptive statistics, applying measures of central tendency and dispersion, including mean and standard deviation for numerical variables, as well as absolute and relative frequencies for sample characterization. Graphical analyses of the accelerometer signals obtained during the functional tasks were also performed.

III. Results

A. Sample Characterization

Five eligible older adults were recruited for participation in the study, including three females and two males. The purpose is to emphasize the clinical applicability of the protocol using wearable sensors.

The sociodemographic and clinical characteristics of the sample are presented in TABLE I, as well as the categorical variables presented in TABLE II.

TABLE I. Sociodemographic and clinical characteristics of the presented volunteers.

ID	Age	Gender	Laterality	Occupation
NMJS	64	F	Right	Public servant
NMRN	62	M	Right	Public servant
ZCP	69	F	Right	Nutritionist
MMS	61	F	Right	Homemaker
LAS	67	M	Right	Retired

TABLE II. Categorical variables of the presented volunteers.

Variable	n (%)
Female	3 (60%)
Male	2 (40%)
Right	5 (100%)

B. Applicability of Wearable Sensors

The wearable sensors demonstrated adequate operational applicability, enabling the acquisition of accelerometer signals during all stages of the functional tests performed on the analyzed participants. No relevant complications related to device use were observed during data collection, such as participant discomfort, movement restriction, sensor displacement, or signal loss, demonstrating the feasibility of using these devices for functional assessment.

C. Analysis of Movement Signals

The obtained recordings enabled an objective analysis of movement, revealing individual variations in motor performance, differences in kinematic patterns, and the presence of asymmetries during the execution of the proposed functional tasks. The analyses presented below correspond to representative examples of the accelerometer signals obtained during the functional protocols performed by the participants.

The volunteer NMJS presented a regular movement pattern in the right arm during abduction, with mild oscillations and reduced amplitude at the end of the task. In the right leg, during stationary gait, repetitive peaks compatible with foot contact with the ground and the swing phase were observed.

The trunk maintained a stable signal with low variation. Quantitatively, the normalized RMS (nRMS) values were 0.454 for the right wrist X-axis, 0.511 for the right ankle Y-axis, and 0.391 for the trunk Z-axis, with corresponding normalized peak-to-peak amplitudes (nP2P) of 6.162, 4.893, and 3.479, respectively.

These accelerometer signals were consistent with the regular movement pattern and differences in signal amplitude observed during the functional tasks, as shown in Fig. 2.

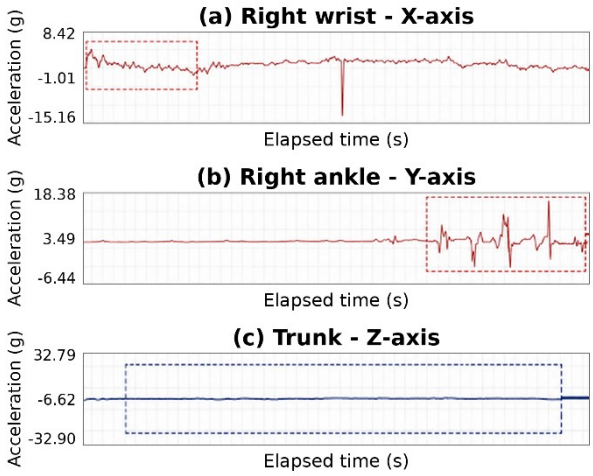

Fig. 2. Upper limb abduction and stationary gait exercises showing the X-axis of the right wrist, Y-axis of the right ankle, and Z-axis of the trunk.

Note: G (Acceleration); S (Time in Seconds)

In the accelerometer signal analysis of the left arm horizontal abduction exercise performed by volunteer NMRN, a pattern of regular medium-amplitude oscillations was observed on the X-axis, suggesting consistent movement execution. On the Y-axis, greater signal variability was identified compared with the other axes, while the Z-axis showed a regular acceleration pattern throughout the task. The quantitative metrics were consistent with these observations: nRMS was 0.215 on the X-axis, 0.559 on the Y-axis, and 0.215 on the Z-axis, while nP2P was 1.793, 2.794, and 1.495, respectively (Fig. 3).

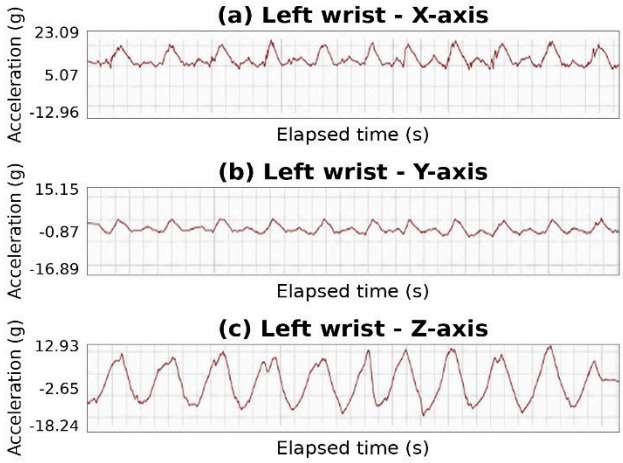

Fig. 3. Accelerometer signal analysis of volunteer NMRN – Horizontal Abduction Exercise (Left Arm).

In volunteer ZCP, a comparison of the accelerometer signals between the right and left lower limbs was performed. In the right leg, the X-axis showed higher-amplitude oscillations, while the Y-axis presented more defined and consistent peaks. On the Z-axis, oscillations of greater magnitude were observed compared with the contralateral limb.

In the left leg, the X-axis presented smooth oscillations and a regular cyclic pattern. On the Y-axis, slightly more pronounced variations were observed throughout the task, and on the Z-axis, lower-magnitude peaks were identified compared with the right leg. Quantitatively, bilateral symmetry indices based on nRMS were 17.6% for the X-axis, 34.4% for the Y-axis, and 5.7% for the Z-axis. Overall, both limbs presented cyclic behavior compatible with the proposed activity, while the quantitative metrics confirmed differences in signal amplitude between limbs (Fig. 4).

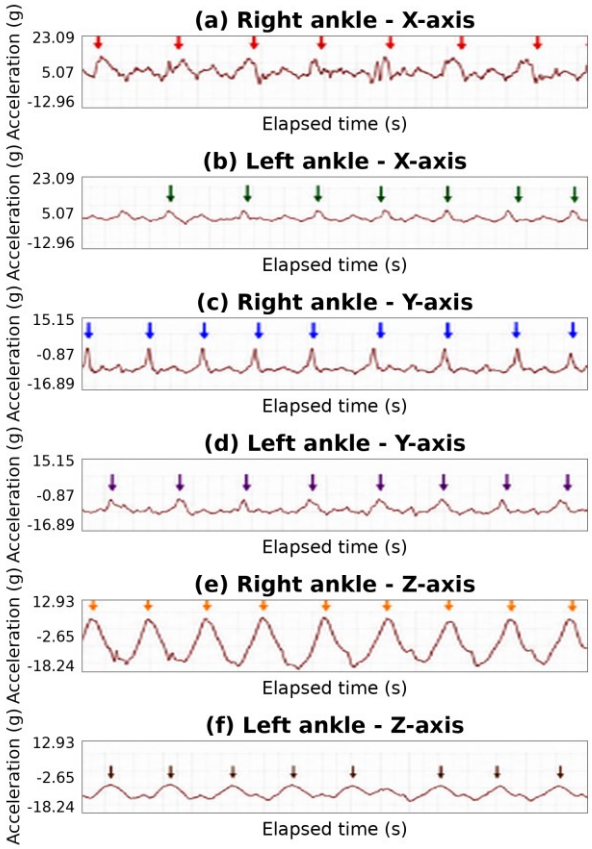

Fig. 4. Stationary gait exercise, right and left legs of volunteer ZCP, along the X, Y, and Z axes.

The analysis of the upper limb abduction movement of volunteer MMS showed that the left arm presented a more regular signal, with low amplitude and absence of pronounced peaks. In contrast, the right arm exhibited greater accelerometer signal variability and higher-amplitude oscillations. On the Y-axis, nRMS was 0.086 for the left wrist and 0.133 for the right wrist, with nP2P values of 0.521 and 0.786, respectively, resulting in a bilateral symmetry index of 43.3%. These quantitative differences were consistent with the observed difference in movement magnitude between limbs (Fig. 5).

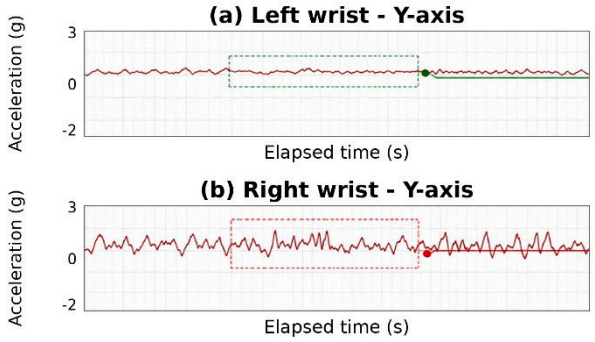

Fig. 5. Analysis of upper limb abduction movement (Y-axis) in volunteer MMS.

In the accelerometer signal analysis of walking along the Y-axis in volunteer LAS, alternating and subsequent patterns between the lower limbs were demonstrated, indicating an alternating pattern during gait execution. Stable temporal patterns were observed without abrupt variations or marked irregularities in the analyzed signals. Quantitatively, nRMS was 0.279 for the left ankle and 0.446 for the right ankle, while nP2P was 3.597 and 3.950, respectively, resulting in a bilateral symmetry index of 46.0%.

The small variations identified in the signals were compatible with postural adjustments, while the smooth transitions between steps indicated a regular and consistent temporal pattern during movement execution. The quantitative metrics additionally demonstrated a difference in acceleration amplitude between the lower limbs, as shown in Fig. 6.

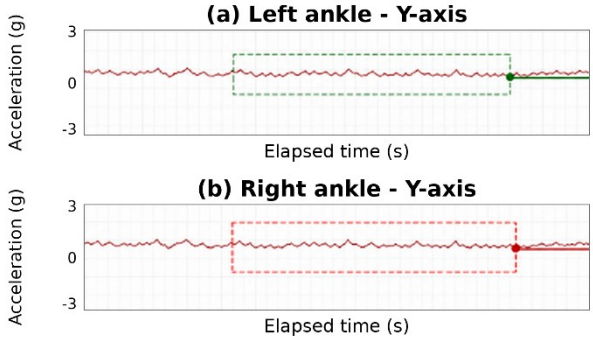

Fig. 6. Gait analysis – Accelerometer (Y-axis) in volunteer LAS.

Across the selected signals, normalized RMS ranged from 0.086 to 0.559 n.u. Bilateral symmetry indices ranged from 5.7% to 46.0%. In Table III, nRMS denotes normalized dynamic RMS, nP2P denotes normalized peak-to-peak amplitude, SI denotes the bilateral symmetry index calculated from the relative difference between left and right nRMS values, and L/R denotes left/right. An SI closer to 0% indicates more similar bilateral RMS amplitude; it does not by itself define normality, impairment, or unequal weight bearing.

TABLE III. Quantitative metrics of accelerometer signals during functional tasks.

Signal	nRMS (n.u.)	nP2P (n.u.)	SI (%)
NMRN wrist-X	0.215	1.793	-
NMRN wrist-Y	0.559	2.794	-
NMRN wrist-Z	0.215	1.495	-
ZCP ankles-X (L/R)	L 0.275 R 0.328	L 1.870 R 2.158	17.6
ZCP ankles-Y (L/R)	L 0.216 R 0.305	L 3.196 R 3.953	34.4
ZCP ankles-Z (L/R)	L 0.294 R 0.277	L 3.650 R 3.953	5.7

NMJS right wrist-X	0.454	6.162	-
NMJS right ankle-Y	0.511	4.893	-
NMJS trunk-Z	0.391	3.479	-
MMS wrists-Y (L/R)	L 0.086 R 0.133	L 0.521 R 0.786	43.3

IV. Discussion

The results demonstrated that wearable sensors presented relevant clinical applicability in the functional assessment of older adults, enabling the objective analysis of parameters related to movement, kinematic patterns, and motor strategies. Accelerometer signals allowed the identification of differences in kinematic patterns, asymmetries, and variations in movement strategies during the functional tasks performed. The quantitative metrics, including nRMS, nP2P, and bilateral symmetry indices, complemented the signal-pattern observations and may assist physical therapists in identifying individual functional patterns and guiding more specific therapeutic interventions.

Michaelsen et al. [8] identified, using accelerometer signals, slower movements and longer deceleration times in individuals with hemiparesis. Similarly, the volunteers in this study presented differences between dominant and non-dominant limbs regarding movement regularity, amplitude, and impact, reinforcing the potential of accelerometer signals for functional kinematic analyses [9].

The asymmetries observed between the right and left legs in this study, during the analysis of volunteer ZCP, demonstrated differences in signal amplitude between limbs, with bilateral symmetry indices of 17.6%, 34.4%, and 5.7% for the X, Y, and Z axes, respectively. These findings corroborate previous studies that associate accelerometer oscillations with individual gait patterns and neuromuscular adjustments for maintaining postural stability [10], [11], [12], [13].

The analysis of acceleration signals across different axes enables the identification of variations in body movement during the execution of functional tasks, allowing the observation of anteroposterior, lateral, and vertical oscillations potentially related to motor control and functional trategies adopted by older adults, reinforcing the importance and applicability of accelerometer-based assessment in the functional and otor evaluation of this population.

Thus, the findings of this research corroborate the analyzed studies by indicating that differences in limb acceleration can be objectively characterized using accelerometer signals and quantitative metrics. Furthermore, they reinforce that accelerometers are useful tools for assessing motor functions and activities in different populations and environments.

The limitations of the study include the small sample size, characteristic of a pilot study, the absence of a control group and inferential statistical analyses, as well as the inherent variability of the home environment during data collection. However, the study demonstrates the feasibility and potential clinical applicability of accelerometers for the functional assessment of older adults in a home environment.

V. Conclusion

This study assessed the applicability of wearable accelerometers for functional evaluation of older adults in home settings, supporting their potential as a tool for ecologically valid, remote functional monitoring in this population.

***Abstract*—Motor imagery (MI) brain-computer interface (BCI), virtual reality (VR), and transcranial direct current stimulation (tDCS) have been investigated as complementary approaches for post-stroke motor rehabilitation. However, EEG longitudinal changes due to these approaches are still poorly understood. In this work longitudinal changes in motor-imagery spectral modulation were analyzed during a 10-session rehabilitation protocol combining MI-BCI neurofeedback, VR-based motor training, and anodal tDCS. Relative power modulation (RPM) during MI with respect to rest was computed per frequency band, hemisphere, and acquisition (pre- and post-intervention), and changes between the first and final sessions were assessed with Wilcoxon signed-rank tests under Bonferroni correction. The most consistent descriptive pattern was observed during post-intervention affected-hand MI in the lesioned hemisphere. All 10 participants exhibited a negative longitudinal change in the relative power modulation (RPM) associated with the β MI, while 9 of 10 showed the same direction in the θ rhythm. These exploratory findings are compatible with stronger event-related desynchronization (ERD) at the end of the protocol and motivate confirmation in larger, controlled studies.**

Keywords—brain-computer interfaces, virtual reality, transcranial direct current stimulation, stroke, rehabilitation

I. Introduction

Persistent upper-limb impairment is one of the most challenging consequences of stroke, particularly when residual voluntary movement is insufficient to support intensive task-oriented practice. In this context, neurorehabilitation approaches that engage motor-related brain activity without requiring complete movement execution, are especially relevant. Motor imagery (MI), defined as the mental simulation of an action without physically executing it, recruits premotor, parietal, and sensorimotor regions that partially overlap with those activated during actual movement [1]. MI can provide a pathway to activate motor representations in individuals with impaired physical movement.

Brain-computer interfaces (BCIs) are systems that translate neurophysiological activity into commands to control an external device. Electroencephalography-based brain-computer interfaces (EEG-BCIs) allow for the detection of MI-related neural activity and its conversion into real-time feedback. During movement and MI, sensorimotor rhythms commonly exhibit event-related desynchronization (ERD), characterized by a reduction in oscillatory power relative to a resting reference, particularly in the μ (8-12 Hz) and β (13-30 Hz) frequency bands. Nevertheless, some studies have shown event-related synchronization (ERS), i.e., band power increases, related to MI [2], [3]. These responses are characterized by frequency and spatial patterns and should be interpreted as changes in oscillatory organization rather than as direct measurements of cortical excitation or inhibition [4]. Thus, sensorimotor rhythms can be used as BCI markers.

The most important point about using MI-BCI in neurorehabilitation is that training can establish a closed sensorimotor loop between movement intention, brain activity, and an observable consequence. Controlled studies have reported motor improvements following BCI-assisted training in both subacute and chronic stroke populations [5], [6].

Nevertheless, EEG responses are heterogeneous after stroke. The magnitude and hemispheric distribution of ERD/ERS may depend on lesion location, impairment severity, task demands, and the participant's ability to generate a consistent MI response. MI-BCI training may be complemented by interventions that provide embodied motor practice and modulate cortical responsiveness. Virtual reality (VR) enables oriented exercises with multisensory feedback, which can be performed while employing transcranial direct current stimulation (tDCS). tDCS consists of applying a weak (1~2mA) electrical current through the scalp to modulate

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

cortical excitability. Rather than directly eliciting action potentials, the resulting electric field is able to produce subthreshold shifts in neuronal membrane polarization, thereby altering the likelihood of neuronal populations responding to ongoing synaptic input. Nevertheless, the physiological response remains incompletely characterized and varies considerably across individuals and stimulation protocols [7].

Fatigue may also influence the participant's ability to sustain MI and operate a BCI. Relative β power has been associated with mental fatigue and MI-BCI performance in stroke survivors, suggesting that changes in oscillatory modulation should be interpreted alongside clinical and subjective outcomes [8].

Previous studies have investigated MI-BCI with VR feedback and tDCS as post-stroke rehabilitation strategies, either separately or in partial combinations. However, less is known about how MI power modulation changes longitudinally when those approaches are integrated in a single study protocol. Therefore, this present study examined task and hemisphere-specific changes in RS EEG power during affected and non-affected hand MI through a 10-session intervention combining MI-BCI neurofeedback, VR motor training, and anodal tDCS in individuals with chronic stroke. Relative power modulation was examined during affected- and non-affected hand MI across lesioned and non-lesioned hemispheres. The relative predominance of each hemisphere. Changes from the first to the final session were evaluated separately before and after the intervention, and exploratory correlations were performed between EEG changes and clinical outcomes. This approach aimed to determine whether repeated training was accompanied by frequency-specific changes in MI-related modulation.

Thus, the novelty of this study lies not in the isolated use of BCI, VR, or tDCS, but in the longitudinal characterization of frequency, task, and hemisphere specific EEG modulation during a multimodal MI-BCI + VR + tDCS rehabilitation protocol.

II. Methods

A. Subjects

Ten adults with chronic stroke (mean 50±29 months post-stroke) were recruited in this study (mean age 46±9 years, range 34-68 years, 7 females). All subjects had a stroke episode more than six months before our clinical intervention, had no history of seizures, no pacemaker, or other metallic implants, and had not removed any part of the brain tissue. Their demographic and clinical characteristics are summarized in Table I.

A minimal voluntary motor activity in the affected upper limb was required to ensure that the subjects could engage with the proposed VR motor tasks.. This was operationally defined as I observable attempt or voluntary muscle contraction during hand opening or closing and/or the ability to initiatIan active reaching movement with the paretic arm.

Participants underwent 10 rehabilitation sessions combining MI-BCI neurofeedback, VR-based upper-limb training, and anodal tDCS. The project was approved by the ethics committee of Universidade Estadual de Campinas (CAAE 80319924.7.0000.5404) and all participants provided written consent before entering the study.

B. Pre- and Post-Intervention Clinical Assessment

Participants were evaluated using clinical tests immediately before the first rehabilitation session and right after the last session. Both evaluations were conducted by the same physical therapist. Before enrollment, participants completed a medical screening questionnaire and the Mini-Mental State Examination (MMSE) to document medication use, verify eligibility according to inclusion and exclusion criteria, and assess preservation of cognitive function after stroke.

Clinical assessments were performed during the first and tenth sessions. These included manual dexterity tests, using the Nine-Hole Peg Test [9] and the Box and Block Test [10], followed by sensory assessments including tactile sensitivity with a monofilament, thermal sensitivity, pain/deep pressure sensitivity, stereognosis, and vibration sensitivity using a tuning fork. Muscle strength was then assessed using a hydraulic Jamar hand dynamometer for handgrip strength [11], as well as isometric elbow and wrist flexion and extension strength tests.

Finally, clinical scales were applied, including the upper-limb Fugl-Meyer Assessment [12], Modified Rankin Scale, Barthel Index [13], and Modified Ashworth Scale[14]. Participants also completed fatigue questionnaires, including the Modified Fatigue Impact Scale (MFIS) [15] and Fatigue Severity Scale (FSS)[16], to evaluate the impact of fatigue on daily activities.

C. Rehabilitation Protocol

As mentioned, participants completed 10 rehabilitation sessions conducted on consecutive weekdays, with no sessions scheduled on weekends. The first and final sessions lasted approximately 3-3.5 h because they included additional assessments, whereas Sessions 2-9 lasted approximately 1.5 h. Before the first acquisition, the MI task and the sequence of procedures were explained. Participants were seated comfortably with their forearms and hands supported on a pillow placed across their lap. They were instructed to remain relaxed and to perform kinesthetic MI of repeatedly opening and closing the cued hand without producing overt movement. In addition to visualizing the movement, they were encouraged to imagine the sensory and proprioceptive sensations associated with the movement.

The EEG cap was positioned while these instructions were provided. Participants were informed that EEG activity and BCI classification performance naturally vary across trials and that inconsistent neurofeedback did not necessarily indicate incorrect task execution. A brief practice period was conducted to ensure that the task and experimental cues were understood.

The acquisition sequence is illustrated in Figure 1. The trial structure was then presented to the participant: 6 s of rest, followed by a 2 s of a directional cue and 6 s of the MI task. Left- and right-hand trials were presented in a pseudorandomized order while maintaining an equal number of trials for each hand.

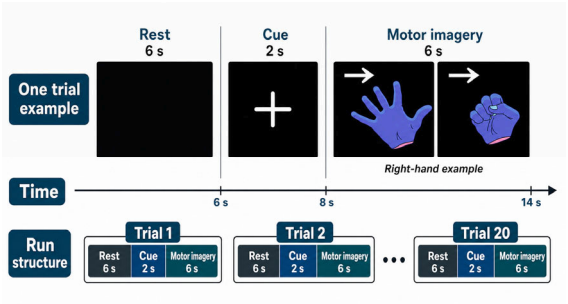

Figure 2. MI-BCI run structure. A neurofeedback run is illustrated in the example. Calibration runs had less trials (10 for the initial calibration and 6 trials for the pre and post tDCS calibrations).

The first session began with a calibration acquisition comprising 10 trials, with five trials assigned to each hand. This initial extended calibration was required to establish the participant-specific BCI model. From Session 2 onward, the data obtained in the preceding session, combined with a brief six-trial training, was used as the initial model of the day. This was followed by two neurofeedback runs comprising 20 trials each, equally divided between left- and right-hand imagery. A 3-min resting interval was provided between runs. Following the pre-intervention EEG assessment, the EEG equipment was removed, and the participant proceeded to the VR and tDCS stage. For this stage, the participant was seated in a chair with armrests while the tDCS electrodes were positioned. Instructions concerning the VR task and the movements required to control the game were provided during preparation. A brief guided familiarization was conducted using the VR headset, while the headset display was mirrored on a television to allow the research team to monitor and explain the upcoming activities.

Participants then completed 20 minutes of VR-based motor training combined with anodal tDCS. After completing the VR+tDCS intervention, participants were escorted back to the EEG room. The EEG equipment was repositioned, and a brief six-trial recalibration acquisition was performed to update the BCI model following the intervention. Two additional 20-trial neurofeedback runs were then completed, separated by a 3-min resting interval.

D. EEG Acquisition

EEG signals were acquired using a g.Nautilus PRO system (g.tec, Austria) with 32 hybrid electrodes operated in dry mode throughout all experimental sessions. The electrodes were arranged according to the montage illustrated in Figure 2, based on the 10-10 international system. The reference and ground electrodes were positioned over the right and left preauricular regions, respectively.

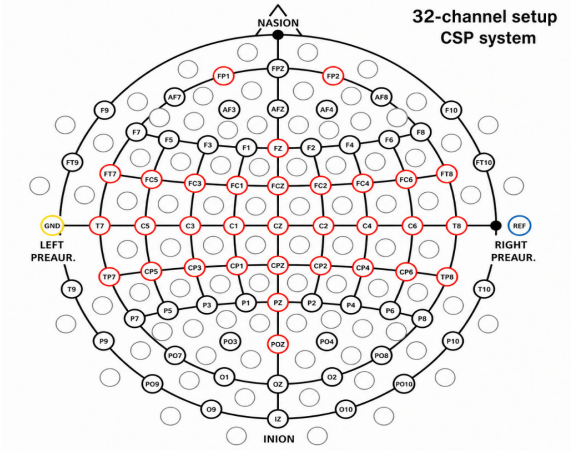

Figure 1. Electrodes used in the EEG acquisition. Red: Active electrodes; Yellow: Ground electrode; Blue: Reference electrode.

Signals were sampled at 250 Hz and recorded using the amplifier's analog band-pass filters between 0.5 and 100 Hz. Communication between the amplifier and the acquisition computer was implemented through the g.tec API, 2024 release, in MATLAB R2023a (MathWorks). Event markers identifying rest, directional cues, and MI periods were recorded synchronously with the EEG signal.

Because impedance measurements obtained from dry electrodes may not be a reliable indicator of electrode-skin contact, signal quality was primarily evaluated through visual inspection of the continuous EEG traces. Before the acquisition, participants were asked to alternate between eyes-open and eyes-closed periods and to briefly clench the jaw to generate chewing artifacts. Channels exhibiting unstable, saturated, or non-physiological signals were adjusted before data collection.

The same signal-quality procedure was repeated after the VR+tDCS intervention. Particular attention was given to amplitude attenuation or possible electrical bridging caused by residual saline from the tDCS electrodes. When these effects were identified, the scalp was dried. EEG acquisition was initiated only after the signals were considered adequate.

E. Online MI-BCI Neurofeedback

The online MI-BCI system was implemented in MATLAB R2023a using the g.tec API and Psychtoolbox. Following the amplifier-level filtering described in Section D, signals from all 32 EEG channels shown in Figure 2 were used for online processing. Before each training or neurofeedback acquisition, the amplifier streamed data for 10 s while the participant remained at rest. These initial samples were discarded to reduce the influence of transient amplifier instability.

Each neurofeedback run comprised 20 trials, equally divided between left- and right-hand MI. Trial order was pseudorandomized while allowing no more than two consecutive trials from the same class. Each trial comprised 6 s of rest, a 2-s preparatory fixation cue, and 6 s of kinesthetic motor imagery. At MI onset, a directional arrow

and an animation of the corresponding hand opening and closing were presented.

For classifier training, the 6-s MI periods were labeled as left-hand class (0) or right-hand class (1) and divided into 2-s windows with a 1-s step, corresponding to 50% overlap. Each window was processed using a bank of six causal Chebyshev Type II band-pass filters: 8-12, 12-16, 16-20, 20-24, 24-28, 28-32 Hz.

For each frequency sub-band, a normalized covariance matrix was calculated for every temporal window:

$$C_i = \frac{X_i X_i^T}{tr(X_i X_i^T)}$$

where X_i represents the multichannel EEG data from window i. Covariance matrices were then averaged separately for the left- and right-hand classes.

To improve numerical stability, each class covariance matrix was regularized using shrinkage toward a scaled identity matrix:

$$\tilde{C}_k = (1-\lambda)C_k + \lambda \frac{tr(C_k)}{p} I$$

where p is the number of EEG channels and $\lambda = 0.3$.

Common Spatial Patterns (CSP) filters were estimated by whitening the composite covariance matrix and solving the corresponding eigenvalue decomposition [17]. The spatial filters were ordered according to their eigenvalues, with filters at opposite extremes maximizing variance for one MI class while minimizing it for the other. Two spatial-filter pairs were retained from each frequency sub-band: the first two and last two CSP components. The variance of each spatially filtered component was calculated and logarithmically transformed. This produced four log-variance features per sub-band and 24 features in total. All features were retained; no additional feature-selection procedure was applied.

Before classification, features were standardized using the mean and standard deviation estimated from the training data. A linear support vector machine (SVM) was trained to discriminate left- from right-hand MI. Posterior probability calibration was applied using Platt scaling [18] when at least 30 training windows were available.

F. VR-Based Motor Training Combined with tDCS Neuromodulation

A custom virtual-reality (VR) game was developed to provide an engaging environment for repetitive upper-limb motor training. The application was developed using Unity and presented through Meta Quest 3. Hand and upper-limb movements were captured using the hand-tracking system illustrated in Figure 3.

Before training, the affected side was selected in the game settings according to the participant's paretic side. An individual calibration procedure was then performed to estimate the participant's minimum and maximum active movement amplitudes. These values were used to adapt the game's interaction thresholds and visual feedback to the participant's possible motor range. The calibration assessed opening and closing hand movements.

While the tDCS electrodes were positioned, participants received an initial explanation of the virtual environment and its objectives. They were then allowed to briefly explore the game before receiving additional task-specific instructions.

Figure 3. Participant exploring the VR-based motor training game in Session 1.

The primary task consisted of reaching toward a virtual "magical seed", grasping it, and transporting it to a vase located at the center of the virtual environment. Seeds appeared pseudo-randomly at left, upper-central, or right spatial locations, encouraging reaching in different directions. When the seed entered the vase's target area, the vase became active. Participants were then instructed to open the affected hand. A virtual flower emerged from the vase, with its growth determined by the hand-opening amplitude relative to the calibration range. Flower type was selected randomly from a predefined pool. Participants subsequently closed their hand before beginning the next reaching cycle. Thus, each cycle combined reaching, object transport, hand opening, and hand closing. The number of completed movement cycles and successfully bloomed flowers was displayed within the participant's field of view. Game difficulty increased progressively by introducing multiple colored seeds. At this stage, the vase indicated a target color, and participants were required to select the seed with the corresponding color.

Participants completed 20 minutes of VR-based upper-limb training. The game recorded movement repetitions, flower count, and hand tracking coordinates.

VR-based motor training was performed concurrently with anodal transcranial direct current stimulation (tDCS). Stimulation was delivered for 20 minutes using a MicroEstim tDCS stimulator (NKL, Brazil) at an intensity of 1 mA, with 30-s ramp-up and ramp-down periods. The anode was positioned over the ipsilesional primary motor cortex at C3 or C4, according to the international 10–20 system, while the return electrode was placed over the contralateral supraorbital region at Fp2 or Fp1, respectively. Anode and cathode consisted of 35-cm² electrodes inserted into saline-soaked sponge pockets. The sponges were evenly soaked without oversaturation to prevent saline leakage and maintain stable skin contact throughout stimulation. Electrode–skin impedance was monitored and maintained below 40 kΩ.

Stimulation began simultaneously with game onset and continued during the VR exercise. Participants were asked about discomfort, itching, burning, headache, or other sensations. No independent effects of VR or tDCS were estimated for this group of participants.

G. Offline EEG Preprocessing and Signal Processing

Offline EEG preprocessing was performed in MATLAB 2023a using EEGLAB [19], whereas subsequent spectral analyses were conducted in Python. Continuous EEG

recordings were imported separately for each participant, session, and run. Event markers corresponding to rest, cue, and MI were reconstructed from the recorded trial-order vectors. Electrode coordinates were assigned according to the 32-channel montage illustrated in Figure 2. The initial 6 s rest period of the first trial was excluded because it overlapped were excluded from baseline-dependent analyses. Line-noise contamination was attenuated using Zapline-plus [20], and the continuous signals were band-pass filtered between 1 and 50 Hz. Transient high-amplitude artifacts were attenuated using artifact subspace reconstruction, with a burst criterion of 20 and burst rejection disabled [21]. Automatic channel-rejection criteria were disabled. Signals were then re-referenced to the common average. Extended Infomax independent component analysis was performed [22]. Independent components were classified using ICLabel [23]. Components were removed when the probability assigned to muscle, eye, cardiac, line-noise, or channel-noise activity was at least 0.70. After preprocessing, the continuous recordings were segmented according to the experimental structure into 6 s rest periods, 2 s cue, and 6 s MI.

For offline analysis, each complete 14 s trial was filtered using a fourth-order Butterworth filter applied in the forward and reverse directions in the δ (1-4 Hz), θ (4-8 Hz), μ (8-12 Hz), and β (13-31 Hz) bands. μ and β were examined as motor-related frequency bands, whereas δ and θ were included as secondary exploratory analyses. Band-specific power was estimated by squaring the filtered signal and applying a 250 ms moving-average smoothing window. For each trial, electrode, and frequency band, baseline power (P_{REST}) was defined as the mean power across the corresponding 6 s rest period, whereas MI power (P_{MI}) was calculated as the mean power across the 6 s imagery period. MI-related relative power modulation (RPM) was estimated following the ERD/ERS quantification proposed by Pfurtscheller and Lopes da Silva [4]:

$$RPM = 100 \times \frac{P_{MI} - P_{REST}}{P_{REST}}$$

Under this convention, negative values indicate ERD, whereas positive values indicate ERS. Feature-level observations were excluded when baseline, MI power, or RPM values were identified as outliers according to either the 1.5 interquartile-range criterion or a four-median-absolute-deviation criterion, calculated within each participant, session, run, frequency band, and electrode. Three task scenarios were examined: all MI trials combined, affected-hand MI trials, and non-affected-hand MI trials. Trial-level values were first averaged for each electrode and run. These run-level estimates were subsequently averaged across Runs 1 and 2 to obtain the pre-intervention (pre-tDCS+VR) value and across Runs 3 and 4 to obtain the post-intervention (post-tDCS+VR) value. This aggregation was performed separately for each participant, session, task scenario, frequency band, and hemisphere, with estimates additionally averaged across the five sensorimotor electrodes assigned to each hemisphere: C3-C4, FC3-FC4, C5-C6, C1-C2, and CP3-CP4. Data from participants with left-hemisphere lesions were logically mirrored so that the same canonical side consistently represented the non-lesioned hemisphere across participants.

Longitudinal changes Δ in RPM were calculated as the difference between the final assessment and Session 1. For with the filtering transient response. The acquisition routine was subsequently corrected for two participants (PC and AS), allowing filter stabilization to occur before experimental data recording; therefore, their initial rest periods were retained. Consequently, trials without a valid preceding rest baseline

most participants, the final session corresponds to Session 10. Because of participant availability, subjects AV, KG, and PC completed their final assessment during Session 9.

H. Statistical Analysis

Longitudinal changes were calculated as $\Delta = \text{Final session} - \text{First session}$. For each RPM combination, two-sided Wilcoxon signed-rank test was utilized to assess whether the participant-level longitudinal changes differed from zero. Bonferroni correction across all 32 RPM tests (two task scenarios, four frequency bands, two hemispheres, two intervention conditions – pre and post) was applied. The resulting adjusted significance threshold was $\alpha = 0.05/32 = 0.0015625$.

I. Exploratory correlations with clinical scales

Exploratory Spearman correlations were calculated between eight longitudinal clinical outcomes and 32 EEG features, resulting in 256 comparisons. Clinical changes comprised grip strength, elbow flexion and extension strength, Fugl-Meyer uppe-limb motor score change, and FSS.

III. Results

Longitudinal changes calculation ($\Delta = \text{Final session} - \text{First session}$) was performed separately for the pre- and post-intervention acquisitions, task scenarios, frequency bands, and hemispheres. For RPM, negative Δ values indicate that RPM became more negative in the final session, corresponding to stronger ERD or weaker ERS under the adopted convention.

After Bonferroni correction, no longitudinal RPM comparison reached statistical significance. However, a consistent descriptive RPM pattern was observed in the post-intervention acquisition during affected-hand MI, illustrated in Figure 4. Specifically, in the β band, all 10 participants exhibited negative ΔRPM values, with a median change of -2.57 percentage points (mean = –3.89; uncorrected p = 0.00195). Thus, RPM became more negative in the final session, indicating a stronger β ERD or weaker β ERS. No comparably consistent β band effect was observed in the pre-intervention acquisition. A second descriptive pattern was found in the θ band for the same task, hemisphere, and intervention condition. Nine of the 10 participants exhibited negative longitudinal changes, with a median ΔRPM of –9.39 percentage points (p = 0.00586). Regarding associations with clinical and functional assessments, the strongest descriptive correlations in sensorimotor band are shown in Figure 5 to illustrate possible trends. Greater non-affected-side elbow-flexion strength gains were associated with more positive β ΔRPM in the affected hemisphere during pre-intervention non-affected-hand MI (ρ = 0.88, uncorrected p = 0.0008). Greater affected-side elbow-flexion strength gains were associated with more positive μ ΔRPM in the non-affected hemisphere during pre-intervention non-affected-hand MI (ρ = 0.83, uncorrected p = 0.0029), and with more positive β ΔRPM in the affected hemisphere during pre-intervention

affected-hand MI (ρ = 0.77, uncorrected p = 0.0092). Greater affected-side elbow-extension strength gains were associated with more negative β ΔRPM in the non-affected hemisphere during post-intervention non-affected-hand MI (ρ = -0.76, uncorrected p = 0.0111). Greater FSS improvement, reflecting reduced fatigue severity, was associated with more negative β ΔRPM in the non-affected hemisphere during post-intervention affected-hand MI (ρ = -0.79, uncorrected p = 0.0119). Finally, greater non-affected-side elbow-flexion gains were associated with more positive μ ΔRPM in the non-affected hemisphere during pre-intervention non-affected-hand MI (ρ = 0.75, uncorrected p = 0.0133). None of these associations survived correction for multiple comparisons; therefore, they should be interpreted as exploratory.

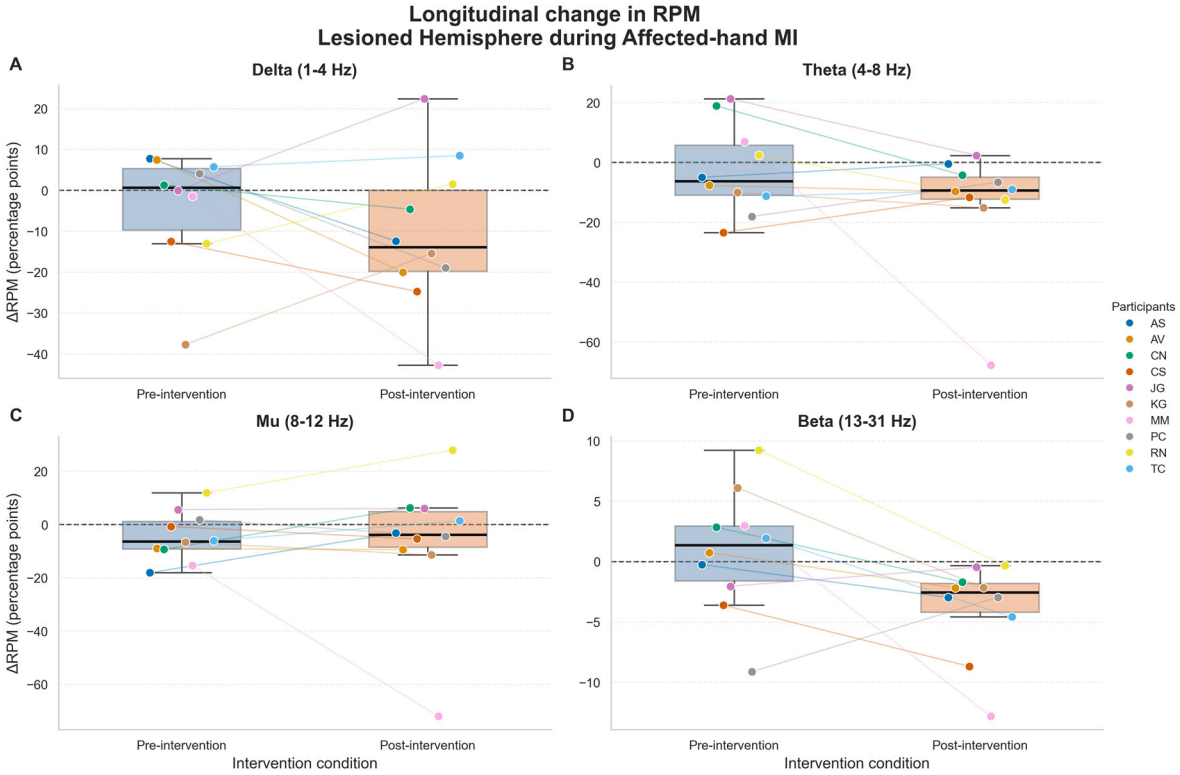

Figure 4. Longitudinal changes in relative power modulation (RPM) during affected-hand MI over the lesioned hemisphere. Values represent ΔRPM = final session – first session and are shown separately for the pre- and post-intervention acquisitions in the δ(A), θ(B), μ (C), and β (D). Boxes summarize the participant distribution, colored points represent individual participants, and connected lines link the two intervention conditions.

IV. Discussion

The present study investigated longitudinal changes in MI-related EEG activity following a 10-session multimodal rehabilitation protocol combining MI-BCI neurofeedback, VR-based motor training, and anodal tDCS.

Two frequency-specific trends were particularly consistent during post-intervention affected-hand MI over the lesioned hemisphere: all participants exhibited negative longitudinal β ΔRPM values, while 9/10 showed the same direction in θ. Under the adopted RPM convention, more negative values are compatible with stronger ERD or weaker ERS during MI relative to rest [4]. However, because RPM is normalized to resting power, this pattern cannot be attributed exclusively to reduced MI-period power; changes in resting power may also have contributed. No RPM comparison remained statistically significant after Bonferroni correction for multiple testing. Thus, these results are better described as longitudinal changes in task-related power modulation rather than direct evidence of improved motor recovery.

The β-band pattern is physiologically plausible because sensorimotor β desynchronization is commonly associated with motor preparation, execution, and imagery, and MI-related desynchronization has been associated with corticospinal excitability [24]. It is also broadly compatible with studies showing that BCI-based motor training can promote functional improvement after stroke [5], [6], [25]. However, stronger ERD should not be equated automatically with improved function or neural recovery. Chen and colleagues found that relationships between motor impairment and ERD/ERS depended on task and hemisphere; during MI, Fugl-Meyer scores were associated with contralesional ERS rather than simply with stronger ERD [26]. Accordingly, the present β result is better interpreted as altered task-related modulation than as restored motor activity.

The θ-band finding should be interpreted more cautiously. θ activity is less established as a direct sensorimotor recovery marker and may reflect attention, cognitive control, action-feedback integration, or coordination within distributed brain networks. In MI-BCI paradigms, θ coupling has been associated with the ability to modulate β rhythms and with sensory feedback modality [27], while slow cortical rhythms have also been implicated in MI-based BCI control [28].

Therefore, the θ pattern may indicate altered engagement with MI and multisensory feedback, but it should remain an exploratory observation.

The exploratory EEG-clinical correlations provide preliminary context but do not support physiological or clinical conclusions. The strongest uncorrected associations involved elbow flexion, elbow extension, and fatigue; none survived correction for the 256 exploratory comparisons, and the smallest Bonferroni-adjusted p-value in the entire family was 0.21. They are therefore reported as descriptive observations only, and the associations in Figure 5 were selected solely as the largest uncorrected coefficients within the sensorimotor bands.

The decision to examine imagined hand and hemisphere separately follows previous evidence that MI after stroke engages distributed, task-dependent sensorimotor networks. De Vico Fallani et al. showed that affected-hand MI after unilateral stroke altered β-band network topology compared with unaffected-hand MI, and that sensorimotor function was predicted by affected-hemisphere connectivity [29]. Similarly, Mansour et al. reported that both ipsilesional and contralesional hemispheres can express ERD/ERS during impaired hand MI, with contralesional signals being especially relevant in more impaired patients [30]. These studies motivated the factorial structure of the present analysis, but they cannot be used to interpret the individual associations reported previously. Our results identify candidate relationships for future studies with larger samples.

These findings may also have limited but useful implications for future adaptive closed-loop neurorehabilitation systems. Although variance- or covariance-based features generally provide stronger MI-BCI classification performance, longitudinal band-specific RPM profiles may provide complementary information about each participant's ability to modulate task- and hemisphere-specific EEG activity across sessions. If replicated, such measures could help monitor interhemispheric modulation over time, guide recalibration, or identify participants who may require alternative MI strategies. This application remains speculative and requires validation in larger controlled studies.

Clinical plausibility is reported by randomized studies reporting benefits from combining VR with tDCS [31], [32]. Nevertheless, the present design cannot determine whether the observed EEG patterns originated from MI-BCI practice, VR motor exercise, tDCS, repeated task exposure, or their interaction at this moment. A sham group is being formed at the present moment. The small sample size is an important limitation of this study. Although n=10 is comparable to several exploratory EEG-BCI neurorehabilitation studies involving repeated sessions and multimodal assessments, it limits statistical power and increases uncertainty about the effect size of our intervention. For this reason, this study should be interpreted as an exploratory analysis. Regarding the intervention, the mechanisms of tDCS are not yet fully understood. The results depend on several anatomical parameters, such as the thickness of the skull and cerebrospinal fluid layer. Consequently, some techniques may need to be individualized.

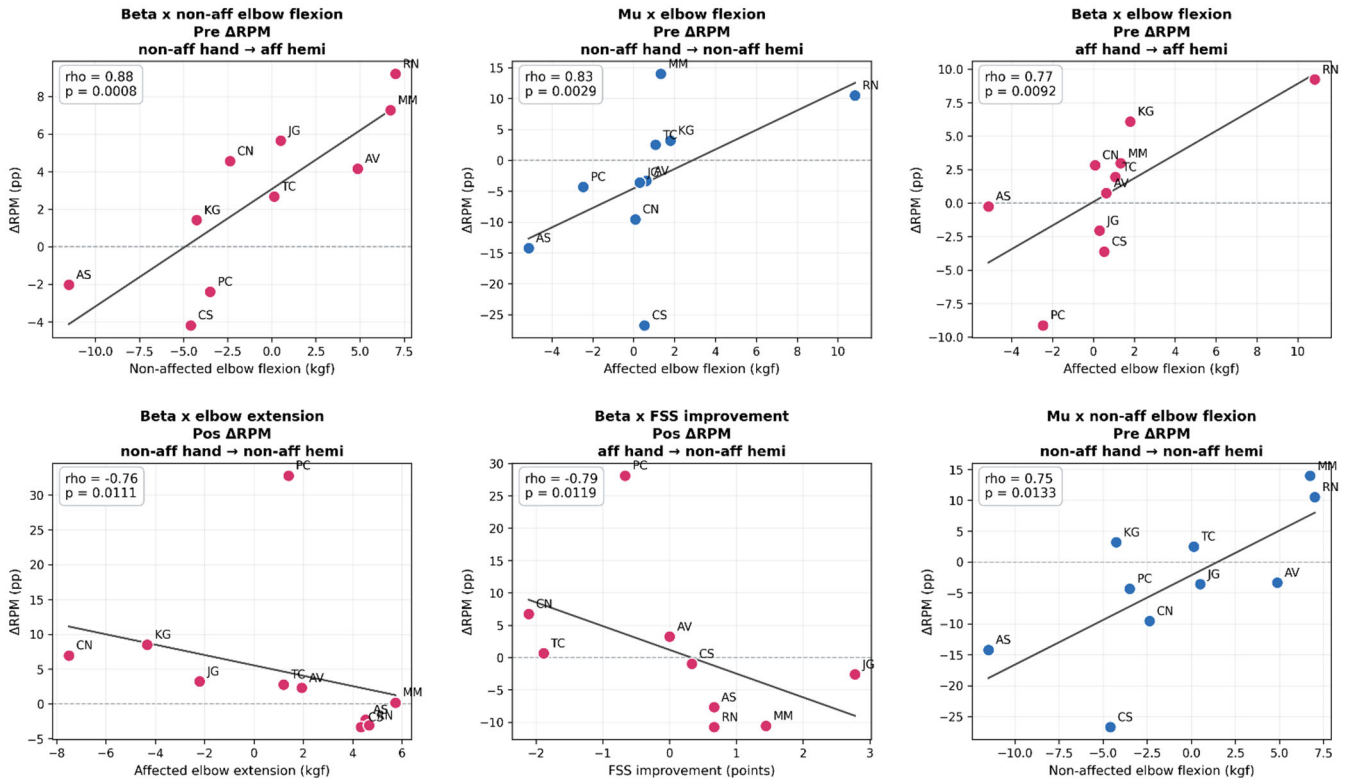

Figure 5. Scatterplots show the strongest uncorrected Spearman correlations between ΔRPM and changes in strength or fatigue. ΔRPM was calculated as final session minus first session and is shown for the indicated acquisition condition, MI task, and hemisphere. Positive clinical change indicates strength gain, whereas positive FSS improvement indicates reduced fatigue severity. These associations did not survive correction for multiple comparisons and should be interpreted as exploratory.

V. Conclusion

This exploratory study investigated longitudinal changes in motor-imagery-related EEG activity during a 10-session intervention combining MI-BCI neurofeedback, VR-based motor training, and anodal tDCS in individuals with chronic stroke. The most consistent descriptive finding was a shift toward more negative RPM during affected-hand MI in the lesioned hemisphere, particularly in the β and θ bands. This pattern is compatible with stronger ERD in the final session, although it does not independently demonstrate improved MI ability or motor recovery. Larger controlled studies are needed to determine whether these changes are reproducible, clinically meaningful, and attributable to specific components of the combined intervention.

Although variance or covariance features have generally achieved stronger MI-BCI classification performance, the present exploratory findings suggest that band-specific power modulation may provide complementary information for adaptive neurorehabilitation. If replicated, individualized β and θ-band RPM profiles could help identify participants who consistently modulate task and hemisphere specific activity across sessions.

***Abstract*— The advancement of assistive technologies has increased the demand for lightweight and structurally efficient materials for rehabilitation devices. In this context, this study presents a comparative investigation of carbon fiber- and glass fiber-reinforced composite laminates for rigid wheelchair seat applications. Mechanical characterization was performed through tensile, compressive, and shear testing, and the resulting material properties were integrated into an analytical design approach based on Classical Laminate Theory (CLT) and further assessed through finite element analysis (FEA). The analytical and numerical results indicated that structural stiffness, rather than material strength, governed the seat design under the prescribed static loading conditions. Both laminate configurations satisfied the adopted deflection criterion and exhibited Tsai-Wu failure indices below the failure threshold, suggesting satisfactory structural performance for the loading scenario considered. The carbon fiber-reinforced laminate achieved the lowest maximum deflection (1.99 mm), together with reduced laminate thickness and lower structural mass, whereas the glass fiber-reinforced laminate represented a more cost-effective alternative based on estimated raw material costs while also satisfying the adopted design criterion. The main contribution of this work is a structured comparison between two composite laminate systems through an integrated experimental-CLT-FEA framework for preliminary structural assessment of wheelchair seat designs. Overall, the results indicate that both laminate configurations are promising candidates for the static loading scenario analyzed. Further studies involving full-scale seat testing, realistic fixation conditions, fatigue, impact, seat-cushion interaction, and user-centered evaluations are necessary before practical implementation can be assessed.**

Keywords—composite material, wheelchair seat, carbon fiber, glass fiber.

I. INTRODUCTION

In recent years, the use of composite materials for wheelchair components has increased significantly. This growing interest is primarily driven by their unique mechanical and physical properties. Composites consist of a matrix phase and a reinforcement phase that are engineered to provide high stiffness, an excellent strength-to-weight ratio, corrosion resistance, and fatigue resistance. Owing to these characteristics, they are particularly well suited for lightweight structural applications, including high-performance wheelchair components. This trend is consistent with international guidelines that promote the development of lighter, more durable assistive devices tailored to users' specific needs [1-5].

Among the various wheelchair components that can benefit from the use of composite materials, the seat plays a fundamental role in providing postural support, user comfort, and functional performance. A rigid seat base improves seating stability by providing adequate support for the wheelchair cushion, thereby promoting a more stable sitting posture and enhancing user safety and mobility [6], [7]. In addition, seating support characteristics directly influence interface pressure, shear forces, and user posture, factors that are associated with pressure injury risk and long-term seating performance [7]. Recent investigations have demonstrated that seat support conditions and seat-base deformation may significantly affect shear loading and sliding behavior during wheelchair use, highlighting the importance of structurally stable seating systems in rehabilitation technologies [8]. Consequently, the development of lightweight and structurally efficient composite seats represents a promising approach for improving seating support while simultaneously reducing the mass of assistive mobility devices.

Although composite materials have been previously investigated for wheelchair structures and lightweight mobility devices, studies focusing specifically on rigid wheelchair seat structures remain limited, particularly regarding the comparative structural performance of different laminate systems under equivalent loading conditions [1], [2]. Furthermore, few studies integrate experimentally determined material properties with analytical laminate design and finite element analysis within a reproducible workflow tailored to assistive technology applications. To address this gap, the present study investigates the use of carbon fiber- and glass fiber-reinforced composite laminates for rigid wheelchair seat applications. The mechanical properties of both laminate systems were determined through tensile, compressive, and shear testing and subsequently incorporated into analytical calculations based on Classical Laminate Theory (CLT) and finite element analyses (FEA) to predict seat deflection, evaluate structural performance, and assess failure indices under prescribed static loading conditions. In addition, laminate thickness, structural mass, and estimated raw material cost were compared to examine the trade-offs between structural efficiency and economic considerations. The main contribution of this work is a structured comparison between two composite laminate families through an integrated experimental-CLT-FEA methodology for the preliminary structural assessment of wheelchair seat designs.

II. Materials and Methods

A. Composite Materials and Laminate Fabrication

To evaluate the influence of the reinforcement material on the structural performance of the seat, two bidirectional woven prepregs were selected: carbon fiber-reinforced (CCS 200) and glass fiber-reinforced (WR 0200), both supplied by the Brazilian manufacturer Texiglass. These materials were selected because they represent two widely used composite reinforcement systems with distinct stiffness-to-weight and cost-performance characteristics. The carbon fiber fabric had an areal weight of 364 g/m², whereas the glass fiber fabric had an areal weight of 200 g/m². Both prepregs employed an epoxy resin matrix.

For the experimental characterization, composite laminates consisting of 12 fabric plies arranged in alternating 0°/90° orientations were manufactured. Following laminate lay-up, vacuum bagging was applied, and the laminates were cured in an oven using a thermal cycle refined through differential scanning calorimetry (DSC) analyses performed to evaluate the curing behavior of the epoxy matrix. Based on these results, a curing cycle of 1 h at 130 °C followed by 4 h at 150 °C was adopted to ensure an adequate degree of cure of the composite laminates. Fig. 1 illustrates the vacuum bag assembly and the laminates positioned inside the oven during processing.

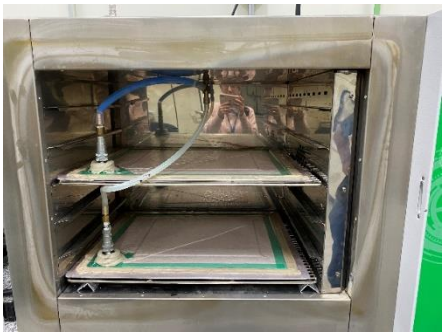

Fig. 1. Laminates positioned inside the oven for the curing cycle.

Mechanical test specimens were subsequently machined from the cured laminates. For the structural analyses, the wheelchair seat was represented by an idealized square composite plate with side dimensions of 400 mm. The plate dimensions were defined based on the seat dimensions of the Dellamed D400 wheelchair, which was used as a reference geometry for the study. This simplified representation was adopted to enable a consistent comparison between the laminate configurations and to ensure compatibility between the analytical and finite element models employed in the structural assessment. The laminate thickness was treated as a design variable and defined according to the number of plies required to satisfy the adopted maximum deflection criterion of 2.5 mm, which was established as a design requirement for the static loading condition investigated in this study.

B. Tensile, Compression, and Shear Testing

Mechanical characterization was performed using an Instron 5982 universal testing machine equipped with a 100 kN load cell. The testing machine and experimental setup are presented in Fig. 2.

Fig. 2. Instron machine used in mechanical tests.

Tensile, compression, and shear tests were conducted according to standards published by ASTM International, including ASTM D3039, ASTM D6641, and ASTM D3518, respectively. All tests were performed on both carbon fiber- and glass fiber-reinforced composite laminates. Five specimens were tested for each material and loading condition.

For the tensile and compression tests, specimens were machined along the 0° and 90° fiber directions, whereas the shear tests employed specimens with a ±45° fiber orientation. The tensile and shear specimens measured 250 × 25 mm, while the compression specimens measured 140 × 13 mm. At least three specimens from each group were instrumented with strain

gauges for strain measurement during testing, enabling the determination of the corresponding elastic properties.

Tensile and shear tests were conducted under displacement control at a crosshead rate of 2 mm/min. Compression tests were performed at a crosshead rate of 0.5 mm/min using a compression fixture, in which both specimen ends were clamped over a length of approximately 63.5 mm prior to testing, in accordance with ASTM D6641.

The experimental results obtained from these tests were subsequently used to determine the elastic properties and strength parameters required for the laminate analyses based on CLT and the Tsai-Wu failure criterion.

C. Classical Laminate Theory and Tsai-Wu Failure Criterion

The mechanical behavior of the laminate was evaluated using CLT, which was employed to determine the equivalent stiffness of the laminate from the elastic properties and stacking sequence of the individual plies. Based on this formulation, the extensional (A), extension–bending coupling (B), and bending (D) stiffness matrices were obtained, as expressed in (1) [9], [10].

$$\begin{Bmatrix} N \\ M \end{Bmatrix} = \begin{bmatrix} A & B \\ B & D \end{bmatrix} \begin{Bmatrix} \varepsilon^0 \\ \kappa \end{Bmatrix} \tag{1}$$

where N and M are the in-plane force and moment resultant vectors, respectively, ε^0 is the mid-plane strain vector, and κ is the laminate curvature vector.

For symmetric laminates, the coupling matrix (B) is equal to zero, allowing the bending stiffness matrix (D) to govern the plate bending behavior through the transformation of the material mechanical properties according to the fiber orientation of each ply. Therefore, the laminate bending stiffness can be determined using (2) [9].

$$D_{ij} = \frac{1}{3}\sum_{k=1}^{N} \bar{Q}_{ij}^{(k)} \left(z_{k+1}^3 - z_k^3\right) \tag{2}$$

where N is the total number of plies, and (k) and (k+1) denote the coordinates of the upper and lower surfaces of the *k*-th ply.

The bending stiffness coefficients were subsequently incorporated into an analytical plate-bending model based on the Lévy solution to estimate the deflection of the wheelchair seat. Due to the mathematical limitations of the analytical formulation, the plate was modeled considering two opposite simply supported edges, providing a conservative approximation of the boundary conditions adopted for the structural assessment. In contrast, the finite element model incorporated the idealized restraints considered in the seat design, allowing the structural response to be evaluated under the prescribed numerical boundary conditions. Consequently, the analytical solution was primarily employed as a preliminary design and verification tool, whereas the finite element model was used for a more detailed assessment of the structural response of the idealized seat configuration investigated in this study. Ply stresses were then obtained from the CLT strain–stress relations.

Failure was evaluated using the Tsai–Wu criterion, which predicts failure when the value of (3) is equal to or greater than 1 [11].

$$F_1\sigma_1 + F_2\sigma_2 + F_{11}{\sigma_1}^2 + F_{22}{\sigma_2}^2 + F_{66}{\tau_{12}}^2 + 2F_{12}\sigma_1\sigma_2 \geq 1 \tag{3}$$

where σ_1 and σ_2 are the stresses in the material principal directions 1 and 2, respectively, and τ_{12} is the in-plane shear stress in the 1–2 coordinate system. The coefficients F_{ij} were calculated from the tensile, compressive, and shear strengths of the material, as defined in (4) [11], [12].

$$F_1 = \frac{1}{X_t} - \frac{1}{X_c}, \quad F_2 = \frac{1}{Y_t} - \frac{1}{Y_c}, \quad F_{11} = \frac{1}{X_t X_c},$$
$$F_{22} = \frac{1}{Y_t Y_c} \quad e \quad F_{66} = \frac{1}{S^2} \tag{4}$$

where X and Y denote the material strengths in the x- and y-directions, respectively, and the subscripts (t) and (c) refer to tensile and compressive strengths. The interaction coefficient F_{12} was calculated according to the procedure proposed in the literature [12].

The criterion was employed to assess whether the predicted stress state of the laminate remained below the failure threshold under the prescribed loading conditions. No progressive damage analysis or ply-by-ply failure propagation modeling was considered in the present study.

D. Numerical Modeling using the Finite Element Method

A finite element model was developed in ANSYS® Parametric Design Language (APDL) 2024 to simulate the structural behavior of the wheelchair seat and to complement the analytical predictions obtained from Classical Laminate Theory (CLT). The composite plate was discretized using SHELL281 elements with an initial element size of 10 mm. A mesh convergence study was performed by reducing the element size to 5 mm to ensure numerical accuracy and mesh-independent results.

The plate geometry was defined as 400 × 400 mm, with thickness varying according to the reinforcement material and laminate configuration. Two opposite edges were fully clamped, whereas the remaining edges were free. The numerical model incorporated idealized constraints intended to represent the attachment of the seat to the wheelchair structure. However, the actual stiffness of the fixation system may vary depending on frame geometry, fastening method, manufacturing tolerances, and assembly conditions. Experimental validation of a full-scale seat mounted on a wheelchair frame is therefore necessary to quantify the influence of these factors on the structural response.

A design load of 1800 N was uniformly distributed over the entire plate surface, as shown in Fig. 3. This load was obtained by applying a safety factor of 1.5 to a nominal service load of 1200 N, corresponding to an adult wheelchair user with a body mass of approximately 120 kg. The adopted loading condition was intended to represent a conservative static loading scenario for the preliminary structural assessment of the wheelchair seat.

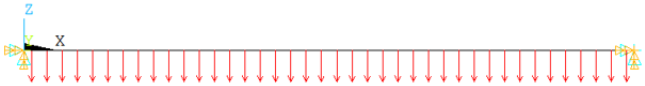

Fig. 3. Boundary conditions for the wheelchair seat.

The finite element models were used to evaluate the structural response of the laminates in terms of maximum

deflection and maximum Tsai–Wu failure index under the prescribed static loading condition. The Tsai-Wu criterion was employed solely to verify whether the predicted stress state remained below the adopted failure threshold, without considering progressive damage evolution, delamination mechanisms, or fatigue effects.

The numerical simulations were based on material properties experimentally determined through tensile, compression, and shear tests performed at the Lightweight Structures Laboratory of the Institute for Technological Research (IPT).

To promote computational reproducibility, the complete ANSYS APDL script used in this study is publicly available in an open-access Zenodo repository [13], enabling the reproduction of the finite element analyses presented in this work.

III. Results and Discussion

A. Mechanical Properties of the Composite Laminates

The tensile, compression, and shear tests conducted on the glass fiber- and carbon fiber-reinforced composites allowed the mechanical properties required for the laminate analyses to be determined. The corresponding results are summarized in Tables I and II.

TABLE I. Mechanical Properties of the WR-200-RE-02B Glass-Fiber-Reforced Laminate.

Property	Symbol	Method	Unity	Value
0° Tensile Strength	F1t	ASTM D3039	MPa (Ksi)	427.521 (62.0)
90° Tensile Strength	F2t	ASTM D3039	MPa (Ksi)	467.771 (67.8)
0° Tensile Modulus	E1t	ASTM D3039	GPa (Msi)	30.722 (4.5)
90° Tensile Modulus	E2t	ASTM D3039	GPa (Msi)	32.08 (4.6)
0° Compressive Strength	F1c	ASTM D6641	MPa (Ksi)	318.271 (46.2)
90° Compressive Strength	F2c	ASTM D6641	MPa (Ksi)	404.945 (58.7)
0° Compressive Modulus	E1c	ASTM D6641	GPa (Msi)	30.604 (4.4)
90° Compressive Modulus	E2c	ASTM D6641	GPa (Msi)	33.428 (4.8)
In-plane Shear Strength 5%	F12	ASTM D3518	MPa (Ksi)	51.996 (7.5)
In-plane Shear Modulus	G12	ASTM D3518	GPa (Msi)	3.865 (0.56)
Poisson's Ratio	v12	ASTM D3039	---	0.131
Poisson's Ratio	v21	ASTM D3039	---	0.135
Cured Ply Thickness	t cured	---	mm (inches)	0.133 (0.0052)

TABLE II. Mechanical Properties of the CCS-200-RE-02B Carbon-Fiber Reforced Laminate.

Property	Symbol	Method	Unity	Value
0° Tensile Strength	F1t	ASTM D3039	MPa (Ksi)	649.397 (94.2)
90° Tensile Strength	F2t	ASTM D3039	MPa (Ksi)	537.167 (77.9)
0° Tensile Modulus	E1t	ASTM D3039	GPa (Msi)	57.279 (8.3)
90° Tensile Modulus	E2t	ASTM D3039	GPa (Msi)	52.087 (7.5)
0° Compressive Strength	F1c	ASTM D6641	MPa (Ksi)	390.499 (56.6)
90° Compressive Strength	F2c	ASTM D6641	MPa (Ksi)	425.673 (61.7)
0° Compressive Modulus	E1c	ASTM D6641	GPa (Msi)	50.285 (7.3)
90° Compressive Modulus	E2c	ASTM D6641	GPa (Msi)	46.634 (6.8)
In-plane Shear Strength 5%	F12	ASTM D3518	MPa (Ksi)	62.625 (9.1)
In-plane Shear Modulus	G12	ASTM D3518	GPa (Msi)	3.692 (0.54)
Poisson's Ratio	v12	ASTM D3039	---	0.07
Poisson's Ratio	v21	ASTM D3039	---	0.044
Cured Ply Thickness	t cured	---	mm (inches)	0.244 (0.0096)

The results indicate that the carbon fiber-reinforced composite exhibits higher stiffness under both tensile and compressive loading conditions. In tension, the tensile modulus reached 57.28 GPa (0°) and 52.09 GPa (90°), while in compression it reached 50.28 GPa (0°) and 46.63 GPa (90°). These values were substantially higher than those obtained for the glass fiber-reinforced composite, which presented tensile moduli of 30.72 GPa (0°) and 32.08 GPa (90°), and compressive moduli of 30.60 GPa (0°) and 33.43 GPa (90°).

In addition, the cured ply thickness of the carbon fiber prepreg (0.24 mm) was approximately 85% greater than that of the glass fiber prepreg (0.13 mm). This characteristic is relevant for laminate design because the flexural stiffness of composite laminates depends not only on the elastic properties of the constituent materials but also on the laminate thickness and ply distribution through the thickness.

The glass fiber-reinforced composite exhibited lower elastic moduli and therefore greater deformability under mechanical loading. Furthermore, the average Poisson's ratio measured for the glass fiber laminate (0.13) was higher than that of the carbon fiber laminate (0.05), indicating a greater tendency for transverse deformation under load. These differences in elastic behavior are expected to influence the bending stiffness and structural response of the laminate configurations evaluated in the subsequent analytical and numerical analyses.

B. Structural Analysis of the Composite Wheelchair Seat

For the calculation of seat deflection in the laminated composite structure, a maximum allowable deflection of 2.5 mm was adopted as a design criterion. This value was selected to limit excessive seat deformation and maintain adequate stiffness of the seating support under the prescribed static loading condition. Although no specific standard prescribing this limit was considered in the present study, minimizing seat deformation may help preserve the mechanical stability of the seating system, since previous studies have shown that seat support conditions and seat-base deformation can influence shear forces, sliding behavior, and seating posture in wheelchair users [7], [8]. The laminate configurations, including the number of plies and laminate thickness, together with the calculated bending stiffness coefficients and the corresponding analytically predicted seat deflections, are summarized in Table III.

TABLE III. Laminate Configuration, Bending Stiffness Coefficients and Analytically Deflection for Carbon and Glass Fiber-Reinforced Composite Materials.

Fiber - reinforced	Number of plies	Thickness (mm)	D11	D22	D12	D66	Maximum deflection (mm)
Carbon	18	4.40	773936.00	773936.01	36704.62	36500.96	2.13
Glass	38	5.05	340821.71	340821.71	45209.54	41578.99	2.46

The analytical results indicated that both laminate configurations satisfied the adopted maximum deflection criterion of 2.5 mm. The experimentally determined elastic properties incorporated into the CLT calculations revealed substantial differences in laminate bending stiffness between the two reinforcement systems. The carbon fiber-reinforced laminate exhibited higher bending stiffness coefficients, particularly for the D_{11} and D_{22} terms, reflecting the higher elastic moduli measured during mechanical characterization. Consequently, the carbon fiber laminate achieved the lowest

predicted maximum deflection (2.13 mm), despite having a smaller thickness of 4.40 mm and fewer plies (18) than the glass fiber laminate, which required 38 plies and a thickness of 5.05 mm to achieve a predicted deflection of 2.46 mm. These results indicate that the higher stiffness of the carbon fiber reinforcement enabled the adopted deflection criterion to be satisfied with a thinner and lighter laminate configuration.

It should be noted that the analytical predictions were obtained using a simplified plate-bending model based on the Lévy solution and therefore represent preliminary estimates of the structural response. Because the analytical formulation employed a conservative approximation of the boundary conditions, the calculated deflections should be interpreted primarily as a design-oriented assessment of the laminate behavior under the prescribed static load.

C. Numerical Evaluation of Stress, Deflection, and Tsai–Wu Failure Index

The first principal stress distribution obtained from the finite element analysis exhibited maximum values near the clamped edges and minimum values in the central region for both laminates, as depicted in Fig. 4.

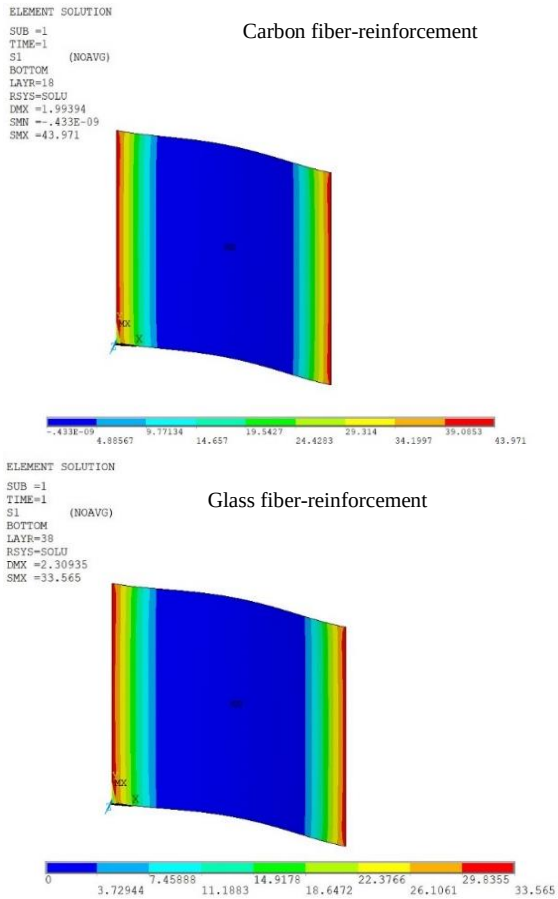

Fig. 4. First Principal Stress distribution for the carbon fiber- and glass fiber-reinforced laminates, respectively.

This behavior is characteristic of rectangular plates subjected to uniformly distributed transverse loading, where fully constrained boundaries generate higher bending moments and consequently higher stress concentrations near the supports. The symmetric stress distribution confirms that the structural response was dominated by bending.

The finite element model predicted maximum deflections of 1.99 mm and 2.31 mm for the carbon and glass laminates, respectively, corresponding to reductions of approximately 7% and 6% compared with the analytical predictions. The finite element results predicted slightly lower deflections than those obtained analytically. This difference is expected because the analytical solution was based on a simplified boundary condition with opposite simply supported edges, whereas the finite element model included additional constraints associated with the seat attachment configuration. Since increased boundary restraint leads to higher structural stiffness and reduced displacement, the analytical predictions can be regarded as conservative estimates of the laminate response under the prescribed loading conditions. The corresponding maximum deflection contours predicted for the carbon fiber- and glass fiber-reinforced laminate configurations are presented in Fig. 5.

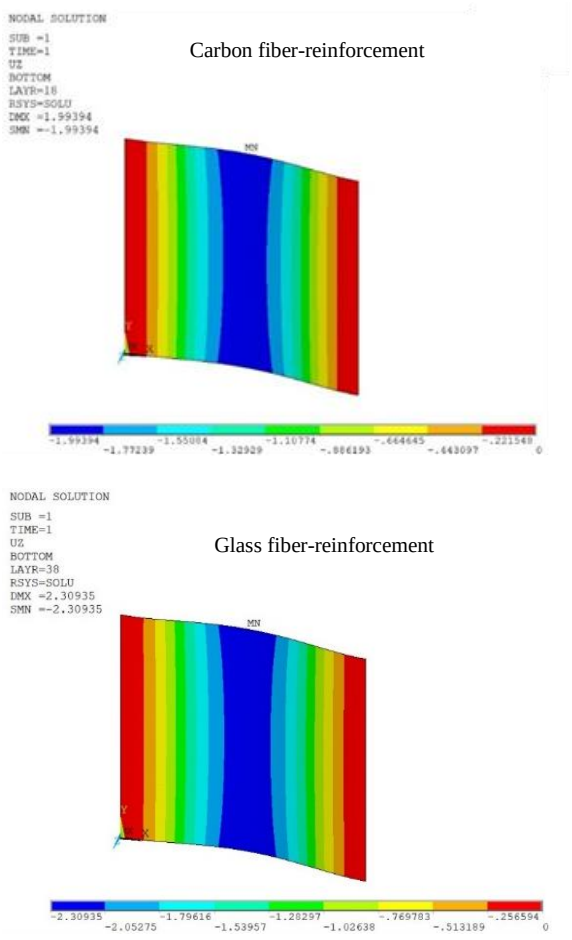

Fig. 5. Maximum deflection contours for the carbon fiber- and glass fiber-reinforced laminates, respectively.

These numerical results are consistent with the bending stiffness coefficients obtained from the Classical Laminate Theory analysis, particularly the D_{11} and D_{22} terms. The higher stiffness experimentally measured for the carbon fiber-reinforced laminate resulted in larger laminate bending stiffness

coefficients and consequently lower deflection values in both the analytical and numerical models.

Although deflection was adopted as the primary design criterion, the Tsai-Wu failure criterion was also evaluated through finite element analysis. The corresponding maximum Tsai-Wu failure indices for the carbon fiber- and glass fiber-reinforced laminates are presented in Fig. 6.

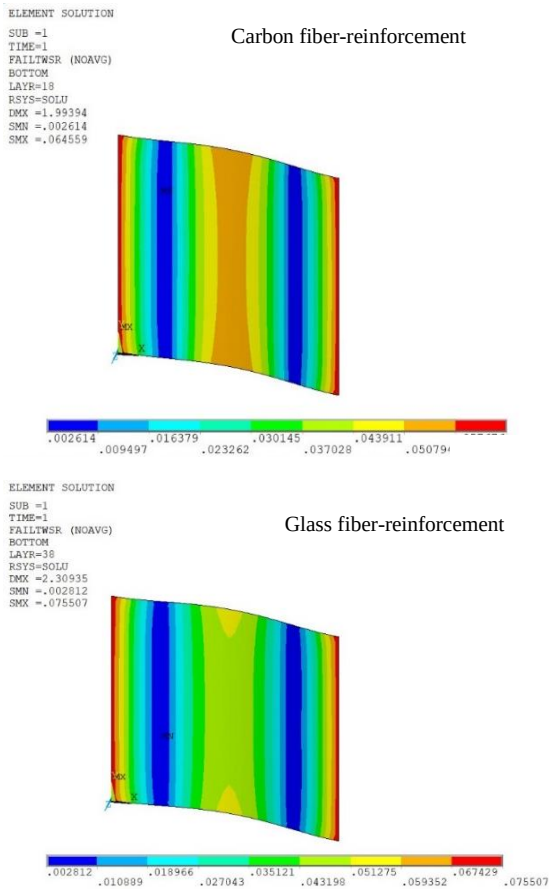

Fig. 6. Tsai-Wu failure index distribution for the carbon fiber- and glass fiber-reinforced laminates, respectively.

As shown in Fig. 6, the maximum Tsai-Wu indices obtained for the carbon (0.065) and glass (0.075) fiber-reinforced laminates remained well below the critical value of 1.0. These results indicate that, for the prescribed static loading condition and within the assumptions adopted by the numerical model, the predicted stress states remained below the failure threshold defined by the Tsai-Wu criterion. It should be noted that the present analysis was limited to the evaluation of the laminate response through the maximum Tsai-Wu index and did not include progressive damage modeling or ply-by-ply failure analysis. Consequently, it was not possible to determine the sequence of potential ply failures or assess damage evolution mechanisms.

Accordingly, the numerical results suggest that the stress levels developed in both laminate configurations remained within the limits defined by the adopted failure criterion for the prescribed loading condition.

The results presented in this study should be interpreted in light of several limitations. The structural assessment was performed using an idealized plate geometry subjected to a prescribed static load, and the complete wheelchair seat was not manufactured or experimentally tested. Consequently, aspects such as fatigue behavior, impact resistance, damage accumulation, long-term durability, and the effects of manufacturing-related imperfections were not evaluated. Furthermore, the interaction between the seat, cushion, and user, as well as realistic pressure distributions and dynamic loading conditions, were not considered in the present analysis.

Although the numerical model included idealized constraints intended to represent the attachment of the seat to the wheelchair frame, variations in fixation stiffness and assembly conditions may influence the actual structural response and should be investigated experimentally in future studies.

Together with the deflection analysis, these results indicate that both laminate configurations satisfied the structural design criteria established for the prescribed static loading scenario and support their preliminary structural assessment within the assumptions adopted in the present study.

D. Technical and Economic Assessment of Carbon Fiber- and Glass Fiber-Reinforced Composites for Seat Applications

From a structural perspective, the results indicate that both carbon fiber- and glass fiber-reinforced laminate configurations satisfied the design criteria established for the prescribed static loading condition. The carbon fiber laminate required a thickness of 4.40 mm, whereas the glass fiber laminate required a thickness of 5.05 mm to satisfy the adopted maximum deflection limit. These differences reflect the higher stiffness of the carbon fiber reinforcement and its influence on the laminate bending response.

In the present study, the cost of carbon fiber prepreg was estimated at R$ 376.40/m², whereas glass fiber prepreg was estimated at R$ 73.84/m². These values were based on supplier quotations obtained in mid-2025 and exclude applicable taxes. Therefore, the reported costs should be regarded as indicative values, as they may vary according to market conditions, supplier availability, and economic factors.

Based on the seat area of 0.16 m², the required number of plies for each laminate configuration, and the corresponding mass per ply, the direct raw material cost and final seat mass were estimated for each reinforcement system. The resulting values are summarized in Table IV.

TABLE IV. COST AND MASS OF CARBON FIBER- AND GLASS FIBER-REINFORCED USED IN A WHEELCHAIR SEAT.

Reinforcement Material	Number of plies	Direct raw material cost	Seat mass (kg)
Carbon	18	R$ 1,545.87	0.977
Glass	38	R$ 477.83	1.545

While the carbon fiber-reinforced laminate exhibited higher specific stiffness and enabled reductions in laminate thickness and structural mass, its estimated direct raw material cost was

substantially higher than that of the glass fiber-reinforced laminate. Based solely on the prepreg material costs considered in this study, the carbon fiber laminate was approximately 223.5% more expensive than the glass fiber laminate. In contrast, the carbon fiber configuration resulted in a 36.7% reduction in seat mass, highlighting the trade-off between lightweight design and material cost.

It should be noted that this economic comparison reflects only the estimated direct raw material cost and does not include manufacturing-related expenses such as material waste, vacuum bagging consumables, curing energy, labor, tooling, machining, assembly, or quality-control procedures. Consequently, the results should not be interpreted as representative of the final manufacturing cost of a complete wheelchair seat.

For the static loading scenario investigated, both laminate configurations satisfied the adopted structural design criterion and remained below the Tsai-Wu failure threshold. The carbon fiber laminate provided the lowest deflection and structural mass, whereas the glass fiber laminate represented a lower-cost material alternative. These results illustrate the trade-off between structural efficiency and material cost that must be considered during the preliminary design of composite wheelchair seating systems.

Although the reduced mass achieved with the carbon fiber laminate may be advantageous in applications where lightweight components are desired, the present study did not assess factors such as propulsion efficiency, user effort, comfort, durability, or clinical performance. Therefore, the potential functional implications of weight reduction should be investigated through future experimental and user-centered studies.

IV. Conclusion

This study compared carbon fiber- and glass fiber-reinforced composite laminates for wheelchair seat applications through an integrated methodology involving mechanical characterization, analytical modeling based on CLT, and FEA. The results indicated that structural stiffness, rather than material strength, governed the response of the proposed seat configuration under the prescribed static loading conditions. Both laminate configurations satisfied the adopted deflection criterion and exhibited Tsai-Wu failure indices below the adopted failure threshold for the loading scenario considered.

The analytical and numerical approaches showed good agreement regarding the structural behavior of the investigated laminates. Slightly lower deflections were obtained from the finite element analyses, which is consistent with the different boundary conditions adopted in each approach. While the analytical Lévy solution required a simplified plate-support condition and therefore provided a conservative estimate of displacement, the finite element model incorporated the idealized boundary restraints adopted for the seat design. Consequently, the numerical analyses provided a more detailed assessment of the structural response of the idealized seat configuration investigated in this study.

It should be emphasized that the adopted maximum deflection limit of 2.5 mm represents a design requirement established for the present study and should not be interpreted as a standardized acceptance criterion for wheelchair seating systems. Similarly, the Tsai-Wu failure indices obtained in the numerical analyses indicate only that the predicted stress states remained below the failure threshold defined by the adopted criterion under the prescribed static loading condition. These results do not provide information regarding fatigue resistance, damage progression, delamination behavior, impact resistance, or long-term durability.

The carbon fiber-reinforced laminate achieved the lowest structural mass and deflection, reflecting the higher specific stiffness of carbon fibers and allowing the adopted design criterion to be satisfied with fewer plies and reduced laminate thickness. In contrast, the glass fiber-reinforced laminate represented a lower-cost alternative when considering direct raw material costs, while also satisfying the structural requirements established for the analyzed loading condition. These findings highlight the trade-off between structural efficiency and material cost that must be considered during the preliminary design of composite seating structures for assistive technology applications.

From an assistive technology perspective, the reduction in structural mass achieved with the carbon fiber laminate may be advantageous because lighter wheelchair components are generally associated with reduced inertial loads during handling, transportation, and propulsion. However, the present study did not evaluate clinical outcomes, user effort, comfort, propulsion efficiency, seating biomechanics, or functional performance. Therefore, any potential benefits associated with mass reduction should be confirmed through experimental and user-centered investigations.

The principal methodological contribution of this work lies in the structured comparison of two composite laminate systems using experimentally determined material properties integrated with CLT-based analytical calculations, failure assessment, and finite element analysis within a reproducible design framework. The main lessons learned from this study are that: (*i*) laminate stiffness was the governing design parameter under the analyzed loading conditions; (*ii*) carbon fiber reinforcement enabled substantial mass reduction with fewer plies and lower laminate thickness; (*iii*) glass fiber reinforcement remained a competitive lower-cost alternative from a raw-material perspective; and (*iv*) the combined use of experimental characterization, CLT, and FEA provided consistent support for the preliminary structural assessment of composite wheelchair seat concepts.

The results should be interpreted as a preliminary structural assessment of two laminate configurations under an idealized static loading scenario. Important research gaps remain and should be addressed in future work, including full-scale seat manufacturing and experimental testing, validation of realistic seat-to-frame fixation conditions, fatigue and impact evaluation, investigation of seat-cushion-user interaction, assessment of realistic pressure distributions, and studies involving comfort, postural support, and functional performance with wheelchair users. Within these limitations, the methodology presented provides a useful foundation for future structural optimization and development of composite wheelchair seating systems.

***Resumo*—O acesso às tecnologias assistivas permanece limitado, especialmente em contextos de vulnerabilidade social, devido aos elevados custos e à baixa disponibilidade de dispositivos adaptados. Nesse cenário, este trabalho teve como objetivo desenvolver um conjunto modular de bancos terapêuticos para crianças com paralisia cerebral, utilizando princípios da cultura maker e processos de fabricação digital. A estimativa dos custos diretos de materiais e serviços resultou em valor inferior à média dos conjuntos comerciais utilizados como referência. O equipamento foi aplicado preliminarmente em ambientes de pesquisa e atendimento terapêutico, permitindo observar sua utilização em atividades funcionais. Os resultados demonstram a viabilidade técnica do processo de desenvolvimento e fabricação digital proposto, evidenciando seu potencial para produção local de dispositivos terapêuticos em ambientes makers.**

***Palavras-chave*—Bancos terapêuticos, tecnologia assistiva, cultura maker; fabricação digital, paralisia cerebral.**

I. Introdução

A tecnologia assistiva (TA), compreendida como o conjunto de produtos, recursos e serviços que promovem funcionalidade, independência e participação de pessoas com deficiência [1], desempenha papel fundamental na melhoria da qualidade de vida e da inclusão social. Entretanto, o acesso a esses recursos permanece restrito, sobretudo em contextos de vulnerabilidade social, devido ao elevado custo, à limitada disponibilidade e à escassa personalização dos dispositivos. Estima-se que mais de 2,5 bilhões de pessoas necessitem de pelo menos um produto de tecnologia assistiva, sendo que uma parcela significativa ainda não possui acesso adequado, especialmente em países de baixa e média renda [2].

Entre os grupos que mais dependem desses recursos estão as crianças com deficiência, especialmente aquelas com paralisia cerebral, cuja condição demanda o uso contínuo de dispositivos de posicionamento, mobilidade e comunicação para favorecer o desenvolvimento funcional, a participação social e a autonomia ao longo do crescimento. A paralisia cerebral (PC) é definida como uma condição do neurodesenvolvimento de início precoce e caráter permanente, que acompanha o indivíduo ao longo de toda a vida. Caracteriza-se por limitações na atividade decorrentes de distúrbios do desenvolvimento do movimento e da postura, manifestando-se por alterações motoras como espasticidade, distonia, coreoatetose e/ou ataxia [3]-[5].

Entre os recursos utilizados na reabilitação dessas crianças destacam-se os dispositivos de posicionamento, que contribuem para o alinhamento postural, o controle de tronco e a realização de atividades terapêuticas e funcionais. Entretanto, esses equipamentos frequentemente apresentam elevado custo e limitada disponibilidade, dificultando seu acesso em serviços públicos de saúde e por famílias de baixa renda.

Nesse sentido, a cultura maker, entendida como um movimento fundamentado na aprendizagem pela prática, na colaboração e no compartilhamento de conhecimentos [6], aliada às tecnologias de fabricação digital — conjunto de processos de manufatura controlados por computador que transformam modelos digitais em objetos físicos [7] — emerge como uma alternativa promissora para o desenvolvimento de tecnologias assistivas acessíveis, personalizadas e reproduzíveis. Essas abordagens possibilitam a fabricação local de dispositivos, contribuindo para a redução dos custos de produção, a adaptação às necessidades específicas dos usuários e a ampliação do acesso aos recursos assistivos.

Embora o uso da impressão 3D e de outras tecnologias de fabricação digital tenha crescido significativamente na área da tecnologia assistiva, ainda são escassos estudos que descrevam o desenvolvimento e a avaliação de dispositivos terapêuticos de baixo custo voltados especificamente à reabilitação de crianças com paralisia cerebral, considerando sua viabilidade técnica e seu potencial de replicação em contextos de recursos limitados.

Diante desse cenário, este trabalho tem como objetivo desenvolver um conjunto modular de bancos terapêuticos por meio de um processo estruturado de fabricação digital baseado nos princípios da cultura maker e realizar uma avaliação preliminar de sua aplicação em ambientes de reabilitação.

II. Bancos Terapêuticos na Reabilitação de Crianças com Paralisia Cerebral

O conjunto de bancos terapêuticos (Fig. 1) consiste em um equipamento modular destinado à realização de atividades terapêuticas voltadas ao desenvolvimento do equilíbrio, do controle postural, do fortalecimento muscular e das habilidades motoras funcionais. Composto por módulos de diferentes alturas, o equipamento possibilita a execução de exercícios como subir e descer degraus, sentar, levantar e deslocar-se entre diferentes níveis de apoio, permitindo adequar as atividades às capacidades funcionais e à evolução clínica de cada criança. Em geral, esses conjuntos são comercializados em kits compostos por três a seis módulos que se encaixam uns dentro dos outros (Fig. 2), característica que facilita seu armazenamento, transporte e organização em ambientes terapêuticos.

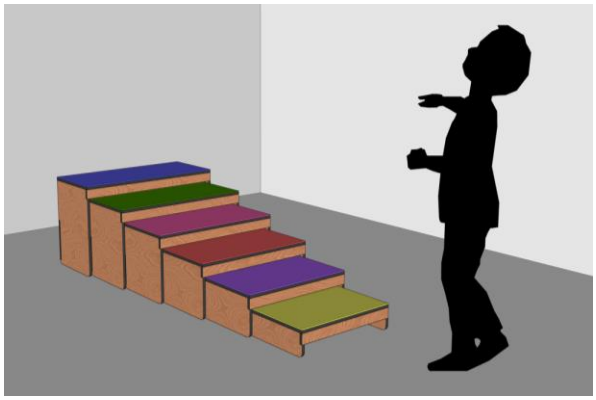

Fig. 1. Conjunto de bancos terapêuticos.

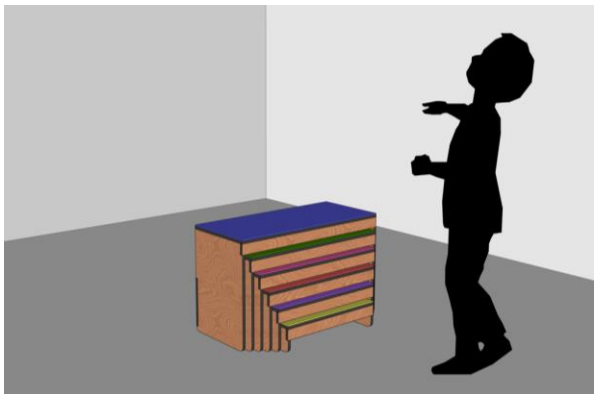

Fig. 2. Conjunto de bancos terapêuticos recolhidos.

Em um estudo piloto com oito crianças com paralisia cerebral, os autores [8] avaliaram um programa de treinamento funcional orientado à tarefa que incluía exercícios como subida e descida de degraus, step-ups, step-downs, sentar e levantar, caminhada em rampas e escadas. Os autores observaram melhora significativa da força muscular, do desempenho funcional, da marcha e da capacidade de realizar o movimento de sentar e levantar após quatro semanas de treinamento.

Considerando que o conjunto de bancos terapêuticos desenvolvido neste estudo pode permitir a execução de atividades semelhantes às descritas em [8], seu uso apresenta potencial para apoiar programas de treinamento funcional voltados ao desenvolvimento das habilidades motoras de crianças com paralisia cerebral. Contudo, ressalta-se que a aplicação do equipamento em ambientes de atendimento, pesquisa ou domiciliares ainda requer estudos específicos que avaliem sua eficácia, segurança e aplicabilidade em diferentes contextos de uso.

III. Concepção, Métodos e Materiais

O projeto foi concebido a partir da análise de conjuntos de bancos terapêuticos disponíveis comercialmente e do levantamento de requisitos identificados durante a prática clínica da fisioterapia pediátrica no Laboratório Inventivo em Tecnologias Assistivas (Lab EITA), da Universidade Federal de Goiás (UFG). A proposta buscou preservar as funcionalidades dos equipamentos convencionais, incorporando soluções voltadas à redução dos custos de produção, à simplificação do processo de fabricação e à possibilidade de replicação em laboratórios makers, em consonância com os princípios da fabricação digital e da cultura maker.

Como requisito inicial de projeto, optou-se pela utilização de chapas de MDF (*Medium Density Fiberboard*), em razão de sua ampla disponibilidade comercial, baixo custo e compatibilidade com processos de fabricação digital, especialmente o corte a laser. O material apresenta características favoráveis ao processamento por corte a laser, possibilitando a obtenção de peças com precisão dimensional e bom acabamento superficial quando empregados parâmetros adequados de processamento [9]. Além disso, sua superfície homogênea e a facilidade de colagem e acabamento favorecem a fabricação de componentes com encaixes precisos, contribuindo para a simplificação da montagem e para a reprodução do equipamento em diferentes laboratórios makers.

Em comparação com processos construtivos que empregam materiais como compensado e perfis metálicos, o uso do MDF associado ao corte a laser permite simplificar determinadas etapas de fabricação, dispensando operações como soldagem e reduzindo a necessidade de usinagem especializada. Essa característica favorece a produção das peças em ambientes de fabricação digital com infraestrutura relativamente simples.

Além do MDF, foram empregados outros materiais no processo de fabricação, cujas especificações são apresentadas na Tabela I. Entre os insumos utilizados estão folhas de etileno-acetato de vinila (EVA) com 4 mm de espessura, adesivo à base de acetato de polivinila (PVA), adesivo instantâneo à base de cianoacrilato e parafusos para madeira. O EVA foi aplicado como revestimento das superfícies superiores dos módulos e fixado ao MDF por meio do adesivo à base de cianoacrilato, enquanto o adesivo PVA e os parafusos foram empregados na união e fixação dos componentes estruturais.

Materiais Empregados		
Material	***Especificação***	***Finalidade***
Chapa de MDF	12mm	Fabricação dos seis módulos
Folha de EVA	4mm	Revestimento
Cola Branca PVA Extra	500g	Colagem das peças de MDF
Cola Cianoacrilato	100g	Colagem do EVA nos Módulos
Parafusos para Madeira	3,5mm x 25 mm	Fixação das peças de MDF

TABELA I

A. Modelagem Digital

A modelagem tridimensional do conjunto de bancos terapêuticos foi desenvolvida no SketchUp para Web, plataforma on-line de modelagem tridimensional com acesso gratuito,

utilizada para a definição da geometria, das dimensões e dos encaixes entre os módulos. Como requisito inicial de projeto, estabeleceu-se a utilização de chapas de MDF com 12 mm de espessura, em razão de sua compatibilidade com o processo de corte a laser e de sua disponibilidade comercial.

A partir dessa restrição dimensional, todas as peças foram projetadas considerando a espessura do material, garantindo o correto encaixe dos componentes e a estabilidade estrutural do conjunto. O ambiente CAD (Computer Aided Design) possibilitou ainda a realização de ajustes dimensionais, a verificação das interferências entre as peças e a visualização do conjunto antes da fabricação física.

Os módulos foram dimensionados de forma progressiva, sendo o primeiro com 10,5 cm de altura e os demais acrescidos de incrementos de 6,5 cm até o sexto módulo (Fig. 3). A definição desses valores teve como referência a experiência prática desenvolvida no Lab EITA em atividades de avaliação funcional e reabilitação pediátrica, considerando a necessidade de oferecer diferentes níveis de altura para adaptação das atividades às capacidades funcionais das crianças. O incremento de 6,5 cm foi adotado como parâmetro de projeto para estabelecer diferenças graduais entre os níveis de apoio, permitindo a progressão das atividades sem produzir variações excessivas de demanda entre módulos consecutivos.

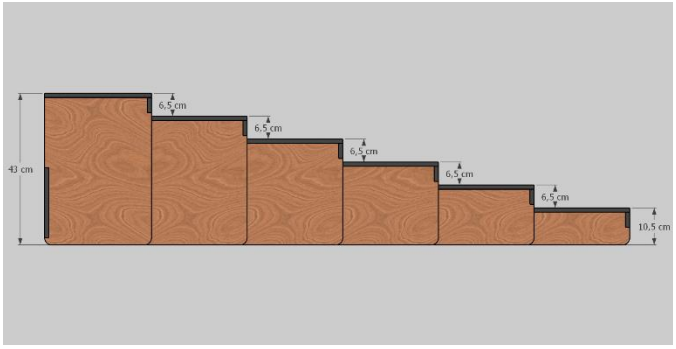

Fig. 3. Vista lateral do conjunto de bancos terapêuticos.

Consequentemente, os incrementos sucessivos de 6,5 cm resultaram em alturas de 17 cm, 23,5 cm, 30 cm, 36,5 cm e 43 cm (Fig. 4). A progressão estabelecida permite selecionar diferentes alturas de apoio de acordo com a atividade terapêutica e as características funcionais de cada criança, além de possibilitar a combinação dos módulos em diferentes configurações.

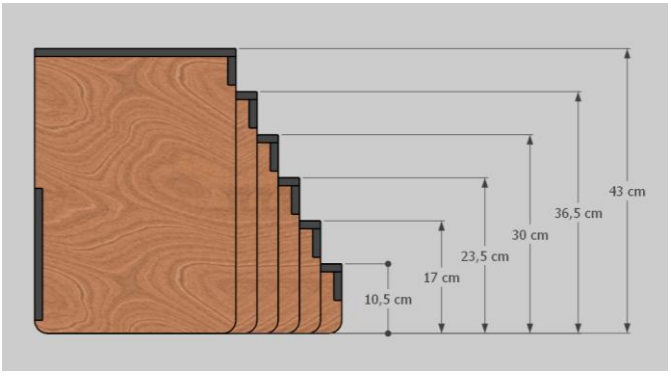

Fig. 4. Vista lateral do conjunto de bancos terapêuticos recolhidos.

Visando ao encaixe entre os módulos, cada banco foi projetado com um comprimento 5 cm inferior ao do módulo imediatamente superior, permitindo que todos fossem armazenados de forma compacta quando não estivessem em uso. Essa solução reduz o espaço necessário para armazenamento, facilita o transporte e a organização do equipamento em ambientes terapêuticos, além de contribuir para sua praticidade durante a rotina clínica.

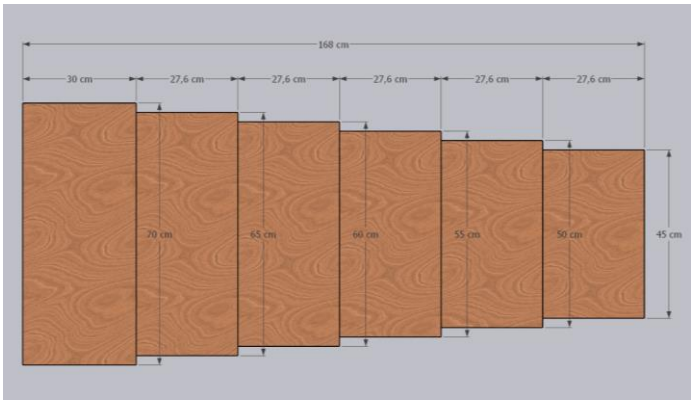

Fig. 5. Vista superior do conjunto de bancos terapêuticos.

Para facilitar o manuseio do conjunto e evitar a separação completa de seus componentes durante a retirada para uso, foram incorporadas abas de retenção em todos os módulos. Esses dispositivos atuam como limitadores mecânicos de deslocamento, impedindo o desprendimento completo entre as peças durante a abertura do conjunto (Fig. 6). Dessa forma, mantém-se o alinhamento lateral dos bancos, facilitando sua organização para utilização. Adicionalmente, a aba frontal do primeiro módulo foi dimensionada para funcionar como um puxador, permitindo a abertura e a organização do conjunto de forma prática.

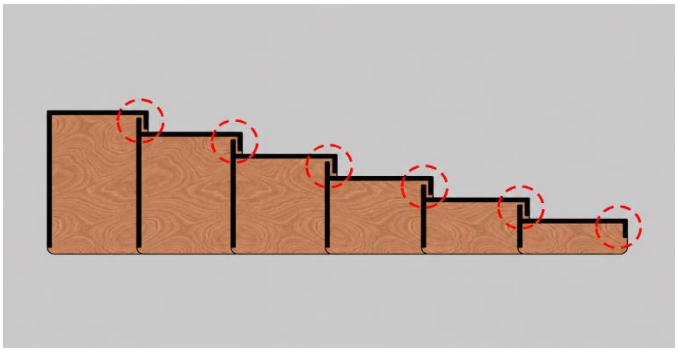

Fig. 6. Corte longitudinal do conjunto de bancos terapêuticos.

Com o objetivo de facilitar o deslocamento do equipamento, o projeto foi concebido de modo que apenas as laterais dos bancos permanecessem em contato com o piso. As extremidades inferiores dessas peças receberam cantos arredondados, permitindo que o conjunto transponha pequenas irregularidades superficiais com menor resistência ao arraste. Adicionalmente, a travessa posterior foi posicionada acima do nível do piso, reduzindo a área de contato durante o deslocamento e, consequentemente, o esforço necessário para a abertura e organização do conjunto. Seus cantos superiores receberam acabamento curvo, minimizando a possibilidade de interferência entre os módulos durante sua movimentação e evitando o travamento entre as peças. (Fig. 7).

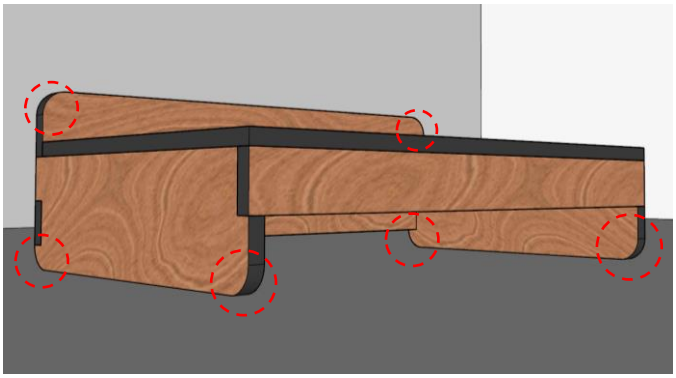

Fig. 7. Vista em perspectiva do primeiro módulo do conjunto.

As peças foram projetadas com encaixes intertravados do tipo dedo (*finger joints*), cuja geometria complementar favorece o acoplamento e o posicionamento entre as peças (Fig. 8). Em processos de fabricação digital, a precisão geométrica das superfícies de contato constitui um aspecto relevante para o adequado ajuste das juntas, uma vez que desvios podem resultar em folgas, interferências ou dificuldades de montagem [11]. A geometria desses encaixes atua como um sistema de orientação, restringindo combinações incompatíveis entre as peças e reduzindo a possibilidade de erros durante a montagem. Essa solução torna o processo construtivo mais intuitivo, contribuindo para que o equipamento possa ser montado por diferentes usuários, mesmo sem experiência prévia.

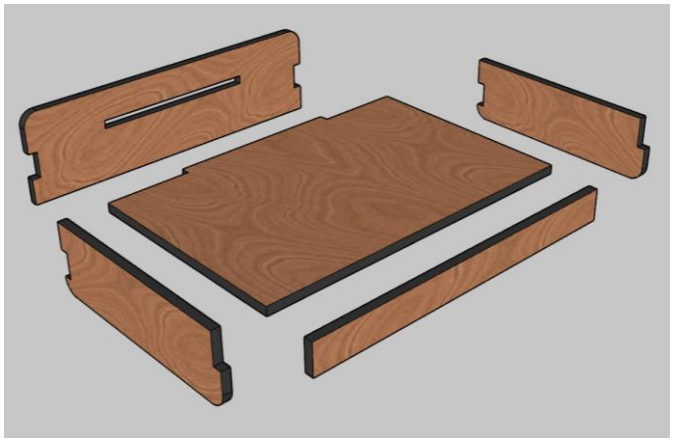

Fig. 8. Diagrama do primeiro módulo do conjunto.

De modo geral, as decisões de projeto priorizaram a simplicidade construtiva, a funcionalidade e a replicabilidade do equipamento, princípios alinhados à cultura maker e à fabricação digital. A utilização da modelagem tridimensional possibilitou validar virtualmente as soluções propostas antes da fabricação, reduzindo a necessidade de retrabalhos e contribuindo para a obtenção de um equipamento modular passível de reprodução.

B. Planificação e Organização das Peças

Em razão de incompatibilidades entre o formato de saída do SketchUp para Web e a interpretação dos arquivos pelo software RDWorks, tornou-se necessária uma etapa intermediária de revisão e compatibilização no AutoCAD. Nessa etapa, foram verificadas as dimensões, os encaixes e a disposição das peças no plano de corte, além da organização dos componentes para melhor aproveitamento da chapa de MDF. Posteriormente, o plano de corte foi exportado em formato PDF e importado para o RDWorks para configuração dos parâmetros operacionais e envio à máquina de corte a laser.

Cada módulo do conjunto foi concebido com cinco peças: duas laterais, uma plataforma superior, uma travessa frontal e uma travessa posterior (Fig. 9).

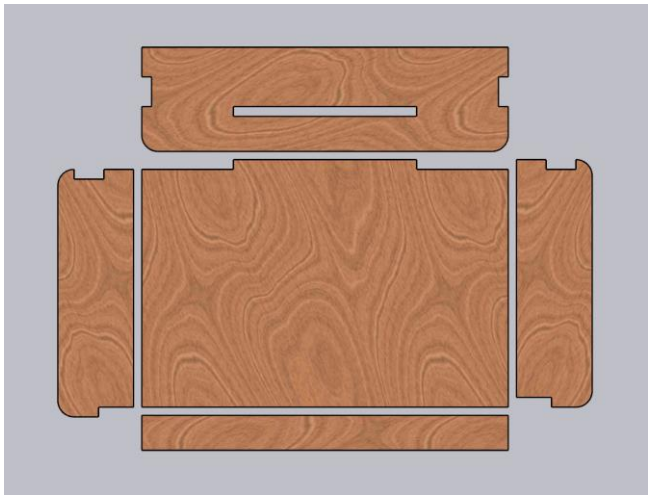

Fig. 9. Módulo planificado.

Uma vez realizada a planificação dos seis módulos e sua disposição em uma área correspondente a uma chapa padrão de MDF (2,75 m × 1,85 m), verificou-se que a fabricação de um conjunto completo de bancos terapêuticos consome aproximadamente 75% da área útil de uma única chapa (Fig. 10). Esse aproveitamento permite estimar que, com três chapas de MDF, seja possível fabricar quatro conjuntos completos de bancos, evidenciando a eficiência do plano de corte e o reduzido desperdício de material.

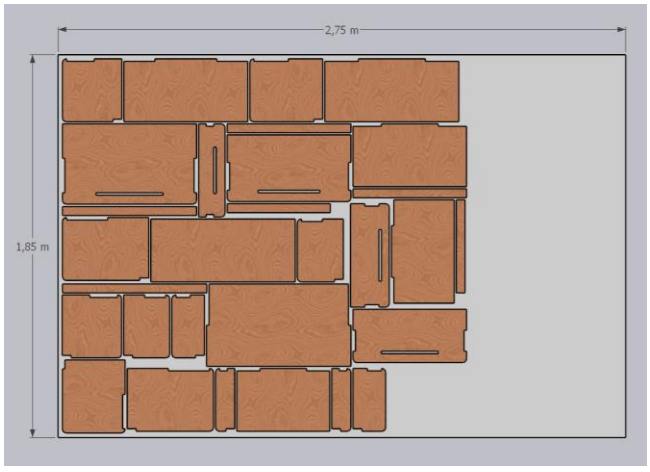

Fig. 10. Bancos terapêuticos planificados na área da chapa de MDF.

Após a exportação do modelo tridimensional das peças planificadas em formato STL, o arquivo foi convertido para o formato DXF por meio da plataforma online de acesso gratuito GroupDocs. Posteriormente, o arquivo DXF foi aberto no software AutoCAD, utilizando-se uma licença educacional, para a remoção de linhas excedentes, a conferência final das dimensões e a geração do arquivo em formato PDF.

Na impossibilidade de obtenção de uma licença educacional do AutoCAD, o software de código aberto LibreCAD pode ser

empregado como alternativa para essa etapa. Dessa forma, o emprego de ferramentas alternativas permite a reprodução do fluxo de trabalho sem a necessidade de aquisição de licença comercial. Em seguida, o arquivo em formato PDF foi importado para o software RDWorks, no qual foram definidos os parâmetros operacionais da máquina de corte a laser, incluindo potência, velocidade e sequência de corte.

A fabricação e montagem dos componentes foi realizada nas instalações do IPE Lab (Laboratório de Ideias, Prototipagem e Empreendedorismo), localizado no Parque Tecnológico Samambaia da Universidade Federal de Goiás (UFG). O laboratório disponibiliza infraestrutura voltada ao desenvolvimento de protótipos e processos de fabricação digital, atendendo demandas de projetos acadêmicos, empresas e inventores independentes, constituindo um ambiente adequado para o desenvolvimento e a validação de tecnologias [10].

O corte das peças foi realizado em uma máquina de corte a laser Delta CNC (Fig. 11), modelo 1310, com potência de 130 W e área útil de corte de 1,30 m × 1,00 m. Em razão das dimensões da área útil do equipamento serem inferiores às da chapa padrão de MDF (2,75 m × 1,85 m), a chapa foi previamente seccionada em quatro partes para adequação ao processo de fabricação. Dentre essas partes, apenas três foram utilizadas na fabricação dos módulos. Aplicando uma velocidade de 5 mm/s e com a potência do laser em 100%, o corte de todas as peças levou aproximadamente 3h para ser concluído.

Fig. 11. Delta CNC, modelo 1310.

Após o corte, os componentes foram separados e agrupados de acordo com o módulo correspondente, evitando a mistura de peças com dimensões distintas. A montagem foi realizada de forma progressiva, inicialmente com o posicionamento de dois componentes por meio dos encaixes previamente projetados. Em seguida, aplicou-se cola PVA nas superfícies de união e realizou-se a fixação com parafusos para madeira.

O procedimento foi repetido sequencialmente, incorporando-se uma peça por vez até a conclusão de cada módulo. A união progressiva dos componentes proporcionou maior estabilidade durante a montagem, facilitando o manuseio e o posicionamento das peças subsequentes. Após a montagem dos seis módulos, obteve-se o conjunto completo, cuja configuração final correspondeu à geometria e às dimensões definidas durante a etapa de modelagem digital (Fig. 12).

Fig. 12. Bancos terapêuticos montados.

Entre os componentes do conjunto, o módulo de maior altura foi considerado potencialmente mais suscetível aos efeitos de carregamentos excêntricos e esforços laterais, em razão de sua maior dimensão vertical. Para essa verificação, foi aplicada uma carga estática correspondente ao peso corporal de um indivíduo adulto com massa de 103 kg, aproximadamente centralizada sobre a superfície superior do módulo. Durante o procedimento, não foram observadas avarias aparentes, desprendimento das uniões ou deformações visíveis (Fig. 13).

Esse procedimento permitiu uma observação inicial da integridade estrutural do módulo sob carregamento estático, mas não caracteriza um ensaio mecânico padronizado, nem permite determinar sua capacidade máxima de carga, resistência a carregamentos excêntricos, estabilidade ou durabilidade. Dessa forma, a avaliação sistemática desses parâmetros constitui uma etapa necessária para estudos futuros, especialmente considerando a utilização do equipamento em atividades de reabilitação pediátrica de longo prazo.

Fig. 13. Aplicação estática de carga sob o módulo mais alto.

Como etapa final do processo de fabricação, as superfícies superiores de cada módulo foram revestidas com folhas de EVA de 4 mm de espessura. Posteriormente, foram aplicadas pinturas e elementos gráficos de temática infantil, conferindo identidade visual e caráter lúdico aos conjuntos produzidos. A personalização visual não seguiu um padrão único, resultando em diferentes composições gráficas entre os equipamentos fabricados (Fig. 14-15).

Fig. 14. Bancos terapêuticos mantidos no Lab EITA.

Fig. 15. Bancos terapêuticos mantidos no Lab EITA.

De modo geral, o processo de desenvolvimento permitiu transformar o modelo digital em um conjunto físico correspondente às características geométricas e construtivas definidas durante a etapa de projeto. A integração entre modelagem tridimensional, planificação, otimização do plano de corte e fabricação digital possibilitou a produção dos seis módulos com aproveitamento eficiente da matéria-prima e emprego de processos construtivos de relativa simplicidade. As soluções incorporadas ao projeto, como os encaixes intertravados, o sistema de retenção e a independência entre os módulos, contribuíram para facilitar a montagem, o manuseio e a organização do equipamento. Dessa forma, o processo adotado demonstrou a viabilidade de fabricação do conjunto por meio da infraestrutura de fabricação digital utilizada, permitindo sua posterior aplicação em atividades de avaliação funcional e práticas terapêuticas.

C. Custo Estimado de Materiais e Serviços Diretamente Empregados na Fabricação

Além das vantagens relacionadas à fabricação digital, a utilização do MDF mostrou-se economicamente viável. De acordo com os valores de referência do Sistema Nacional de Pesquisa de Custos e Índices da Construção Civil (SINAPI), adotado como parâmetro oficial de custos da construção civil brasileira [12], uma chapa de MDF cru com espessura de 12 mm e dimensões de 2,75 m × 1,85 m apresentava custo aproximado de R$ 188,50, considerando a tabela de referência de maio de 2026. Como o plano de corte desenvolvido neste trabalho possibilita a fabricação de um conjunto completo utilizando cerca de 75% da área útil da chapa, estima-se que o custo da principal matéria-prima corresponda a aproximadamente R$ 142,00 por conjunto.

Como o Lab EITA é um projeto de pesquisa vinculado à Universidade Federal de Goiás (UFG), o custo do corte a laser foi calculado com base na tarifa subsidiada prevista na política institucional de utilização do IPE Lab para projetos de pesquisa vinculados à UFG e a outras instituições de ensino superior. Assim, o valor empregado neste estudo foi de R$ 270,00, correspondente à tarifa de R$ 1,50 por minuto de utilização da máquina. Para usuários externos não contemplados por essa política, a tarifa vigente é de R$ 2,50 por minuto.

O custo do revestimento em EVA foi estimado a partir da média de preços obtida junto a três fornecedores nacionais de materiais para artesanato e revestimento. Para o revestimento das superfícies superiores dos módulos foram utilizados aproximadamente 1,30 m² de EVA com espessura de 4 mm. Considerando um valor médio de mercado de R$ 33,00/m², estimou-se um custo de aproximadamente R$ 43,00 para esse material. Considerando os custos dos demais materiais e serviços empregados no processo de fabricação, o custo total estimado para a produção de um conjunto de bancos terapêuticos foi de aproximadamente R$ 530,00, conforme apresentado na Tabela II.

A montagem do conjunto foi realizada pelo próprio pesquisador, com duração aproximada de três horas. Embora esse período corresponda a um esforço de mão de obra, não foi atribuído um custo monetário a essa etapa, uma vez que a proposta do projeto está fundamentada na possibilidade de reprodução do conjunto por laboratórios makers, instituições de pesquisa e demais organizações que atuem no apoio à reabilitação de crianças com paralisia cerebral. Dessa forma, foram considerados na estimativa os custos diretamente relacionados aos materiais e serviços empregados na fabricação, sem incorporar remuneração de mão de obra, considerando a possibilidade de que a montagem seja realizada de forma voluntária ou como parte das atividades institucionais desses espaços.

Da mesma forma, os custos relacionados à pintura e aos materiais empregados na personalização visual dos bancos não foram incluídos na estimativa, uma vez que esses elementos não foram considerados componentes essenciais à funcionalidade estrutural e terapêutica do conjunto. Além disso, não foi adotado um padrão único de pintura, resultando em variações nos materiais e nas quantidades empregados em cada equipamento. Assim, esses elementos foram considerados etapas complementares e facultativas do processo de fabricação, não sendo incorporados à composição dos custos apresentada neste estudo.

Custos de Produção		
Material	***Metragem Utilizada***	***Valor***
Chapa de MDF	3,82 m²	R$ 142,00
Corte do MDF	Não se aplica	R$ 270,00
Cola Branca PVA Extra	Não se aplica	R$ 30,00
Folha de EVA	1,30 m²	R$ 43,00
Parafusos para Madeira	Não se aplica	R$15,00
Cola de Cianoacrilato	Não se aplica	R$ 30,00
VALOR TOTAL		**R$ 530,00**

TABELA II

Como parâmetro de comparação econômica, foram considerados os valores de aquisição de conjuntos comerciais compostos por seis bancos terapêuticos, confeccionados em diferentes materiais: compensado, com valor de R$ 1.200,00; e estrutura metálica, com valor de R$ 1.830,00. A média dos preços dos dois conjuntos comerciais foi de R$ 1.515,00, enquanto o conjunto desenvolvido neste estudo apresentou custo estimado de

fabricação de aproximadamente R$ 530,00. A diferença corresponde a R$ 985,00, representando um valor aproximadamente 65% inferior à média dos preços comerciais utilizados como referência. Esses resultados indicam o potencial da fabricação digital e da infraestrutura compartilhada de laboratórios makers para a redução dos custos associados à produção de equipamentos terapêuticos.

Ressalta-se, entretanto, que os valores comparados correspondem a categorias econômicas distintas, uma vez que o valor do equipamento desenvolvido representa o custo estimado de fabricação, enquanto os valores dos conjuntos comerciais correspondem aos preços de aquisição de produtos acabados, que podem incorporar despesas com mão de obra, logística, tributos, custos indiretos e margens comerciais. Dessa forma, a comparação possui caráter referencial e busca evidenciar o potencial de acessibilidade econômica do processo produtivo proposto, não constituindo uma comparação direta entre custos industriais equivalentes.

IV. Aplicação do Conjunto de Bancos Terapêuticos

O conjunto de bancos terapêuticos foi aplicado em situações reais de uso em três ambientes de atendimento e pesquisa localizados em Goiânia, Goiás: o Laboratório de Estudos Inventivos em Tecnologias Assistivas (Lab EITA), da Universidade Federal de Goiás (UFG); o Instituto dos Raros Christiane Toledo (IRCT); e a Associação Crianças de Microcefalia por Zika Vírus e Outras Deficiências (AMizika). O objetivo dessa etapa não foi avaliar a eficácia clínica do equipamento, mas verificar sua aplicabilidade prática, estabilidade durante o uso e potencial de incorporação à rotina de atendimento das instituições participantes.

O estudo foi submetido e aprovado pelo Comitê de Ética em Pesquisa da Universidade Federal de Goiás (UFG), sob CAAE nº 87957025.7.0000.5083 e parecer nº 7.688.714. A participação das crianças nas atividades ocorreu mediante assinatura do Termo de Consentimento Livre e Esclarecido (TCLE) pelos respectivos responsáveis legais e, quando aplicável, do Termo de Assentimento pelos participantes. A utilização das imagens apresentadas neste trabalho foi autorizada pelos responsáveis legais, em conformidade com os procedimentos éticos aprovados no estudo.

No Lab EITA, o conjunto foi utilizado como recurso complementar durante a avaliação funcional das crianças, permitindo aos profissionais observar seu desempenho em diferentes tarefas motoras. As atividades realizadas nos módulos contribuíram para a observação de aspectos relacionados ao controle postural, equilíbrio e mobilidade, fornecendo informações complementares ao processo de avaliação para indicação e desenvolvimento de dispositivos de tecnologia assistiva, como o parapodium.

Já no Instituto dos Raros Christiane Toledo (IRCT) e na Associação Crianças de Microcefalia por Zika Vírus e Outras Deficiências (AMizika), o conjunto foi empregado como recurso de apoio às atividades terapêuticas desenvolvidas pelos profissionais. Os bancos foram utilizados tanto na composição de circuitos de atividades (Fig. 16) quanto em exercícios isolados (Fig. 17), nos quais apenas um ou alguns módulos eram empregados. Por serem independentes, os módulos podem ser organizados em diferentes configurações, permitindo aos profissionais adaptar sua disposição às atividades propostas e às capacidades funcionais de cada criança.

Fig. 16. Atividade terapêutica desenvolvida no IRCT.

Fig. 17. Atividade terapêutica desenvolvida no IRCT.

Os três ambientes mencionados utilizam o conjunto de bancos terapêuticos em suas atividades há aproximadamente quatro meses e, até o momento de elaboração deste artigo, não foram relatadas avarias nos módulos. Nesse período, o Lab EITA utilizou o equipamento com 10 crianças durante atividades de avaliação funcional. No IRCT, aproximadamente 240 crianças fizeram uso de um ou mais módulos do conjunto em atividades terapêuticas, enquanto na AMizika esse número foi de 35 crianças. Embora o período de acompanhamento e a ausência de ensaios mecânicos específicos não permitam estabelecer conclusões definitivas quanto à resistência e à durabilidade do equipamento, a manutenção da integridade física dos módulos durante o período de uso constitui um indicativo preliminar da adequação da solução construtiva adotada.

V. Considerações Finais

O desenvolvimento do conjunto de bancos terapêuticos demonstrou o potencial da cultura maker e da fabricação digital

como estratégias aplicáveis à produção de tecnologias assistivas destinadas ao contexto da reabilitação pediátrica. A utilização da modelagem digital associada ao corte a laser possibilitou a fabricação de um equipamento modular a partir de materiais de ampla disponibilidade comercial e de processos construtivos de relativa simplicidade. As soluções incorporadas ao projeto, como os módulos independentes com alturas progressivas, o sistema de recolhimento dos módulos para armazenamento e as abas de retenção, contribuíram para facilitar o manuseio, a organização e a adaptação do conjunto a diferentes atividades.

Sob o aspecto econômico, o custo estimado de fabricação de aproximadamente R$ 530,00 indica uma possibilidade de produção economicamente mais acessível quando comparado aos valores de aquisição dos conjuntos comerciais adotados como referência. Embora a comparação não represente uma equivalência direta entre custos de fabricação e preços de produtos comerciais acabados, a diferença observada evidencia o potencial da fabricação local e da infraestrutura compartilhada de laboratórios makers para reduzir os recursos financeiros necessários à obtenção desse tipo de equipamento.

A aplicação exploratória dos conjuntos no Lab EITA, no IRCT e na AMizika permitiu observar diferentes possibilidades de utilização em contextos reais. A utilização dos conjuntos durante aproximadamente quatro meses sem relatos de avarias constitui um indicativo preliminar de manutenção da integridade física dos módulos nas condições de uso observadas. Entretanto, o período de acompanhamento ainda é reduzido e a ausência de danos visíveis não permite estabelecer conclusões definitivas sobre a resistência mecânica, a durabilidade ou a segurança do equipamento em longo prazo.

Embora a verificação preliminar realizada não tenha identificado falhas aparentes sob a carga aplicada, a ausência de ensaios mecânicos padronizados constitui uma limitação deste estudo. Nesse sentido, estudos futuros deverão incluir ensaios mecânicos controlados para avaliação da capacidade de carga dos módulos, considerando cargas estáticas, dinâmicas e excêntricas, bem como a realização de testes cíclicos capazes de simular o uso repetitivo do equipamento ao longo do tempo. A verificação empírica realizada com a aplicação estática da massa corporal de um indivíduo de 103 kg sobre o módulo de maior altura constitui apenas uma observação preliminar e não substitui ensaios padronizados para determinação dos limites estruturais e dos fatores de segurança.

Outro aspecto a ser investigado refere-se ao comportamento do MDF diante das condições ambientais presentes nos locais de utilização. Por se tratar de um material derivado da madeira, torna-se relevante avaliar os efeitos da umidade, do contato frequente com o piso e dos procedimentos de higienização sobre a integridade dos módulos. Estudos posteriores poderão analisar a aplicação de seladores, revestimentos ou outros sistemas de proteção superficial capazes de reduzir a absorção de umidade e facilitar a limpeza do equipamento, sem comprometer sua acessibilidade econômica e sua possibilidade de fabricação em laboratórios makers.

Na versão atual, os arquivos digitais ainda não são disponibilizados publicamente, constituindo essa uma limitação quanto à reprodução imediata do equipamento por terceiros. Como perspectiva de continuidade do trabalho, após uma avaliação mais abrangente do equipamento, pretende-se disponibilizar os arquivos digitais do projeto em diretórios públicos voltados ao compartilhamento de projetos de fabricação digital, como o Vetor Maker. Essa medida deverá contribuir para ampliar a replicabilidade do conjunto, permitindo que outros laboratórios, instituições e usuários interessados tenham acesso aos arquivos necessários para sua reprodução e eventual adaptação às suas necessidades.

Mais do que apresentar um conjunto de bancos terapêuticos de menor custo, este trabalho demonstra a viabilidade de um processo estruturado de desenvolvimento baseado em fabricação digital e princípios da cultura maker. A integração entre levantamento de requisitos, modelagem CAD, otimização do plano de corte, fabricação e aplicação em ambientes de atendimento estabelece um fluxo potencialmente reproduzível por laboratórios universitários, serviços de reabilitação e espaços makers, contribuindo para o desenvolvimento de tecnologias assistivas personalizáveis e economicamente acessíveis.

Abstract— **This article presents the development of a customizable vibrotactile communication device (DCV) designed to support deaf and deafblind individuals. The device receives commands from a mobile application via Wi-Fi and converts them into vibration patterns that can be freely configured by the user, who assigns each pattern a specific meaning. The DCV consists of an ESP32-C3 Mini board, an ERM (Eccentric Rotating Mass) vibration motor, a removable battery, and a 3D-printed case, and is attached to the body using adhesive Kinesiotape. Preliminary laboratory tests were conducted to evaluate participants' recognition of vibrotactile commands. The results showed a recognition accuracy of 93.33%, indicating that participants were able to correctly associate most vibration patterns with the corresponding commands after a brief familiarization period. The proposed device represents a low-cost, portable, and customizable platform with the potential to contribute to the development of accessible communication solutions and to support future research on vibrotactile interaction for deaf and deafblind individuals.**

Keywords— **Assistive technology; vibrotactile communication; deafblindness; deafness; haptic feedback; wearable device.**

I. INTRODUÇÃO

A comunicação constitui uma necessidade constante nas relações humanas, em diversos aspectos de suas vidas. Para pessoas surdas e surdocegas, entretanto, barreiras comunicacionais podem dificultar interações cotidianas e trocas mínimas necessárias em diferentes contextos (1).

A perda auditiva representa um desafio significativo em diferentes contextos da sociedade, podendo dificultar o acesso à informação, a interação com outros indivíduos, a realização de atividades cotidianas, assim como reduzir sua autonomia em situações que dependem de comunicação rápida e clara (2).

Caracterizada pela ausência simultânea da visão e da audição, a surdocegueira impõe desafios particulares, uma vez que estratégias utilizadas por pessoas com apenas uma deficiência sensorial nem sempre podem ser empregadas da mesma forma. Nesse contexto, a língua de sinais tátil destaca-se como uma das formas de comunicação mais utilizadas por pessoas surdocegas, permitindo a percepção de sinais por meio do contato físico e do tato (3).

Tecnologias assistivas voltadas à deficiência auditiva podem ser classificadas em cinco categorias principais: conversão de fala em texto, conversão de texto em fala, sistemas de exibição de informações, mecanismos de feedback háptico ou visual e recursos de suporte para dispositivos móveis (4). Para pessoas com surdocegueira, tecnologias baseadas em feedback háptico estão entre as mais utilizadas (3).

Entre os sistemas hápticos, a tecnologia vibrotátil tem sido utilizada em dispositivos assistivos voltados a pessoas surdas e surdocegas como uma forma alternativa de transmissão de informações. Nesses recursos, sinais, mensagens e alertas podem ser convertidos em estímulos percebidos pela pele, permitindo sua aplicação em dispositivos que convertem texto em fala, fornecem alertas de segurança e oferecem suporte à comunicação, entre outros usos (5).

Entre as tecnologias assistivas voltadas a pessoas surdas, os dispositivos vestíveis baseados em vibração podem ser utilizados para sinalizar informações de forma tátil ao usuário. Em um estudo com um dispositivo vestível testado em pessoas surdas, observou-se a transmissão de sons importantes do ambiente por meio de vibrações, permitindo seu reconhecimento em tempo real (6).

A vibração já vem sendo explorada em recursos portáteis e acessíveis para transmissão de alertas relevantes a pessoas surdas. Nesse contexto, sistemas de sinalização vibratória em dispositivos móveis têm sido investigados para a emissão de alertas de emergência, demonstrando o potencial da vibração como recurso assistivo em situações cotidianas que exigem percepção rápida e segura de informações (7).

Esse potencial se estende também à percepção musical. (8) demonstraram, por meio de registros eletroencefalográficos, que estímulos vibrotáteis aplicados nas mãos de pessoas com perda auditiva severa foram capazes de ativar as mesmas regiões cerebrais envolvidas na percepção emocional da música em ouvintes, como o córtex auditivo e o córtex temporal superior. Esses achados indicam que a vibração não representa apenas uma alternativa sensorial, mas um canal capaz de acionar respostas neurais semelhantes às produzidas pelo som.

Apesar dos avanços observados no desenvolvimento de dispositivos vibrotáteis assistivos, a possibilidade de personalização dos padrões vibratórios pelo próprio usuário ainda é pouco explorada na literatura. De modo geral, os dispositivos desenvolvidos até o momento operam com padrões vibratórios pré-definidos, voltados a funções específicas, como alertas sonoros, navegação ou comunicação em contextos delimitados. Como consequência, o usuário possui poucas possibilidades de adaptar os estímulos às suas necessidades, preferências e contexto de utilização. Flores Ramones e del-Rio-Guerra destacam que a literatura ainda carece de dispositivos hápticos configuráveis, capazes de permitir ajustes em parâmetros como intensidade da vibração, limiar de detecção sonora, seleção dos sons monitorados e padrões vibratórios, proporcionando uma experiência personalizada de acordo com os requisitos de cada usuário (5).

O presente artigo propõe a utilização de um dispositivo vibrotátil com capacidade de modulação de vibrações para uso personalizado no cotidiano de pessoas surdas e surdocegas. Os usuários podem escolher padrões de vibração e correlacioná-los com os significados de comunicação desejados.

O restante deste artigo está organizado da seguinte forma: na Seção II descrevemos o desenvolvimento do dispositivo, detalhando suas especificidades; na Seção III demonstramos o funcionamento do aplicativo e a forma como pode ser programado; na Seção IV apresentamos o posicionamento do dispositivo no corpo; na Seção V são apresentadas algumas possibilidades de uso; na Seção VI são apresentados os testes preliminares em ambiente de laboratório e as análises dos resultados obtidos; na Seção VII é realizada a discussão dos resultados; por fim, na Seção VIII são apresentadas as conclusões e os trabalhos futuros.

II. Descrição do Dispositivo de Comunicação Vibrotátil

O dispositivo de comunicação vibrotátil (DCV) foi desenvolvido com foco na portabilidade, leveza e simplicidade construtiva, de forma que pudesse ser utilizado em diferentes contextos sem exigir adaptações estruturais. Essas diretrizes orientaram diretamente a escolha dos componentes e o design do conjunto, resultando em um sistema compacto e de baixo custo, com potencial de uso amplo por pessoas surdas e surdocegas em situações cotidianas.

Os componentes eletrônicos do DCV são apresentados na Tabela 1 e consistem em uma placa ESP32-C3 Mini com conectividade Wi-Fi integrada, um motor de vibração do tipo ERM versão mini, uma bateria removível de 200 mAh e 3,7 V com autonomia aproximada de duas horas, e um LED indicador de funcionamento.

Table 1: Componentes Eletrônicos do DCV

Componente	**Características**
Placa ESP32-C3 Mini	Placa compacta e programável com conectividade Wi-Fi integrada, utilizada para controlar os sinais enviados aos motores.
Bateria removível	Capacidade: 200 mAh, tensão: 3,7V.
Motor de vibração ERM	Utilizado para geração dos estímulos vibrotáteis.
LED vermelho	Indicador de funcionamento, sinaliza que o dispositivo está ligado e conectado ao aplicativo.

O motor de vibração do tipo ERM (Eccentric Rotating Mass) foi escolhido por sua simplicidade estrutural, baixo custo e facilidade de integração ao conjunto (9). A potência do motor oferece uma janela maior de ajuste de intensidade que permite ao usuário encontrar o nível de sensibilidade mais adequado à sua percepção. Além disso, motores ERM produzem forças de cisalhamento lateral na pele que, combinadas com vibrações verticais, evocam sensações táteis robustas mesmo em regiões com menor densidade de mecanorreceptores (9).

A placa ESP32-C3 Mini é responsável pelo controle e pela transmissão dos sinais do DCV. Ela opera por meio de uma rede Wi-Fi própria, gerada pelo próprio dispositivo, à qual o aplicativo de controle se conecta diretamente. A estimativa de alcance, avaliada nos testes preliminares, é de até 10 metros em ambientes internos com paredes entre o emissor e o receptor, de até 50 metros em ambientes internos sem

barreiras e 100 metros em ambientes abertos. A autonomia em uso varia conforme o número de sinais enviados, uma vez que o maior consumo é referente ao motor vibratório. Em estado de repouso, apenas com a placa de controle ativa, o dispositivo apresentou uma autonomia média de mais de 24 horas sem necessidade de recarga.

O Sistema foi concebido buscando garantir mobilidade e liberdade de movimento ao usuário. Seu baixo consumo energético e suas dimensões reduzidas de 22,5 x 18 mm contribuem para tornar o dispositivo compacto e portátil. O case do DCV foi projetado em software de modelagem tridimensional e impresso em 3D, com dimensões de 7,0 x 4,0 x 2,0 cm e bordas arredondadas para conforto no contato com a pele. Uma divisória interna separa o motor de vibração dos demais circuitos eletrônicos conforme ilustrado na Figura 1. Para fixação ao corpo, foi utilizada uma bandagem elástica adesiva do tipo Kinesiotape, escolhida por sua aderência e compatibilidade com uso direto na pele.

Fig. 1: Projeto 3D do case do DCV: visão geral do conjunto (superior esquerda), visão externa fechada (superior direita), visão interna mostrando a divisória (inferior esquerda) e visão da base (inferior direita). Fonte: A autora.

O conjunto de componentes escolhidos reflete diretamente os princípios que orientaram o desenvolvimento do DCV, compondo um sistema funcional, compacto e de baixo custo, com potencial de uso em diferentes contextos cotidianos.

III. Aplicativo de Controle

Uma das características centrais do DCV é a possibilidade de personalização dos padrões vibratórios pelo próprio usuário, que pode configurar cada sinal de acordo com suas necessidades e atribuir a ele o significado que desejar.

O DCV é controlado por um aplicativo móvel desenvolvido para o sistema Android, que se comunica com o dispositivo por meio de rede Wi-Fi. A interface conta com oito botões programáveis, por meio dos quais o usuário define os parâmetros de cada sinal vibratório, incluindo quantidade de pulsos, duração e intensidade da vibração. O usuário pode escolher quais botões estão ativos ou não, caso não necessite de um número menor de comandos, diminuindo assim a possibilidade de erro de acionamento durante o uso.

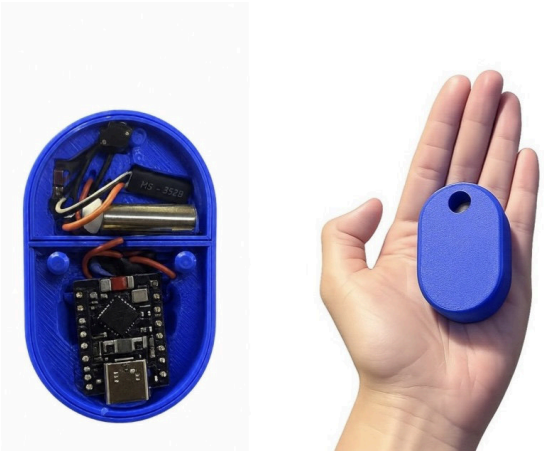

Fig. 2: Dispositivo de Comunicação Vibrotátil (DCV), apresentando o circuito eletrônico interno (à esquerda) e o dispositivo posicionado sobre a palma da mão para referência de suas dimensões (à direita).

Todos os botões podem ser configurados individualmente, permitindo a criação de padrões vibratórios distintos. A configuração individual de cada botão é realizada em uma aba específica no aplicativo. Para cada botão o usuário pode programar a emissão de um a três sinais vibratórios em cada execução, cada padrão composto por uma combinação de vibrações ”curtas”, ”médias” e ”longas”, o que permite uma grande flexibilidade na criação dos sinais de comunicação desejados. É possível também utilizaer um número menor de sinais programados em cada botão, utilizando-se na configuração do parâmetro ”zero”, que transmite um sinal nulo naquela combinação.

Os tempos de vibração ”longo”, ”médio” e ”curto” são configurados independentemente através de três *sliders*, e são os mesmos para todos os botões ativos no aplicativo. Isso permite a programação de uma grande gama de padrões, progamados de acordo com a necessidade da utilização ou experimento proposto. As figuras 3 e 4 apresentam as telas dos botões para envio dos comandos, a configuração dos tempos e potência e a tela da programação dos padrões, respectivamente.

Ao pressionar o botão, o padrão programado é transmitido ao dispositivo em aproximadamente 4 milissegundos, garantindo uma resposta praticamente imediata. Dessa forma,

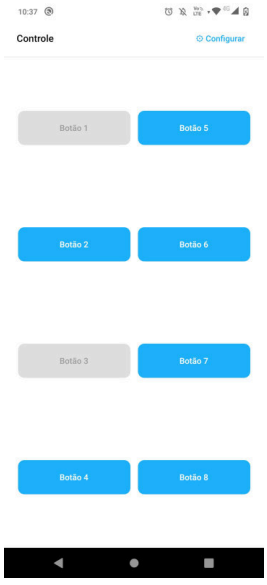

Fig. 3: Interface do aplicativo de controle do DCV, contendo cinco botões programáveis para envio dos comandos vibratórios e controles para ajuste do tempo e da intensidade da vibração.

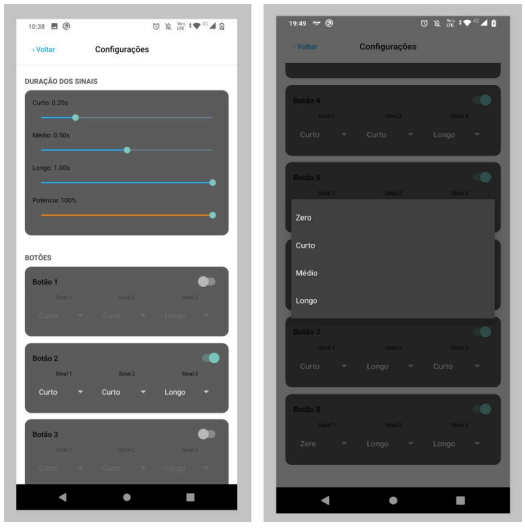

Fig. 4: Tela de configuração dos padrões de cada botão: ”Zero”, ”Curto”, ”Médio” e ”Longo” e tela de configuração dos tempos e potência.

o usuário pode associar cada padrão vibratório a um significado próprio, como uma comunicação previamente combinada entre as pessoas envolvidas.

Por meio do aplicativo, é possível conectar mais de um DCV simultaneamente, permitindo que a mesma mensagem vibrotátil seja transmitida para diferentes usuários. Essa característica amplia o potencial de aplicação do sistema em contextos coletivos, como atividades educacionais, esportivas, treinamentos, deslocamentos guiados ou situações em que um mesmo comando precisa ser recebido por várias pessoas de forma discreta e sincronizada.

IV. Posicionamento do Dispositivo

No trabalho apresentado em (10) avaliou-se a sensibilidade vibrotátil em 16 posições corporais distintas. A Figura 5 apresenta um mapeamento de sensibilidade para o corpo humano. A escala de cores indica áreas de alta sensibilidade (verde) e sensibilidade média a baixa (amarelo), enquanto os marcadores em roxo exemplificam possíveis locais de implementação do DCV.

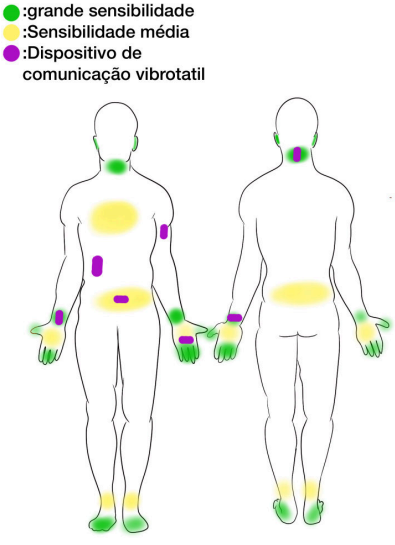

Fig. 5: Mapeamento de sensibilidade vibrotátil para o corpo humano. Áreas em verde indicam alta sensibilidade, amarelo indicam sensibilidade média a baixa, e marcadores em roxo exemplificam possíveis locais de implementação do DCV. Fonte: adaptado de (10).

O posicionamento do dispositivo no corpo é personalizado de acordo com a preferência do usuário. O DCV pode ser acoplado em qualquer região do corpo por meio de Kinesiotape, uma bandagem elástica adesiva que se adapta a diferentes superfícies e oferece fixação confortável e segura, permitindo ao usuário escolher o local que melhor se adequa às suas necessidades e sensibilidade individual.

A sensibilidade vibrotátil pode ser estudada e mapeada; apesar disso, a percepção da vibração varia de forma individual, assim como o conforto e a preferência pelo local de uso. Portanto, mesmo que algumas regiões sejam

indicadas como mais sensíveis, o usuário pode ter uma sensibilidade que considere melhor para o dispositivo, ou sentir mais conforto de uso. Assim, o DCV pode ter sua localização personalizada para o usuário.

V. Possibilidades de Aplicação do DCV

O DCV foi desenvolvido para se adaptar a diferentes necessidades e contextos de uso, considerando que a comunicação pode mudar conforme a situação, o ambiente e a preferência de cada usuário. A personalização dos padrões vibratórios permite que o dispositivo transmita mensagens simples e específicas, como instruções de "inicie" e "pare", alertas do tipo "preste atenção em mim" e respostas como "sim" e "não".

Em sua versão atual, como protótipo funcional, a aplicação tanto em pesquisa quanto para uso cotidiano já é viável e acessível, uma vez que sua construção é bastante simples tanto em relação à eletrônica quanto em relação ao design 3D. Um arquivo público online está sendo elaborado para disponibilizar os arquivos STL, o código do ESP, o aplicativo, circuito esquemático e manuais de montagem para permitir sua reprodução pelo público interessado.

Os padrões vibratórios podem ser personalizados de acordo com a necessidade de cada usuário. Por exemplo, uma pessoa surdocega acompanhada por alguém que não conhece Braille ou outra forma específica de comunicação pode combinar diferentes padrões vibratórios para transmitir informações simples do dia a dia. Um padrão pode indicar que a pessoa acabou de entrar no ambiente, outro pode informar que ela está saindo, enquanto um terceiro pode identificar quem está presente, como "é a Maria". Dessa forma, mesmo sem utilizar uma linguagem formal ou conhecimentos prévios, torna-se possível estabelecer uma comunicação simples e útil para situações cotidianas.

Em situações nas quais o usuário precisa manter a atenção em uma atividade principal, sem deixar de receber comunicações secundárias, o dispositivo pode ser utilizado como um sistema de alertas discretos. Por exemplo, durante uma aula, um estudante surdo pode estar concentrado na escrita de um exercício enquanto o professor deseja chamar sua atenção. Em vez de caminhar até a carteira ou tocar no aluno, o professor pode enviar um padrão vibratório previamente combinado com o significado "olhe para mim". Em algumas situações, essa abordagem pode evitar que o estudante receba uma forma de chamada diferente da utilizada com os demais colegas, favorecendo uma interação mais natural e integrada ao ambiente da sala de aula.

Durante uma atividade física, o dispositivo também pode ajudar o treinador a transmitir comandos simples. Em uma aula coletiva, uma pessoa surda pode estar pulando corda, um movimento que exige manter o olhar fixo para conservar o ritmo. Nessa situação, olhar para o professor pode prejudicar a execução do exercício. Com o DCV, comandos como "iniciar" e "parar" podem ser enviados por meio de padrões vibratórios, sem interromper o movimento. Para pessoas surdocegas, essa forma de comunicação se torna ainda mais importante, pois não depende da audição nem da visão.

Situação semelhante pode ser observada durante a execução de uma flexão de braço. Nesse exercício, o praticante permanece próximo ao chão e com o olhar voltado para a frente, o que dificulta acompanhar a contagem visual realizada pelo treinador. Para pessoas surdocegas, essa barreira é ainda maior, pois a contagem não pode ser percebida nem pela audição nem pela visão. Nesse caso, o DCV pode transmitir as contagens por meio de vibrações, permitindo que a informação seja recebida pelo tato.

Os exemplos apresentados ilustram apenas algumas das possibilidades de aplicação do DCV. O dispositivo estabelece um canal de comunicação intuitivo, rápido e prático para informações simples, sem exigir conhecimento prévio de linguagens específicas como Braille ou língua de sinais. Qualquer pessoa pode utilizá-lo, criando pontes de comunicação acessíveis e abrindo possibilidades para pessoas surdas e surdocegas se comunicarem com qualquer outra pessoa ao seu redor.

A. Aplicação do Dispositivo em Pesquisas Aplicadas em Comunicação Vibrotátil

Uma das dificuldades encontradas pelos pesquisadores da área de comunicação e dispositivos assistivos é justamente a disponibilidade e o custo para aquisição de equipamentos que permitam a construção do arranjo experimental. Não é fácil encontrar dispositivos desenvolvidos especificamente para a aplicação neste tipo de pesquisa.

Uma alternativa é o grupo de pesquisa desenvolver as suas próprias ferramentas, tarefa não trivial e que consome muito tempo. Dessa forma, demonstra-se que o DCV também pode ser utilizado como ferramenta de apoio em pesquisas desenvolvidas na área da comunicação vibrotátil para pessoas surdas e surdocegas. Por ser um dispositivo funcional e configurável, ele permite que pesquisadores investiguem diferentes aplicações da comunicação tátil sem a necessidade de desenvolver um novo protótipo desde o início, concentrando seus esforços no planejamento experimental e na análise dos resultados.

Entre as possibilidades de aplicação estão pesquisas sobre percepção vibrotátil, sensibilidade em diferentes regiões do corpo, posicionamento do dispositivo, reconhecimento

de padrões vibratórios e comparação entre diferentes estratégias de comunicação. O dispositivo também pode servir como base experimental para estudos envolvendo códigos, sequências e alfabetos vibrotáteis, contribuindo para o desenvolvimento de novas formas de comunicação para pessoas surdas e surdocegas.

Além disso, o DCV pode ser empregado em estudos preliminares para avaliar a viabilidade de novas aplicações da comunicação vibrotátil em diferentes contextos. Mesmo quando o objetivo final da pesquisa for o desenvolvimento de outro dispositivo, o DCV pode ser utilizado como plataforma experimental para validar conceitos, testar hipóteses e orientar o desenvolvimento de novas tecnologias assistivas.

VI. Testes Preliminares em Ambiente de Laboratório

Os testes preliminares foram conduzidos em ambiente laboratorial controlado para explorar, de forma inicial, se a comunicação vibrotátil seria funcional. Essa etapa exploratória buscou observar, em um primeiro momento, se os sinais vibratórios poderiam ser percebidos e diferenciados pelos participantes, servindo como investigação inicial sobre a viabilidade da tecnologia. Todos os participantes eram pesquisadores do laboratório.

Participaram do teste três voluntários adultos ouvintes, sem familiarização prévia com o dispositivo vibrotátil. Durante a realização das atividades, os participantes utilizaram fones de ouvido reproduzindo música em volume elevado, enquanto o ambiente de teste permaneceu silencioso e com mínima interferência externa.

Antes do início da coleta, foi realizado um período de treinamento com duração aproximada de cinco minutos. Nessa etapa, cada participante teve contato com os quatro padrões vibratórios utilizados no teste e recebeu a explicação correspondente a cada movimento. Esse treinamento teve curta duração e foi utilizado apenas para familiarização inicial com o dispositivo e com os comandos, permitindo que os voluntários reconhecessem previamente a relação entre cada estímulo e a ação corporal esperada.

Table 2: Padrões vibrotáteis utilizados no teste preliminar.

Código	Padrão vibratório	Movimento
V1	Uma vibração curta	Levantar braço direito
V2	Duas vibrações curtas	Levantar braço esquerdo
V3	Uma vibração longa	Dar um passo para frente
V4	Duas vibrações longas	Dar um passo para trás

Para a realização do teste, o dispositivo foi posicionado na região superior e externa do braço, próximo ao músculo deltóide. Esse local foi escolhido por oferecer boa área de contato para fixação, permitir a percepção clara dos estímulos vibratórios e apresentar baixa interferência na execução dos movimentos solicitados. Além disso, essa posição favoreceu a estabilidade do equipamento durante as respostas motoras dos participantes.

O aplicador permaneceu com o dispositivo móvel posicionado atrás de um anteparo, impedindo que o participante visualizasse o acionamento dos comandos no aplicativo. Os sinais vibratórios foram enviados de forma aleatória entre os quatro padrões estabelecidos, evitando uma sequência previsível de estímulos. Cada participante realizou três séries de vinte comandos, totalizando 60 movimentos por voluntário e 180 movimentos no conjunto do teste.

A. Resultado e Análise

Os resultados dos testes preliminares foram analisados a partir das respostas motoras realizadas pelos três voluntários durante a execução dos comandos vibrotáteis. Ao todo, foram avaliados 180 movimentos, correspondentes às três séries de vinte comandos realizadas por cada participante. Para esta análise, considerou-se como acerto a execução do movimento previamente associado ao padrão vibratório enviado, enquanto o erro foi registrado quando não houve resposta correta ao comando.

De modo geral, os participantes apresentaram bom desempenho na identificação dos comandos vibrotáteis. Dos 180 movimentos realizados, 168 foram executados corretamente e 12 foram classificados como erro, correspondendo a 93,33% de acertos e 6,67% de erros. Esse resultado demonstra que, mesmo após um curto período de familiarização inicial e sendo este o primeiro contato dos voluntários com o dispositivo, a maior parte dos estímulos vibratórios foi percebida e associada corretamente aos movimentos previamente estabelecidos (Figura 6).

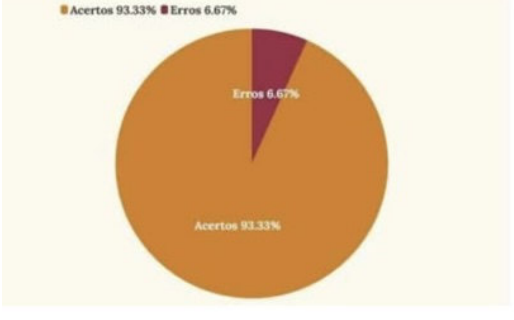

Fig. 6: Distribuição percentual de acertos e erros obtidos no teste de reconhecimento dos padrões vibratórios.

A análise por padrão vibratório permitiu observar

diferenças no reconhecimento dos estímulos. O comando V1 apresentou 49 acertos e 6 erros, enquanto o V2 registrou 38 acertos e 5 erros. O V3 obteve o melhor desempenho entre os padrões analisados, com 42 acertos e nenhum erro registrado. Já o V4 apresentou 39 acertos e apenas 1 erro. Esses dados indicam que todos os padrões foram reconhecidos pela maioria dos participantes, com destaque para os sinais longos, que apresentaram menor ocorrência de erros em comparação aos sinais curtos(Figura 7).

Fig. 7: Distribuição do número de acertos e erros para cada padrão vibratório avaliado (V1 a V4).

Além dos dados quantitativos, foi realizada uma análise visual da interação dos participantes com o dispositivo durante o teste. De acordo com a observação dos aplicadores, o equipamento permaneceu estável no local de fixação e não apresentou sinais aparentes de desconforto ou interferência na execução dos movimentos solicitados. Os participantes conseguiram responder aos estímulos durante a prática e demonstraram rápida assimilação da relação entre os padrões vibratórios e os movimentos correspondentes. Esse comportamento, associado ao elevado número de acertos, reforça a viabilidade inicial da comunicação vibrotátil para a transmissão de comandos simples em ambiente controlado.

VII. Discussão

Os resultados obtidos nos testes preliminares indicam a viabilidade inicial do DCV como recurso de comunicação vibrotátil simples. Mesmo com um curto período de familiarização e sendo este o primeiro contato dos voluntários com o dispositivo, os participantes conseguiram associar a maior parte dos padrões vibratórios aos movimentos previamente combinados. Esse desempenho sugere que estímulos vibrotáteis podem ser assimilados de maneira rápida quando organizados em comandos simples, permitindo que a vibração funcione como um canal alternativo para a transmissão de informações básicas.

Além dos resultados funcionais observados, o DCV apresenta características que reforçam sua proposta como dispositivo portátil e acessível. O sistema foi desenvolvido a partir de um conjunto compacto, com componentes simples, de baixo custo e disponíveis no mercado, associados a um aplicativo próprio de controle. Essa estrutura permite uma lógica de funcionamento direta e adaptável, sem exigir equipamentos complexos ou alto investimento para sua produção.

Outro aspecto relevante do DCV é sua versatilidade para atender diferentes necessidades comunicacionais de pessoas surdas e surdocegas. Por ser portátil, vestível e controlado por aplicativo, o dispositivo pode ser utilizado em situações cotidianas que exigem sinais rápidos e objetivos, como alertas, chamadas de atenção, orientações simples e comunicações previamente combinadas. Dessa forma, o DCV não se limita a uma função única, mas se apresenta como um recurso de comunicação tátil ajustável ao contexto e à necessidade do usuário.

O principal diferencial do DCV está na personalização dos padrões vibratórios e de seus significados. Diferentemente de tecnologias vibrotáteis assistivas com padrões previamente definidos, o dispositivo permite configurar intensidade, duração e quantidade de pulsos pelo aplicativo, associando cada sinal a uma mensagem combinada pelo usuário. Essa característica dialoga com a necessidade de dispositivos vibrotáteis mais programáveis e adaptáveis (5), permitindo que a vibração funcione como uma linguagem tátil simples, personalizada e compartilhada em diferentes situações do cotidiano.

Nesse sentido, os resultados preliminares e as características do DCV convergem para uma mesma compreensão: a vibração pode ser utilizada como uma forma simples de comunicação tátil quando organizada em padrões reconhecíveis e adaptáveis ao usuário, especialmente para apoiar pessoas surdas e surdocegas em situações que exigem comunicação rápida e acessível.

VIII. Conclusões e trabalhos futuros

Este artigo apresentou o desenvolvimento de um dispositivo de comunicação vibrotátil voltado ao apoio comunicacional de pessoas surdas e surdocegas. A construção do DCV mostrou-se relevante por reunir portabilidade, simplicidade estrutural, baixo custo dos componentes e possibilidade de controle por aplicativo móvel. Essas características aproximam o dispositivo de uma proposta de tecnologia assistiva acessível, pensada para uso prático e adaptável a diferentes contextos.

Os testes preliminares indicaram que o dispositivo

apresenta potencial para a transmissão de comandos simples por meio da vibração. Mesmo com um curto período de familiarização, os participantes conseguiram associar a maior parte dos padrões vibratórios aos movimentos previamente combinados, sugerindo que a comunicação vibrotátil pode ser compreendida de forma rápida quando organizada em sinais objetivos e reconhecíveis. Dessa forma, o DCV demonstra potencial como recurso auxiliar para comunicações rápidas, discretas e personalizáveis no cotidiano.

Como trabalhos futuros, pretende-se ampliar os testes com um número maior de participantes, incluindo pessoas surdas e surdocegas, a fim de avaliar o uso do dispositivo em situações mais próximas da realidade cotidiana. Também são previstos aprimoramentos no aplicativo e na estrutura física do DCV, buscando melhorar sua usabilidade, resistência, autonomia e possibilidades de personalização. Em etapas posteriores, espera-se disponibilizar o dispositivo ao público, contribuindo para ampliar o acesso a tecnologias assistivas simples, funcionais e socialmente relevantes.

IX. Agradecimentos

A autora agradece à Universidade Tecnológica Federal do Paraná, instituição onde a pesquisa relacionada ao dispositivo de comunicação vibrotátil teve início. Agradece também ao Laboratório de Robótica e Computação Aplicadas do Instituto Federal do Paraná – Campus Pinhais, pela implementação do DCV utilizado neste trabalho. Estende-se o agradecimento aos pesquisadores, colaboradores e integrantes do grupo de pesquisa envolvidos no desenvolvimento do projeto, pelo apoio técnico e científico ao longo da realização deste estudo.

X. Cumprimento dos requisitos éticos

A. *Conflito de interesses*

Os autores declaram não haver conflito de interesses no desenvolvimento desse trabalho.

B. *Declaração de direitos humanos e animais*

Os procedimentos realizados neste trabalho seguiram os padrões éticos do Comitê Ético da UFES e da Declaração de Helsinque de 1975.

***Resumo*—Cerebral palsy (CP) impairs motor coordination and can limit children's participation in writing activities, creating barriers to educational inclusion. This paper presents the development of three low-cost assistive writing devices designed to address specific functional demands identified in two children with CP assisted at the Early Childhood Education Center (NEI) of the Federal University of Rio Grande do Norte (UFRN). The first device is a pencil gripper made of ethylene-vinyl acetate (EVA) with an elastic fastening system, aimed at supporting difficulties in gripping conventional writing instruments. The second is a multi-angle tool with three gel crayon tips positioned at approximately 0°, 90°, and 180°, designed to expand the possibilities of writing according to the available upper-limb movement. The third is a Tactile Navigation Module designed to support pre-writing activities and fine motor skills development. The devices were developed through an iterative prototyping process based on observations of the educational context and feedback from a multidisciplinary team comprising an occupational therapist and pedagogues. The experience demonstrates the feasibility of developing low-cost and customizable assistive solutions from specific educational demands, while highlighting the importance of multidisciplinary collaboration in the development of assistive technology for inclusive education.**

***Palavras-chave*—cerebral palsy, assistive technology, adapted device, educational inclusion.**

I. Introdução

A paralisia cerebral (PC) é um grupo de desordens permanentes do desenvolvimento do movimento e da postura, atribuídas a distúrbios não progressivos que ocorrem no cérebro em desenvolvimento fetal ou infantil [1]. Com prevalência estimada entre 1,5 e 3 por 1 000 nascidos vivos [2], a PC manifesta-se de formas variadas, impactando de modo significativo a capacidade motora fina dos indivíduos afetados.

A escrita manual é uma das habilidades motoras mais complexas exigidas no ambiente escolar [3], envolvendo a integração de coordenação motora fina, controle postural, atenção e planejamento motor [4]. Para crianças com PC, essas exigências podem tornar a atividade de escrita inacessível ou extremamente desgastante, comprometendo a participação acadêmica, a expressão individual e, consequentemente, a inclusão social [5].

O desenvolvimento da coordenação motora fina deve ser entendido como uma habilidade prévia essencial para o desenvolvimento da escrita, especialmente em crianças com PC, uma vez que a produção gráfica depende de preensão adequada, controle do punho e dos dedos, velocidade de membro superior e integração visomotora. Estudos mostram que crianças com PC apresentam pior desempenho em padrões de preensão e desenho quando comparadas a crianças com desenvolvimento típico, indicando atraso em marcos de pré-escrita [6]; além disso, déficits de integração visomotora persistem mesmo quando usam a mão menos afetada, o que compromete tarefas básicas de cópia de formas relacionadas à prontidão para escrever [7]. Em amostras escolares com PC, fatores como desvio lateral do punho e velocidade do membro superior estiveram associados ao desempenho da escrita [8], enquanto intervenções focadas em atividades de pré-escrita mostraram efeito positivo sobre motricidade fina e percepção visual [9].

Em conjunto, esses achados reforçam que fortalecer a coordenação motora e a função manual não é apenas um treino complementar, mas uma base necessária para favorecer a aquisição da escrita e a participação escolar de crianças

com paralisia cerebral [10]. Desse modo, o desenvolvimento de tecnologias assistivas (TA) que favoreçam habilidades de pré-escrita torna-se fundamental para promover a autonomia e a participação de pessoas com deficiência [11]. No contexto escolar, dispositivos assistivos bem projetados ampliam as capacidades motoras, promovem autoestima e engajamento no processo educativo [12], [13]. Contudo, grande parte das soluções disponíveis comercialmente apresenta alto custo ou não é adequada ao perfil motor específico de cada criança, especialmente no contexto educacional público brasileiro [14].

Neste cenário, o presente trabalho apresenta o desenvolvimento de três dispositivos assistivos de baixo custo, concebidos a partir de demandas funcionais identificadas no contexto educacional e aprimorados por meio de um processo iterativo de prototipagem. O objetivo é descrever o processo de concepção, desenvolvimento e refinamento de soluções de tecnologia assistiva voltadas ao apoio às atividades de escrita e pré-escrita, destacando a contribuição da atuação multidisciplinar entre estudantes, profissionais da educação e terapia ocupacional.

II. Metodologia

A. Contexto da atividade extensionista e caracterização das demandas

O desenvolvimento dos dispositivos ocorreu no contexto de uma atividade extensionista realizada no Núcleo de Educação da Infância (NEI) da Universidade Federal do Rio Grande do Norte (UFRN), instituição que oferece atendimento educacional com suporte multidisciplinar. A atividade envolveu estudantes da UFRN e profissionais vinculados ao contexto educacional e de terapia ocupacional, tendo como finalidade o desenvolvimento de soluções de tecnologia assistiva de baixo custo a partir de demandas funcionais observadas no ambiente escolar.

As demandas que orientaram o desenvolvimento dos dispositivos foram identificadas a partir de visitas ao contexto educacional, observação das atividades realizadas pelas crianças e discussões com os profissionais envolvidos no atendimento. Essas informações foram utilizadas como subsídios para a definição dos requisitos funcionais dos dispositivos, não tendo como finalidade a produção de medidas clínicas ou a avaliação experimental de eficácia.

O processo de desenvolvimento foi organizado de forma iterativa, contemplando as etapas de identificação da demanda, concepção da solução, prototipagem, apreciação técnica e funcional pelos profissionais envolvidos e refinamento do dispositivo. Dessa forma, o trabalho é apresentado como um relato de experiência extensionista de desenvolvimento tecnológico aplicado à tecnologia assistiva.

B. Dispositivo 1 — Engrossador de Lápis em EVA

1) Perfil: A Criança 1 apresenta comprometimento da coordenação motora fina, com dificuldade na preensão de instrumentos de escrita de espessura convencional. A instabilidade do lápis durante a escrita gera fadiga precoce e frustração.

2) Diagnóstico e concepção: A observação inicial revelou que o diâmetro reduzido do lápis convencional não era adequado à preensão da criança. Foram testados protótipos com diferentes materiais e formas, incluindo peças de brinquedo (tipo esponja), isopor texturizado de ar-condicionado sobre marcadores e diferentes geometrias em EVA (Fig. 1a).

3) Prototipagem iterativa: O primeiro protótipo relevante adotou EVA amarelo com design escalonado: a região central era a mais espessa, com diâmetro diminuindo gradualmente em direção às extremidades, preenchendo a palma da mão e guiando o posicionamento dos dedos. Um elástico branco foi incorporado ao dispositivo para estabilizar a mão durante a escrita. A apreciação realizada com a TO indicou como pontos positivos o formato "gordinho" escalonado, mas apontou que a espessura total estava excessiva para a mão da criança e que o elástico inicial era largo demais.

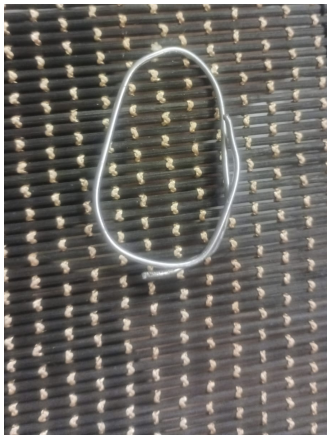
4) Design final: Com base no feedback, a espessura foi reduzida e padronizada, resultando em engrossador cilíndrico uniforme de EVA macio. O elástico foi substituído por versão mais estreita e ajustada para mãos menores. O instrumento de escrita adotado foi o lápis em gel, por exigir menor pressão sobre o papel [15]. O conjunto final, produzido em cores vibrantes para aumentar o engajamento, foi apreciado pela TO e pelas professoras da turma (Fig. 1b).

(a) Protótipos de texturas. (b) Modelos finais em EVA.

Figura 1: Evolução do engrossador de lápis: (a) protótipos desenvolvidos para explorar diferentes texturas e (b) modelos que atenderam aos critérios estabelecidos para a etapa final de desenvolvimento. Fonte: elaborado pelos autores (2026).

C. Dispositivo 2 — Ferramenta Multiangular de Escrita

1) Perfil: A Criança 2 apresenta limitações significativas na coordenação motora grossa e fina, além de déficits atencionais. O comprometimento resulta em restrição dos graus de liberdade do braço dominante, de modo que os ângulos de movimento disponíveis não possuem ponta ativa na maioria das posições, tornando a execução da escrita praticamente inviável com instrumentos convencionais [16].



2) Concepção: Para ampliar o conjunto de ângulos de escrita funcionais, concebeu-se um dispositivo que oferece múltiplas pontas em ângulos distintos em uma única ferramenta, buscando aumentar as possibilidades de posicionamento de uma ponta ativa de acordo com o movimento disponível em cada momento.

3) Desenvolvimento do protótipo: O dispositivo foi desenvolvido em etapas, ilustradas na Fig. 2:

1) *Princípio de funcionamento:* A criança segura a base do dispositivo com a mão dominante e posiciona-o de modo que uma das três pontas entre em contato direto com o papel. A presença de pontas em ângulos distintos faz com que, mesmo com amplitudes de movimento reduzidas, haja maior possibilidade de uma ponta adequadamente posicionada para executar o traçado [11].
2) *Arquitetura do dispositivo:*
   - *Estrutura base:* Um fio de arame 14 de 20 cm (Fig. 2a) foi moldado em um formato elíptico, apresentando um eixo maior de 7 cm e eixo menor de 4,5 cm, permitindo o posicionamento versátil de componentes, aliado ao baixo custo.
   - *Revestimento:* A estrutura de arame foi revestida com 3 seções de tubo de espuma de polietileno expandido (EPE) (Fig. 2b), material que cria superfícies ergonômicas adaptadas à preensão da criança, sustentada mecanicamente por fita adesiva.
   - *Pontas de giz em gel:* Três pontas equipadas com giz em gel foram fixadas ao protótipo com massa epóxi (Fig. 2c), posicionadas em ângulos de aproximadamente 0°, 90° e 180°. O giz em gel foi escolhido por ser deslizante.
   - *Fixador:* Foram adicionados 2 segmentos de 10 cm de velcro (Fig. 2d) para fixação do dispositivo na mão da criança.

Além do protótipo artesanal, o dispositivo foi posteriormente projetado em ambiente digital e fabricado por meio de impressão 3D (Fig. 3).

4) Evolução para impressão 3D: Após a apreciação ergonômica e funcional do protótipo artesanal, o projeto evoluiu para a etapa de manufatura aditiva. A geometria da ferramenta foi primeiramente refinada em ambiente virtual (Fig. 3), garantindo o posicionamento angular das pontas. O resultado final, materializado por meio de impressão 3D em filamento PLA (Fig. 4), resultou em um dispositivo mais leve e com acabamento refinado, mantendo as características funcionais definidas durante o processo de desenvolvimento.

D. Dispositivo 3 — Módulo de Navegação Tátil

1) Perfil: Ambas as crianças apresentaram demandas atencionais importantes (devido a outros diagnósticos associados à PC como Transtorno do Espectro Autista (TEA) na Criança 2 e Microcefalia na Criança 1), além da necessidade do desenvolvimento da coordenação motora fina, uma habilidade requisitada previamente ao desenvolvimento da escrita.

2) Diagnóstico e concepção: Tendo em vista a demanda atencional de ambas as crianças e a importância do desenvolvimento de habilidades pré-escrita, tais como coordenação motora fina, propriocepção e reconhecimento de padrões, concebeu-se então um dispositivo baseado em uma arquitetura modular que permite a customização da trilha e do nível de desafio.

3) Prototipagem iterativa: Primeiro, foram levadas réguas vazadas, convencionais de mercado, com formas variadas, conforme Fig. 5a, para explorar a possibilidade de interação com as crianças. No entanto, as formas eram pequenas e isso dificultou a interação. Nos encontros com a TO e a rede de cuidado educacional, ao explicar a ideia do Módulo de Navegação Tátil (MNT) personalizado para as necessidades das crianças, foi incentivada a continuação do projeto. Mesmo o ensino do NEI-UFRN aplicando o princípio do desenho à mão livre, percebeu-se a necessidade do MNT para as crianças com PC.

Então foi criado um modelo utilizando uma caixa de papelão de hortifrúti (embalagem 8/10 kg – $48 \times 25 \times 13$ cm). A caixa foi desmontada, os caminhos e formas foram cortados com

Figura 3: Representação virtual do dispositivo modelado em software 3D. Fonte: elaborado pelos autores (2026).

Figura 4: Resultado final do dispositivo impresso em PLA, pronto para uso, produzido pela InPacta (ECT/UFRN).

auxílio de estilete e foram montados botões feitos com papelão com formas (emojis e borboleta). O processo foi feito seguindo o fluxograma gerado por IA, conforme Fig. 5b, e, em seguida, o material foi pintado com tinta guache para proporcionar melhor harmonização visual ao protótipo (Fig. 5c).

4) Design final: O design final do MNT levou em consideração, durante sua estruturação, os parâmetros de tolerância mecânica, os encaixes modulares tipo quebra-cabeça e a disposição dos atuadores nos trilhos e sua integração com as zonas de pré-escrita, podendo ser observado em madeira na Fig. 7.

Após a apreciação do conceito e do componente lúdico por meio do protótipo em papelão, o Módulo de Navegação Tátil (MNT) evoluiu para sua versão definitiva, confeccionada em madeira. A transição de materiais visou conferir maior durabilidade, estabilidade e segurança estrutural durante as sessões de interação com as crianças. O dispositivo finalizado apresenta acabamento lixado e trilhas bem definidas, proporcionando um percurso tátil contínuo, seguro e resistente ao desgaste diário, características compatíveis com a proposta de apoiar atividades de desenvolvimento da coordenação motora fina.

(a) Testes com réguas vazadas.

(b) Fluxograma por IA.

(c) Protótipo funcional em papelão.

Figura 5: Etapas de concepção do Módulo de Navegação Tátil: (a) testes iniciais com réguas vazadas; (b) fluxograma de planejamento gerado por IA; e (c) protótipo funcional estruturado em papelão reaproveitado. Fonte: elaborado pelos autores (2026).

O MNT é composto por painéis modulares com canais de baixa fricção, subdivididos em:

- *Guias de Precisão (Slots):* trilhas onduladas, zigueza-gues e padrões geométricos integrados para atividades de controle motor fino. O perfil dos canais é projetado para minimizar o atrito, exigindo força controlada para o movimento.
- *Trilhas de Interferência:* a geometria das trilhas cria desafios de navegação que estimulam a coordenação óculo-manual e proprioceptiva.

Além disso, foram definidos os seguintes componentes:

1) *Atuadores (Sliders):* botões com formas geométricas e peso controlado, impressos em PLA via impressora 3D.
2) *Pino de Guia e Retenção:* mecanismo interno de pino que mantém o atuador dentro do trilho, permitindo apenas movimentos controlados ao longo da trilha.
3) *Recortes Geométricos de Precisão:* espaços com formas (coração, triângulo, quadrado) e linhas de pré-escrita.

4) *Guias de Alinhamento de Papel:* recuo integrado para o posicionamento preciso de folhas de papel, permitindo que a criança use a caneta dentro das formas guias.
5) *Pinças:* as pinças em madeira permitem o acoplamento do MNT em planos inclinados.
6) *Peças para encaixe:* peças do mesmo tamanho dos recortes geométricos permitem que a criança reconheça padrões geométricos e os encaixe de forma correspondente.

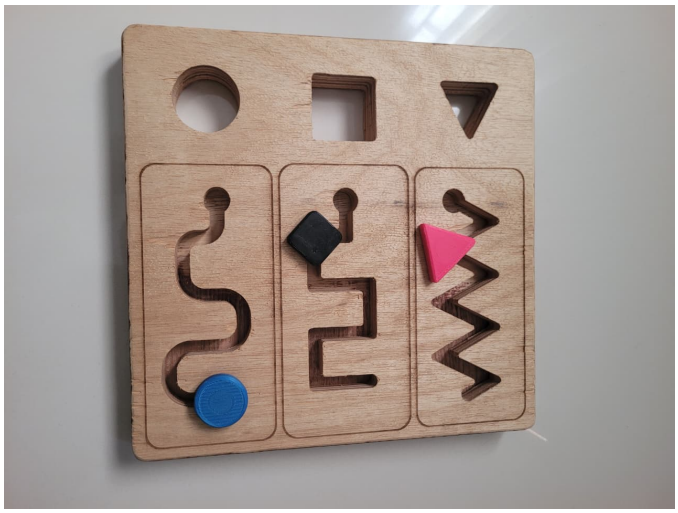
III. Resultados



A. Engrossador de EVA

Após três ciclos de prototipagem e avaliação, foi definida a configuração final do engrossador, considerando as características funcionais observadas e as contribuições da terapeuta ocupacional e das professoras da turma. A Tabela I sumariza as especificações do produto final.

Os principais pontos de melhoria identificados ao longo da iteração foram: (i) redução da espessura para adequação à mão da criança; (ii) substituição do elástico inicial por versão mais estreita; e (iii) adoção do lápis em gel em substituição ao lápis grafite convencional. Os próximos passos incluem a fixação permanente do elástico com cola quente — dado que o dispositivo se soltou durante uso mais intenso — e a expansão da paleta de cores disponíveis [13].

B. Ferramenta Multiangular

As apreciações exploratórias realizadas durante o desenvolvimento indicaram que a configuração com múltiplas pontas ampliava as possibilidades de posicionamento da extremidade ativa diante das restrições de movimento observadas. Em experimentações iniciais de uso, foi possível observar a realização de marcações no papel com diferentes posicionamentos do dispositivo. Esses registros tiveram caráter exclusivamente exploratório e orientaram o refinamento do protótipo, não constituindo avaliação quantitativa de desempenho ou estudo de eficácia.

(a) Vista superior da versão em madeira.

(b) Vista frontal da versão em madeira.

Figura 7: Resultado final do Módulo de Navegação Tátil manufaturado em madeira, projetado para suportar o uso contínuo e garantir segurança durante o desenvolvimento de habilidades pré-escritas. Confeccionado pelo LabMAN-PotiProt/UFRN.

Os principais desafios operacionais documentados foram: (i) dificuldades no agendamento de visitas técnicas em função das necessidades específicas da criança; (ii) escassez de profissionais treinados para manusear protótipos adaptados em contexto educacional [17]; e (iii) aceitação sensorial do dispositivo por parte da criança. Esses fatores limitaram a extensão das experimentações e a obtenção de dados quantitativos.

C. Módulo de Navegação Tátil

O MNT é uma solução de engenharia concebida para apoiar atividades de pré-escrita, integrando princípios de controle motor e processamento sensorial. Sua modularidade, o feedback tátil e o design lúdico conferem ao dispositivo características que podem favorecer sua adaptação a diferentes atividades voltadas ao desenvolvimento de habilidades de pré-escrita e coordenação motora fina.

A Tabela II apresenta os principais componentes e respectivas funções do MNT.

Tabela I: Especificações do Engrossador de EVA (Dispositivo 1)

Componente	**Especificação**
Instrumento de escrita	Lápis em gel
Material do engrossador	EVA macio
Geometria	Ciliíndrica uniforme
Fixação	Elástico estreito ajustável
Cores disponíveis	Múltiplas (vibrantes)
Custo estimado	$<$ R$ 5,00 por unidade

IV. Conclusões

Este trabalho apresentou o desenvolvimento de três dispositivos assistivos de escrita e pré-escrita de baixo custo, concebidos a partir de demandas funcionais específicas identificadas no contexto educacional. O processo de desenvolvimento evidenciou a importância da prototipagem iterativa e da colaboração entre estudantes, profissionais da educação e terapeuta ocupacional para a definição e o refinamento de soluções de tecnologia assistiva.

As duas crianças consideradas no desenvolvimento das TA apresentaram demandas motoras distintas, reforçando a necessidade de soluções individualizadas. Enquanto o primeiro dispositivo foi direcionado à adaptação da preensão do instrumento de escrita, o segundo buscou ampliar as possibilidades de posicionamento da extremidade ativa diante de restrições de movimento do membro superior. O terceiro dispositivo foi concebido para apoiar atividades de pré-escrita e coordenação motora fina, incorporando elementos táteis, geométricos e lúdicos.

Os resultados apresentados devem ser compreendidos como evidências preliminares do processo de desenvolvimento e da adequação das soluções às demandas. Utilizamos metodologia ativa e design centrado no usuário e no contexto envolvendo os diversos profissionais envolvidos no contexto educacional das crianças Portanto, este estudo demonstrou como foi o processo de desenvolvimento das soluções não tendo como finalidade demonstrar eficácia terapêutica ou educacional nem permitir generalizações para a população de crianças com paralisia cerebral. Estudos futuros são necessários para validar os dispositivos envolvendo uma amostra maior e com crianças com diferentes níveis de comprometimento motor, envolvendo medidas objetivas da função motora, da coordenação e precisão de movimentos por meio de estudo longitudinal.

A experiência também evidencia a extensão universitária como espaço de articulação entre formação acadêmica, demandas concretas do contexto educacional e desenvolvimento de soluções tecnológicas socialmente orientadas.

Como continuidade, estudos futuros poderão incorporar protocolos específicos de avaliação, instrumentos padronizados e métricas quantitativas, como tempo de execução, precisão dos traçados, estabilidade da preensão, amplitude funcional do movimento e fadiga. Também poderão ser realizadas avaliações longitudinais, comparações sistemáticas do desempenho com e sem os dispositivos e investigações envolvendo maior número de crianças e diferentes perfis de comprometimento motor. Essas etapas poderão contribuir para avaliar de forma sistemática a efetividade, a adaptabilidade e a possibilidade de replicação das soluções em diferentes contextos educacionais.

Agradecimentos

Os autores agradecem à equipe do Núcleo de Educação da Infância (NEI-UFRN), em especial às pedagogas e à terapeuta ocupacional, pelo suporte durante as visitas técnicas e pela participação no processo de desenvolvimento e avaliação dos dispositivos. Agradecem também à Incubadora de Processos Acadêmicos, Científicos, Tecnológicos e Aplicados da Escola de Ciência e Tecnologia da UFRN (InPacta/UFRN) pelos dispositivos impressos em PLA. Agradecem também ao Laboratório de Manufatura da Rede PotiProt da UFRN (LabMAN-PotiProt/UFRN) pela confecção do módulo de navegação tátil em madeira.

Nota sobre o uso de Inteligência Artificial

Durante a elaboração deste texto, ferramentas de Inteligência Artificial foram utilizadas como apoio à revisão linguística, à organização das ideias, à reestruturação de trechos e ao aprimoramento da clareza textual. O uso dessas ferramentas ocorreu de forma auxiliar, sem substituir a análise crítica,

Tabela III: Comparação entre os Dispositivos Desenvolvidos

Característica	Dispositivo 1	Dispositivo 2	Dispositivo 3
Problema-alvo	Preensão inadequada	Ângulos limitados	Dificuldade de atenção e coordenação motora fina
Materiais principais	EVA, elástico, lápis gel	Arame 14, EPE, giz em gel, massa epóxi	Madeira
N.º de iterações	3	1	2
Custo estimado	$<$ R$ 5	$<$ R$ 15	$<$ R$ 20
Avaliação	TO + professoras	TO + pedagoga	TO + pedagoga

Resumo— ***A Distrofia Muscular de Duchenne é caracterizada por degeneração muscular progressiva que compromete a função motora e a qualidade de vida de pacientes do sexo masculino. As opções terapêuticas disponíveis não alteram o desfecho da doença, mas contribuem para retardar seu avanço e manter a funcionalidade por mais tempo, sendo os dispositivos ortopédicos personalizados ferramentas importantes nesse processo. O estudo descreveu o processo de desenvolvimento de uma palmilha por impressão 3D para uma criança com Distrofia Muscular de Duchenne, que apresentava fraqueza de musculatura dorsiflexora de tornozelo e desabamento do arco plantar e a satisfação do dispositivo pela família. Foi realizada a confecção de uma palmilha personalizada, cujo processo incluiu escaneamento tridimensional do pé, modelagem em software DEC/MAC, impressão 3D e revestimento interno. O dispositivo inicial apresentou baixa adesão após a primeira semana devido a preferência da criança por sandálias, sendo confeccionado um novo modelo fixado diretamente ao calçado. A satisfação foi avaliada pelo Questionário Quebec de Satisfação com a Tecnologia Assistiva em três momentos distintos, indicando satisfação consistente ao longo do seguimento. Os resultados deste estudo de caso demonstram a viabilidade técnica do desenvolvimento interativo de uma palmilha personalizada por impressão 3D, evidenciando a importância da adaptação do dispositivo às necessidades clínicas e cotidianas do usuário.***

Palavras-chave — ***Distrofia Muscular de Duchenne, Tecnologia Assistiva, Órtese Plantar***

I. INTRODUÇÃO

A Distrofia Muscular de Duchenne (DMD) é uma doença genética recessiva ligada ao cromossomo X, pertencente ao grupo das distrofinopatias, caracterizada por degeneração muscular progressiva que compromete significativamente a função motora e a qualidade de vida dos pacientes do sexo masculino [1,2]. Atualmente, as opções terapêuticas disponíveis, como fisioterapia e corticosteróides, não alteram o desfecho da doença, mas são fatores que contribuem para retardar seu avanço e manter a funcionalidade por mais tempo [3].

Na perspectiva da biomecânica funcional, o organismo de crianças com DMD reorganiza-se motoramente para manter a deambulação devido ao padrão de marcha significativamente alterado em decorrência da fraqueza muscular progressiva [4, 5]. Entre essas alterações biomecânicas, observam-se inclinação pélvica anterior excessiva, abdução aumentada na fase de balanço e comprometimento da flexão do joelho na resposta à carga [6,7]. Em muitos casos, desenvolve-se hiperextensão do joelho, como estratégia compensatória para a fraqueza do quadríceps [8,6,7]. Os pés permanecem em equino no contato inicial, com flexão plantar excessiva durante o balanço, enquanto o comprimento da passada é reduzido e a largura do passo é aumentada para preservar o equilíbrio [8].

Dessa forma, dispositivos ortopédicos constituem parte do manejo clínico da DMD, e a prescrição precoce pode prolongar a deambulação e retardar o declínio funcional, reforçando a importância dessa intervenção [9]. As órteses de tornozelo e pé (OTPs) são comumente prescritas nesse contexto por promoverem o alinhamento dos segmentos corporais, controlarem a instabilidade articular e prevenirem deformidades musculoesqueléticas, otimizando o desempenho biomecânico durante a marcha [10,11]

À medida que a força muscular diminui, no entanto, a eficácia dessas órteses tende a reduzir-se progressivamente. Por isso, as prescrições devem ser individualizadas e adaptadas ao nível de comprometimento dos membros inferiores de cada

criança, funcionando como ferramentas auxiliares na promoção das atividades de vida diária e na facilitação da marcha [12,9,13]

Nesse cenário, a tecnologia de impressão 3D tem ampliado as possibilidades de produção personalizada de dispositivos ortopédicos. Os softwares de modelagem aliados ao tempo de produção permitem adequações anatômicas precisas às necessidades individuais de cada paciente quando comparado ao método tradicional [14,15]. A prototipagem rápida representa, assim, um avanço relevante para o desenvolvimento de soluções terapêuticas mais eficazes e acessíveis para crianças com DMD.

Diante disso, o presente estudo tem como objetivo descrever o processo de desenvolvimento de uma palmilha personalizada produzida por impressão 3D para uma criança com Distrofia Muscular de Duchenne, bem como analisar o processo de reprojeto do dispositivo a partir do acompanhamento longitudinal da satisfação e da adesão da família.

II. METODOLOGIA

O estudo foi desenvolvido nas dependências do Centro Estadual de Reabilitação e Readaptação Dr. Henrique Santillo, um Centro Especializado de Reabilitação (CERs) nível IV localizado em Goiânia, Goiás. Os dispositivos de TA são desenvolvidos pelo Laboratório de Estudos Inventivos em Tecnologia Assistiva (Lab. E.I.T.A.), da Universidade Federal de Goiás, por uma equipe multidisciplinar e são entregues aos pacientes da instituição, conforme o parecer do Comitê de Ética 7.828.871, durante os meses de março a junho de 2026.

O fluxo de solicitação do dispositivo iniciou-se por meio da demanda identificada pelo profissional do serviço responsável pelo atendimento do paciente. A responsável pela criança assinou o Termo de Consentimento Livre e Esclarecido (TCLE) e participou de uma entrevista de anamnese pré-estruturada contendo perguntas sobre diagnóstico clínico da criança, uso de órteses, acesso à saúde, entre outras e, em seguida, foi realizada avaliação fisioterapêutica.

O recurso de tecnologia assistiva foi definido após a avaliação fisioterapêutica pela equipe multiprofissional, composta por fisioterapeutas, designer de produtos e arquiteto. Para isso, foi realizado o escaneamento tridimensional com a criança posicionada sentada em um banco, com a articulação do tornozelo posicionada passivamente a 90 graus.

As medidas anatômicas obtidas no escaneamento e a identificação das necessidades clínicas na avaliação fisioterapêutica auxiliaram a modelagem digital do dispositivo e a definição da geometria do dispositivo. Assim, foi desenvolvida uma palmilha com objetivos de promover suporte ao arco medial longitudinal plantar e melhorar a acomodação do pé durante o uso de calçado. A palmilha foi confeccionada por impressão 3D, testada e entregue ao paciente. Os parâmetros da impressão tridimensional estão apresentados na tabela I.

TABELA I. **PARÂMETROS DA IMPRESSÃO 3D**

Parâmetros	Palmilha
Material	TPE
Preenchimento	Variável
Espessura da Camada	0.2mm
Temperatura do Bico	220 ºC
Temperatura da Mesa Impressão	60 ºC
Diâmetro do Bico	0.4mm
Padrão de preenchimento	Variável
Tempo total impressão	180 min.

Após a entrega da palmilha, foi aplicado o Questionário de Satisfação do Usuário com a Tecnologia Assistiva de Quebec (QUEBEC/B-QUEST) em três momentos: 7 dias, 30 dias e 90 dias. O instrumento foi criado em 2010 por Demers, Weiss-Lambrou, Ska [16] com o objetivo de quantificar a satisfação dos usuários com a tecnologia utilizada, traduzido e validado para a língua portuguesa em 2014 por Carvalho, Júnior, Sá [17], contendo 12 perguntas: oito relacionadas ao recurso de tecnologia assistiva (dimensões, peso, ajustes, segurança, durabilidade, facilidade de uso, conforto e eficácia) e quatro relacionadas aos serviços prestados (processo de entrega, reparos, serviços profissionais e serviços de acompanhamento), e uma questão sobre quais os itens o usuário considera mais importantes em um recurso de TA. Cada item do instrumento é pontuado em uma escala de 1 a 5, sendo: 1 (insatisfeito), 2 (pouco satisfeito), 3 (mais ou menos satisfeito), 4 (bastante satisfeito) e, 5 (totalmente satisfeito).

No acompanhamento do uso da palmilha pelo paciente foi identificada a necessidade de ajustes. Assim, um novo modelo de palmilha foi desenvolvido e reimpresso. Os parâmetros obtidos no escaneamento e na avaliação fisioterapêutica foram mantidos para a confecção da nova palmilha.

O fluxograma de todas as etapas está apresentado na Fig. 1. O processo de desenvolvimento foi baseado no fluxo de prototipagem rápida previamente estabelecido pelo Lab.EITA.

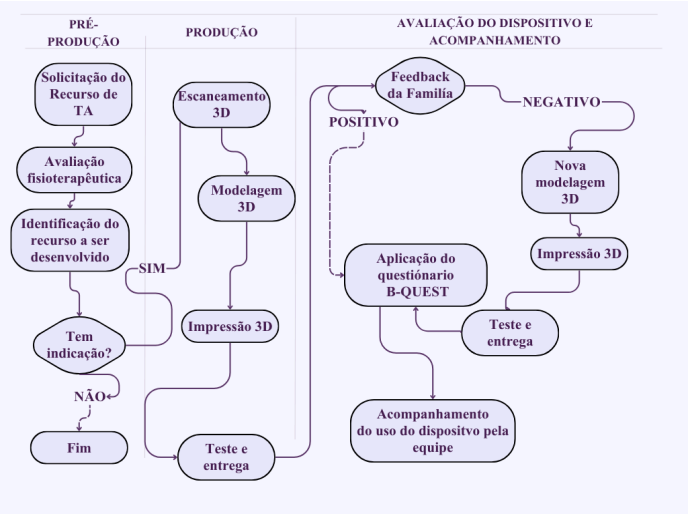

Fig. 1. Fluxograma do processo de produção da palmilha adaptada

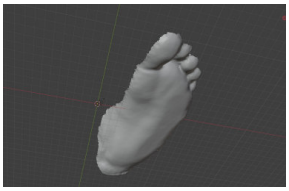
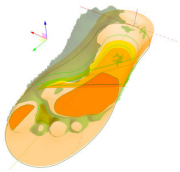
III. RESULTADOS

Paciente do sexo masculino, 7 anos de idade, com diagnósticos de Distrofia Muscular de Duchenne (DMD), Transtorno do Espectro Autista (TEA) e Transtorno do Déficit de Atenção e Hiperatividade (TDAH). No exame físico realizado pela equipe de fisioterapia, foi identificada fraqueza da musculatura dorsiflexora de tornozelo, associada a desabamento do arco plantar, pés pronados, com tônus e

trofismo musculares preservados, apresentando indicação clínica para utilização de palmilha. Em sedestação, o paciente apresentou boa distribuição de peso em região pélvica e descarga de peso bem distribuída em membros inferiores, sendo capaz de realizar mudanças posturais. O paciente fez uso prévio de órtese tornozelo-pé (OTP), porém não apresentou adaptação ao dispositivo. Diante desse contexto, a equipe optou pela confecção de uma palmilha para fins de posicionamento.

Inicialmente, foi realizado o escaneamento tridimensional do pé do paciente, com o scanner RevoPoint scanner 3D Range 2 (Fig. 2a). Posteriormente, utilizando a malha gerada pelo escaneamento, a equipe de design realizou a modelagem 3D utilizando o software gratuito Gensole (Fig. 2b). Nesse aplicativo, o modelo digital obtido, por meio do Design Assistido por Computador (DEC), constituiu a base para as fases subsequentes do fluxo de trabalho de fabricação. O arquivo digital projetado no ambiente DEC foi posteriormente traduzido em instruções para os equipamentos de fabricação, por meio da Manufatura Assistida por Computador (MAC). Esse fluxo de desenvolvimento refletiu na transição entre a modelagem tridimensional da palmilha e a posterior fabricação por impressão 3D, conforme detalhado a seguir.





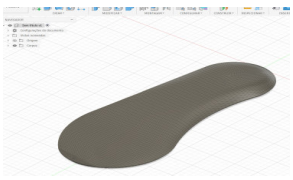
(a)   (b)

Fig. 2. (a). Malha gerada pelo escaneamento. Fig. (b) modelagem da primeira tentativa.

Em seguida, o modelo foi exportado em estereolitografia (STL) e impresso em 3D, utilizando a impressora Creality S1 PRO, com um bico de 0,4mm, filamento TPE (Shore 83-A), levando 1 hora e 57 minutos. Durante o pós-processamento, foi realizada a retirada dos suportes de impressão permitindo o ajuste das bordas para a fixação. Em seguida, a parte interna foi revestida com Plastazote e colada com cola adesiva de contato. Os gastos e quantidades dos materiais foram descritos na Tabela II.

TABELA II. CUSTOS DE PRODUÇÃO DO PAR DE PALMILHAS EM IMPRESSÃO 3D

Variável	Quantidade	Custo Estimado
TPE	50g	R$ 18,00
Plastazote	8g	R$19,00
Custo Total		R$37



Ressalta-se que esse valor corresponde exclusivamente aos materiais consumidos durante a fabricação, não contemplando custos relacionados à mão de obra especializada, escaneamento tridimensional, modelagem digital, energia elétrica, depreciação dos equipamentos e acabamento.

Ao final desse processo,a palmilha foi testada com a criança e entregue para uso (Fig. 3), sendo estruturada para ser posicionada dentro do tênis. Ademais, a responsável foi orientada a iniciar o uso gradual do produto, em ambiente escolar e na comunidade.

Fig. 3. Teste e entrega do primeiro modelo

Entretanto, após uma semana, a mãe relatou dificuldade no uso deste primeiro dispositivo, pois a criança não aderiu ao uso com o tênis, demonstrando preferência pelo uso de sandálias. Diante disso, a equipe optou pela confecção de um segundo modelo de palmilha, projetado para ser fixado diretamente na sandália (Fig. 4a), utilizando o software Fusion 360 (Fig. 4b).

(a)   (b)

(Fig. 4. (a) Sandália para fixação. Fig. (b).Segundo modelo de palmilhas

A baixa adesão ao primeiro modelo não foi interpretada como falha, mas como evidência da necessidade de adaptação do dispositivo às características funcionais e comportamentais da criança. Dessa forma, o feedback da família foi incorporado ao processo de desenvolvimento, culminando no reprojeto completo do dispositivo, resultando em um segundo modelo de palmilha.

O segundo modelo da palmilha foi testado presencialmente durante o atendimento fisioterapêutico e entregue à criança (Fig. 5).

Fig. 5. Segundo modelo da palmilha em uso

O acompanhamento subsequente à entrega do segundo modelo da palmilha foi realizado de forma virtual, durante um período de três meses. O B-QUEST foi reaplicado 30 e 90 dias após a entrega do segundo modelo de palmilha. Os resultados do questionário podem ser visualizados na Tabela III.

TABELA III. PONTUAÇÃO SUBTOTAL DO B-QUEST

Momento de avaliação	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*	*11*	*12*	*TOTAL*
7 dias após 1ª entrega	4	4	4	4	4	4	3	4	4	4	4	4	3,91
B-QUEST 1*	4	4	-***	3	4	3	3	3	4	4	4	4	3,63

B-QUEST 2 **	3	4	3	4	4	3	3	4	5	4	5	4	3,83

*Aplicado após 30 dias de entrega

** Aplicado após 90 dias de entrega

*** Questão não respondida, foi retirada do cálculo do escore total.

Na pontuação dos itens sobre Recursos (itens 1-8), o escore do B-QUEST 1 foi 3,57 e B-QUEST 2 foi 3,5, resultando em satisfação mais ou menos. A pontuação dos itens sobre Serviços (itens 9-12) foi 4,0 e 4,5 respectivamente (bastante satisfeito).

IV. DISCUSSÃO

A confecção de palmilhas adaptadas por impressão 3D apresentou-se como uma alternativa tecnicamente viável e passível de adaptação às necessidades individuais do paciente, levando em consideração as comorbidades do neurodesenvolvimento que, possivelmente, interferiram na adesão ao dispositivo.

Um dos principais achados deste estudo foi demonstrar que o sucesso da tecnologia assistiva esteve diretamente relacionado à capacidade de adaptação do dispositivo às necessidades cotidianas da criança, e não apenas às suas características biomecânicas. A reformulação do projeto a partir do feedback da família evidenciou a importância de processos de desenvolvimento centrados no usuário, nos quais a não adesão ao uso do primeiro modelo da palmilha pode representar uma oportunidade de aperfeiçoamento do dispositivo, e não necessariamente um insucesso terapêutico.

Crianças com TEA podem apresentar dificuldades de adesão a dispositivos ortopédicos em decorrência da rigidez e textura dos materiais e das limitações impostas à mobilidade residual resultados da integração sensorial que gera uma intolerância a esses estímulos táteis e proprioceptivos provocados pelo uso prolongado de dispositivos ortopédicos [18,19], como relatado pela responsável. Em razão disso, houve uma dificuldade do cuidador em incentivar/insistir no uso da palmilha. Portanto, essa interação entre DMD, TEA e uso de tecnologias assistivas representa, por si só, uma lacuna importante a ser investigada em estudos futuros.

Os ajustes realizados no desenvolvimento da palmilha após a baixa adesão na primeira semana, levando em consideração a escuta ativa da responsável pela criança, foi um fator determinante para que a equipe redirecionasse a conduta de forma ágil, preservando a continuidade do uso do dispositivo e, consequentemente, os potenciais benefícios para o posicionamento do arco plantar.

Sobre a utilização da impressão 3D para a confecção da palmilha adaptada, estudos prévios sugerem vantagens de custo, tempo e ambientais em relação aos métodos tradicionais de fabricação [20,21]. A modelagem em software DEC/MAC permite a customização regional de durezas, já a impressão 3D permite a escolha do padrão de preenchimento e geometrias com precisão milimétrica, levando em consideração o escaneamento do pé da criança. Assim, possibilitando o desenvolvimento de geometrias capazes de direcionar o suporte plantar de forma individualizada, embora esse efeito biomecânico não tenha sido mensurado no presente estudo.

As palmilhas convencionais, por sua vez, apresentam limitações na capacidade de personalização, dependendo da experiência manual do ortesista e das propriedades físicas dos materiais disponíveis, devido a pré-moldagem e termoformagem do gesso e termoplástico, respectivamente [20,21]. A reprodutibilidade do arquivo digital é outro aspecto relevante, pois permite que o dispositivo seja reimpresso com exatidão em caso de desgaste ou necessidade de ajuste, o que representa uma vantagem prática em serviços de reabilitação de longa permanência, como o contexto do presente estudo e levando em consideração o crescimento da criança.

A escolha do filamento TPE deu-se a partir de sua combinação de plástico e borracha, que possui alta absorção de impacto, resistência ao desgaste e capacidade de dobrar ou esticar sem quebrar. Características essas, necessárias para as palmilhas quando comparada com as palmilhas já existentes. O filamento flex demonstra-se eficaz na flexibilidade, força máxima e dureza estrutural adequada para palmilhas ortopédicas [22].

Os escores do B-QUEST demonstram percepção favorável da família quanto ao dispositivo e ao processo de acompanhamento oferecido pela equipe. Entretanto, esses resultados devem ser interpretados como indicadores de aceitabilidade da tecnologia assistiva, não constituindo evidências diretas de sua eficácia clínica ou biomecânica. A avaliação do domínio Satisfação demonstrou escores totais consistentemente acima de 3,6 nos três momentos de acompanhamento (3,91; 3,63; 3,83), indicando boa satisfação geral da família com o dispositivo ao longo do seguimento.

Um fator que comumente está atrelado a descontinuação do uso de TA é a falta de acompanhamento e reavaliação do dispositivo após a implementação, tanto pela escassez de pessoas para avaliar o uso, bem como realizar a manutenção dos dispositivos [23,24]. Desta forma, o acompanhamento sistemático realizado em três momentos pode ter contribuído para a consistência dos escores da subescala de Serviços ao longo do seguimento (4,0 para 4,5). A disponibilidade da equipe para reavaliar o dispositivo e propor um novo modelo diante da baixa adesão inicial reforça que o processo de prescrição de TA não se encerra na entrega do dispositivo, mas exige monitoramento contínuo e responsividade às demandas do usuário e de sua família. Nesse contexto, a impressão 3D mostrou-se vantajosa por permitir o reprojeto e a fabricação de um novo dispositivo em um curto intervalo de tempo, favorecendo um processo iterativo de desenvolvimento centrado no usuário, sem a necessidade de reiniciar todas as etapas convencionais de confecção.

A subescala de Recursos, por sua vez, apresentou discreta redução (3,8 para 3,5), o que pode refletir aspectos do dispositivo ainda passíveis de refinamento, como conforto, facilidade de uso ou durabilidade. A mudança no perfil de itens com menor pontuação entre a primeira e as demais avaliações, itens 4, 8 e 11 para itens 5, 6 e 7, pode indicar que a substituição do primeiro modelo para o segundo modelo respondeu a parte das insatisfações anteriores pelos usuários, o que deve orientar eventuais ajustes no dispositivo durante o seguimento.

O presente estudo apresenta limitações inerentes ao seu delineamento. Por tratar-se de um estudo de caso único, os resultados não permitem generalizações para outras populações com DMD ou perfis clínicos distintos. Também não foram realizadas avaliações biomecânicas instrumentadas, como análise cinemática da marcha, distribuição de pressão plantar ou outras medidas objetivas capazes de quantificar os efeitos do dispositivo sobre a função motora. Assim, os achados restringem-se à descrição

do processo de desenvolvimento e à percepção de satisfação da família, não sendo possível estabelecer inferências sobre a eficácia clínica da palmilha. Estudos futuros com períodos de seguimento mais prolongados e sistematizados poderão proporcionar uma compreensão mais abrangente dos efeitos do dispositivo em longo prazo. Da mesma forma, a inclusão de amostras maiores e grupos de comparação contribuirá para fortalecer as evidências acerca do uso da impressão 3D na confecção de palmilhas personalizadas para crianças com distrofinopatias.

V. CONCLUSÃO

O presente estudo demonstrou a viabilidade do desenvolvimento de uma palmilha personalizada por impressão 3D em um contexto clínico de reabilitação. O processo, desde o escaneamento tridimensional até a entrega, acompanhamento e reprojeto do dispositivo, mostrou-se reprodutível e adaptável às necessidades do usuário, sendo necessária a confecção de um segundo modelo para atender às demandas cotidianas e comportamentais da criança. A escuta ativa da família e a responsividade da equipe frente à baixa adesão inicial evidenciaram que a prescrição de tecnologias assistivas constitui um processo dinâmico, que demanda monitoramento contínuo e adaptações ao longo do uso. Os achados reforçam o potencial da manufatura aditiva como ferramenta para o desenvolvimento de recursos personalizados de tecnologia assistiva. Entretanto, estudos com amostras maiores, acompanhamento em longo prazo e avaliações funcionais objetivas são necessários para ampliar a generalização dos resultados e determinar os efeitos clínicos do dispositivo.

Resumo- ***As cadeiras de rodas infantis constituem tecnologias assistivas desenvolvidas para promover melhorias na mobilidade, na participação social e na qualidade de vida de crianças com deficiência física. Entretanto, persistem dificuldades relacionadas ao acesso, ao custo e dificuldade de adaptação, evidenciando a necessidade de alternativas de baixo custo, personalizadas e sustentáveis. O objetivo é desenvolver e descrever um fluxo de manufatura digital para a produção de cadeiras de rodas infantis personalizadas a partir de plásticos reciclados, avaliando sua viabilidade técnica, produtiva e seu potencial como modelo de economia circular aplicado ao campo das tecnologias assistivas. Trata-se de um estudo de desenvolvimento tecnológico descritivo, as etapas consistiram na revisão de literatura, arrecadação de tampas de plástico, separação, trituração, prensagem, coleta das medidas antropométricas, modelagem tridimensional parametrizada, fresagem, impressão 3D e montagem da cadeira de rodas infantil. Foi desenvolvida uma cadeira de rodas infantil personalizada produzida a partir de plásticos reciclados, com peso de 4,01 kg, custo de produção de R$ 249,60 e tempo de produção de aproximadamente 11 horas e 10 minutos. O modelo apresentou baixo peso, baixo custo e capacidade de personalização conforme as medidas antropométricas do usuário. A integração entre economia circular e tecnologia assistiva representa uma estratégia promissora para a produção de cadeiras de rodas infantis personalizadas, reduzindo custos e impactos ambientais.***

Palavras- chave**—Cadeira de Rodas, Tecnologia Assistiva, Crianças, Reciclagem**

I. INTRODUÇÃO

As deficiências físicas em crianças contribuem para a presença de barreiras à participação, à inclusão, à independência, à prática de atividades físicas e favorecem o desenvolvimento de comorbidades associadas e deformidades [1,2]. Nesse sentido, as cadeiras de rodas infantis constituem tecnologias assistivas (TA) desenvolvidas para promover melhorias nas habilidades posturais, no suporte independente, na mobilidade ativa e na participação social [3,4].

Considerando sua importância para a funcionalidade e a inclusão social, observa-se um constante desequilíbrio entre a necessidade e a disponibilidade. Entre 10% e 15% da população mundial apresenta algum tipo de deficiência, e cerca de 10% dessas pessoas necessitam de cadeira de rodas para garantir mobilidade independente [5]. Apesar dessa demanda expressiva, a Organização Mundial da Saúde (OMS) estima que apenas 15% das pessoas que necessitam de uma cadeira de rodas conseguem obtê-la [6], evidenciando um importante desafio relacionado ao acesso [7].

No Brasil, a oferta de TA é prevista no art. 18, inciso XI, da Lei Brasileira de Inclusão da Pessoa com Deficiência (LBI), que garante o fornecimento de órteses, próteses e meios auxiliares de locomoção, conforme as normas do Ministério da Saúde, mediante cadastro e avaliação multiprofissional na rede do Sistema Único de Saúde (SUS) [8]. Entretanto, em 2023, Bastos [9] evidenciou insatisfação em relação ao desenvolvimento e ao uso dessas TA's, destacando a insuficiente compreensão das necessidades dos usuários, inadequações dimensionais dos dispositivos e a necessidade de um processo de desenvolvimento centrado no usuário. Além disso, persistem dificuldades relacionadas ao tempo de entrega, à manutenção e ao acompanhamento das cadeiras de rodas fornecidas pelo SUS. Na população infantil, essas limitações tornam-se ainda mais relevantes em razão do rápido crescimento das crianças, que exige adaptações frequentes dos dispositivos [10,11].

Nesse contexto, é necessário o desenvolvimento de alternativas de baixo custo e que apresentem alta capacidade de

alteração e personalização. Assim, o presente estudo teve como objetivo propor estratégias capazes de integrar acessibilidade, personalização e sustentabilidade em um mesmo processo produtivo. Bem como, desenvolver e descrever um fluxo de manufatura digital para a produção de cadeiras de rodas infantis personalizadas a partir de plásticos reciclados, avaliando sua viabilidade técnica, produtiva e seu potencial como modelo de economia circular aplicado ao campo das TAs, favorecendo a mobilidade, a inclusão social, a participação nas atividades cotidianas, e a qualidade de vida dessa população.

II. METODOLOGIA

Trata-se de um estudo de desenvolvimento tecnológico descritivo realizado nas dependências do Laboratório de Estudos Inventivos em Tecnologias Assistivas na Universidade Federal de Goiás por uma equipe de docentes e discentes dos cursos de Fisioterapia, Design de Produtos e Arquitetura. Este trabalho descreve o desenvolvimento de uma cadeira de rodas infantil a partir das medidas antropométricas de uma criança participante do projeto "Avaliação e acompanhamento de crianças de 0 a 5 anos com alterações neurológicas e/ou deficiências que necessitavam de tecnologias assistivas", aprovado no Comitê de Ética (Nº 7.688.714). No entanto, o processo de desenvolvimento para cada cadeira necessita da personalização do dispositivo conforme as características antropométricas de cada criança, o presente trabalho descreveu apenas um dos dispositivos entregues. O processo envolveu 10 etapas, dispostas no fluxograma (Fig. 1): revisão de literatura; arrecadação de tampas de plástico; separação das tampas por cores e tipos de plástico; trituração; prensagem e compactação das tampas trituradas; coleta das medidas antropométricas; modelagem da cadeira; fresagem das placas; produção das rodas e pneus e montagem.

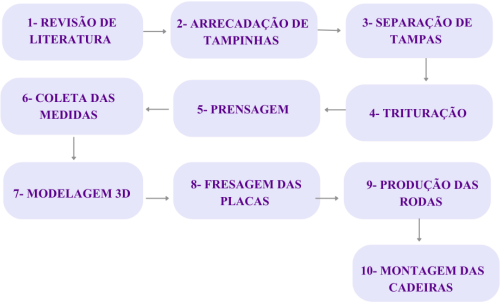

Fig. 1. Fluxograma das etapas

O processo foi estruturado segundo os princípios da economia circular, buscando manter os materiais em ciclos sucessivos de utilização. Dessa forma, desde a seleção da matéria-prima até a concepção estrutural da cadeira , priorizou-se a reutilização dos componentes e a possibilidade de reprocessamento dos materiais ao final da vida útil dos dispositivos.

Inicialmente foi realizada uma revisão de literatura na base de dados PUBMED, com busca dos descritores "wheelchair" e "sustainable development" utilizando o operador booleano "AND", os resultados foram filtrados para artigos publicados nos últimos cinco anos. Nessa etapa, buscou-se compreender os critérios de funcionalidade, adaptação e design necessários para o desenvolvimento de uma cadeira de rodas. Posteriormente, para a construção do dispositivo foi realizada a arrecadação das tampinhas plásticas recicláveis , por meio da divulgação do projeto nas redes sociais do laboratório, com informações sobre os locais para recebimento e os plásticos admitidos (Polietileno de Alta Densidade e Polipropileno), contando com 5 pontos de coleta. Em seguida, o material foi separado por cores e tipo de plástico, sendo descartadas as tampas que não se enquadraram no critério, essa ação reforça a sensibilização ambiental junto à comunidade, incorporando princípios de responsabilidade socioambiental ao processo de desenvolvimento tecnológico. .

Na fase seguinte, o material foi triturado duas vezes em uma trituradora de 3KWatts em velocidade de 6000 rotações por minuto (Fig. 2), e prensado na prensa térmica à 265ºC por 60 minutos para a criação de placas de 625 x 445 x 9 milímetros contendo Polietileno de Alta Densidade e Polipropileno que apresentou a fusão completa de ambos os materiais sem apresentar fissuras ou rachaduras (Fig. 3), e resfriado por 40 minutos em ar ambiente até as chapas metálicas se separarem da placa, as quais foram utilizadas para o recorte das peças.

Fig. 2. Trituração das tampas

Fig. 3. Prensagem e compactação

Uma fisioterapeuta realizou durante a avaliação a coleta das medidas antropométricas na posição sentada com uma fita antropométrica, além de avaliadas restrições de amplitude de movimento e alterações musculoesqueléticas para constatar se é necessário fazer adaptações adicionais. Os dados essenciais coletados eram: Altura do tronco (base do assento até o topo do ombro), Largura axilar/tronco (Laterais mais externas do tronco ao nível axilar), Largura quadril (Laterais mais externas dos

quadris), Comprimento da coxa (fossa poplítea até o ponto mais posterior do quadril) e Comprimento da perna (Base do calçado até a fossa poplítea). Elas foram utilizadas para modelar a altura do encosto, largura do encosto, largura do assento, profundidade do assento e distância do assento até o apoio dos pés, respectivamente.

Para a produção da cadeira foi adotada a modelagem tridimensional (3D), feita no programa Fusion 360 de forma parametrizada permitindo alterações dimensionais rápidas a partir das medidas antropométricas do usuário,possibilitando adaptações do dispositivo de forma individual sem necessidade de reconstrução completo do modelo digital. Adiante, o arquivo foi exportado em estereolitografia para a Fresadora CNC 3 eixos com tecnologia Nesting para a fresagem das placas de plástico produzidas anteriormente. Ademais, para compor a cadeira foram modeladas as rodas e os pneus no programa supracitado e foram impressas na Impressora 3D Creality K1 Max, com Polietileno Tereftalato Glicol (PETG) com Fibra de Carbono para as rodas e Poliuretano Termoplástico Flex (TPU) para a os pneus. Por fim, foi realizada a montagem da cadeira de rodas infantil por meio da união dos componentes estruturais utilizando parafusos, porcas, porcas travantes, espaçadores e rolamentos. Em seguida, foram instalados dois rodízios giratórios, um dianteiro e outro traseiro, concluindo a montagem da cadeira de rodas infantil.

III. RESULTADOS

Durante a revisão da literatura (etapa 1), foi possível identificar uma quantidade limitada de estudos que buscavam desenvolver cadeiras de rodas de baixo custo e com foco em sustentabilidade. Além disso, essa etapa forneceu subsídios para a compreensão dos processos envolvidos na prescrição e na avaliação do dispositivo de locomoção e dos principais desafios relacionados ao acesso e uso desses dispositivos.

Através da campanha de arrecadação foram obtidas cerca de 550 quilogramas no período de um ano e deste total já foram processados 417 quilogramas em 3 meses, considerando que aproximadamente 4.000 tampinhas foram necessárias para a produção de uma cadeira infantil, a quantidade arrecadada demonstra o elevado potencial de escalabilidade do processo produtivo, permitindo a fabricação sucessiva de dispositivos utilizando resíduos sólidos urbanos como matéria-prima. As tampinhas recebidas eram separadas de forma manual e armazenadas em caixas organizadoras na etapa 3, sendo necessárias 4 mil para cada cadeira de rodas infantil. Posteriormente, nas etapas 4 e 5, foi necessário 2 horas e 3 horas respectivamente para a sua execução, já que foi preciso 3 placas para o equipamento desenvolvido neste trabalho, mas a quantidade pode variar de acordo com o tamanho das peças. A Fig. 4 ilustra as placas fabricadas

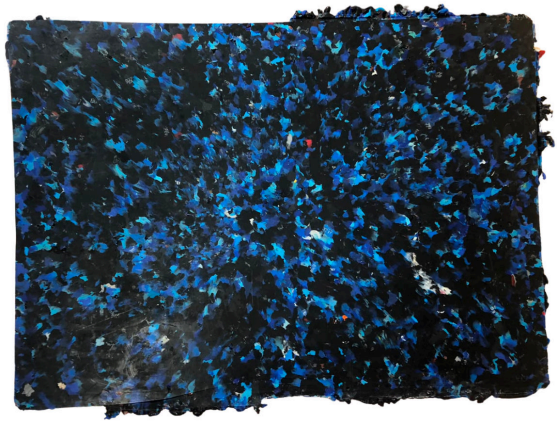

Fig. 4. Placa de tampinhas

As medidas antropométricas utilizadas para a realização do dispositivo foram descritos na tabela 1, a partir delas foi feita a etapa de personalização e adaptação subsequente e não foi necessário nenhum dispositivo adicional de adaptação relacionado ao posicionamento postural.

TABELA 1. MEDIDAS ANTROPOMÉTRICAS

MEDIDAS ANTROPOMÉTRICAS	TAMANHO (centímetros)
Altura do tronco (Base do assento até o topo do ombro)	25
Largura quadril (Laterais mais externas dos quadris)	32
Largura axilar/tronco (Laterais mais externas do tronco ao nível axilar)	35
Comprimento da coxa (fossa poplítea até o ponto mais posterior do quadril)	22
Comprimento da perna (Base do calçado até a fossa poplítea).	28

Concomitante às etapas anteriores, a modelagem 3D resultou em seis peças de plástico reciclável: Encosto, assento, apoio para os pés, lateral direita, lateral esquerda e apoio para a roda traseira. Além das peças com esse material, foi necessário a produção de 2 rodas, a disposição das rodas estão ilustradas na figura 7, as quais compuseram o resultado final (Fig. 5).

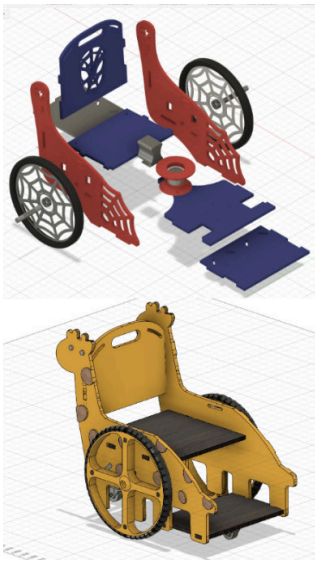

Fig. 5. Exemplos de modelos 3D das cadeiras de rodas infantil

Com a modelagem finalizada, na fresagem as seis peças foram cortadas, que durou aproximadamente 30 minutos, e a impressão das rodas, que ocorreu em 8 horas, com filamento de Polietileno Tereftalato Glicol (PETG), resultando em um peso de 630 gramas cada uma. Com todas as peças prontas, ocorreu a última etapa, a montagem da cadeira de rodas infantil. As peças e materiais utilizados constam na tabela 2 e levou aproximadamente 40 minutos.

Tabela 2- Materiais e peças utilizadas

Material	Quantidade
Parafusos 3,5 x 22 mm	2
Parafusos 3,5x14	26
Porcas	4
Porcas travantes	2
Rolamentos	2
Espaçadores 2 cm x 1,5 cm de diâmetro	2
Rodízio giratório 100 mm	1
Rodízio giratório 25 mm	1
Arruelas 28 mm	4

A cadeira de rodas infantil totalizou um peso de 4,01 quilogramas, precisou de aproximadamente 11 horas e 10 minutos para sua produção e teve um custo de 249,60, resultando no produto da imagem (Fig. 6) , o baixo peso final do dispositivo representa uma característica relevante para cadeiras infantis, pois reduz o esforço necessário para transporte pelos cuidadores e potencialmente diminui a resistência à propulsão quando comparado aos modelos convencionais disponíveis comercialmente.

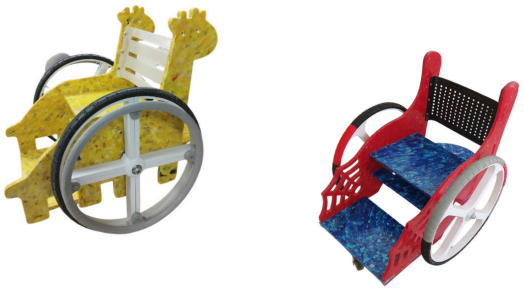

Fig. 6. Exemplos das cadeiras de rodas infantis finalizadas

Fig. 7. Disposição das rodas

IV. DISCUSSÃO

Usuários de cadeiras de rodas enfrentam muitas barreiras para a sua aquisição, sendo a principal delas o custo elevado [7]. Para crianças essa situação é ainda mais grave, visto que há o crescimento infantil e a necessidade de adaptações para cada usuário, dificultando o acesso a esse equipamento [10]. Pensando nisso, buscou-se materiais de baixo custo com boa durabilidade e possibilidade de personalização para a confecção do dispositivo desenvolvido neste trabalho. Alguns dos materiais e técnicas cogitados foram o Medium Density Fiberboard (MDF) por meio do corte a laser e o Polietileno Tereftalato Glicol (PETG) por impressão 3D, contudo, ambos foram descartados devido aos critérios mencionados anteriormente.

Mais do que desenvolver uma cadeira de rodas infantil, o presente trabalho propôs um modelo integrado de produção de tecnologia assistiva baseado na economia circular, no qual resíduos plásticos são reinseridos em uma cadeia produtiva capaz de gerar dispositivos personalizados de baixo custo. Essa abordagem amplia o conceito tradicional de manufatura de cadeiras de rodas ao incorporar simultaneamente aspectos ambientais, econômicos e sociais. Essa característica aumenta significativamente o potencial de replicação do modelo em laboratórios, makers, centros de reabilitação e instituições públicas.

Visando a sustentabilidade, também procurou-se materiais recicláveis que poderiam ser utilizados no desenvolvimento, sendo encontrados os plásticos Polietileno de Alta Densidade e Polipropileno que poderiam ser derretidos e transformados em placas. Para a realização desses processos, foi utilizado o maquinário disponível no Laboratório de Estudos Inventivos em Tecnologias Assistivas, mas sendo possível a utilização de outros equipamentos ou o aluguel desses.

Os dispositivos disponíveis no mercado em sua maioria são feitos de metal e possuem baixa capacidade de adaptação. Não foi encontrado na literatura artigos que descrevessem média de preço e peso das cadeiras de rodas infantis, mas durante uma análise de preços em cinco lojas online de fornecedores nacionais selecionadas por conveniência (mobility Brasil, Casa Ortopédica, Drogaria Araujo, Casa Médica e Medicar Material), notou-se que o custo médio das cadeiras de rodas infantil manual foi de 1.640,04 reais, o peso das cadeiras variam entre 12 e 20 kg. Em relação a esses aspectos foi demonstrado que há uma vantagem socioeconômica, pois o custo de produção é cerca de 15% do valor médio de mercado significativamente menor quando comparados.

Ainda quando comparamos o peso, o modelo proposto é aproximadamente 67% mais leve que o modelo mais leve do mercado. Esse fator reflete diretamente no esforço necessário para a propulsão da cadeira de rodas. Esse aspecto é relevante, pois as forças exercidas nos ombros causam estresse nas estruturas anatômicas, somadas aos movimentos repetitivos dos membros superiores. A situação se torna ainda pior quando há presença de dor, que contribui para a baixa variabilidade escapular de rotação interna e externa, causando maior fadiga tecidual cumulativa. Isso contribui também para alterações na biomecânica, com maiores oscilações de tórax, menor pico de torque no ombro e maior variabilidade de torque como estratégias de redução da dor [12,13].

Ademais, em 2015 a Organização das Nações Unidas definiu 17 metas para serem atingidas até 2030, os Objetivos de Desenvolvimento Sustentável (ODS) [14], tendo o Brasil como país signatário. Dentre esses objetivos estão a promoção da saúde e bem- estar (objetivo 3) e a garantia da produção e consumo sustentáveis (objetivo 12). Nesse sentido, o recurso desenvolvido buscou reciclar o material plástico e utilizá-lo de forma a promover os objetivos supracitados. Tendo retirado do meio ambiente 4.000 tampinhas a cada cadeira de rodas infantil desenvolvida, essa iniciativa é altamente reprodutiva e escalável. Como supracitado, com poucos pontos de coletas e no período de um ano foi possível arrecadar aproximadamente 550 kg, cerca de 311.000 tampas de garrafas, desse total foram processado 417 kg, 75% do total, contando apenas com as duas máquinas da figura 2 e 3, reforçando a importância social e ambiental envolvida na produção.

O modelo proposto apresenta características de sustentabilidade tanto em sua produção quanto nas etapas de pós-uso e reaproveitamento. Para isso, foram previstas duas estratégias de reutilização dos componentes da cadeira de rodas. A primeira consiste no repasse do equipamento para outra criança quando a estatura do, desde que a estrutura esteja preservada e possua compatibilidade com as adaptações. A segunda estratégia consiste no desmonte do produto para que os materiais empregados em sua fabricação possam ser reaproveitados. Os elementos de fixação, como parafusos, porcas, porcas travantes, espaçadores e rolamentos, podem ser reutilizados em uma nova montagem. Da mesma forma, as rodas e os rodízios giratórios podem ser utilizados em outro modelo de cadeira de rodas. Já os componentes plásticos podem ser reinseridos no processo de produção por meio do reprocessamento por prensagem, possibilitando sua reutilização na fabricação de novas cadeiras.

As limitações observadas na fase da produção desse dispositivo foi em relação às dimensões das placas de plástico reciclado devido ao tamanho da prensa térmica, que restringiu o comprimento e a altura das peças, delimitando os usuários dessa cadeira às crianças com estaturas menores.Além dissos, este estudo não realizou testes de durabilidade, avaliação da satisfação dos usuários e acompanhamento a longo prazo.

Um aspecto que diferencia o presente estudo de iniciativas convencionais de reciclagem consiste no fato de que o material reciclado não foi utilizado apenas como substituto de matéria-prima, mas incorporado a um fluxo completo de desenvolvimento de Tecnologia Assistiva. Nesse processo, resíduos plásticos urbanos foram transformados em componentes estruturais personalizados por meio de modelagem digital e manufatura assistida por computador, estabelecendo uma integração entre sustentabilidade ambiental, inovação tecnológica e reabilitação. Essa abordagem amplia o potencial de aplicação da economia circular para além da gestão de resíduos, posicionando-a como estratégia para democratização do acesso às tecnologias assistivas.

V. CONCLUSÃO

A cadeira de rodas infantil de tampinha reciclável desenvolvida apresentou um baixo custo, peso reduzido e capacidade de personalização para cada usuário, atendendo às principais limitações encontradas para a aquisição desse dispositivo. Os resultados evidenciam que a integração entre economia circular e Tecnologia Assistiva constitui uma estratégia promissora para ampliar o acesso a dispositivos personalizados, reduzindo custos e impactos ambientais simultaneamente. Além disso, possui grande capacidade de reprodutibilidade e um impacto positivo para a redução e a reciclagem do material plástico descartado no meio ambiente, durante a produção e após o uso dos usuários. Nesse sentido, esse projeto promove a acessibilidade para os usuários de cadeira de rodas e propõe a reprodutibilidade do produto em outros laboratórios e centros de desenvolvimento. No entanto ainda se faz necessário, novas pesquisas que tragam estudos de resistência do material, da estrutura da cadeira, como também avaliem o uso da tecnologia assistiva por essa população. Mais do que a fabricação de um produto, o trabalho apresenta um

modelo produtivo potencialmente replicável por instituições de ensino, laboratórios de inovação e serviços de reabilitação.

***Resumo*—Este estudo aborda a necessidade de ferramentas acessíveis para avaliação da pressão exercida pelos dedos durante a escrita manual, relevante para análises em terapia ocupacional e reabilitação motora. O objetivo foi aprimorar um protótipo de baixo custo capaz de medir a pressão aplicada pelos dedos durante a escrita utilizando uma plataforma baseada em Arduino. O sistema trabalha com sensores de pressão conectados a uma plataforma Arduino e integrado a um software desenvolvido em Python para aquisição, armazenamento e análise dos dados coletados. Os resultados indicaram que o protótipo foi capaz de registrar variações de pressão entre os dedos durante a escrita. Conclui-se que o sistema apresenta potencial como ferramenta de apoio para coleta de dados grafomotores.**

***Palavras-chave*—Sensor de pressão, Arduino, Escrita manual**

I. Introdução

A escrita manual é uma atividade complexa que envolve coordenação motora fina, controle da força aplicada pelos dedos e integração entre sistemas sensoriais e motores [1]. Durante essa atividade, a pressão exercida pelos dedos sobre o instrumento de escrita pode influenciar diretamente o desempenho motor, o conforto e a qualidade da escrita, sendo um parâmetro relevante para a análise de padrões motores [2].

No contexto da terapia ocupacional, a avaliação da escrita manual pode contribuir para a identificação de dificuldades motoras e para o planejamento de intervenções voltadas à reabilitação funcional. Estudos indicam que a análise de parâmetros biomecânicos, como força aplicada e padrão de movimento durante a escrita, pode auxiliar na compreensão de alterações no controle motor fino [3], [4].

Entretanto, dispositivos capazes de medir quantitativamente a pressão exercida durante a escrita geralmente apresentam custos elevados ou acesso limitado, o que dificulta sua aplicação em ambientes clínicos, educacionais e de pesquisa. Nesse contexto, o desenvolvimento de soluções tecnológicas de baixo custo surge como uma alternativa para ampliar o acesso a ferramentas de avaliação motora e de coleta de dados experimentais. Plataformas de prototipagem eletrônica, como o Arduino, possibilitam o desenvolvimento de sistemas acessíveis para aquisição de dados por meio de sensores e integração com sistemas computacionais. Além disso, ferramentas de programação científica, como a linguagem Python, permitem o armazenamento, processamento e visualização dos dados coletados, favorecendo a análise dos parâmetros medidos.

Dessa forma, este trabalho dá continuidade a um protótipo previamente desenvolvido em um trabalho de conclusão de curso, propondo melhorias no sistema de medição da pressão exercida pelos dedos durante a escrita manual. A principal contribuição deste estudo é a integração de uma instrumentação de baixo custo e de fácil implementação, baseado em sensores resistivos, microcontrolador Arduino e ambiente de processamento em Python, voltado para a aquisição e análise comparativa preliminar de sinais de pressão exercidos na atividade de escrita, servindo como uma ferramenta para futuras investigações ergonômicas e clínicas.

II. Metodologia

A. Descrição Geral do Sistema

A arquitetura do sistema é composta por três etapas principais: aquisição de dados por meio de sensores de pressão, processamento inicial realizado pelo microcontrolador e transmissão dos dados para um ambiente computacional para visualização, armazenamento e análise (Figura 1).

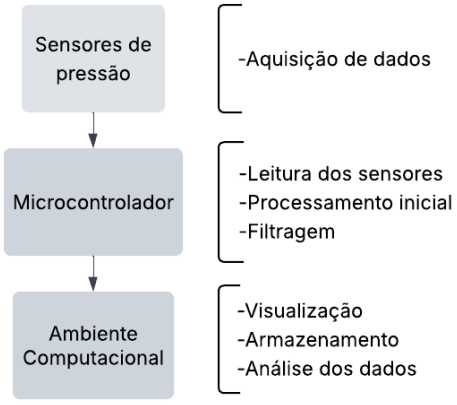

Figura 1. Fluxograma do funcionamento do sistema de avaliação de pressão

Financiado pela FINEP (Financiadora de Estudos e Projetos), Processo nº 2163/22.

B. Hardware

O sistema de aquisição foi construído utilizando a plataforma Arduino (microcontrolador ATmega328P, ADC de 10 bits de resolução). Foram utilizados três sensores de pressão do tipo resistivo (FSR 402), com faixa de medição nominal de 0 a 5kg, cuja resistência elétrica varia inversamente à força compressiva aplicada, permitindo a conversão do sinal mecânico em sinal elétrico, captado pelo sistema.

O sensor foi acoplado ao instrumento de escrita de forma a captar diretamente a pressão exercida pelos dedos durante a atividade. O circuito foi configurado em um divisor de tensão com resistores fixos de $10\,\mathrm{k}\Omega$, permitindo a leitura do sinal analógico por meio de uma das entradas do Arduino. Ao todo, foram usados 3 sensores para a coleta dos dados de pressão. Tal esquema pode ser visto na Figura 2.

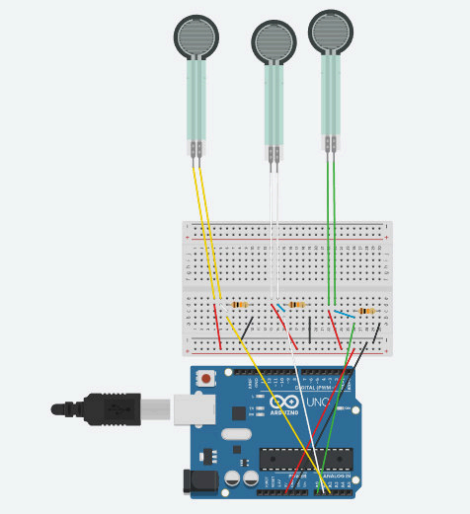

Figura 2. Esquemática do sistema de avaliação de pressão via *Tinkercad*

C. Aquisição e Monitoramento de Dados

A aquisição dos dados foi realizada por meio da leitura contínua dos sinais analógicos dos sensores, utilizando o conversor analógico-digital (ADC) do Arduino. Os valores foram amostrados com um período de 200 milisegundos (taxa de amostragem de 5Hz) e transmitidos via comunicação serial. Não houve filtragem digital aplicada aos sinais.

Para o monitoramento em tempo real e validação inicial do funcionamento do sistema, foi utilizado o software *Tera Term*, que possibilita a visualização dos dados enviados pela porta serial. Essa ferramenta permitiu verificar a integridade dos sinais, identificar falhas e realizar ajustes no sistema durante a fase de desenvolvimento.

Além disso, o *Tera Term* foi utilizado para o registro preliminar dos dados em formato de texto, possibilitando uma análise inicial e validação do comportamento do sensor antes da integração com o ambiente computacional principal.

D. Calibração dos sensores

Os sensores de pressão foram calibrados utilizando-se um dinamômetro hidráulico de mão (Figura 3), correlacionando a força mecânica aplicada com o sinal analógico gerado no Arduino.

O procedimento de calibração consistiu em aplicar uma força manual constante sobre o sensor por um período de tempo de dez segundos (Figura 4), coletando os dados de medição do Arduino durante esse período. A partir dos dados coletados, utilizou-se a média das amostras obtidas durante o tempo de aplicação da força como valor de calibração. Foram coletados dados correspondentes a 1kgf, 2kgf, 4kgf e 6 kgf.

Com os pontos de calibração foi possível gerar a curva de calibração e converter os valores arbitrários analógicos em força (N).

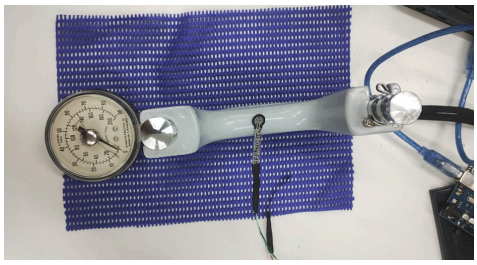

Figura 3. Dinamômetro hidráulico de mão

Figura 4. Aplicação de força manual constante

E. Software e Processamento de Dados

Para o tratamento e visualisação dos dados, foi desenvolvido um ambiente computacional, utilizando a linguagem Python, para recepção, armazenamento e análise dos dados. A comunicação com o Arduino foi realizada por meio da biblioteca *pyserial*, permitindo a leitura contínua dos dados transmitidos. Para o processamento dos dados, foram utilizadas bibliotecas como *NumPy* e *Matplotlib*, possibilitando a análise dos sinais de pressão e a geração de gráficos

representativos. Os dados coletados foram organizados em arquivos estruturados, facilitando a análise posterior.

F. Procedimento Experimental

A instrumentação proposta foi desenvolvida para servir de ferramenta de coleta de dados para o projeto de pesquisa "Desenvolvimento de Tecnologia Assistiva para autonomia cotidiana/laboral de pessoas com deficiência e formação de recursos humanos (sigla TECLABORAL), aprovada em chamada pública MCTI/FINEP/AÇÃO TRANSVERSAL – TECNOLOGIA ASSISTIVA para a estruturacao do Sistema Nacional de Laboratorios de Tecnologia Assistiva (SISASSISTIVA-MCTI), ref. Finep n. 2163/22.

O referido projeto foi e aprovado pelo Comitê de Ética em Pesquisa com Seres Humanos, sob Número do Parecer: 7.719.058, CAAE 89977025.9.0000.5208. A fim de avaliar a aplicabilidade da instrumentação, realizou-se um estudo de caso com um voluntário. O participante em questão apresenta dificuldade de coordenação dos membros superiores decorrente de um acidente de moto. Os experimentos foram conduzidos em ambiente controlado, no Laboratório de Tecnologia Assistiva e Terapia Ocupacional (LabTATO) da Universidade Federal de Pernambuco, mantendo-se o mesmo instrumento de escrita, postura e superfície de apoio durante todos os testes.

Durante os testes, o participante foi instruído a escrever textos padronizados. O teste foi dividido em duas etapas. Na primeira o participante realizou a atividade utilizando uma caneta e vestindo a luva instrumentada. Na segunda etapa o participante repetiu a atividade utilizando uma adaptação para lápis e a luva instrumentada (Figura 5). Os dados obtidos nas duas etapas serão comparados entre si para avaliar a aplicabilidade da instrumentação para a coleta de dados de pressão para avaliação grafomotora.

A escolha dos três pontos de instrumentação baseou-se na identificação prévia das áreas de maior contato, por meio de um teste piloto: o participante vestiu uma luva de látex e escreveu seu nome usando uma caneta banhada em tinta. Dessa maneira, a tinta transferida para a luva permitiu identificar os principais pontos de pressão entre a caneta e a mão do voluntário, correspondentes ao polegar, dedo indicador e área de apoio da mão. Tal procedimento foi fundamental no auxílio da definição das áreas de instalação dos sensores.

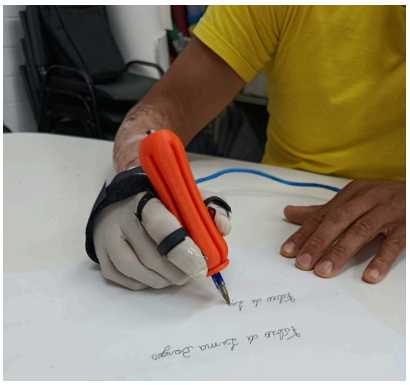

Figura 5. Utilização do instrumento adaptado com os 3 sensores

Após o posicionamento adequado dos sensores, iniciou-se o experimento e os sinais de pressão foram registrados ao longo do tempo, permitindo a análise do comportamento da força aplicada durante a escrita, com e sem adaptador. A coleta era iniciada antes do inicio de cada atividade e interrompida após o fim da atividade. Antes da atividade e após largar a caneta, os sensores marcam zero e dessa forma é possível sincronizar os dados com a atividade realizada. Os dados obtidos de pressão na escrita foram coletados em um arquivo .log para posterior arguição e análise.

III. Resultados e discussões

O sistema desenvolvido coletou dados de pressão durante uma atividade grafomotora. A comunicação serial entre o Arduino e o software desenvolvido em Python ocorreu sem perdas perceptíveis de dados, permitindo a aquisição contínua dos sinais provenientes dos sensores de pressão. Além disso foram gerados gráficos que representam a diferença de pressão proveniente dos três sensores no experimento da escrita sem o adaptador e com o adaptador. O resultado dos gráficos está evidenciado nas Figuras 6 e 7.

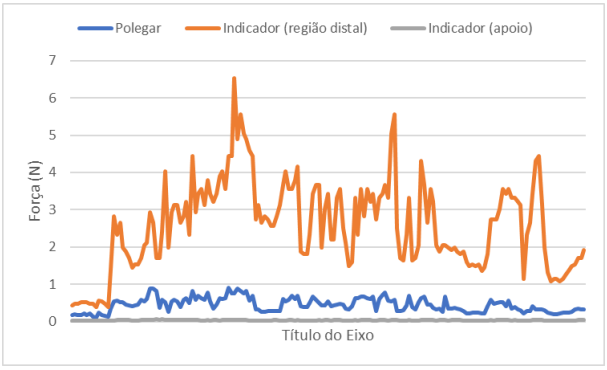

Figura 6. Gráfico de pressão na escrita sem adaptador

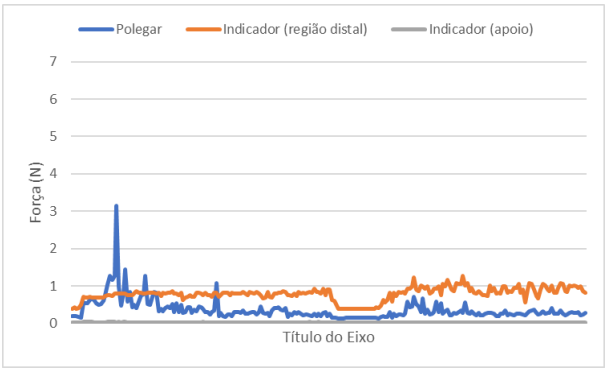

Figura 7. Gráfico de pressão na escrita com adaptador

A análise dos sinais obtidos evidenciou diferenças no comportamento da pressão aplicada pelos dedos entre as duas condições experimentais. Na escrita sem o adaptador, observou-se maior variabilidade dos sinais e ocorrência de

picos elevados de pressão, principalmente nos sensores posicionados nas regiões correspondentes ao polegar e ao dedo indicador. Esses resultados sugerem maior concentração de força durante a empunhadura convencional da caneta.

Por outro lado, durante a utilização do adaptador instrumentado, verificou-se redução nos picos de pressão e maior estabilidade dos sinais ao longo da atividade de escrita. A análise quantitativa dos dados revelou que, na condição sem adaptador, o pico máximo de pressão do dedo que foi maior acionado (nesse caso foi o indicador na região distal) foi de 6,53N, com uma média de 2,59N. Em contraste, a utilização do adaptador reduziu o pico máximo para 1,27N e a média para 0,79N. O desvio padrão foi de 1,182 sem adaptador e 0,175 com adaptador.

A redução da pressão concentrada em regiões específicas da mão pode contribuir para maior conforto durante a escrita, além de potencialmente reduzir fadiga muscular associada à realização prolongada dessa atividade. Esses resultados demonstram o potencial do sistema proposto como ferramenta de apoio para análise biomecânica da escrita manual e futuras aplicações em contextos de ergonomia e reabilitação motora.

Entretanto, o presente estudo apresenta limitações relacionadas a validação frente a equipamentos de referência padrão-ouro para confirmar sua exatidão, histerese e repetibilidade. Para ampliar a relevância, estudos futuros devem buscar correlacionar os sinais de pressão adquiridos com parâmetros funcionais da escrita, como legibilidade, velocidade e fadiga.

IV. Conclusões

O presente trabalho apresentou o desenvolvimento de um protótipo de baixo custo para aquisição e análise da pressão exercida pelos dedos durante a escrita manual, utilizando sensores de pressão integrados a uma plataforma Arduino e a um ambiente computacional desenvolvido em Python.

Os resultados experimentais demonstraram que o sistema foi capaz de realizar a aquisição contínua dos sinais provenientes dos sensores, sem perdas de dados durante a comunicação serial. Além disso, os gráficos gerados permitem que profissionais da área de Terapia Ocupacional sejam capazes de analisar o comportamento da pressão exercida pelos dedos em diferentes condições de escrita.

A comparação entre a escrita convencional e a escrita utilizando um adaptador instrumentado evidenciou redução nos picos de pressão, principalmente nas regiões correspondentes ao polegar e ao dedo indicador. Os principais aprendizados obtidos incluem a viabilidade da integração de sensores resistivos à plataforma Arduino e o processamento inicial em Python de forma estável, permitindo a observação preliminar de que o daptador instrumentado pode influenciar a distribuição das forças e reduzir picos de preensão localizados.

Dessa forma, o protótipo apresentou potencial como ferramenta de apoio para estudos de biomecânica da escrita, ergonomia e estudos sobre reabilitação motora. Como perspectivas futuras, pretende-se realizar testes com um maior número de participantes, assim como expandir a análise computacional dos dados para aplicações clínicas e terapêuticas.

Resumo- A paralisia cerebral é um distúrbio neurológico que compromete o desenvolvimento motor e dificulta a manutenção da posição ortostática, tornando necessária a utilização de tecnologias assistivas para promover o alinhamento postural e a descarga de peso. O presente estudo teve como objetivo desenvolver uma tala extensora personalizada para utilização associada ao parapodium em crianças com paralisia cerebral com incapacidade de manter a extensão dos joelhos durante o ortostatismo. Trata-se de um estudo de desenvolvimento tecnológico descritivo, no qual foi realizada a busca na literatura e no mercado, desenvolvimento do molde, escolha dos materiais, coleta de medidas antropométricas, produção do protótipo, testagem, avaliação fisioterapêutica e percepção de satisfação através do B-QUEST após dois meses de uso. O dispositivo desenvolvido apresentou adequada adaptação ao usuário, manutenção da extensão dos joelhos durante a descarga de peso, alinhamento biomecânico do quadril e membros inferiores, ausência de dor ou desconforto e elevada satisfação em todos os domínios do B-QUEST. A tala apresentou custo de produção de R$ 58,72, correspondente a 16,34% da média de preço encontrada na busca de mercado. Os resultados demonstram a viabilidade de produção, alta aceitabilidade e o potencial da tala extensora como recurso auxiliar para o ortostatismo durante o uso do parapodium.

I. INTRODUÇÃO

Os distúrbios neurológicos são caracterizados por acometimentos no sistema nervoso que causam comprometimentos no desenvolvimento motor, na função física, no cognitivo e/ou na fala, e esses se subdividem em diferentes diagnósticos clínicos, como a Paralisia Cerebral (PC) [1,2]. A PC ocorre em crianças de até 3 anos de idade, com prevalência geral de 2 por 1.000 nascidos vivos, e classificada pelo Gross Motor Functional Classification Sys (GMFCS) em 5 níveis [2,3,4]. Nos níveis mais altos, IV e V, os indivíduos não mantêm de forma independente posturas anti-gravíticas, como o sentar e a posição ortostática, sendo necessário equipamentos auxiliares para a sua manutenção [2]. A falta da postura ortostática e da descarga de peso na articulação do quadril nessa população são as principais causas de subluxação e luxação de quadril, acarretando no desenvolvimento de outras disfunções, como escoliose, dores progressivas e obliquidade pélvica [5,6]. Ademais, o tempo exacerbado em decúbito, aumenta o risco da ocorrência de complicações gerais (broncoaspiração, hemorragias e pneumonias) e lesões ortopédicas (subluxação e luxação de quadril e pé equino) [5,7]. Por isso, é recomendado treinos ortostáticos dentro dessa população para evitar esses desfechos e promover os benefícios dessa posição, como o aumento da deposição de cálcio nos ossos, favorecimento da função dos órgãos, melhora do controle autônomo cardiovascular e da deglutição e estimulação vestibular [5,8].

Um dos equipamentos responsáveis por promover a verticalização em crianças neurológicas é o parapodium (figura X), uma tecnologia assistiva que fomenta o alinhamento postural e a descarga de peso [8,9]. Nos níveis IV e V da PC, esse alinhamento é prejudicado comparado ao desenvolvimento típico, comprometendo o desempenho motor para a manutenção de posturas altas, sendo necessário a utilização de equipamentos acessórios para a manutenção da função e estabilização das articulações [10,11].

O ortostatismo proporciona a postura ereta essencial no desenvolvimento infantil, a força gravitacional axial promove maior estabilidade postural e do centro de gravidade promovendo alinhamento das articulações do tornozelo, joelho e quadril e das curvaturas da coluna vertebral [12]. No entanto, o indivíduo com PC apresenta fraqueza muscular e contraturas que

dificultam o ortostatismo, e causam maiores demandas energéticas, sendo necessário dispositivos auxiliares de estabilização [12].

A tala extensora é um desses equipamentos que ajuda na biomecânica esquelética, por meio de hastes rígidas de alumínio cobertas por tecido que provocam a extensão do joelho. Evitando a assimetria entre os membros inferiores por flexão da articulação e adaptações posturais compensatórias, propiciando o alinhamento dos membros que é fundamental em treinos ortostáticos e para o uso do parapodium.

Apesar dos benefícios proporcionados pelo parapodium, crianças com comprometimento motor grave frequentemente apresentam incapacidade de manter o alinhamento adequado dos membros inferiores apenas com esse dispositivo, especialmente em decorrência da flexão persistente dos joelhos. Embora essa limitação seja observada na prática clínica, há escassez de estudos que descrevam o desenvolvimento de recursos auxiliares específicos para ampliar a estabilidade durante o ortostatismo. Partiu-se da hipótese de que a associação de uma tala extensora personalizada ao parapodium seria capaz de proporcionar melhor alinhamento clínico dos membros inferiores durante o ortostatismo em crianças com paralisia cerebral que apresentam incapacidade de manter a extensão dos joelhos apenas com o suporte convencional.

II. METODOLOGIA

Este estudo caracteriza-se como uma pesquisa de desenvolvimento tecnológico, de natureza descritiva, conduzida por equipe multiprofissional no Laboratório de Estudos Inventivos em Tecnologia Assistiva (LabEITA). O processo foi estruturado em oito etapas sequenciais (Figura 1), contemplando desde a identificação da demanda clínica até a validação inicial do dispositivo junto ao usuário. O equipamento foi desenvolvido para um participante do projeto "Avaliação e acompanhamento de crianças de 0 a 5 anos com alterações neurológicas e/ou deficiências que necessitavam de tecnologias assistivas", com parecer do comitê de ética da Universidade Federal de Goiás (CEP-UFG: Nº 7.688.714).

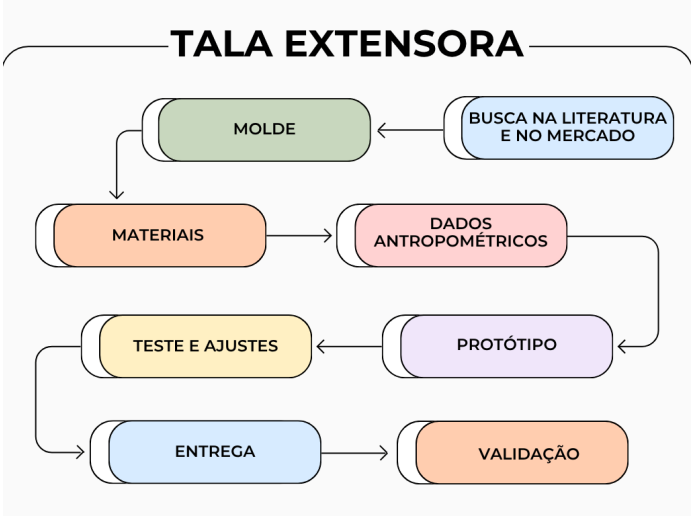

Fig. 1. Fluxograma

Na primeira etapa, a busca na literatura e de mercado ocorreu para entender a funcionalidade da tala extensora no alinhamento postural em dispositivos de ortostatismo, normas para sua produção, materiais utilizados e demanda do mercado (acessibilidade e disponibilidade). Foram utilizadas bases de dados, como: PubMed National Library of Medicine, LILACS Literatura Latino-Americana e do Caribe em Ciências da Saúde, SciELO Scientific Eletronic Library Online e Biblioteca Virtual em Saúde, utilizando os descritores "Tala extensora" e "Extension Splint", com artigos dos últimos 10 anos. Para a busca de mercado, 5 lojas nacionais foram consultadas (ITA Assistiva, Amigo Panda Brasil, Mundo Adaptado e Biofisio Saúde e Reabtecmyhand), escolhidas por conveniência, tendo como critério ser um equipamento sem uso prévio e ter as medidas personalizadas para o usuário.

Para a confecção da tala, os próximos passos foram o desenvolvimento do molde e a escolha dos materiais, que ocorreram por meio da análise de outros equipamentos disponibilizados no mercado e do diálogo com profissionais que desenvolvem esse produto. A partir do molde e materiais definidos, foi realizada a coleta das medidas antropométricas de um participante do projeto "Avaliação e acompanhamento de crianças de 0 a 5 anos com alterações neurológicas e/ou deficiências que necessitavam de tecnologias assistivas", aprovado pelo Comitê de Ética da Universidade Federal de Goiás, para a confecção de um protótipo. Foi realizado durante uma avaliação fisioterapêutica no LabEITA, com a coleta de 3 medidas em pontos anatômicos determinados (trocanter maior a maléolo lateral, circunferência da coxa e circunferência do tornozelo).

Após a coleta desses dados, materiais definidos e molde concluído, houve a produção do protótipo com o maquinário disponível no LabEITA. Sendo utilizado a máquina de costura Facilita Pro 4411 da Singer e a Serra Tico Tico 380 watts da Skil.

Posteriormente houve o teste do protótipo no participante supracitado por uma das fisioterapeuta e delineamento dos ajustes necessários. A avaliação clínica inicial

consistiu na observação sistemática do posicionamento dos membros inferiores durante a utilização do parapodium, verificando-se a manutenção da extensão dos joelhos, o alinhamento do quadril e a estabilidade global do posicionamento ortostático. Embora de caráter observacional, essa avaliação permitiu verificar a adequação funcional inicial do dispositivo antes de sua entrega ao usuário. Como parte da validação, também houve a aplicação de um instrumento de avaliação da percepção dos responsáveis sobre o uso do dispositivo, B-Quest, após 2 meses da data da entrega com o principal cuidador do usuário. Tal questionário analisa 12 tópicos, sendo eles: Dimensões, peso, ajustes, estabilidade/segurança, durabilidade, facilidade de uso. conforto, eficácia, entrega, assistência técnica, serviços profissionais e serviços de acompanhamento, e os 3 itens mais importantes da perspectiva do usuário ou responsável.

III. RESULTADOS

Como resultados da busca na literatura não foram encontrados artigos sobre o uso da tala extensora para a promoção do alinhamento postural em dispositivos de ortostatismo e poucos sobre o uso da tala extensora para qualquer finalidade. A reduzida quantidade de estudos identificados evidencia que a utilização de talas extensoras associadas a dispositivos de ortostatismo permanece pouco explorada na literatura científica, reforçando o caráter inovador da presente proposta. Esse achado demonstra que a principal contribuição do presente estudo não reside apenas no desenvolvimento do dispositivo, mas na proposição de um protocolo estruturado para sua concepção, produção e aplicação clínica em associação ao parapodium. Os trabalhos encontrados possuíam pouca evidência científica e apresentaram resultados positivos para a prevenção de encurtamento e contraturas em pacientes. Durante a busca de mercado, encontrou-se uma diversidade de fornecedores de lojas virtuais com uma média de preço de 359,32, sem a adição da taxa de frete. As medidas eram enviadas de forma online e coletadas pelo próprio consumidor, sem a verificação de algum profissional.

Durante o desenvolvimento do molde e a escolha de materiais, foram analisados 4 extensores de tamanhos e fabricantes diferentes. Esse processo foi importante para entender a progressão de tamanho, por exemplo a quantidade e grossura dos velcros para cada comprimento, e a diferença de materiais utilizados, como o tipo de haste estabilizadora (ferro, aço, alumínio e filamento) e o tecido (neoprene e algodão cru). Também houve o diálogo com profissionais de um centro de reabilitação de Goiânia-GO, classificado como CER IV, que desenvolvem esse equipamento, sendo explicado como o molde era feito e quais materiais utilizaram. Por fim, replicamos o mesmo molde apresentado, como mostra na Fig. 2, e optamos pela utilização do tecido neoprene e tricoline, velcro 50mm, linha de costura e alumínio.

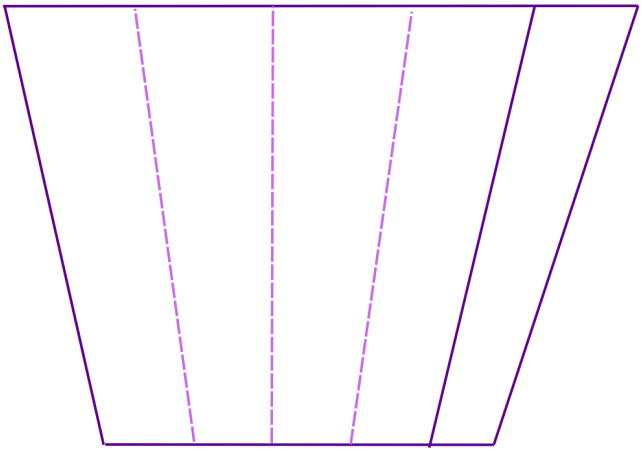

Fig. 2. Molde da tala

O desenvolvimento do dispositivo foi orientado pelo princípio da personalização antropométrica, buscando adequar simultaneamente o posicionamento das hastes estabilizadoras, a distribuição das forças de contenção e o conforto durante o uso prolongado do equipamento.

Para as medidas antropométricas aplicadas no molde, elas constam na tabela a seguir (tabela I).

TABELA I. MEDIDAS ANTROPOMÉTRICAS

MEDIDAS ANTROPOMÉTRICAS	TAMANHO (centímetros)
Trocanter maior do fêmur até maléolo lateral	25
Circunferência da coxa	32
Circunferência do tornozelo	35

A produção do protótipo contou com a costura dos tecidos e o corte de 6 barras de alumínio, exemplo de um protótipo pronto na Fig. 3.

Fig. 3. Protótipo da tala extensora

Durante o teste do dispositivo, as hastes fixas ficaram nos locais idealizados (face posterior, lateral e medial da perna), o velcro central ficou sobre a articulação do joelho e a tala ficou posicionada 3 centímetros abaixo da virilha e 3 centímetros acima do maléolo lateral. Durante a avaliação inicial, o dispositivo apresentou adaptação satisfatória ao usuário, mantendo o posicionamento previamente planejado sem necessidade de modificações estruturais após o primeiro teste funcional.

Na validação, a fisioterapeuta não notou flexão de joelho durante a descarga de peso no parapodium e o alinhamento biomecânico do quadril e membros inferiores estava adequado, assim como aparece na Fig. 4. Além disso, a criança não apresentou feição de dor ou desconforto durante a utilização da tala. Observou-se manutenção da extensão dos joelhos durante a descarga de peso e adequado posicionamento dos membros inferiores no parapodium segundo avaliação fisioterapêutica. Embora essa análise tenha sido predominantemente clínica e observacional, os achados sugerem que o dispositivo cumpriu a finalidade proposta para essa etapa inicial do desenvolvimento.

Fig. 4. Foto do participante no parapodium

Os resultados encontrados no B-Quest após 2 meses de uso constam na tabela II.

TABELA II. Respostas do B-Quest

Itens do B-Quest	Pontuação
Dimensões	5 - Totalmente satisfeito
Peso	5 - Totalmente satisfeito
Ajuste	5 - Totalmente satisfeito
Estabilidade/segurança	5 - Totalmente satisfeito
Durabilidade	5 - Totalmente satisfeito
Facilidade de uso	5 - Totalmente satisfeito
Conforto	5 - Totalmente satisfeito
Eficácia	5 - Totalmente satisfeito
Tempo de espera	5 - Totalmente satisfeito
Assistência técnica	5 - Totalmente satisfeito
Serviços profissionais	5 - Totalmente satisfeito
Serviços de acompanhamento	5 - Totalmente satisfeito
3 itens mais importantes	Durabilidade Conforto Entrega

A tala extensora teve um custo de 58,72 reais, cerca de 16,34% da média de preço encontrada na busca de mercado. O par do equipamento totalizou um valor de 117,44 reais. Os materiais, as quantidades e os valores para o par da tecnologia assistiva constam na tabela III.

TABELA III. Materiais, quantidades e custo de produção da tala extensora

Material	Quantidade	Valor
Neoprene	1 metros quadrados	52,00
Tricoline	1 metros quadrados	12,00
Alumínio (25x2 milímetros)	2 metros	51,94
Linha	-	1,50

Velcro	6,4 metros	14,34
TOTAL		117,44

Os elevados escores obtidos em todos os domínios avaliados indicam elevada aceitabilidade inicial do dispositivo pelos responsáveis. Destaca-se que os três aspectos considerados mais relevantes — durabilidade, conforto e entrega — estão diretamente relacionados às decisões adotadas durante o processo de desenvolvimento e fabricação da tala.

IV. DISCUSSÃO

A literatura é escassa quanto a utilização de tala extensora de membros inferiores associadas a dispositivos que promovam o ortostatismo. No entanto, o seu uso já foi proposto para reduzir o grau de flexão do cotovelo hipertônico em pacientes com doença do neurônio motor superior e demonstrou melhora na condição [13], em paralelo o presente trabalho discute também a capacidade da tala em manter os membros inferiores estendidos em posição ortostática.

As evidências para órteses de controle distal aumentaram a duração da postura em pé em crianças com PC sobre órteses de membros inferiores em crianças com paralisia cerebral [12]. Crianças com paralisia cerebral espástica bilateral apresentaram menor estabilidade postural durante a posição ortostática e o uso de órteses tornozelo-pé podem ser úteis para melhorar a estabilidade [14], Esses achados corroboram o princípio biomecânico adotado no presente estudo, no qual a tala extensora foi utilizada para favorecer o alinhamento dos membros inferiores.

O dispositivo proposto nesse artigo durante a inspeção da utilização da tala foi possível analisar a estabilidade da cadeia cinética durante a descarga de peso, reduzindo a flexão da articulação do joelho e favorecendo o alinhamento do quadril e tornozelo. Dessa forma, a tala atua como um elemento estabilizador durante o uso do parapodium. Além disso, o dispositivo apresentou custo significativamente inferior ao observado nos equipamentos comerciais pesquisados.

A utilização da tala extensora foi acompanhada durante dois meses, nesse período foram realizadas orientações aos responsáveis quanto ao uso adequado do dispositivo e monitoramento da adaptação da criança. Ao final desse período, a aplicação do B-QUEST demonstrou elevada satisfação em todos os domínios avaliados, sugerindo boa aceitabilidade inicial do dispositivo, adequada adaptação ao usuário e potencial para adesão ao uso no contexto domiciliar. Os três itens considerados mais importantes pelos responsáveis foram durabilidade, conforto e entrega, que são aspectos diretamente dependentes do processo de produção e acompanhamento do dispositivo.

Entre as limitações do presente estudo destacam-se a avaliação realizada em um único participante, o curto período de acompanhamento e a ausência de medidas instrumentadas para quantificação objetiva do alinhamento dos membros inferiores durante o ortostatismo. Além disso, não foram realizados ensaios biomecânicos ou comparações com dispositivos comerciais, limitando as conclusões à demonstração da viabilidade técnica e da aceitabilidade inicial da solução proposta.

O principal achado deste estudo foi demonstrar a viabilidade de integrar uma tala extensora personalizada ao parapodium como estratégia para ampliar sua aplicabilidade em crianças que apresentam incapacidade de manter os joelhos em extensão durante o ortostatismo. Mais do que desenvolver um novo dispositivo, o trabalho apresenta uma solução complementar destinada a superar uma limitação frequentemente observada na prática clínica e pouco discutida na literatura especializada.

V. CONCLUSÃO

O presente estudo descreveu o desenvolvimento de uma tala extensora de baixo custo destinada ao uso associado ao parapodium em crianças com paralisia cerebral que apresentam dificuldade em manter os membros inferiores estendidos durante a posição ortostática. O dispositivo apresentou adequada adaptação inicial ao usuário, elevada aceitabilidade pelos responsáveis e potencial para favorecer o alinhamento dos membros inferiores durante o ortostatismo, segundo avaliação clínica observacional. Além do baixo custo de fabricação, a possibilidade de personalização antropométrica representa um diferencial relevante para serviços de reabilitação.

Contudo, estudos futuros deverão incluir amostras maiores, avaliações biomecânicas objetivas e acompanhamento longitudinal, permitindo confirmar a efetividade clínica e estabelecer critérios mais robustos para sua indicação terapêutica.

Abstract—A órtese suropodálica (AFO — Ankle-Foot Orthosis) é um dispositivo exoesquelético destinado ao suporte do complexo tornozelo-pé, indicado no tratamento de deformidades, distúrbios neuromusculares e alterações da marcha. No contexto pediátrico, sua relevância clínica é acentuada: crianças com condições como paralisia cerebral, mielomeningocele e sequelas de AVC perinatal constituem um dos grupos de maior demanda por esse dispositivo no Sistema Único de Saúde. Entre as principais indicações estão deformidades como pé caído, pé equino, pé varo, pé valgo e suas combinações — condições que comprometem o alinhamento biomecânico, a estabilidade e a eficiência da marcha, impactando diretamente a autonomia e o desenvolvimento motor infantil. Contudo, os métodos convencionais de fabricação — baseados em moldagem em gesso e conformação manual de termoplásticos — apresentam limitações documentadas em personalização anatômica, custo, prazo de entrega e adequação ao crescimento infantil contínuo. Este trabalho investigou a viabilidade do uso integrado de escaneamento tridimensional, modelagem CAD e impressão 3D por Fused Deposition Modeling (FDM) na produção de órteses AFO personalizadas para crianças de 1 a 10 anos. A metodologia adotada foi o Design Thinking. O escaneamento foi realizado com o scanner RANGE 2 (Revopoint); a modelagem, no software Fusion 360, com espessura uniforme de 2 mm; e a impressão, na Creality K1 Max utilizando polipropileno (PP), com camadas de 0,2 mm e velocidade de 200 mm/s. Os resultados indicam que o fluxo digital reduz significativamente o número de etapas manuais, minimiza o desperdício de material e permite ajustes rápidos sem reinício do processo, favorecendo elevada fidelidade geométrica e potencial para maior padronização do processo quando comparado ao método convencional. Conclui-se que a manufatura aditiva representa uma alternativa tecnicamente viável, economicamente acessível e clinicamente promissora para a produção de órteses AFO pediátricas.

Palavras-chave—órtese suropodálica; impressão 3D; manufatura aditiva; tecnologia assistiva; design e saúde.

I. I. INTRODUÇÃO

A origem do termo órtese vem da palavra grega "Orthos", que significa direto, reto, normal. A órtese é definida como um dispositivo exoesquelético que, aplicado a um ou vários segmentos do corpo, tem a finalidade de proporcionar o melhor alinhamento possível, priorizando a funcionalidade de cada indivíduo [1].

As órteses suropodálicas — também denominadas Ankle-Foot Orthosis (AFO) — são dispositivos para o complexo articular de tornozelo e pé. Esse modelo divide-se em fixas, nas quais não é permitido o movimento articular do tornozelo, e articuladas, que permitem o movimento de dorsiflexão plantar [2]. Suas funções principais incluem a prevenção de deformidades em equino, controle do alinhamento do pé e do tornozelo, equilíbrio e melhora do desempenho na marcha [3].

No contexto pediátrico, o uso da órtese impacta diretamente o desempenho de atividades de vida diária. Crianças com condições como paralisia cerebral, mielomeningocele e sequelas de AVC perinatal constituem um dos grupos de maior demanda por órteses do tipo AFO no Sistema Único de Saúde [1]. Contudo, os métodos convencionais de fabricação apresentam limitações bem documentadas: longos prazos de entrega, dificuldade de ajuste anatômico e custo elevado — barreiras que comprometem especialmente pacientes em situação de vulnerabilidade socioeconômica [3].

No contexto pediátrico, essas limitações são agravadas pelo crescimento contínuo da criança, que exige substituições periódicas do dispositivo. Aspectos como conforto, peso e aceitação estética influenciam diretamente a adesão infantil ao tratamento, tornando a personalização não apenas desejável, mas clinicamente necessária [4].

Nesse cenário, a manufatura aditiva — em especial a impressão 3D associada ao escaneamento tridimensional e à modelagem CAD — surge como alternativa promissora. Wixted et al. [5] reforçam que essa abordagem apresenta resultados comparáveis aos métodos tradicionais em termos de resistência e funcionalidade, com vantagens em personalização e tempo de entrega. Bezek et al. [6] apontam que o desenvolvimento contínuo de novos materiais biocompatíveis para impressão 3D amplia as possibilidades de aplicação clínica desses dispositivos. Embora a literatura demonstra resultados promissores para a impressão 3D de órteses, ainda existem lacunas relacionadas à sistematização de fluxos digitais completos aplicados à ortopedia pediátrica. Nesse contexto, o presente estudo propõe a integração entre escaneamento tridimensional, modelagem paramétrica e manufatura aditiva como estratégia para otimizar o desenvolvimento de órteses suropodálicas personalizadas.

II. II. REVISÃO BIBLIOGRÁFICA

A. A. Biomecânica de Membros Inferiores

A biomecânica é a área de estudo responsável pela análise da estrutura e da função dos sistemas biológicos por meio dos princípios da mecânica. O termo deriva das palavras gregas *bio* (vida) e *mecânica* (movimento), sendo aplicada para compreender como o corpo humano reage às forças internas e externas durante a realização dos movimentos [7]. Segundo Hamill e Knutzen (1999), a biomecânica pode ser qualitativa quando se limita à descrição do movimento, ou quantitativa quando envolve medidas e cálculos para sua avaliação.

Segundo Brasil (2014) [1], os membros inferiores desempenham papel essencial na sustentação do peso corporal, na manutenção do equilíbrio e na realização da marcha. Sua estrutura é composta pela cintura pélvica, coxa, perna e pé, formando um sistema biomecânico capaz de absorver impactos, distribuir cargas e gerar propulsão durante o deslocamento. O funcionamento adequado desse sistema depende da interação harmoniosa entre os segmentos corporais e do controle neuromuscular responsável pela coordenação dos movimentos [13].

A análise biomecânica permite compreender como os músculos geram força, como os ossos suportam e absorvem cargas e como as articulações realizam seus movimentos. Essas informações contribuem diretamente para a avaliação da segurança de dispositivos ortopédicos, para a melhoria do desempenho físico e para o desenvolvimento de produtos mais eficientes, ergonômicos e funcionais [7].

No contexto dos membros inferiores, os pés desempenham papel central na sustentação, estabilidade e mobilidade do corpo humano, exercendo funções como absorção de impactos, adaptação às irregularidades do terreno, distribuição das cargas corporais e geração de força propulsiva. Além disso, o complexo tornozelo-pé atua como importante mecanismo de estabilidade, contribuindo para o equilíbrio e para a eficiência dos movimentos realizados durante a locomoção [14].

Os tornozelos e pés constituem um complexo sistema biomecânico capaz de executar movimentos como flexão plantar, dorsiflexão, inversão e eversão, permitindo adaptação às diferentes superfícies e absorção das forças geradas durante o ciclo da marcha. Alterações nesse sistema, sejam de origem neurológica, musculoesquelética ou traumática, podem comprometer significativamente a mobilidade e o equilíbrio do indivíduo, justificando a necessidade de intervenção por meio de dispositivos de suporte como as órteses AFO [1].

Diante disso, compreender a biomecânica dos membros inferiores torna-se fundamental para o desenvolvimento de órteses suropodálicas, pois esses dispositivos atuam diretamente na estabilização do tornozelo e do pé, auxiliando no alinhamento biomecânico, no controle dos movimentos e na melhora da funcionalidade durante a marcha. O conhecimento anatômico e biomecânico contribui para o desenvolvimento de soluções mais adequadas às necessidades dos usuários, especialmente quando associado às possibilidades de personalização proporcionadas pela modelagem e impressão 3D [8].

B. B. Estrutura Anatômica do Tornozelo e Pé

O corpo humano é dividido em membros responsáveis pelos movimentos e pela locomoção, sendo classificados em superiores e inferiores. Entre os componentes dos membros inferiores, encontram-se o pé e o tornozelo, estruturas estudadas neste trabalho de forma mais aprofundada devido à sua relação direta com a necessidade de utilização das órteses suropodálicas. De modo geral, o membro inferior é formado pela cintura, pela coxa, perna e pé [1].

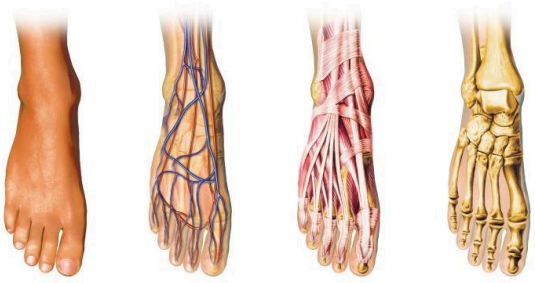

Figura 1 - A Complexa Anatomia do Pé
Fonte: Dr. Tiago Baumfeld

O complexo tornozelo-pé constitui uma das estruturas mais importantes do sistema musculoesquelético humano, sendo responsável pela sustentação do peso corporal, manutenção do equilíbrio, absorção de impactos e execução dos movimentos necessários para a locomoção. Sua composição anatômica envolve ossos, articulações, músculos, tendões e ligamentos que atuam de forma integrada para proporcionar estabilidade e mobilidade durante as atividades diárias, especialmente durante o ciclo da marcha [1].

Os membros inferiores são formados pela cintura pélvica, coxa, perna e pé, sendo o tornozelo e o pé estruturas fundamentais para o deslocamento humano. Devido à sua participação direta nos movimentos de marcha e equilíbrio, alterações funcionais nessa região podem comprometer significativamente a mobilidade do indivíduo, tornando necessária, em diversos casos, a utilização de órteses suropodálicas para auxiliar na estabilização e no controle dos movimentos articulares [1].

Do ponto de vista ósseo, o pé apresenta uma estrutura complexa composta por 26 ossos organizados em três grupos

principais: tarso, metatarso e falanges (Figura 2). Os ossos do tarso incluem o tálus, calcâneo, navicular, cubóide e os três ossos cuneiformes. O tálus destaca-se por sua participação direta na articulação do tornozelo, recebendo e distribuindo as cargas provenientes da tíbia durante a locomoção. O calcâneo, por sua vez, constitui o maior osso do pé e atua como importante estrutura de suporte e absorção de impactos [1].

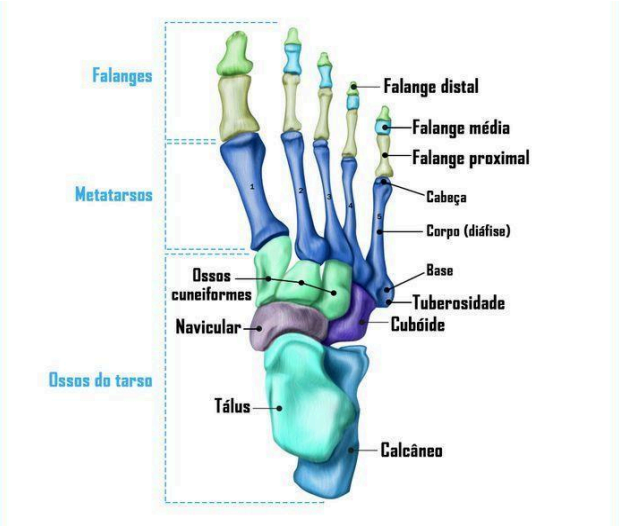

Figura 2 - Ossos do Pé
Fonte: Info.enf

C. C. Deformidades do Pé

As principais deformidades que indicam o uso de AFO incluem: (a) Síndrome do Pé Caído — fraqueza dos músculos dorsiflexores, com arrasto dos dedos na marcha, frequentemente associada a lesões do nervo fibular ou doenças neurológicas; (b) Pé Equino — flexão plantar excessiva com dificuldade de apoio do calcanhar, associado à espasticidade; (c) Pé Calcâneo — dorsiflexão excessiva com comprometimento da propulsão; (d) Pé Varo/Valgo — desvios laterais do retropé com instabilidade; (e) deformidades combinadas, como equinovaro e equinovalgo, frequentes em comprometimentos neurológicos [1].

Essas deformidades podem provocar alterações significativas na mobilidade, no equilíbrio e na capacidade funcional dos indivíduos. Dessa forma, a utilização de órteses suropodálicas torna-se uma importante estratégia terapêutica para promover alinhamento biomecânico adequado, auxiliar no controle dos movimentos articulares e melhorar o desempenho durante a marcha. A escolha do tipo de órtese depende das características da deformidade, dos objetivos terapêuticos e das necessidades específicas [1].

D. D. Classificação das Órteses AFO

As AFOs classificam-se em três categorias: (1) Não articuladas rígidas — mantêm o tornozelo fixo a 90°, indicadas em casos de fraqueza muscular severa ou instabilidade articular; (2) Não articuladas flexíveis — permitem algum grau de movimento articular, modelos Codivilla, Espiral e Semi-espiral; (3) Articuladas — indicadas para pacientes com capacidade de realizar marcha, alinhadas com os maléolos para evitar rotação indesejada durante a transferência de peso [1], [2].

Dessa forma, a órtese é recomendada após uma avaliação detalhada da biomecânica do paciente, tanto em movimento quanto de forma estática, para analisar as características do alinhamento e funcionamento dos pés. Em crianças o uso da órtese impacta diretamente no desempenho de atividades de vida diária, e pode orientar o processo de avaliação e intervenção dos profissionais.

E. E. Métodos de Produção e Impressão 3D

O processo convencional de produção de AFOs é composto por dez etapas manuais, envolvendo moldagem em gesso, conformação de termoplástico, recorte e acabamento. Esse processo é demorado, sujeito a variações e gera significativo desperdício de material [1].

Em contraste com o método tradicional, os avanços tecnológicos têm possibilitado a utilização de fluxos de trabalho digitais para a fabricação de órteses suropodálicas, especialmente por meio do escaneamento tridimensional e da impressão 3D. Nesse processo, a obtenção das características anatômicas do paciente é realizada por meio de scanners 3D, que capturam digitalmente a geometria do membro inferior, eliminando a necessidade da confecção de moldes físicos em gesso [8].

Após a aquisição das imagens, os dados são processados em softwares de modelagem assistida por computador (CAD), permitindo a realização de ajustes virtuais, correções de alinhamento e personalização do dispositivo de acordo com as necessidades clínicas do usuário. Em seguida, o modelo digital é convertido para um formato compatível com a manufatura aditiva, sendo produzido camada por camada por meio de impressoras 3D [8].

As principais diferenças em relação ao método tradicional concentram-se na digitalização das etapas de obtenção do molde e de modelagem da órtese. Enquanto a técnica convencional depende de processos manuais, frequentemente mais demorados e suscetíveis a variações decorrentes da manipulação dos materiais, o fluxo digital proporciona maior precisão geométrica, reprodutibilidade e possibilidade de armazenamento permanente dos modelos em formato digital. Além disso, a impressão 3D permite a produção de estruturas complexas e personalizadas com menor desperdício de material, favorecendo a otimização do processo produtivo.

De acordo com Bezek (2025) [6], a tecnologia de impressão 3D tem revolucionado a área da saúde devido à sua capacidade de produzir estruturas complexas e personalizadas

para cada paciente. Além disso, os avanços nas tecnologias de imagem digital e nos sistemas de design e manufatura assistidos por computador (CAD/CAM) têm simplificado os processos de projeto e fabricação, reduzindo o tempo de produção e aumentando o conforto, a funcionalidade e a adaptação dos dispositivos. Segundo o autor, o desenvolvimento contínuo de novos materiais e técnicas de impressão favorece o surgimento de soluções médicas cada vez mais inovadoras e personalizadas, consolidando a impressão 3D como uma ferramenta de grande relevância para a saúde moderna.

III. III. OBJETIVOS

Desenvolver um fluxo digital integrado para produção de órteses suropodálicas pediátricas utilizando escaneamento tridimensional, modelagem CAD e manufatura aditiva.

Os objetivos específicos são: (a) averiguar a precisão do ajuste anatômico, o conforto ao usuário e o desempenho mecânico da estrutura impressa; (b) validar a viabilidade da manufatura aditiva na produção de dispositivos ortopédicos personalizados para o público infantil.

IV. IV. METODOLOGIA

F. *A. Design Thinking*

A metodologia adotada foi o Design Thinking, abordagem centrada no ser humano voltada para a resolução criativa de problemas [9]. A escolha justifica-se pela necessidade de compreender não apenas os aspectos técnicos da confecção de órteses AFO, mas também as necessidades ergonômicas, funcionais e estéticas dos usuários. O processo foi estruturado em cinco etapas: imersão, definição, ideação, prototipagem e testes.

Na etapa de imersão, foram realizadas pesquisas bibliográficas e análise de similares. Na definição, identificaram-se os principais requisitos projetuais: adaptação anatômica, leveza, resistência, flexibilidade controlada e viabilidade de fabricação por impressão 3D. Na ideação, realizou-se o escaneamento do membro e a modelagem digital. Na prototipagem, executou-se a impressão. Na etapa de testes, avaliou-se o desempenho funcional e estrutural do protótipo.

G. *B. Parâmetros Projetuais*

A definição dos critérios projetuais constitui uma etapa fundamental para o desenvolvimento da órtese, uma vez que orientou as decisões relacionadas aos aspectos funcionais, ergonômicos, estruturais e estéticos do produto. Essas diretrizes foram estabelecidas com base nas informações obtidas durante as etapas de pesquisa bibliográfica, análise de similares, e compreensão das necessidades do usuário levantadas na fase de imersão do Design Thinking.

A adaptação anatômica foi definida como requisito prioritário, considerando a necessidade de encaixe preciso ao membro do paciente. Para isso, o escaneamento tridimensional foi utilizado como ferramenta de aquisição das dimensões e curvaturas da região tornozelo-pé, possibilitando a geração de um modelo digital individualizado e garantindo maior fidelidade geométrica na produção da órtese.

Os requisitos de ergonomia e conforto foram definidos a partir dos relatos de usuários coletados na imersão, que apontaram pressão excessiva em proeminências ósseas, atrito prolongado e baixa ventilação como principais queixas dos dispositivos convencionais. Foram priorizados distribuição uniforme de pressão, aberturas na estrutura para ventilação e redução do peso total. A espessura uniforme de 2 mm, definida durante a modelagem no Fusion 360, foi adotada com base em referências da literatura que indicam essa faixa como adequada para órteses FDM (Modelagem por Deposição Fundida) em termoplásticos de uso ortopédico [5].

A viabilidade de fabricação por manufatura aditiva constituiu outro critério relevante do projeto. Foram avaliados fatores como tempo de impressão, consumo de material, possibilidade de ajustes rápidos no modelo digital e facilidade de reprodução. Arce e Foggiatto (2017) destacam que o fluxo digital de produção reduz significativamente o número de etapas manuais em relação ao método convencional, diminuindo custos operacionais e o tempo entre a prescrição e a entrega do dispositivo. Por fim, os critérios definidos serviram como diretrizes para a prototipagem, contribuindo para a criação de um produto funcional, personalizado e alinhado às necessidades clínicas do usuário [8].

H. *C. Escaneamento Tridimensional*

O escaneamento foi realizado com o scanner RANGE 2 da Revopoint, que capturou digitalmente a geometria do membro inferior, eliminando a necessidade de moldes físicos. O membro foi posicionado adequadamente para garantir a captura completa das regiões de interesse. Neste estudo, foram desenvolvidas órteses personalizadas para crianças de até 10 anos.

I. *D. Modelagem 3D (CAD)*

Para o desenvolvimento do modelo digital, foi utilizado o software Fusion 360 (Autodesk). O processo de modelagem foi realizado na aba de superfícies do software, por meio da criação de uma forma orgânica delimitada à região anatômica de aplicação da órtese. O modelo foi ajustado à geometria do membro escaneado para garantir o correto encaixe na região do calcanhar. Após a definição da geometria externa, a estrutura foi submetida ao processo de extrusão com espessura uniforme de 2 mm, seguido de arredondamento de bordas e inserção de furos para fixação. Essas características foram consideradas requisitos de projeto e não foram submetidas, nesta etapa, a testes de conforto, pressão ou desempenho funcional.

A Figura 3 apresenta o modelo tridimensional obtido a partir do escaneamento, posicionado a 90°, bem como o resultado final da órtese após a conclusão da etapa de modelagem.

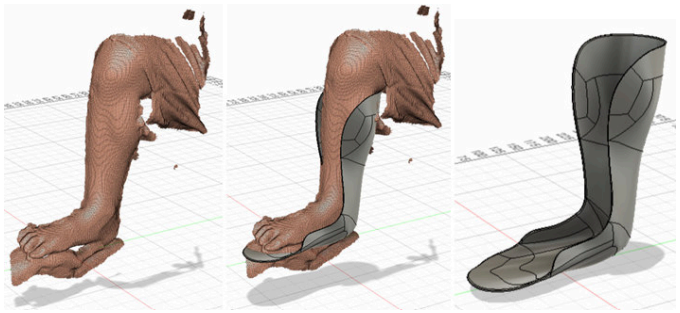

Figura 3 - Modelagem da órtese

J. E. Prototipagem (Impressão 3D)

A etapa de prototipagem corresponde à materialização do modelo desenvolvido durante a fase de modelagem tridimensional. Para a fabricação dos protótipos, foi utilizada a tecnologia de manufatura aditiva denominada Fused Deposition Modeling (FDM), a qual possibilita a construção de objetos por meio da deposição sucessiva de camadas de material termoplástico. A escolha dessa tecnologia foi motivada por sua viabilidade econômica, facilidade de acesso e ampla aplicabilidade em projetos experimentais voltados à área da tecnologia assistiva. Portanto, para dar-se início ao processo, o modelo tridimensional da órtese foi convertido para um formato compatível com os processos de manufatura aditiva, sendo exportado em formato STL. Em seguida, o arquivo foi importado para um software de fatiamento, no qual foram definidos os parâmetros de impressão, incluindo orientação da peça, altura das camadas, percentual de preenchimento, velocidade de impressão e estruturas de suporte, quando necessárias, especificado na tabela 1.

TABELA I

Parâmetros de Impressão 3D

Parâmetro	Valor
Material	Polipropileno (PP)
Preenchimento	100%
Espessura da Camada	0,2 mm
Temperatura do Bico	240 °C
Temp. Mesa Impressão	100 °C
Velocidade de Impressão	200 mm/s
Diâmetro do Bico	0,8 mm

A impressora utilizada foi a Creality K1 Max. Durante a impressão, foram monitorados a adesão da peça à mesa, a estabilidade do processo e a qualidade da deposição do material. Após a fabricação, a órtese foi submetida a pós-processamento com remoção de suportes, lixamento de bordas e inspeção visual de conformidade dimensional.

V. V. RESULTADOS ESPERADOS

O fluxo digital de produção — escaneamento, modelagem CAD e impressão FDM — Os resultados obtidos indicam que o fluxo digital apresenta potencial para substituir diversas etapas manuais do processo convencional, simplificando o desenvolvimento da órtese e reduzindo a dependência de procedimentos artesanais. A principal vantagem observada foi a eliminação da etapa de moldagem em gesso, substituída pelo escaneamento tridimensional, que garante maior fidelidade geométrica à anatomia do paciente. Além da redução do número de etapas, essa substituição elimina fontes de erro associadas ao processo manual, como deformações do gesso durante a secagem, dependência da habilidade individual do técnico ortesista e a impossibilidade de armazenar digitalmente o modelo para reproduções futuras.

O arquivo digital gerado a partir do escaneamento pode ser reaproveitado para ajustes, réplicas ou reimpressões em caso de perda ou dano da órtese, algo inviável no fluxo convencional, em que cada molde de gesso é descartado após o uso.

O uso do polipropileno (PP) como material de impressão mostrou-se adequado para a aplicação ortopédica pediátrica, dado seu equilíbrio entre resistência mecânica, leveza e flexibilidade controlada. Esse equilíbrio é particularmente relevante no contexto pediátrico, no qual a órtese precisa acompanhar o crescimento e a movimentação natural da criança sem gerar pontos de rigidez excessiva que possam causar desconforto ou lesões por atrito. A espessura de 2 mm, baseada em literatura específica para órteses FDM [5], conferiu rigidez suficiente para suporte do tornozelo sem comprometer a mobilidade funcional, representando um ponto de equilíbrio entre a necessidade de imobilização parcial e a preservação da amplitude de movimento residual, essencial para o desenvolvimento motor infantil.

Os resultados preliminares indicam que a manufatura aditiva representa uma alternativa viável, capaz de produzir órteses personalizadas com qualidade comparável aos métodos convencionais, em menor tempo e com menor custo operacional [3], [5]. Vale destacar que essa viabilidade não se limita ao aspecto técnico, mas também abrange a dimensão logística do processo: a digitalização do fluxo de produção permite o armazenamento em nuvem dos modelos, a padronização de parâmetros de impressão e a possibilidade de produção remota, características que podem ser especialmente relevantes para ampliar o acesso a órteses personalizadas em regiões com escassez de profissionais especializados em ortopedia técnica.

VI. VI. DISCUSSÃO

A principal contribuição deste estudo não reside apenas na utilização da impressão 3D para fabricação de órteses, mas na proposição de um fluxo digital integrado que conecta escaneamento tridimensional, modelagem CAD, definição de critérios projetuais e manufatura aditiva. Essa integração reduz a dependência de etapas artesanais e amplia o potencial de padronização e reprodutibilidade do processo de desenvolvimento. Os resultados obtidos estão alinhados com a

literatura sobre manufatura aditiva aplicada à ortótica. Wixted et al. [5] identificaram que órteses AFO produzidas por impressão 3D apresentam resistência e funcionalidade comparáveis às convencionais, com vantagens claras em personalização e tempo de entrega. Essa convergência com os achados do presente trabalho reforça a hipótese de que o fluxo digital de produção não representa apenas uma alternativa tecnológica, mas um processo capaz de igualar — e em determinados aspectos superar — o desempenho funcional das órteses convencionais, sobretudo quando se considera a capacidade de adequação geométrica individualizada proporcionada pelo escaneamento tridimensional. Chen et al. [10] reforçam que a fabricação aditiva reduz significativamente o desperdício de material em relação aos métodos tradicionais, tornando o processo mais sustentável, uma vez que a deposição de material ocorre de forma aditiva e controlada, ao contrário dos processos subtrativos ou de conformação térmica, que frequentemente geram excedentes de material descartados após o ajuste da peça ao paciente. Essa característica dialoga diretamente com a proposta deste trabalho, que buscou aliar viabilidade técnica à racionalização de recursos no processo produtivo.

No contexto pediátrico, a contribuição do fluxo digital é especialmente relevante. A capacidade de armazenar o modelo digital e reimprimí-lo rapidamente responde diretamente à demanda por substituições frequentes decorrentes do crescimento infantil [4], eliminando a necessidade de repetição integral do processo de moldagem a cada nova adequação. Esse aspecto adquire particular importância no público pediátrico, cujo crescimento ósseo acelerado exige trocas periódicas de dispositivo, tornando o custo e o tempo de produção fatores críticos para a continuidade do tratamento. A possibilidade de ajustar parâmetros no arquivo CAD original — em vez de reiniciar todo o processo de moldagem — representa um ganho direto de eficiência clínica e operacional. Bezek et al. [6] apontam que os avanços contínuos em materiais biocompatíveis para impressão 3D ampliam progressivamente as possibilidades de aplicação clínica desses dispositivos, sugerindo que a tendência observada neste trabalho — de substituição de materiais convencionais por polímeros impressos — tende a se consolidar e se expandir à medida que novos materiais com propriedades mecânicas e biológicas aprimoradas se tornem disponíveis comercialmente.

A metodologia do Design Thinking mostrou-se adequada para integrar as perspectivas clínicas, ergonômicas e técnicas no desenvolvimento da órtese. Essa integração se mostrou extremamente relevante no projeto, nos quais decisões puramente técnicas — como escolha de material ou espessura de parede — não podem ser dissociadas da experiência prática do usuário. A etapa de imersão foi fundamental para identificar as principais queixas dos usuários e traduzi-las em requisitos projetuais concretos, evidenciando a importância da abordagem centrada no usuário em projetos de tecnologia assistiva. Nesse sentido, a articulação entre método de projeto centrado no usuário e processo de fabricação digital sugere um caminho promissor para o desenvolvimento de dispositivos ortopédicos personalizados, no qual a flexibilidade tecnológica da manufatura aditiva se soma à sensibilidade metodológica do Design Thinking para gerar soluções tecnicamente viáveis e clinicamente relevantes.

Diante disso, a pesquisa resultou no desenvolvimento e fabricação de órteses suropodálicas (AFO) personalizadas. Após a impressão do dispositivo, a peça passou por etapas de acabamento, incluindo aplicação de velcro para fixação e EVA em pontos de pressão, visando maior conforto durante o uso.

Os critérios para avaliação foram definidos em conjunto com profissionais da fisioterapia, dessa forma, foram considerados, ajuste anatômico, conforto, fixação e estabilidade.

A avaliação permitiu verificar a funcionalidade do protótipo e sua adaptação às necessidades do paciente, caracterizando o uso bem sucedido do dispositivo. Dessa forma, os resultados reforçam o potencial da impressão tridimensional como alternativa para a produção de órteses AFO personalizadas.

VII. VII. CONCLUSÃO

Este trabalho demonstrou que o uso integrado de escaneamento tridimensional, modelagem CAD e impressão 3D por FDM representa uma alternativa tecnicamente viável,

economicamente acessível e clinicamente promissora para a produção de órteses AFO pediátricas. O fluxo digital reduz o número de etapas manuais, minimiza o desperdício de material e permite ajustes rápidos sem reinício do processo, com precisão geométrica superior ao método convencional. Esses resultados, ainda que preliminares, indicam que a substituição do processo tradicional de moldagem em gesso por um fluxo inteiramente digital não compromete — e em diversos aspectos aprimora — os requisitos técnicos e funcionais esperados de um dispositivo ortopédico, ao mesmo tempo em que introduz ganhos operacionais dificilmente alcançáveis pelos métodos convencionais, como a possibilidade de reprodução rápida do modelo e o armazenamento digital do histórico de cada paciente.

A convergência entre a demanda clínica concreta — crianças que necessitam de órteses personalizadas e acessíveis — e uma tecnologia em consolidação justifica e motiva a continuidade desta pesquisa. Essa convergência é particularmente significativa no cenário público de saúde, no qual o acesso a órteses personalizadas é frequentemente limitado por custos elevados, longos prazos de confecção e escassez de profissionais especializados em técnicas convencionais de moldagem. A proposta aqui investigada sugere um caminho concreto para mitigar essas barreiras, ao aproximar tecnologias de manufatura digital — cada vez mais acessíveis em termos de custo de equipamento e material — das necessidades específicas da ortopedia pediátrica.

Por fim, espera-se que a consolidação desse fluxo digital contribua para ampliar o acesso a órteses personalizadas, reduzindo barreiras relacionadas ao tempo de fabricação, à repetibilidade do processo e à dependência de técnicas exclusivamente artesanais, fortalecendo a integração entre Engenharia, Design e Tecnologia Assistiva no desenvolvimento de soluções voltadas à reabilitação pediátrica.

AGRADECIMENTOS

Os autores agradecem à Universidade XXX, ao Laboratório YYY e à Fundação de Apoio à Pesquisa (FUNAPE) pelo suporte institucional no desenvolvimento deste trabalho.

***Abstract*—Children with severe cerebral palsy (GMFCS levels IV and V) face extreme motor limitations that hinder participation in educational robotics and interactive learning activities. This paper presents the design, specification, and preliminary validation of the Local Learning Environment (LLE), the central component of the NeuroBeep platform. The LLE integrates a noninvasive brain-computer interface based on hemoencephalographic (HEG) neurofeedback with a modular physical space designed for educational and behavioral applications in children with severe motor disabilities. The system is presented through four engineering subsystems: (i) a mechanical design comprising a 2.5 by 2 by 2 m aluminum V-Slot frame with vertical projection and partial acoustic isolation; (ii) a wall-mounted linear robot with a single horizontal degree of freedom, driven by a concentration-relaxation HEG protocol; (iii) an application layer that orchestrates pedagogical sessions aligned with the Brazilian National Common Curricular Base (BNCC); and (iv) a cloud platform with multi-tenant architecture and LGPD-compliant data governance. The LLE has been assembled and is operational in preliminary testing at the i-LITPEG laboratory (UFPE) since December 2024. Structural validation via finite-element analysis confirmed a maximum von Mises stress of 3.83 MPa and a maximum deflection of 0.283 mm under a 100 N load, both far below the admissible limit of aluminum 6061-T6. Bench tests (n = 200 trials) showed an HEG-to-robot command latency averaging 86.85 ms (SD 18.16 ms, maximum 152.65 ms) with 94.0% correct command execution, and acoustic noise peaking at 53 dB, compatible with requirements well below the auditory discomfort threshold (above 100dB). The resulting system, with its modular frame, standardized dimensions, and reconfigurable components, constitutes a reproducible platform for future clinical and school validation of neurofeedback-driven assistive technologies.**

***Index Terms*—assistive technology, brain-computer interface, neurofeedback, educational robotics, cerebral palsy, inclusive education**

This work, named NeuroAssist/NeuroBeep, was funded by the Brazilian Funding Authority for Studies and Projects (FINEP), agreement 01.24.0124.00 (ref. 2199/22).

I. Introduction

Humanity has followed multiple historical paths in dealing with compassion and ethics. Some have normalized the abandonment of the frail; others have chosen responsibility for the care of the other, above all, the vulnerable [1]–[3]. Technological development is inscribed in these paths and faces the same ethical choice. Assistive Technology (AT) emerges in this context [7]. The inclusion of children with severe motor disabilities in teaching and learning processes mediated by emerging technologies still represents a significant challenge for Special Education and AT. According to the World Health Organization, about one billion people live with some form of disability, and approximately 190 million present severe disabilities [4]. Among these, children with cerebral palsy (CP) at levels IV and V of the Gross Motor Function Classification System (GMFCS) have extreme movement limitations, which in most cases hinder their participation in educational robotics, an increasingly common tool in Brazilian schools. Educational robotics has been associated with gains in children's engagement and learning of curricular content [5], [19]–[21]. However, access to such activities presupposes motor capabilities these individuals lack. Brain-computer interfaces (BCI) have enabled people with severe paralysis to communicate and control external devices without relying on movement [22], [23]. A noninvasive form of BCI, neurofeedback, allows a person to voluntarily self-regulate a measured brain signal [6]; captured by hemoencephalography (HEG) over the frontal region, this self-regulation can be turned into a command channel. The NeuroBeep project proposes integrating educational robotics with BCI to overcome motor limitations through the Local Learning Environment (LLE), a physical and technological space designed to receive this new population (universal design), reduce distractions,

and enable standardized training sessions. The LLE aims to provide a modular, controlled, and monitored environment for teaching and learning through educational robotics and neurofeedback, usable by typically developing children and children at GMFCS levels IV and V, meeting ethical and safety standards for research with minors. Unlike approaches that use ocular signals or other residual pathways, the LLE uses neurofeedback from the frontal lobe region, preserving visual exploration and promoting a more natural learning experience. This paper is descriptive and does not present experimental data. Its goal is to document the current configuration of the LLE, its components, technical specifications, and operational flow, serving as a reference for future validation in clinical and school settings. Fig. 1 shows the overall integration of the LLE components around the controlling application (APP), which operates in two complementary modes. In recording mode (Fig. 1(a)), the APP acquires the HEG signal and camera streams, drives the robot, projected stimuli, and audio in a closed loop, and uploads each trial to the cloud. In view mode (Fig. 1(b)), the data flow is reversed: the APP retrieves selected trials from the cloud and replays them on the projection and speakers, while the acquisition devices and robot remain idle.

II. Theoretical Background

Educational robotics is a pedagogical strategy for promoting learning, problem solving, and the development of cognitive and social skills in school-age children. By integrating design, programming, and collaborative work, robotic platforms foster motivation and engagement with curricular content. Systematic reviews document their potential to increase students' interest in science, technology, engineering, and mathematics, especially when implemented as an iterative, problem-based learning tool, as opposed to passive instructional models. In the Brazilian context, these platforms are predominantly Arduino- and ESP32-based kits that still require manual assembly and operation, a constraint that persists even when adapted as assistive technology for students with sensory, neurological, and neurodevelopmental disabilities [24], [25]. These characteristics position educational robotics as a versatile framework for developing complex cognitive competencies throughout formal schooling. Neurofeedback is a closed-loop technique in which a person learns to self-regulate a measured brain signal [6]. Hemoencephalography (HEG) and functional near-infrared spectroscopy (fNIRS) estimate cortical activation, particularly in the prefrontal cortex, from hemodynamic changes, and have been associated with executive function and attention in children and young adults [12], [13]. Cognitive and affective BCI research nonetheless favors cognitive-load metrics over motivational factors and gives insufficient attention to students with disabilities [26], a gap mirrored in assistive-technology delivery, where untrained staff, long waiting times, and low motivation undermine adoption regardless of device sophistication [27], [28]. In the LLE, a concentration-relaxation protocol over the frontal region serves as the command channel for the robot; because the raw HEG signal is subject-specific, the channel requires individual calibration and training before each session, which keeps the visual pathway free for the educational task. The load-bearing structure that hosts these components must be verified before assembly. Structural validation relies on the Finite Element Method (FEM), which discretizes the domain into interconnected elements to approximate the displacement, strain, and stress fields of a part [29], [30]; under a linear static analysis, the von Mises equivalent stress condenses the three-dimensional stress state into a single value comparable with the yield strength of ductile alloys such as aluminum, a standard criterion for sizing metallic frames.

III. Methodology

A. Mechanical design

The mechanical subsystem realizes the LLE as a controlled, partially isolated space that partially decouples the external sensory context and standardizes session conditions across schools. A supporting metal frame with fabric covering provides partial visual isolation. A design driver is the postural constraint of the target population: children at GMFCS levels IV and V need a slight upward inclination to stabilize the neck, which makes a floor-moving robot impossible to view. For this reason, the originally planned horizontal printed floor mat was replaced by a vertical wall projection, and the robot concept changed from a ground robot to a wall-mounted linear robot. The environment also integrates an orthopedic wheelchair adapted for GMFCS IV-V, an audiovisual system (projector, screen, cameras, and speakers), the robot, a control notebook, and support tables. The frame is built from extruded aluminum V-Slot profiles of 20 by 40 mm, chosen for their high strength-to-weight ratio, corrosion resistance, and ease of assembly and reconfiguration; the profiles are joined with M5 bolts, hammer (T-)nuts, and triangular, square, and T brackets, and cable routing uses 3D-printed PLA holders. The design requirements specify a 2.5 by 2 by 2 m enclosure that must not fail under longitudinal and transverse loads, remain disassemblable for car transport, and be safe for children. Before assembly, the profile was verified by a finite-element linear static analysis in ANSYS Workbench [31] on aluminum 6061-T6: a 100 N load (an overestimate of the projector weight) at the center of a profile modeled as a beam with fixed ends, plus its self-weight, over a mesh of about 18,200 tetrahedral elements.

B. Robotics design

The robot is a low-cost, wall-mounted linear robot with a single horizontal degree of freedom, produced mostly by additive manufacturing and responding to commands derived from neurofeedback. Among the interface options considered, aerial platforms (three-dimensional) were discarded for the safety risk they pose to the child, and planar XY systems (two-dimensional), inspired by CNC machines and plotters, were rejected because multidimensional control from a hemoencephalographic (HEG) signal would impose an excessive cognitive load; a one-dimensional horizontal rail was therefore adopted, which also matches the slight upward gaze that suits children at GMFCS levels IV and V. The mechanical concept

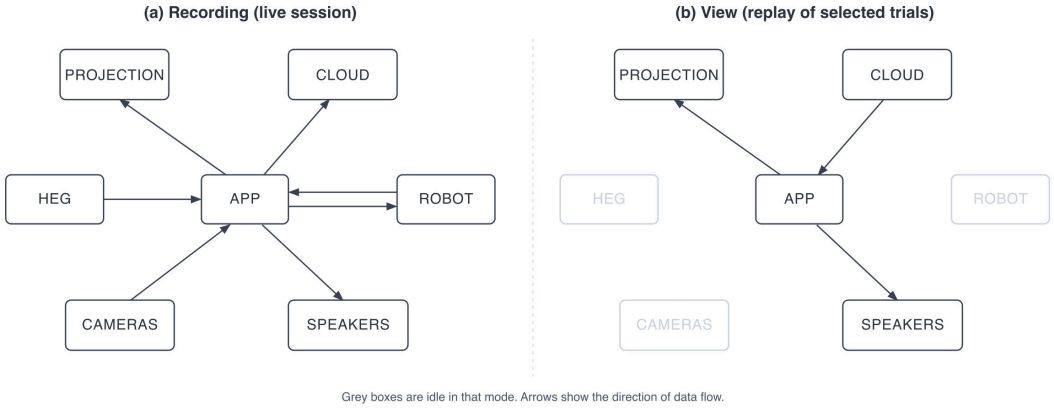

Fig. 1. Overall functioning of the LLE in its two operating modes. The controlling application (APP) is the hub that links HEG acquisition, projection, robot, cameras, speakers, and cloud. (a) In recording mode, sensors and the robot feed the APP, which drives live stimuli and uploads each trial to the cloud. (b) In view mode, the cloud feeds the APP, which replays selected trials on the projection and speakers; acquisition devices and the robot are idle (shown in grey).

emulates the X axis of a Cartesian 3D printer: a fixed base of 40 by 40 mm aluminum profile, cut to a 1900 mm stroke, carries a NEMA 17 stepper motor with a toothed pulley at one end and a free idler pulley acting as a belt tensioner at the other. A moving carriage, built on a PLA plate with four bearings on eccentric spacers for anti-backlash calibration against the rail, is driven by an open timing belt anchored at both ends that converts the motor torque into translation. The logic runs on an ESP32 microcontroller with a DRV8825 driver, powered by a 12 V DC supply and communicating over Bluetooth Low Energy; a single mechanical end-stop defines the origin during a homing routine, while all remaining travel limits are enforced by step counting within a real-time finite-state machine (FSM). The command channel uses an HEG neurofeedback protocol: in the two-command version (2C), the sequence Relax (10 s), Concentrate (3 s), Relax (10 s) triggers a command from a single concentration peak; the four-command version (4C) distinguishes commands by the number of consecutive peaks, using Morse-like logic. A NeuroBeep middleware with four modules (Communication, Commands, User Profile, and Learning) decouples the neural acquisition from the robotic actuation, allowing interoperability with different robots and EEG/HEG devices.

C. APP design

The application is the operational layer that runs the teaching and learning session in the field: it presents the script, orchestrates the robot and projected stimuli, records performance, and synchronizes data with the cloud. As shown in Fig. 1, the APP is the closed-loop hub of the recording mode (HEG, cameras, stimuli, and cloud upload) and, in view mode, replays selected trials from the cloud with the acquisition devices and the robot idle. The pedagogical content follows the Brazilian National Common Curricular Base (BNCC) [17] for the first year of primary education, in Portuguese Language and Mathematics, with a structure of twenty sessions of four to eight questions each (eighty to one hundred and twenty items). The number of alternatives per question (five to nine) follows Miller's law [16], respecting the information-processing capacity of the student. Performance is classified into four standards inspired by state assessment systems SAEPE and SIMAS: Elementary I, Elementary II, Proficient, and Advanced. The binary beep response was replaced by formative video feedback, organized in a flowchart with three paths (correct answer, robot not stopped, and incorrect answer). The application is specified through use cases (user authentication, environment and equipment, scripts and schedule, session execution, data collection and transmission, and monitoring) and roles (Administrator, Researcher, Education Researcher, Mediating Teacher, Student Guardian, and Coordinator).

D. Cloud design

The cloud subsystem provides centralized storage, organization, and indexing of the collected data, as well as administrative project management. It was designed as a modular web solution, hosted at PUC-Rio and accessed by the four executing institutions through a single application programming interface (API), which is the only read and write interface to the database, for both the field application and the web clients. The architecture is multi-tenant: each institution is registered as a region, with scope isolation or consolidation under global governance. Because the data concern minors in schools, the design follows the Brazilian data protection law (LGPD) [18]: it implements multi-method authentication, role-based access control with a hierarchy of profiles, and a detailed audit trail of each event. In the governance model, PUC-Rio acts as the technical operator and the academic partners as controllers of the field data, under ethics approval (CAAE 92643225.8.0000.5208).

IV. Results and Discussion

The main result of this work is the physical materialization and specification of the Local Learning Environment (LLE). The consolidation of this space validates the feasibility of

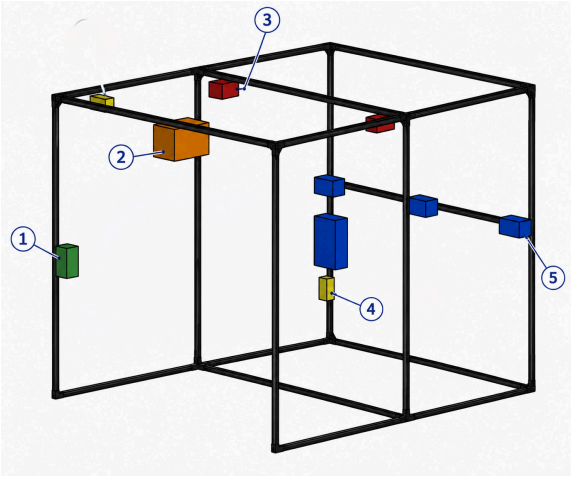

Fig. 2. Isometric view of the LLE supporting frame (2.5 m by 2 m by 2 m), built from aluminum V-Slot profiles, showing the placement of the main components: (1) speaker, (2) projector, (3) cameras, (4) power outlets, and (5) linear robot.

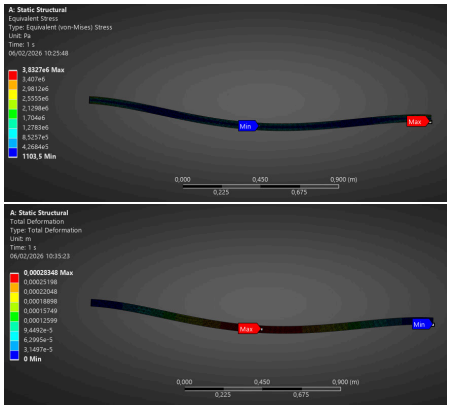

Fig. 3. Finite-element structural analysis of a frame profile under a 100 N central load with fixed supports (aluminum 6061-T6). (a) Equivalent von Mises stress, with a maximum of 3.83 MPa. (b) Total deformation, with a maximum of 0.283 mm. Both values remain far below the admissible limit of the alloy.

integrating a hemoencephalographic (HEG) brain-computer interface into a functional robotic and pedagogical arrangement.

A. Mechanical design

The LLE was assembled and is operational in a preliminary mode (hosted at i-LITPEG since December 2024), comprising the metal frame, fabric covering, orthopedic wheelchair, audiovisual system, robot, control notebook, and support tables. The replacement of the floor mat by a vertical wall projection (Fig. 2) was recorded as an operationalization method adapted to severe motor impairment, with potential for replication in other clinical and school settings. The installation of the acoustic partition walls that complete the isolation is still pending. The finite-element analysis of the structure (Fig. 3) confirmed a wide safety margin: under the 100 N load the profile showed a maximum deflection of 0.283 mm and a maximum von Mises stress of 3.83 MPa, both far below the admissible limit of aluminum 6061-T6, and the estimated maximum load capacity of about 700 N (71.4 kg) greatly exceeds the weight of the installed equipment, a load safety margin of about sevenfold relative to the 100 N design load. The shift from a floor to a wall concept illustrates how a clinical accessibility requirement reorganizes the mechanical design and, in cascade, the firmware, middleware, and environment layout.

B. Robotics design

Two functional units of the linear robot were produced, and the homing routine, FSM-based travel limits, and real-time Bluetooth telemetry were validated on the bench. The mechanical assembly of the wall-mounted track and carriage, with an overall envelope of 442 by 400 by 117 mm, is shown in Fig. 4. Initial bench tests characterized the HEG-to-robot loop latency over $n = 200$ repetitions, exceeding the minimum $n = 73$ determined via Cochran's formula [32] as the maximum of the latency-mean estimate ($n = 28$; $\alpha = 0.05$, $E = 6.757$ ms) and the proportion estimate ($n = 73$; $\pi \geq 0.95$, $\alpha = 0.05$), yielding $\bar{x} = 86.85$ ms ($s = 18.16$ ms, observed maximum $= 152.65$ ms), with 94.0% correct command execution ($188/200$) and 6.0% lost commands ($12/200$). Following the ISO 9283:1998 protocol [33], a bench test repeated without human participation over $n = 30$ repetitions at each of five target positions distributed along the 1800 mm rail (150 measurements in total) showed a systematic overshoot of the commanded position between +0.36 mm and +0.73 mm with standard deviations below 0.55 mm at all positions, evidencing high positioning accuracy and repeatability. The acoustic noise emitted by the robot, measured from the participant's chair, peaked at 53 dB with a mean of 48 dB, remaining significantly below the auditory discomfort level (above 100dB) as required by the environment. These levels are substantially lower than the loudness discomfort level (LDL)—the sound intensity at which discomfort begins, approximately 100 dB HL in normal-hearing adults without tolerance complaints, corresponding to an auditory dynamic range of about 95 dB [34], [35]—and lower than the uncomfortable loudness (UCL) of pediatric listeners, who tolerate levels about 12 dB higher than adults in direct comparison, with UCL exceeding the acoustic reflex threshold by 8.9 dB in children while the values were similar in adults [36], although the absolute values of that study were not accessible. Given the developmental differences in LDL, the wide variability among children of the same age despite relatively consistent loudness growth, and the error that estimating LDL from hearing thresholds can introduce [37], such normative comparisons should be interpreted with caution. The choice of a simple cognitive gesture and its extension by peak counting from two to four commands widens the command space without increasing the load on the child. The middleware is the contribution with the greatest reuse potential, since it enables adoption without replacing existing robot and EEG inventory in schools and laboratories. The code is available in public repositories.

Fig. 4. Mechanical CAD model of the wall-mounted linear robot, with an overall envelope of 442 by 400 by 117 mm: the aluminum-profile track, the wheeled carriage driven by a timing belt, and the stepper-motor drive module at one end. The second rail, set at an angle, reproduces a corner of the wall track.

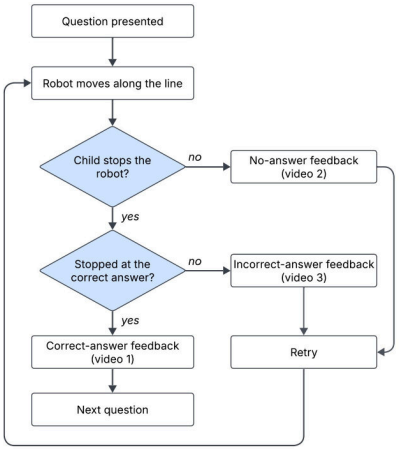

Fig. 5. Formative feedback logic of the APP. For each projected question, the robot moves along the line and the child uses concentration and relaxation to stop it. The stop is evaluated along three paths (no answer, incorrect, correct), each returning a formative video, with retries looping back to a new attempt.

C. APP design

At the content level, the following were completed: the script structure with pilot questions covering BNCC skills, the adaptive formative-feedback flowchart (Fig. 5), a per-session performance registry, and a simulation video of the proposed application on the 2C platform, whose session-monitoring interface is shown in Fig. 6. What remains is deployment of the field application layer, a prerequisite for populating the database. Separating a cloud layer from an application layer allows offline operation at school and later synchronization, a realistic requirement under variable connectivity. Anchoring the content in the BNCC and the assessment in state standards gives the system pedagogical legitimacy and comparability with instruments already used by education networks, while the formative feedback reduces the risk of negative reinforcement in a vulnerable population.

D. Cloud design

The cloud layer reached a consolidated functional stage in its administrative dimension: multi-method authentication, user and role management, multi-tenant operation with the four executing institutions registered as active regions (Fig. 7), an administration panel, and the LGPD audit trail are all operational. The platform is pre-operational: it is functional and ready to receive data, but large-scale collection in schools has not yet begun, as it depends on finalizing the field application, robot, and data-collection equipment. Prioritizing the administrative and governance layer before field collection was a design choice consistent with the context, since, without scope isolation and an audit trail, data collection from minors could not comply with the LGPD. The single-API, multi-tenant model balances institutional autonomy and consolidation, preparing the system to scale to the planned school network.

V. Conclusion

This paper documented the design, specification, and preliminary validation of the LLE, achieving the objective of a modular environment for teaching and learning through educational robotics and neurofeedback for children at GMFCS levels IV and V. The mechanical, robotics, application, and cloud subsystems were specified and partially built: the aluminum V-Slot frame showed a wide structural safety margin (3.83 MPa von Mises stress, 0.283 mm deflection, about sevenfold the 100 N design load); the wall-mounted linear robot exhibited an average HEG loop latency of approximately 86.85 ms and a noise level of 48 dB; the APP orchestrates BNCC-aligned sessions; and the cloud subsystem provides LGPD-compliant, multi-tenant governance. The most significant and original design decision was the change from a floor robot to this wall-mounted linear robot with vertical projection, driven by the postural needs of this population. Limitations of the current stage include the absence of clinical and behavioral validation, pending field application and cloud data collection, and still-incomplete acoustic isolation. The LLE is in preliminary testing at i-LITPEG; future work includes deploying additional units to partner schools and validating the pedagogical scripts with the target population in clinical and school settings.

Acknowledgment

The authors thank Universidade Federal de Pernambuco (UFPE), Universidade Federal do Rio Grande do Norte (UFRN), Pontifícia Universidade Católica do Rio de Janeiro (PUC-Rio), and Universidade Federal do Recôncavo da Bahia (UFRB) for their institutional support throughout the design, development, and integration of the Local Learning Environment. This work, named NeuroAssist/NeuroBeep, was funded

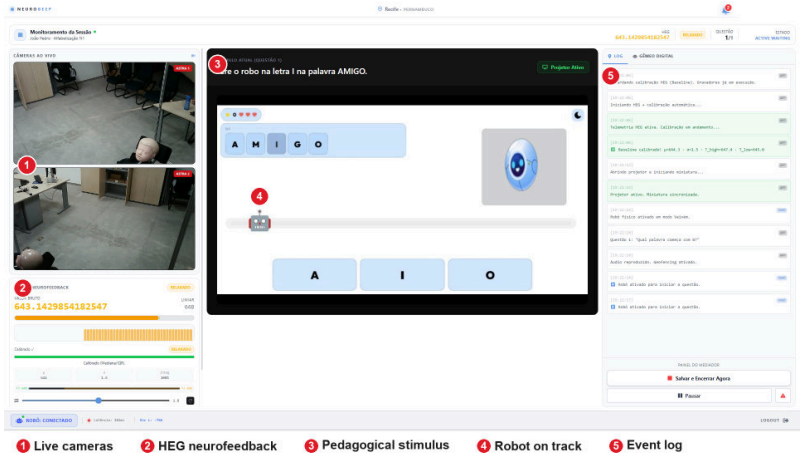

Fig. 6. Session-monitoring screen of the NeuroBeep APP during a running trial (preliminary deployment in Recife, Brazil; the interface is in Portuguese). The APP orchestrates the full closed loop: (1) live cameras of the environment, (2) the HEG neurofeedback panel with the raw value and threshold, (3) the current pedagogical stimulus (here, "stop the robot at the letter I in the word AMIGO"), (4) the robot moving along the track, and (5) the time-stamped event log. The displayed session uses illustrative data.

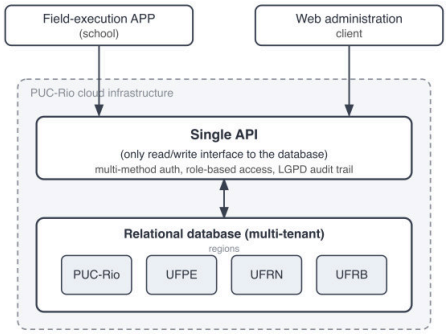

Fig. 7. Architecture of the cloud platform. A single API is the only read and write interface to the relational database, used both by the field-execution APP and by the web administration client. The multi-tenant database registers each executing institution as a region, under PUC-Rio infrastructure and LGPD governance.

***Abstract*—COVID-19 pandemic caused significant cardiorespiratory and functional repercussions, increasing the need for remote monitoring strategies during physiotherapeutic rehabilitation programs. In this context, wearable devices emerge as promising tools for the continuous acquisition of physiological parameters in a home environment. The objective of this study was to develop and evaluate the applicability of a wearable system for cardiorespiratory monitoring during physiotherapeutic exercises performed by individuals with post-COVID-19 sequelae. Therefore, a system composed of wearable modules was developed to acquire peripheral oxygen saturation (SpO_2), heart rate (HR), body temperature, and electrocardiogram (ECG), all integrated into a web platform, called SISMO-UFPE, via Wi-Fi communication. Ten individuals with post-COVID-19 sequelae participated in the study and underwent a protocol consisting of 13 physiotherapeutic exercises. The system allowed continuous acquisition of physiological signals during rehabilitation sessions, enabling real-time remote monitoring. Eighty percent of the participants presented cardiorespiratory responses classified as highly satisfactory and 20% as satisfactory. The results demonstrate the technical and clinical feasibility of the developed system for applications in telerehabilitation and remote patient monitoring.**

Keywords— Physiological monitoring; Wearable devices; Telerehabilitation; COVID-19; Cardiorespiratory assessment.

I. INTRODUCTION

The pandemic caused by SARS-CoV-2 represented one of the greatest health challenges of recent decades, resulting in millions of hospitalizations and a growing number of individuals with persistent post-acute sequelae [1]. Among the main clinical manifestations, persistent dyspnea, fatigue, exercise intolerance, and reduced functional capacity stand out, frequently demanding prolonged physiotherapeutic rehabilitation [1].

During exercise exertion, acute physiological shifts—such as increased myocardial oxygen demand, altered autonomic tone, dynamic changes in ventilation-perfusion matching, and transient peripheral desaturation—may occur. In post-COVID-19 patients who often present residual pulmonary lesions, altered vascular reactivity, or autonomic dysfunction, unmonitored physical exercise poses severe safety risks, including malignant arrhythmias, exertion-induced silent hypoxia, and abnormal pressor or thermal responses. Therefore, continuous and real-time monitoring of vital signs during physiotherapeutic sessions is clinically essential to titrate exercise intensity, assess therapeutic safety, prevent exertion-triggered cardiovascular events, and evaluate the efficacy of proposed rehabilitation interventions. [2][3]

During the pandemic, telehealth and telerehabilitation played a fundamental role in the continuity of care, enabling remote consultations and reducing risks related to patient exposure and displacement [4]. However, executing physiotherapeutic exercises outside the hospital environment requires mechanisms capable of ensuring clinical safety and continuous monitoring of physiological signals [4].

Despite recent advancements, current commercial off-the-shelf devices and existing wearable systems exhibit notable limitations when applied to remote physiotherapeutic rehabilitation: Most existing commercial wearables (e.g., fitness bands or standalone pulse oximeters) lack multi-parameter synchronization, providing fragmented data across different applications.[5] Many portable monitors suffer from high motion artifact sensitivity during dynamic motor tasks and lack clinical-grade ECG acquisition capable of detailed electrophysiological wave analysis.[6] Existing commercial

platforms rarely offer dedicated web interfaces that allow physiotherapists to monitor raw physiological signals in real-time while correlating them directly with specific exercise protocols.[7]

To overcome these limitations, this work introduces an integrated, low-cost multi-sensor wearable system specifically tailored for telerehabilitation. The novelty of this study lies in the simultaneous, synchronized wireless acquisition of multi-lead equivalent ECG, continuous SpO_2, heart rate, and surface body temperature integrated into a custom-designed web platform (SISMO-UFPE) that directly maps physiological responses to specific upper-limb, lower-limb, and respiratory exercise protocols in real time. Therefore, this work presents the development and application of a wearable system for cardiorespiratory monitoring during physiotherapeutic exercises performed by patients with post-COVID-19 sequelae [9].

II. MATERIALS AND METHODS

A. Study Design

This is a translational study involving the technological development, functional validation, and preliminary clinical application of a wearable system for remote cardiorespiratory monitoring. The study was approved by the Research Ethics Committee under opinion No. 5.135.351.

The developed system consisted of wearable modules capable of acquiring relevant physiological parameters during the execution of physiotherapeutic exercises, being positioned on the patient according to Fig. 1. The hardware specifications and acquisition settings are detailed below:

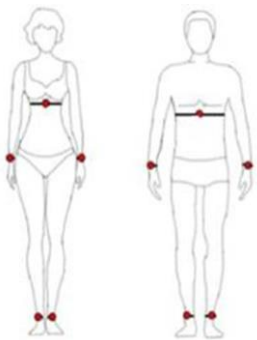

Fig. 1. Anatomical positioning of the ECG and SpO2 wearable sensors. Source: The authors, 2025.

The set was constituted by:

- Body Temperature Sensor: The AHT10 high-precision digital sensor module was used. The sensor was housed in a wearable module positioned on the participant's thoracic region, calibrated prior to data collection using a commercial digital clinical thermometer (Fig. 2A and 2B).
- ECG Acquisition Module: Developed using an INA126 instrumentation amplifier with a gain of 301, a passive high-pass filter with a cutoff frequency of 0.5 Hz (to eliminate baseline wander), and an active low-pass filter with a cutoff frequency of 100 Hz providing an additional 21.3 times amplification. Digitization was performed via the microcontroller's 12-bit A/D converter at a sampling rate of 500 Hz, utilizing pre-gelled disposable Ag/AgCl surface electrodes positioned in a modified chest lead configuration (Fig. 2C).
- Optical Sensor for SpO_2 and HR Acquisition: The MAX30102 module was used, which is an integrated pulse oximetry and heart rate monitor module based on photoplethysmography (PPG) technology sampled at 100 Hz (Fig. 2D).
- Microcontroller with Wireless Transmission: The ESP32-S3 MINI wireless module (Xtensa® dual-core 32-bit LX7 processor) transmitted data via 2.4 GHz Wi-Fi connectivity to the SISMO-UFPE web platform.
- The Post-COVID-19 Patient Physiotherapeutic Monitoring System (SISMO-UFPE) (Fig. 3) consists of a web platform developed for real-time storage, visualization, and analysis of physiological signals acquired during telerehabilitation sessions, allowing for secure storage of clinical and physiological information to support the physiotherapist's decision-making.

The acquired signals were converted to digital format and transmitted via Wi-Fi to a remote server, allowing for real-time monitoring by the physiotherapist.

B. Participants

Ten individuals with post-COVID-19 sequelae recruited by convenience participated in the study. Inclusion criteria encompassed patients with a confirmed COVID-19 diagnosis, presence of persistent post-acute cardiorespiratory symptoms (> 3 months post-infection), age ≥ 18 years, and preserved cognitive capacity to perform the proposed exercises. Excluded from the study were individuals presenting clinical instability, severe motor limitations precluding the execution of the protocol, or lack of internet access for communication with the platform.

Medical histories were reviewed to verify comorbidities. Systemic Arterial Hypertension (SAH), Diabetes Mellitus, and Heart Disease were diagnosed based on medical records

following standard clinical guidelines. Participant pharmacological regimens (e.g., antihypertensives, beta-blockers, oral hypoglycemics) were documented to account for potential pharmacological influences on heart rate and autonomic responses.

Fig. 3. Representative screens of the SISMO/UFPE web platform used for the acquisition, storage, visualization, and analysis of remotely collected physiological signals. Source: The authors, 2025.

C. Procedures & Exercise Protocol

The sessions occurred remotely, lasting on average between 30 and 50 minutes, three times a week. The participants underwent a structured protocol composed of 13 exercises distributed into three distinct categories designed to impose varying cardiorespiratory and physiological demands:

1. Respiratory Exercises: Static and low-movement exercises (e.g., fractional 3-time inspiration, diaphragmatic breathing) aimed at enhancing ventilatory capacity while generating minimal motion artifacts.
2. Motor Exercises for Upper Limbs: Dynamic resistance exercises (e.g., shoulder flexion and horizontal abduction with dumbbells, shoulder press) generating moderate metabolic demand and localized muscular activity.
3. Motor Exercises for Lower Limbs: Dynamic cyclic tasks (e.g., seated cycle ergometer pedaling, leg extensions) producing high systemic cardiorespiratory demands and higher mechanical movement.

Throughout the execution of the protocol, physiological signals were continuously acquired by the developed system.

D. Statistical Analyses

Data were analyzed using descriptive statistics, employing measures of central tendency and dispersion, reported as Mean ± Standard Deviation (Mean ± SD) along with minimum and maximum values for numerical variables, as well as absolute and relative frequencies to characterize the sample. Graphical analyses of the cardiorespiratory parameter signals obtained during the functional tasks were also conducted.

To evaluate signal consistency across repeated exercise sets, measurement reliability was estimated via Intraclass Correlation Coefficient ($ICC_{3,1}$) and Standard Error of Measurement (SEM) across baseline, peak exercise, and recovery phases.

III. Results

A. Sample Characterization

The sample was composed of 10 participants, of which 70% were male and 30% were female, with a mean age of 63.4 ± 5.2 years (age group between 60 and 69 years accounting for 70%). Among the observed comorbidities, systemic arterial hypertension (50%), diabetes mellitus (20%), and heart disease (10%) stood out (Tab. 1). Fifty percent of participants were actively receiving antihypertensive therapy. Sedentary lifestyle was considered a lifestyle habit rather than an associated clinical condition.

TABLE I. – Participant Characterization

Variable	**Results**
Male	70%
Female	30%
60–69 years	70%
Age (years) [Mean ± SD]	63.4 ± 5.2
SAH (Systemic Arterial Hypertension)	50%
Diabetes	20%
Heart Disease	10%
Sedentary	60%
Pharmacological Use (β-blockers / ACEi)	10% / 40%

B. Physiological Monitoring

The system allowed continuous acquisition of physiological signals during all sessions performed by the participants. The

ECG recordings showed sufficient quality for the identification of major cardiac electrophysiological components, including P waves, QRS complex, and T wave, at a 500 Hz sampling rate during the exercises (Fig. 3A and 3B). During lower-limb ergometer tasks, motion artifacts caused transient baseline fluctuations in < 4% of total signal duration, which were effectively filtered.

Quantitative mean values obtained during resting and exercise protocols were as follows:

Heart Rate (HR): Baseline resting HR was 71.2 ± 6.4 bpm, increasing to a peak during cycle ergometry of 108.5 ± 12.1 bpm.

Oxygen Saturation (SpO_2): Peripheral oxygen saturation signals remained within expected physiological limits averaging 97.1 ± 1.1% at rest and 95.8 ± 1.4% (range: 92%–99%) during peak exercise, demonstrating cardiorespiratory stability (Fig. 3C).

Body Temperature: Mean skin temperature remained stable at 36.4 ± 0.4 °C (range: 35.8 °C–37.1 °C) with no evidence of clinically relevant alterations (Fig. 3D).

Fig. 3. Physiological signals monitored and visualized on the SISMO/UFPE platform during the execution of the exercise protocol. (A) Electrocardiographic (ECG) recording in an expanded time window; (B) Electrocardiographic (ECG) recording in a continuous time scale; (C) Peripheral oxygen saturation (SpO_2) monitoring; and (D) Body temperature monitoring. Source: The authors, 2025.

System reliability across trial repetitions yielded an $ICC_{3,1}$ of 0.92 (95% CI: 0.85–0.96) for HR and 0.88 (95% CI: 0.79–0.94) for SpO_2, with SEM values of 2.1 bpm and 0.6% respectively, confirming adequate measurement reproducibility for telerehabilitation monitoring.

C. Global Assessment of Vital Signs

The analysis of hemodynamic responses demonstrated good tolerance to the exercise protocol, with 80% of participants classified as "highly satisfactory" and 20% as "satisfactory," with no records of "unsatisfactory" responses. The "highly satisfactory" classification was assigned to participants who maintained vital signs within normal limits throughout the activity, considering $SpO_2 \geq 95\%$, heart rate between 60 and 100 bpm at rest or an increase compatible with exercise intensity, and the absence of relevant symptoms. Participants classified as "satisfactory" presented only mild and transient physiological alterations, such as SpO_2 between 90% and 94% or slight heart rate elevation, with no need to interrupt the exercise. The "unsatisfactory" category would include individuals with $SpO_2 < 90\%$, significant cardiovascular alterations, or limiting symptoms. These results indicate hemodynamic stability and reinforce the safety and good tolerability of the applied protocol (Tab. 2).

TABLE II. – CLASSIFICATION OF VITAL SIGNS DURING THE PROTOCOL

Classification	Frequency
Highly satisfactory	80%
Satisfactory	20%
Unsatisfactory	0%

IV. DISCUSSION

Continuous monitoring of cardiorespiratory parameters represents an important tool to increase the safety of telerehabilitation, especially in elderly individuals and those with systemic arterial hypertension or heart diseases. The simultaneous monitoring of heart rate, peripheral oxygen saturation, body temperature, and electrocardiogram allows for early identification of physiological changes potentially related to physical exertion, facilitating immediate interventions by the physiotherapist and reducing risks during remote sessions. The results demonstrated that the developed wearable system was capable of performing continuous and remote monitoring of multiple cardiorespiratory parameters during home-based physiotherapy sessions.

Recent studies show significant progress in the development of wearable devices for remote monitoring of physiological parameters, albeit with different levels of integration between sensors and functionalities. The Withings ScanWatch, validated by Kirszenblat and Edouard [10], was developed primarily for non-invasive monitoring of peripheral oxygen saturation (SpO_2) using reflectance photoplethysmography on the wrist, in addition to heart rate, showing adequate clinical performance for detecting hypoxia and sleep-related breathing disorders during rest and sleep. The study by Liu et al. [11] utilized a continuous remote electrocardiogram (ECG) monitoring system to track patients' cardiac safety during the pandemic, allowing the identification of electrophysiological alterations and possible arrhythmias associated with drug treatment, without

incorporating additional sensors for respiratory or thermal monitoring.

The TELECOVID device, described by Baldinger et al.[12], employs an in-ear biosensor capable of continuously monitoring heart rate, peripheral oxygen saturation (SpO_2), body temperature, and respiratory rate, aimed at home monitoring of COVID-19 patients in isolation. In turn, the Respinos system, developed by Adiono et al. [13], consists of portable multiparameter equipment designed for remote monitoring of COVID-19 patients, integrating SpO_2, heart rate, respiratory rate, and body temperature, focusing on clinical screening and home follow-up.

In comparison, the system developed in this study stands out due to the simultaneous integration of electrocardiogram (ECG), peripheral oxygen saturation (SpO_2), heart rate, and body temperature into a specific platform for physiotherapeutic telerehabilitation (SISMO-UFPE), allowing continuous acquisition of signals during exercise execution, real-time transmission via Wi-Fi, and remote tracking by the physiotherapist, broadening its applicability for cardiorespiratory rehabilitation programs and home-based functional monitoring

From a Biomedical Engineering perspective, the integration of sensors, wireless communication, and a telemonitoring platform represents a potentially cost-effective solution due to the use of widely available commercial sensors, low-power microcontroller modules, and an open ESP32-based architecture, enabling home monitoring and tracking of patients with chronic diseases.

Limitations of this preliminary study include the small sample size (n=10) and the absence of a control group. Moreover, Wi-Fi transmission may limit the system's application in outdoor environments lacking network coverage. Future works plan to expand the sample and include clinical validation protocols compared to gold-standard hospital equipment.

V. CONCLUSIONS

The results demonstrate that the developed wearable system constitutes a promising tool for remote monitoring of patients with post-COVID-19 sequelae undergoing physiotherapeutic rehabilitation, contributing to greater clinical safety, real-time monitoring, and decision-making support in telerehabilitation programs. The continuous acquisition of ECG, heart rate, peripheral oxygen saturation, and body temperature allows real-time tracking of participants' physiological responses, highlighting its potential use in telerehabilitation programs and remote healthcare assistance. The obtained results reinforce the contribution of Biomedical Engineering to the development of technologies applied to healthcare, especially in scenarios demanding secure and efficient remote monitoring.

***Abstract*—This study aimed to develop and evaluate a digital system to support physical telerehabilitation by integrating active control of treadmill speed and incline with remote heart rate monitoring. The proposed system addresses the growing demand for technological solutions that enable the continuity of remote rehabilitation programs, particularly for individuals with mobility limitations and restricted access to specialized rehabilitation centers. The system was evaluated through a mixed-methods approach, including open-ended questionnaires administered to therapists (n = 13) and participants (n = 13), usability assessment using the System Usability Scale (SUS), and analysis of the agreement of the physiological data acquired. The results demonstrated high perceived usability (SUS = 95.19 ± 4.26) and strong agreement in physiological data transmission (mean absolute error = 0.41 bpm; session ICCs ranging from 0.972 to 0.999), confirming the integrity of the data acquisition and synchronization pipeline from a shared sensor source. Qualitatively, therapists and participants identified remote accessibility, perceived safety, and real-time interaction as relevant advantages, while suggesting automated clinical protocols and expanded monitoring as areas for improvement. These findings support the preliminary technical and usability feasibility of the proposed platform under controlled experimental conditions. Future work should focus on improving the user interface, expanding monitoring capabilities, and evaluating the system in more representative clinical and home-based settings.**

***Index Terms*—patient rehabilitation, teleoperation, remote patient monitoring, patient-therapist interaction, telerehabilitation**

I. Introduction

At least one-third of the world's population could benefit from physical or cognitive rehabilitation [1]. Musculoskeletal disorders represent one of the leading demands for rehabilitation, affecting approximately 1.71 billion people worldwide and often resulting in reduced mobility and impaired gait [2]. These conditions diminish individuals' independence and quality of life while imposing substantial financial and social burdens on patients, caregivers, and healthcare systems [3], [4]. Although physical rehabilitation programs can mitigate these impacts [5], access to such services remains limited, particularly for individuals living in rural areas or with low socioeconomic status, due to geographic and socioeconomic barriers [6].

In this context, telerehabilitation has emerged as an accessible alternative, enabling continuous care and greater patient independence through remote sessions [7], [8]. Within this modality, treadmills are particularly well suited because they require minimal space, provide a safe exercise environment, and allow intensity to be adjusted via speed and incline [9], [10]. However, extending this model to remote settings remains a technological challenge. Systems capable of remotely controlling treadmills are still scarce, and their integration with real-time heart rate (HR) monitoring is essential for the safe, personalized adjustment of exercise intensity based on the patient's physiological response [11], [12].

Beyond technological challenges, the limited collaboration between software developers and healthcare professionals has hindered the acceptance and adoption of new technologies in

clinical practice [13], [14]. Although telerehabilitation platforms are designed to support both patients and therapists, the perspectives of these end users remain underrepresented in the telehealth literature. Considering their needs is essential for developing clinically relevant and applicable technologies. Therefore, this study aimed to develop and evaluate a digital system to support physical telerehabilitation by integrating the remote control of treadmill speed and incline with synchronous HR monitoring. The main contribution of this work is the deployment and evaluation of a human-in-the-loop bidirectional framework that empowers therapists to actively modulate exercise intensity based on real-time physiological feedback. System evaluation included the assessment of usability and user experience from both therapists and participants, alongside an analysis of data transmission agreement.

II. Methodology

A. Participants

The study sample consisted of 26 participants in total, organized into 13 independent dyads. Each dyad was composed of one therapist (broadly defined as exercise and movement science professionals) and one exercising subject. The therapist group consisted primarily of Master's students in Physical Education, alongside Ph.D. holders and senior undergraduate students, representing a mix of academic and clinical experience levels. Initially, 15 potential subjects were screened using the Physical Activity Readiness Questionnaire (PAR-Q), a screening instrument used to identify potential health risks associated with participation in physical exercise [15]. Two individuals were excluded for not meeting the safety criteria, resulting in a final sample of 13 healthy adults (age: 22.0 ± 3.39 years).

B. System Description

The system architecture (Fig. 1) comprises four main software components: (1) a mobile application developed in Kotlin (Android SDK v2.2); (2) an InfluxDB (v2.7) time-series database; (3) a RESTful Application Programming Interface (API) implemented in Kotlin using the Spring Boot framework (v3.5.5); and (4) a therapist interface (Fig. 2). The RESTful API is hosted on an Amazon Web Services (AWS) Elastic Compute Cloud (EC2) instance, which provides a virtual cloud computing environment for deploying and running the system.

The mobile application runs on a tablet (Galaxy Tab S9 Ultra, Samsung, South Korea) and communicates via Bluetooth Low Energy (BLE) with a treadmill (TR5, Speedo, Brazil) and a heart rate monitor (H10, Polar, Finland). Communication with the treadmill is based on the Bluetooth Fitness Machine Service (FTMS) protocol.

The exercising participant is monitored using the Polar monitor, which provides heart rate (HR), electrocardiogram (ECG), and RR interval data. From the treadmill, the system acquires the actual speed (Vr), actual incline (Ir), and elapsed exercise time (ETr). These measurements are initially received as hexadecimal values and subsequently converted into floating-point format for processing.

Physiological and treadmill data are transmitted to the InfluxDB database in real time at the sampling rates provided by each device (approximately 1 Hz for the treadmill and 130 Hz for the heart rate monitor). The stored data can

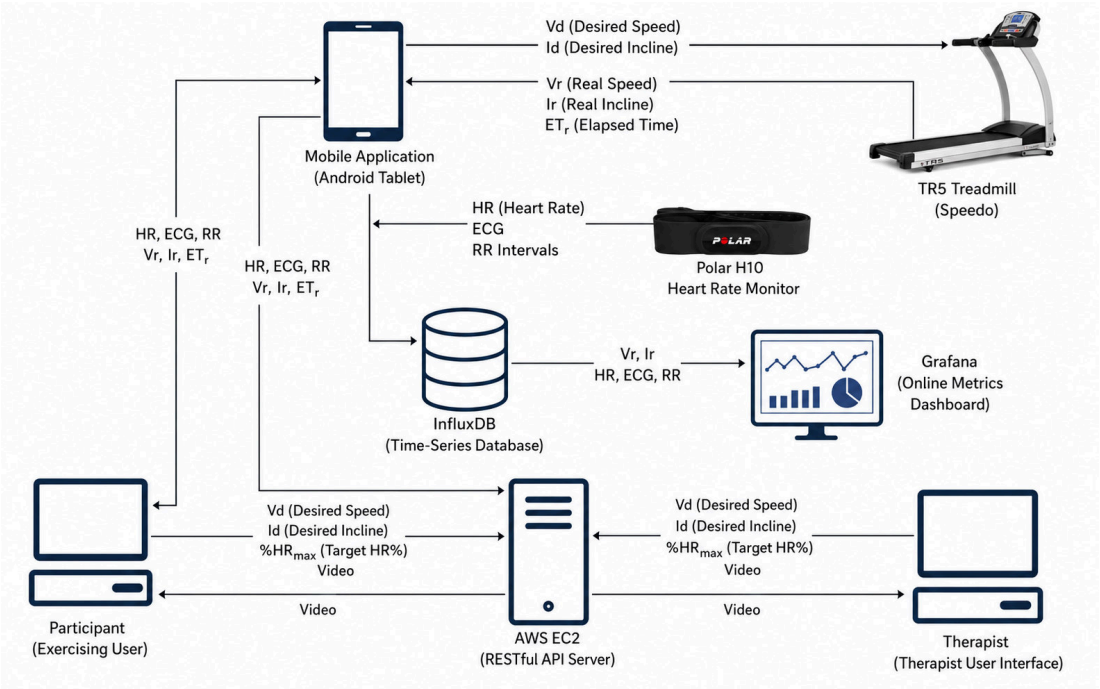

Fig. 1. Overall architecture of the bidirectional telerehabilitation system, illustrating the data flow between the local hardware, the cloud-based API, and the remote interfaces.

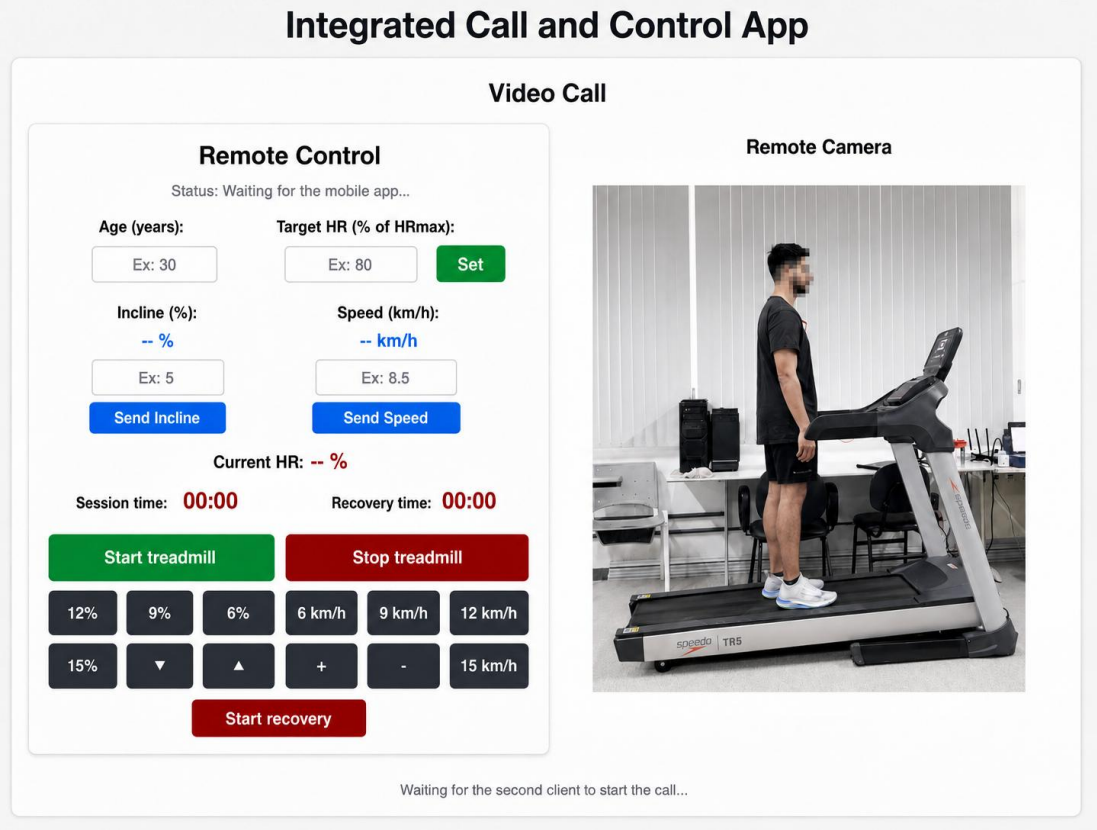

Fig. 2. Therapist user interface integrating synchronous video communication (right panel) with the human-in-the-loop bidirectional remote-control dashboard (left panel). The interface enables real-time monitoring of physiological variables, such as current HR percentage, and active adjustment of treadmill speed and incline.

be visualized using Grafana or exported as comma-separated values (.csv) files for offline analysis. Simultaneously, the mobile application communicates with the remote RESTful API to transmit the desired speed (Vd) and desired incline (Id) commands specified by the therapist to the treadmill.

The bidirectional communication architecture enables remote monitoring of the participant while allowing the therapist to adjust treadmill parameters in real time. The Therapist User Interface (TUI) provides controls for transmitting treadmill commands, configuring the target percentage of maximum heart rate (%HRmax), visualizing monitored variables (%HRmax, Vr, Ir, ETr, and recovery time (RTr)), and conducting video calls to support synchronous communication between the therapist and the participant. To align with general data protection regulations (e.g., LGPD), the InfluxDB database stores only anonymized session data without personally identifiable information (PII). Furthermore, all remote communication, including video streaming and RESTful API requests, is encrypted via HTTPS. Comprehensive access control and authentication mechanisms are slated for future clinical deployment.

C. Experimental Design and Procedures

The experimental protocol was designed as a technical and usability evaluation of the digital platform. The study was approved by the Research Ethics Committee of the Federal University of Espírito Santo (approval no. 6,294,101; CAAE: 70158523.2.0000.5542), and all participants provided written informed consent before data collection. The experimental protocol consisted of a telerehabilitation session conducted using the proposed platform. During the session, HR and RR interval data acquired from the Polar H10 heart rate monitor were simultaneously recorded by both the proposed system and the manufacturer's application (Polar Flow).

The therapist remained in a separate building from the participant and interacted exclusively through the video call integrated into the platform.

Before the experimental session, each therapist completed a 10-minute familiarization session with the TUI, including training on treadmill control commands (speed and incline adjustment), physiological data monitoring, and video-based communication.

1) Treadmill Exercise Protocol: To simulate an exercise session with progressively increasing intensity, a submaximal protocol adapted from the Bruce protocol [16] was employed. The original protocol consists of progressive stages of treadmill speed and incline, starting at 2.7 km/h with a 10% incline and increasing by 1.3 km/h in speed and 2% in incline every 3 minutes until volitional exhaustion.

The Bruce protocol was selected because its standardized

progression allows the evaluation of multiple remote treadmill control commands throughout the exercise session. The protocol was adapted to ensure participant safety while assessing the functionality of the proposed system under controlled submaximal conditions. The target exercise intensity was defined as 70% of the estimated maximum HR (%HRmax), calculated using (1) [17]. The target HR was subsequently calculated using (2), where A denotes the participant's age in years.

$$HR_{\max} = 208 - 0.7A \tag{1}$$

$$HR_{\text{target}} = 0.70\, HR_{\max} \tag{2}$$

Before the session began, the therapist configured the participant's target %HRmax. The session consisted of 3-minute stages with progressive increases in treadmill speed and incline, as detailed in Table I.

TABLE I
SUBMAXIMAL EXERCISE PROTOCOL ADAPTED FROM THE BRUCE PROTOCOL

Stage	Incline (%)	Speed (km/h)
1	5	2.7
2	7	4.0
3	9	5.3
4	11	6.6
5	13	7.9
6	15	9.2

When the participant reached the target %HRmax, a visual alert was displayed on the Therapist User Interface (TUI), prompting the therapist to manually activate the recovery mode via a dedicated button. Once activated by the therapist, the system assumed control of the treadmill and executed a 3-minute cool-down period by linearly reducing the maximum speed and incline achieved during exercise in six equal steps at 30-second intervals until the treadmill came to a complete stop. For safety purposes, a researcher remained present in the room with the exercising participant to act as a local supervisor and engage the treadmill's physical emergency stop if necessary. Furthermore, the system was designed to halt commands in the event of severe network instability or Bluetooth disconnection.

2) Procedures: Immediately after the experimental session, data regarding system usability and user perceptions were collected [18]. First, therapists completed the System Usability Scale (SUS), a validated questionnaire that assesses perceived system usability on a scale ranging from 0 (worst imaginable) to 100 (best imaginable) [19], [20]. Finally, therapists and participants individually answered the following open-ended questions:

1) What do you consider the main advantage of using this system?

2) Which additional functionality would have been useful but was not available in the system?

3) In your opinion, what could be improved to facilitate or enhance the use of the system?

D. Data Analysis

Responses to the SUS questionnaires were analyzed descriptively. SUS scores were calculated according to the standard scoring procedure [19] and summarized using descriptive statistics (mean ± standard deviation). The overall mean SUS score was subsequently interpreted according to established adjective rating categories [20].

Responses to the open-ended questions provided by therapists and participants were transcribed, organized, and subjected to a descriptive thematic analysis. Initially, the responses were reviewed by two independent researchers to identify recurring ideas and meaningful units. Any divergences in thematic categorization were resolved through consensus discussions. Similar responses were subsequently grouped into thematic categories representing the main perceptions regarding the proposed system, including perceived advantages, desired functionalities, and suggested improvements. The identified themes were then summarized descriptively and used to support the interpretation of the quantitative findings [18], [21].

Heart rate (HR) recordings obtained throughout the experimental session from both the proposed system and the manufacturer's application (Polar Flow) were exported as .csv files, synchronized, and paired for direct comparison. Using the NumPy and Pandas libraries in Python, the mean absolute error (MAE), mean absolute percentage error (MAPE), Pearson's correlation coefficient, and the intraclass correlation coefficient (ICC) were calculated to quantify the measurement error, linear association, and agreement between the two systems. Prior to comparison, the data streams from both sources were synchronized using timestamp alignment and resampled at 1 Hz. The ICC was computed based on a two-way mixed-effects model for absolute agreement. To determine the overall system reliability (Global ICC), the time-series data from all 13 sessions were concatenated into a single pooled dataset prior to computation, thereby capturing the full variance across all participants.

III. RESULTS

Importantly, all 13 sessions were completed successfully, and no adverse events or unexpected technical failures compromising user safety occurred during the experimental protocol. On average, the exercising subjects reached the 70% HRmax target at the beginning of Stage 4 (approximately 9 to 10 minutes of active exercise). For two participants, the 70% HRmax target was reached during Stage 3, whereas one participant reached the target during Stage 5. Including the 3-minute automated cool-down period, the total active session duration averaged 12 to 13 minutes per dyad.

A. Usability Evaluation and System Perception

The usability evaluation conducted with the therapist group revealed high perceived usability of the proposed system. The mean SUS score was 95.19 ± 4.26, corresponding to the "best imaginable" adjective category. Similarly, the qualitative analysis of the open-ended responses identified ease of use, remote

accessibility, and real-time monitoring as important perceived strengths of the proposed system. Suggestions for improving the system, obtained from the second and third open-ended questions, were grouped into four thematic categories, which are summarized in Table II. To illustrate these themes, one therapist [T4] emphasized the need for complementary clinical tools: *"I would include a subjective perceived exertion scale [Borg] and an annotation field to record potential patient complaints or pain."* Another therapist [T12] highlighted the desire for enhanced automation and clearer visual feedback: *"It would be helpful to have pre-programmed tests with automatic increments, and to make it visually clearer when the recovery phase has been triggered."*

The qualitative analysis of the participants' responses to the first open-ended question identified the possibility of receiving rehabilitation remotely as an important perceived advantage of the system. Illustrating the sense of safety reported by the participants, one participant [P8] noted: *"Even performing the experiment alone, I felt well-monitored knowing the therapist was talking to me remotely."* Another participant [P5] emphasized the potential to overcome geographic barriers: *"The specialist can control physiological variables and the treadmill remotely, allowing me to continue my treatment even if I move to another city or country."* Participants also highlighted the convenience of performing rehabilitation sessions at home and the integration of HR monitoring, which contributed to their reported sense of safety during exercise. Suggestions for improving the proposed system were grouped into three thematic categories and are summarized in Table III.

B. Agreement of Physiological Data Acquisition

Session-specific agreement metrics are summarized in Table IV.

TABLE IV
AGREEMENT AND RELIABILITY METRICS BY PARTICIPANT SESSION ($n = 13$)

Session	MAE [bpm]	MAPE [%]	Correlation	ICC
1	0.27	0.29	0.999	0.999
2	0.31	0.28	0.999	0.999
3	0.60	0.59	0.985	0.985
4	0.43	0.41	0.996	0.996
5	0.26	0.27	0.999	0.999
6	0.72	0.60	0.972	0.972
7	0.25	0.22	0.999	0.999
8	0.35	0.34	0.997	0.997
9	0.50	0.48	0.992	0.992
10	0.38	0.33	0.998	0.998
11	0.39	0.36	0.998	0.998
12	0.43	0.45	0.996	0.996
13	0.61	0.52	0.982	0.982

The agreement of the heart rate (HR) measurements was evaluated by comparing the data acquired by the proposed platform with those recorded by the manufacturer's application (Polar Flow), both originating from the same Polar H10 sensor. This comparison serves to validate the integrity of the data transmission and synchronization pipeline rather than independent physiological accuracy. The proposed system achieved a mean absolute error (MAE) of 0.41 bpm and a mean absolute percentage error (MAPE) of 0.39%. Pearson's correlation coefficient between the measurements was 0.998,

TABLE II
THEMATIC ANALYSIS OF THERAPISTS' QUALITATIVE FEEDBACK

Analysis Dimension	Suggested Improvements
Interface design and information display	Therapists emphasized the need to improve the clarity and visibility of physiological variables and treadmill parameters (e.g., speed, incline, age, and heart rate), as well as recovery controls. They also suggested improving the participant's video display by providing more suitable viewing angles to facilitate clinical observation during exercise.
System functionality	Therapists highlighted the need for features that increase autonomy and safety during exercise sessions, including programmable automated protocols for speed and incline progression and simplified manual controls, with greater emphasis on the emergency stop function.
Clinical monitoring tools	Therapists identified the need to expand the system's clinical assessment capabilities by incorporating measures of perceived exertion, pain, emotional state, and exercise readiness, together with fields for recording participant-reported events. They also suggested automatic logging of physiological variables and data export functionality to support external analyses.
User support	Therapists emphasized the importance of resources that facilitate familiarization with the system, such as video tutorials and instructional materials that guide therapists through the execution of exercise sessions.

TABLE III
THEMATIC ANALYSIS OF PARTICIPANTS' QUALITATIVE FEEDBACK

Analysis Dimension	Suggested Improvements
Communication and interaction with the therapist	Participants emphasized the need for greater visual proximity and real-time interaction with the therapist. Suggested improvements included optimizing camera positioning and providing additional viewing options to strengthen the sense of presence and facilitate understanding of the therapist's instructions.
User interface and visual feedback	Participants highlighted the importance of improving the clarity of the user interface by incorporating visual indicators of exercise duration and stage transitions, previewing upcoming speed and incline adjustments, and enhancing the visibility of monitored physiological variables. Additional visual elements were also suggested to increase engagement during the rehabilitation session.
Physiological monitoring	Participants expressed interest in expanding the physiological information provided by the system, including metrics such as oxygen consumption and movement quality. They also suggested exploring monitoring alternatives that reduce or eliminate the need for wearable sensors.

while the ICC was 0.9982, indicating excellent reliability (ICC $\geq$ 0.90) [22].

IV. Discussion

This section discusses the study's findings in light of the existing literature, addressing the two primary axes of the investigation. First, the usability and user experience of the platform are analyzed based on the SUS scores and the qualitative interpretation of the feedback provided by therapists and participants. Subsequently, the results regarding the technical validation of the system's reliability in HR data transmission are examined by comparing its performance against the manufacturer's application. Finally, the practical implications of these findings, along with the study's limitations and directions for future research, are explored.

A. Usability and User Perception

The findings of this study support the operational viability of a bidirectional telerehabilitation system that combines high perceived usability with high-fidelity heart-rate data acquisition. The observed SUS score (95.19 ± 4.26), which falls within the "best imaginable" adjective category [20], indicates very favorable perceived usability among therapists after the standardized familiarization period. This is particularly relevant in telerehabilitation, where technological complexity and poorly designed interfaces have been identified as barriers to clinical adoption [13], [23]. In this context, the present findings indicate that the proposed interface was perceived as highly usable under the evaluated conditions. However, given the relatively small sample and controlled experimental setting, these results should be interpreted as preliminary and should not be generalized to broader clinical populations or practice settings.

The descriptive qualitative analysis complements the quantitative SUS findings by providing additional insight into potential improvements to the user experience. As presented in Table II, the qualitative themes highlight the necessity for improved layout clarity, automated clinical protocols (e.g., integrated timers, pre-programmed submaximal tests, and automated recovery transitions), complementary clinical assessment tools (e.g., Borg Rating of Perceived Exertion scale and standardized clinical reporting), and structured user support (e.g., video tutorials). These findings align with recent telehealth literature emphasizing that therapists require systems that not only control physical hardware but also automate routine clinical tasks to reduce cognitive load during remote supervision [11], [14].

Similarly, the participant feedback summarized in Table III reinforces the psychological and technical requirements of remote exercise. Participants emphasized the need for continuous visual proximity with the specialist to maintain a sense of clinical presence and safety, a well-documented success factor in remote patient monitoring systems [8]. Furthermore, their requests for predictive interface cues regarding speed and incline transitions, alongside an interest in advanced physiological metrics (e.g., estimated maximum oxygen consumption and motion analysis without additional wearable sensors), reflect a growing patient expectation for interactive, comprehensive, and non-intrusive digital health platforms. Collectively, these qualitative insights provide a valuable roadmap for future system iterations, aiming to transition the platform from merely functional to fully tailored for clinical practice.

B. Agreement of Physiological Data

Beyond interface usability, the clinical viability of a remote exercise platform relies fundamentally on the reliability of its data transmission, as physiological consistency dictates therapeutic decision-making. The comparison between the proposed platform and the manufacturer's application revealed exceptionally low discrepancy, a near-perfect linear correlation, and elevated reliability across all experimental sessions (see Table IV). Since both data streams originate from the exact same hardware source, these metrics are inherently expected to be nearly identical, and any minor differences observed are likely attributable to synchronization artifacts. Ultimately, this validation step primarily serves to confirm that the platform's data acquisition and transmission pipelines function correctly. These results indicate that the proposed platform tracks real-time HR variations with high fidelity, enabling timely interventions, such as triggering safety recovery modes, and logging exercise load responses.

Even the lowest reliability observed in an individual session (ICC $= 0.9720$) remained well above the threshold for excellent clinical agreement [22]. This high degree of agreement is critical for human-in-the-loop telerehabilitation systems, where latency or signal inaccuracies can compromise patient safety or lead to inappropriate treadmill speed and incline adjustments [12]. Nevertheless, it is important to emphasize that these metrics reflect a specific hardware configuration (treadmill and HR monitor models) operating within a controlled environment. Consequently, the system's performance must be further validated under real-world conditions, particularly concerning potential Bluetooth signal interference and packet loss, as well as among diverse clinical populations.

C. Practical Implications, Limitations, and Future Work

The proposed architecture addresses a technological gap in the current telerehabilitation literature. While previous studies have demonstrated the use of video-based physiotherapy and remote physiological monitoring [8], [11], many existing platforms emphasize unidirectional monitoring workflows, requiring therapists to verbally instruct patients to manually adjust their own exercise equipment [12]. In contrast, the present study introduces a bidirectional, human-in-the-loop framework. By coupling real-time physiological telemetry (e.g., synchronous HR) with active hardware actuation (treadmill speed and incline control), the system enables therapists to actively modulate exercise intensity remotely, approximating the therapist-mediated control available in supervised in-person settings. The combination of high perceived usability and high agreement between the HR acquisition pathways supports the platform's potential to facilitate remote care through structured

exercise protocols, %HRmax-based alerts, and automated recovery routines. From a clinical engineering perspective, the qualitative feedback (Tables II and III) delineates clear developmental priorities: implementing visual adjustment previews, enhancing transition clarity, and integrating subjective clinical assessment scales. Implementing these improvements may further enhance the system's technological maturity and support subsequent evaluation in clinical settings.

However, the scope and limitations of the present study must be properly considered. The primary constraints include the relatively small sample size; the use of healthy young adults rather than the target population of individuals with musculoskeletal or cardiopulmonary limitations; the use of a single hardware configuration (treadmill and HR sensor); testing within a controlled laboratory environment; the absence of functional clinical outcomes, longitudinal adherence tracking, and cost-effectiveness analyses; and the lack of quantitative network-performance metrics (e.g., command latency, packet loss, and command execution success rates). While these methodological choices were appropriate for an initial technical and usability evaluation, the generalizability of the present findings to broader clinical contexts remains limited.

Future research should extend the evaluation of the platform beyond the laboratory to assess its technical performance, feasibility, and safety in more representative clinical and home-based environments. Subsequent studies should include older adults, individuals with varying levels of familiarity with digital technologies, and patients with musculoskeletal or cardiopulmonary conditions. Transitioning from controlled laboratory settings to real-world environments will also require systematic evaluation of operational robustness, including Bluetooth signal variability, communication latency, packet loss, and environmental interference, together with diagnostic logging of communication failures.

Beyond technical robustness, it is vital that research moves toward evaluating the platform's long-term clinical impact. Prospective studies are needed to quantify longitudinal patient adherence, safety profiles, and functional recovery markers, as well as to investigate how the user experience evolves over extended rehabilitation cycles. This transition will be supported by ongoing product evolution, integrating the user-centered refinements identified in this study—such as protocol automation, visual transition previews, and the integration of standardized clinical tools like the Borg scale.

Finally, for the system to achieve its full potential in clinical practice, future development will focus on interoperability and auditing. Developing standardized data export protocols and comprehensive command-execution logs will be essential to facilitate seamless integration with Electronic Health Records (EHRs) and align the platform with the rigorous quality assurance standards required for professional healthcare deployment.

V. Conclusion

The bidirectional telerehabilitation platform developed in this study demonstrated high perceived usability and preliminary technical viability for synchronous physical therapy. Empirical results confirmed the integrity of real-time heart rate data transmission from a shared sensor source and the perceived usability of the interface for therapists. Importantly, 13 independent sessions were successfully completed without adverse events, demonstrating that therapists could effectively utilize the remote control framework to actively modulate exercise intensity.

While these findings are promising, the study evaluates a first-generation prototype in a controlled environment with healthy participants. Clinical safety, network performance under unstable conditions, and application in target patient populations require specific future studies. Ultimately, this work provides foundational evidence for a bidirectional remote control framework, offering a technological step toward more accessible rehabilitation services.

***Abstract*—Musculoskeletal Disorders (MSDs), including Work-Related Musculoskeletal Disorders (WMSDs) and Adolescent Idiopathic Scoliosis (AIS), represent a public health concern with a strong functional impact. Postural self-correction strategies utilizing biofeedback represent a promising approach to assist in the reduction of biomechanical overload. This study proposes the development and preliminary technical evaluation of a low-cost wearable system focused on the continuous monitoring of lateral trunk inclination (Z-axis) and real-time vibrotactile biofeedback. The architecture comprises two MPU-6500 IMUs and an Arduino Nano, utilizing the Digital Motion Processor (DMP) for iterative calibration and sensor fusion into quaternions that trigger directional alerts. A preliminary static assay identified a drift of 0.14 degrees/min in the yaw axis, while extended assessments of up to 240 minutes quantified a consistent linear accumulation of 0.27 degrees/min. This drift was mitigated by a linear temporal compensation algorithm embedded in the firmware, ensuring long-term stability. During dynamic validation against Kinovea, the system demonstrated a strong correlation (r = 0.90; R2 = 0.81), a mean absolute error of 0.61 degrees, an RMSE of 0.69 degrees, and a bias of -0.48 degrees via Bland-Altman analysis. The results confirm adequate performance for postural tracking, establishing a promising and low-cost solution to promote active self-correction, with future improvements aimed at miniaturization and clinical validation.**

***Index Terms*—Biofeedback, postural monitoring, ergonomics, scoliosis, inertial sensors.**

I. Introduction

According to the World Health Organization (WHO), Musculoskeletal Disorders (MSDs) encompass over 150 conditions affecting the locomotor system, including spinal conditions such as scoliosis, kyphosis, and lordosis, as well as Work-Related Musculoskeletal Disorders (WMSDs), frequently associated with repetitive movements [1], [2]. It is estimated that MSDs affect approximately 1.71 billion people worldwide, regardless of age, sex, or sociodemographic status, potentially causing temporary or permanent functional limitations and reducing social participation [3]–[5].

MSDs can alter body alignment and modify the distribution of external forces and gravity, leading to muscular compensations that result in excessive shortening or lengthening of muscles. This process reduces the body's mechanical efficiency and increases the overload on joints and intervertebral discs, favoring the onset of chronic pain, premature wear, and various postural alterations such as hyperlordosis, hyperkyphosis, scoliosis, and gait abnormalities [6]. Among these conditions, Adolescent Idiopathic Scoliosis (AIS) stands out; it is a three-dimensional structural deformity defined by the Scoliosis Research Society (SRS) as a structured lateral curvature of the spine equal to or greater than 10° by the Cobb angle, of unknown etiology, with onset between 10 and 18 years of age [7]–[9].

Consequently, MSDs have significant repercussions on quality of life, functional capacity, and costs for healthcare systems and companies, especially due to occupational absences. These conditions can affect workers across various roles and sectors, such as executives and taxi drivers who remain in the same

position for extended periods, factory workers exposed to repetitive movements or the handling of suspended loads, and nursing professionals subjected to long shifts [10], [11].

Treatments for MSDs vary according to the affected locomotor structure and the epidemiological characteristics of each condition. For WMSDs, management is predominantly conservative, based on ergonomic measures, postural correction, regular breaks, and the reorganization of work tasks [6]. For AIS, treatment includes specific physiotherapeutic exercises and, for curvatures between 20° and 45°, the use of orthopedic braces, with surgery indicated for more severe cases [9], [10]. Despite the specificities of each approach, postural self-correction constitutes a common and fundamental strategy in MSD management, as it promotes biomechanical alignment and reduces overload on soft tissues and joints [12]. This process can be enhanced by real-time biofeedback, which increases body awareness and encourages active postural adjustments during functional and occupational activities [13], [14].

As a strategy for implementing postural self-correction, wearable technologies and electromyographic monitoring methods have been shown to significantly reduce ergonomic risks, enabling individuals to minimize chronic muscle tension and prevent the aggravation of painful conditions through constant postural vigilance [13]–[15]. This approach is grounded in principles of biomechanics and motor control, which explain how the body perceives and corrects postural deviations in response to received stimuli.

In this context, motor learning and postural re-education depend on the nervous system's capacity to process sensory stimuli and dynamically adjust body alignment [7]. Thus, vibrotactile biofeedback can serve as a real-time haptic stimulation tool capable of promoting active self-correction, one of the pillars of physiotherapeutic approaches such as the Schroth Method. Studies demonstrate that biofeedback improves motor control, particularly in individuals with postural instability, provided that the stimuli are subtle and low-intensity, and function as reminders to encourage postural adjustments without causing sensory fatigue or discomfort [16]. Furthermore, strategies based on controlling lateral trunk inclination guided by real-time biofeedback have been validated in biomechanical literature for motor retraining and postural adjustment in the frontal plane [17], [18], reinforcing the relevance of continuously monitoring this kinematic parameter during the postural re-education process.

Although optical motion capture systems, such as Qualisys, are considered the gold standard for postural assessment, their high cost and the need for laboratory environments limit their application in continuous monitoring. Alternatively, Inertial Measurement Units (IMUs) can estimate trunk orientation in real-time using accelerometers and gyroscopes, making postural tracking more accessible and applicable to everyday activities. Combined with biofeedback, these technologies facilitate postural self-correction, promoting greater body awareness, reducing muscle fatigue, and preventing WMSDs. In this context, this study proposes the development of a low-cost wearable system based on IMUs and real-time vibrotactile biofeedback. This paper presents a preliminary technical validation focused strictly on tracking lateral trunk inclination (Z-axis). Establishing robust tracking accuracy for this specific axis provides an essential technological foundation for future clinical trials, which will evaluate the system's true efficacy in promoting active postural self-correction to prevent musculoskeletal disorders.

II. Methodology

The methodology proposed for the development and validation of the wearable postural monitoring system was structured into seven consecutive stages: (A) system architecture and signal processing; (B) iterative calibration algorithm and quaternion fusion; (C) biofeedback and postural signaling; (D) anatomical positioning and mechanical fixation protocol; (E) static stability assay (drift); (F) dynamic kinematic validation protocol; and (G) statistical analysis.

A. System Architecture and Signal Processing

The developed postural monitoring system prototype is based on inertial kinematics. The hardware consists of two low-cost Inertial Measurement Units (IMUs), model MPU-6500 (InvenSense Inc.), integrated with an ATmega328P microcontroller (Arduino Nano). Communication between the sensors and the microcontroller is performed via a shared I^2C bus, configured to operate in Fast Mode (400 kHz). To enable simultaneous reading of both devices without addressing conflicts, the AD0 logic selection pin was used. The sensor corresponding to the left scapula was configured with the address 0x68 (AD0 connected to 3.3V), while the sensor positioned on the right scapula was assigned the address 0x69 (AD0 pulled low - GND).

Given the mathematical processing limitations of the 8-bit microcontroller and to reduce computational delay, we opted to use the native Digital Motion Processor (DMP) integrated into the IMUs. The DMP's native sensor fusion provides spatial orientation directly in unit quaternions ($q = [w, x, y, z]$), eliminating static integration errors and occurrences of mathematical singularities (gimbal lock). To access this functionality, the firmware utilizes the open-source `MPU6050_6Axis_MotionApps20` library integrated into the I2Cdev architecture [19], acting as a Hardware Abstraction Layer (HAL) for extracting packets from the DMP's FIFO buffer. Complementing this layer, a strict 3 ms timeout was implemented for I^2C transactions, alongside an asynchronous routine to manage buffers and drain the FIFOs independently, preventing permanent bus lockups caused by transmission failures and avoiding buffer overflows during rapid movements.

B. Iterative Calibration Algorithm and Quaternion Fusion

To mitigate the static offset errors characteristic of low-cost MEMS sensors, an iterative calibration algorithm was implemented upon initialization, consisting of 6 consecutive moving average filtering cycles over a block of 500 static samples (with a 3 ms sampling interval). At each iteration,

the system quantifies the remaining scalar residual from the previous cycle and uses it to incrementally correct the IMU's internal offset registers. Specifically for the MPU-6500 accelerometer, the least significant bit (Bit 0) of the offset register functions as an internal hardware flag that must be preserved to avoid reading corruption. Therefore, a bitwise masking operation was implemented for the cumulative adjustments, as demonstrated in (1):

$$\text{Off}_{\text{new}} = \left[\left(\text{Off}_{\text{old}} - \frac{\text{Bias}_{\text{res}}}{k}\right) \wedge \sim 1\right] \vee (\text{Off}_{\text{old}} \wedge 1) \quad (1)$$

where $\wedge$ denotes the bitwise AND operator, $\vee$ is the bitwise OR, $\sim$ is the bitwise NOT, and the scale factor k is defined according to the chip manufacturer's register resolution guidelines [20]. Following calibration, the algorithm waits an additional 8 seconds, discarding the vectors generated during this interval to mitigate initial drift effects.

After stabilization, the neutral posture reference is established in an upright standing posture: upon triggering an external mechanical button (pin 4), the firmware calculates the arithmetic mean and geometric renormalization of 30 consecutive quaternion packets, establishing the reference quaternions for each sensor (q_{RefL} and q_{RefR}). During continuous monitoring, each new rotation (q_{Current}) is converted into relative deviation quaternions (q_δ) using the Hamilton product with the conjugate of the reference quaternion:

$$q_\delta = q_{\text{Ref}}^{-1} \otimes q_{\text{Current}} \quad \text{where} \quad q_{\text{Ref}}^{-1} = \text{conj}(q_{\text{Ref}}) \quad (2)$$

From q_δ, the yaw Euler angle (rotation around the Z-axis) is extracted, which, in the present system, represents the lateral inclination of each scapula in the frontal plane. Based on this angle, two postural monitoring parameters are continuously calculated: the lateral scapular asymmetry given by (3), and the global trunk inclination, given by (4):

$$\alpha = \theta_L - \theta_R \quad (3)$$

$$\theta_{\text{global}} = \frac{\theta_L + \theta_R}{2} \quad (4)$$

The variable θ_{global} was adopted as the primary comparative variable in the validation assays described in Section II-F, as it represents the synchronous lateral displacement of the thoracic block and avoids false negatives when both sensors tilt together in the same direction, a condition in which asymmetry (α) approaches zero.

C. Biofeedback and Postural Signaling

The firmware employs two independent postural alert thresholds: one for asymmetry ($|\alpha| > 4.0°$) and one for global inclination ($|\theta_{\text{global}}| > 6.0°$), the latter designed to capture scenarios where both shoulders lean simultaneously in the same direction. The prototype physically features a pair of vibrotactile microactuators. In the developed firmware version, a threshold violation triggers a signal in the serial monitor and activates the actuator corresponding to the direction of the deviation. For directional mapping, positive values on the local Z-axis were associated with leftward inclinations, while negative values were associated with rightward inclinations.

The algorithm was structured so that the initial motor activation occurs ipsilateral to the inclination. Upon detecting a threshold violation, three vibration pulses lasting 200 ms each are emitted, separated by 0.5 s intervals. If the improper posture persists, the cycle is repeated every 5 s, continuously re-evaluating the inclination direction at the beginning of each cycle to allow dynamic correction if the direction of the deviation reverses. Additionally, the algorithm monitors postural return in real-time, immediately interrupting the vibratory signal as soon as the angles return to the established tolerance zone.

It should be noted that the angular threshold values and temporal intervals used in this stage were initially defined to assess the prototype's functional viability, following a common approach in early investigations of biofeedback systems aimed at trunk postural adjustment [17]. The definitive and individualized parameterization will depend on factors to be investigated in future trials, including the determination of the optimal inclination threshold, as well as the intensity and exposure time to vibration to prevent sensory adaptation.

Finally, the definitive logic for tactile feedback activation remains open. Although findings by Lee et al. [21] demonstrate that proprioceptive stimulation induces a non-volitional postural shift in the direction of the stimulus (suggesting the use of contralateral feedback to induce a compensatory response), the literature indicates divergences between contralateral and ipsilateral approaches regarding learning rates and the cognitive demand imposed on the central nervous system [27], [28]. Therefore, the final device activation logic will be defined after comparative experimental testing with volunteers.

D. Anatomical Positioning and Fixation Protocol

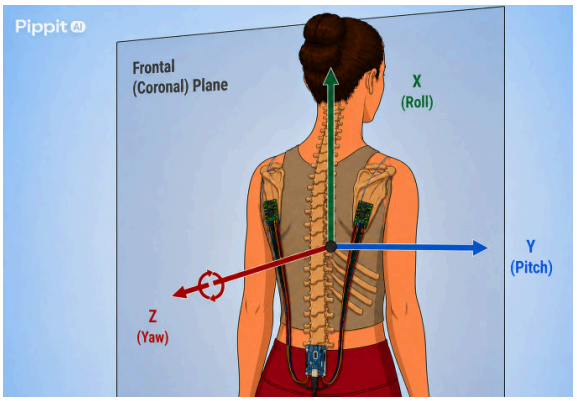

Fig. 1. Sensor mounting and referential axes. Illustration generated via Pippit AI and graphically edited using OpenAI [25].

The positioning of the sensors and kinematic markers was based on the International Society of Biomechanics (ISB) guidelines applied to the scapular complex [22]. The kinematic mapping employed two primary reference points, located

bilaterally at the inferior angles of the scapulae, serving as the placement site for the two IMUs. Complementary reflective markers were placed on the superior scapular angles as auxiliary visual guides for video analysis.

To enable sensor fixation without compromising the volunteer's mobility, the IMUs were attached parallel to the scapula, meaning the sensors were rotated relative to the standard reference frame (z-axis pointing downward). In the adopted assembly, illustrated in Fig. 1, the Z-axis was perpendicular to the frontal plane. This modification justifies the use of the yaw axis to record lateral trunk inclination, as presented in Section II-B. To minimize movement artifacts caused by soft tissue sliding during motion, the sensors were placed over a light elastic compression vest (sports bra) and secured with adhesive tape. The Arduino Nano module was centrally positioned in the lumbar region to allow symmetrical and safe cable routing between the two sensors.

E. Static Stability Assay (Drift)

Initially, a static stability assay was conducted to estimate the short-term firmware temporal drift rate in the absence of any real motion component. The system remained rigidly fixed to a flat, horizontal, and leveled surface under controlled room-temperature conditions for 15 minutes. This preliminary test, performed in duplicate, identified an average drift rate of $0.14^\circ/\text{min}$ in the yaw axis.

To investigate the integration drift inherent to the Z-axis during prolonged use and establish a definitive software-based solution, extended long-duration static assays were conducted. In addition to the preliminary 230-minute trials, robust new data collections comprising four independent 80-minute assays allowed for the consolidation of error modeling across different operation windows. The results of these data collections evidenced a highly predictable and consistent linear drift accumulation, consistent with the rate of approximately $0.27^\circ/\text{min}$ observed in the 240-minute evaluations. Based on this finding, a temporal compensation was implemented in the code. This constant error rate is continuously subtracted from the raw yaw angle output as a function of the time elapsed since the last reference capture, effectively neutralizing static temporal drift and enabling continuous monitoring throughout an entire work shift.

F. Dynamic Kinematic Validation Protocol

For kinematic validation in a dynamic regime, angular accuracy was evaluated against a reference method under real motion conditions. To achieve this, the sensor pair was attached to a volunteer, as detailed previously. At the start of the assay, the volunteer was asked to assume a neutral upright posture, standing as erect as possible. From this point, the reference posture was captured by triggering the hardware's mechanical button. Subsequently, the volunteer performed cycles of lateral trunk inclination to the left and right, with a free and variable amplitude, holding the position briefly to allow stable recording, and then returning to the initial neutral posture, defined as approximately 0.0°.

The assay consisted of collecting 12 dynamic postural samples, each recorded simultaneously by the hardware and via video. During this accuracy validation stage, the tactile vibration actuator on the vest was kept physically deactivated to ensure the mechanical alert stimulus did not induce reflexive changes in the volunteer's natural movement or posture, strictly isolating the device's intrinsic kinematic measurement error.

The 12 samples were recorded from a posterior view in the frontal plane under controlled lighting conditions. The generated videos were processed using the Kinovea biomechanical analysis software [23], adopted as a reference due to its widespread use in 2D kinematics studies. To establish the comparative baseline, the software's "angle relative to horizontal" tool was used, continuously calculating the angular deflection formed by the geometric line connecting the two markers on the inferior scapular angles relative to an idealized fixed horizontal reference line (0°), thereby replicating the measurement principle used by the sensor array.

To neutralize millimeter-scale imperfections in static postural alignment within the video image, data from both systems were processed in terms of Relative Angular Variation ($\Delta\theta$) based on the respective measured initial posture. For the Kinovea software, the geometric difference was calculated relative to the initial neutral image; for the microcontroller system, the global inclination variable extracted from the serial monitor was directly compared with the video measurements, as synchronous block movement of the thorax would cancel out the pure asymmetry parameter.

G. Statistical Analysis

The agreement between the proposed wearable system and Kinovea was validated using Pearson's linear correlation and Bland-Altman analysis of paired differences between the two methods [24], estimating the systematic error (bias, given by the mean of the differences) and the 95% limits of agreement (bias $\pm$ 1.96 $\times$ standard deviation of the differences), as presented in (5):

$$\text{ULA, LLA} = \text{bias} \pm (1.96 \cdot \sigma_{\text{diff}}) \tag{5}$$

where σ_{diff} denotes the standard deviation of the paired differences between the two methods, not the standard deviation of the amplitude means—a distinction that proved relevant for the correct interpretation of the results.

III. Results

The results obtained from the experimental evaluations of the wearable inertial prototype were divided into the analysis of long-duration static temporal stability (incorporating the 240-minute monitoring and the consolidated results of the four 80-minute collections), the functional verification of the biofeedback, and the dynamic kinematic validation against the Kinovea video analysis software [23].

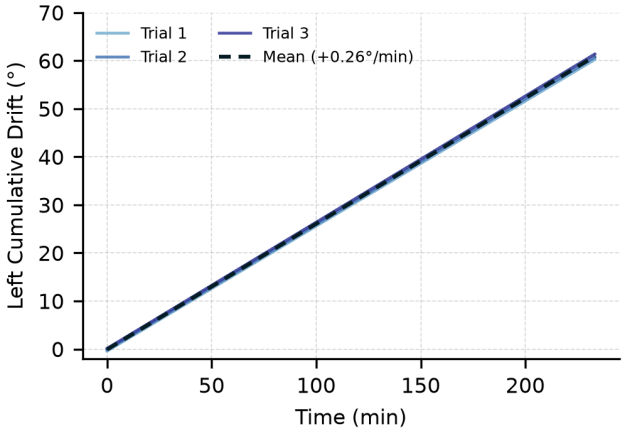

Fig. 2. Cumulative drift throughout 240-minute static assays for the left scapular sensor (individual assays and consolidated mean).

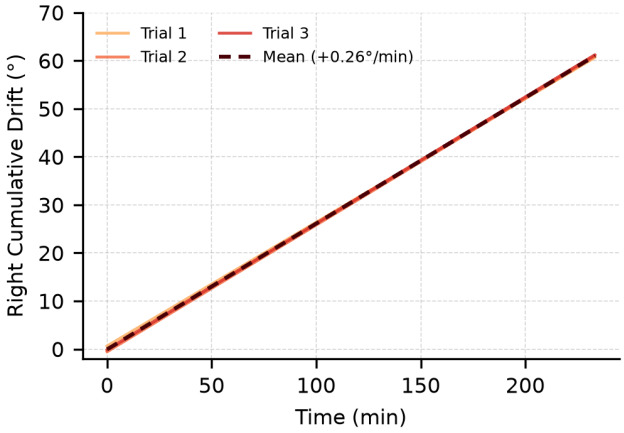

Fig. 3. Cumulative drift throughout 240-minute static assays for the right scapular sensor (individual assays and consolidated mean).

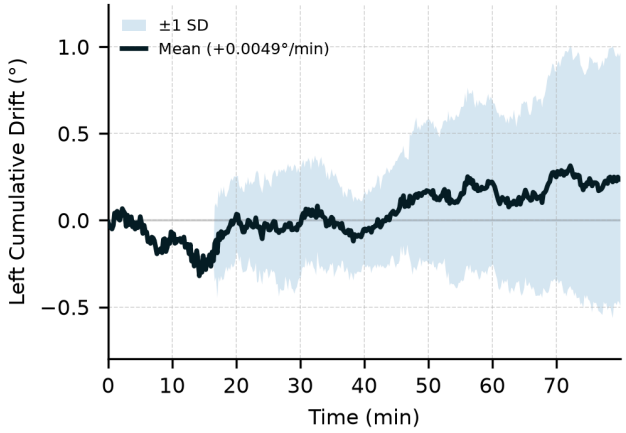

Fig. 4. Residual cumulative drift on the left after firmware compensation across the 4 validation assays (80 min), displaying the mean and ±1 SD.

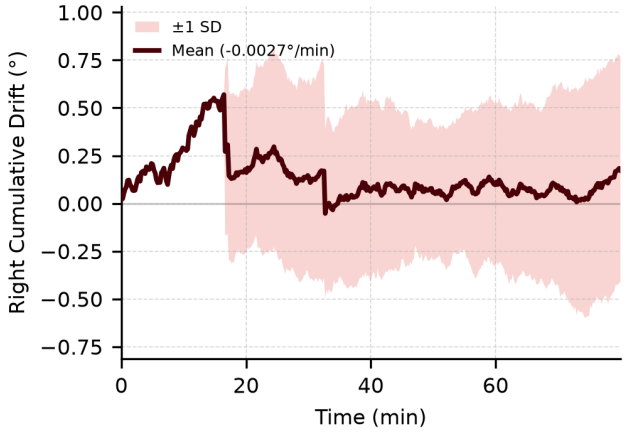

Fig. 5. Residual cumulative drift on the right after firmware compensation across the 4 validation assays (80 min), displaying the mean and ±1 SD.

A. Static Stability Analysis (Drift) and Compensation

According to the experimental protocol described in Section II-E, the preliminary short-duration static evaluation indicated an average drift rate of $0.14°/\text{min}$ in the yaw axis. Furthermore, extended static assays—encompassing long-duration monitoring of up to 240 minutes and the consolidation of four independent 80-minute collections—revealed a highly predictable and consistent linear error accumulation over the operation.

As illustrated in the consolidated panels of Figs. 2 and 3 (referring to the 240-minute measurements) and Figs. 4 and 5 (highlighting post-compensation performance across the 4 80-minute collections), linear regression fitting determined a mean uncorrected drift rate of approximately $0.27°/\text{min}$ for both sensors. The application of the corrective algorithm in the firmware drastically reduced this deviation, confining the mean residual error to near-zero levels ($\approx +0.0049°/\text{min}$ on the left and $\approx -0.0027°/\text{min}$ on the right) with narrow standard deviation bands (± 1 SD). This empirically observed consistency supports the robustness of the linear temporal compensation, enabling continuous and stable monitoring during prolonged shifts.

B. Biofeedback

In the bench tests described in Section II-C, the tactile signaling system behaved robustly. Each threshold violation triggered a sequence of three vibratory pulses accompanied by synchronous logging in the serial monitor. Upon returning to the postural neutrality zone, the system immediately interrupted the vibratory stimulus, confirming the proper operation of the real-time control loop.

C. Dynamic Kinematic Validation

After validating stability and mitigating drift, the system's performance was evaluated under a dynamic regime. Table I summarizes the 12 samples comparing the relative angular variations ($\Delta\theta$) obtained by Kinovea and the proposed system, with a mean inclination amplitude of $4.8° \pm 1.0°$.

Pearson's linear correlation between the two methods demonstrated strong agreement ($r = 0.90$; $R^2 = 0.81$), modeled by the linear regression equation described in (6):

$$\Delta\text{MPU} = 1.04 \cdot \Delta\text{Kinovea} + 0.28 \tag{6}$$

TABLE I
DYNAMIC KINEMATIC VALIDATION ACROSS THE 12 TESTED SAMPLES.

Sample	Δ Kinovea (°)	Δ MPU (°)	Difference (°)
1	3.1	4.3	-1.2
2	3.4	4.2	-0.8
3	4.3	4.2	0.1

The Bland-Altman analysis, calculated according to (5), indicated a systematic bias of $-0.48°$, reflecting a slight tendency of the prototype to overestimate the angle compared to the optical reference. The 95% limits of agreement, derived from the standard deviation of the paired differences ($0.52°$), were established at ULA $= 0.55°$ and LLA $= -1.50°$.

Fig. 6 and Fig. 7 illustrate, respectively, the scatter plot with the linear correlation and the Bland-Altman diagram of the dynamic validation.

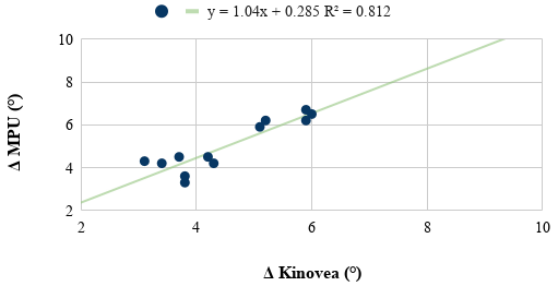

Fig. 6. Pearson's linear correlation analysis between the wearable system and the Kinovea software.

IV. DISCUSSION

Taken together, the conducted assays help to understand the performance and main sources of error of the proposed system. The mean absolute error in dynamic validation ($0.61°$; RMSE $= 0.69°$) was relatively low given the tested amplitude, and the bias of $-0.48°$ is comparable in magnitude to the combined effect of the gyroscope's resolution ($0.05°$) and the potential error associated with manual marking in Kinovea. This indicates that part of the difference stemmed from the visual reference method itself rather than intrinsic sensor errors.

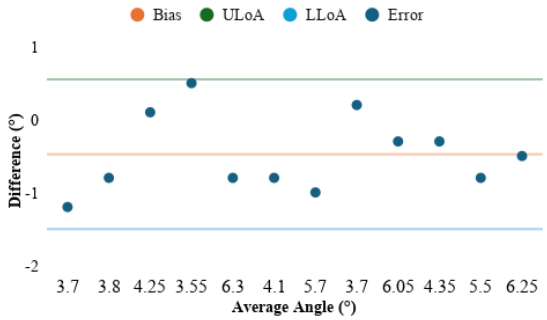

Fig. 7. Bland-Altman plot assessing kinematic agreement between the two methods.

Regarding temporal stability, the extended tests—including 240-minute monitoring and the four 80-minute collections—showed a predictable linear drift accumulation of about $0.27°/\text{min}$ in the yaw axis (Z-axis). It is worth noting that the study strictly focused on the Z-axis precisely because it represents the greatest challenge in 6-degree-of-freedom (6-DoF) sensors lacking a magnetometer: while roll and pitch are naturally corrected by gravity, the Z-axis lacks an absolute reference and accumulates error over time. The linear correction embedded in the firmware effectively solved this issue, dropping residual drift to near-zero values ($+0.0049°/\text{min}$ and $-0.0027°/\text{min}$) and allowing for prolonged device use.

Concerning tactile biofeedback, the bench tests confirmed that the control loop operates satisfactorily, although the exposed wiring still slightly hinders portability. The next practical step will be migrating to a custom Printed Circuit Board (PCB) and integrating a compact battery into the vest. In the future, upgrading to 9-axis sensors (such as the MPU-9250 with a magnetometer) will not only provide an absolute reference for the Z-axis via the Earth's magnetic field but will also enable complete and simultaneous three-dimensional tracking across the three anatomical planes of motion.

Finally, it is important to emphasize that this study is strictly technical and preliminary, focused on validating hardware and tracking precision. As the test was conducted with a single individual as a proof of concept, the main objective was to isolate errors and understand drift behavior. Trials with volunteers and practical biofeedback testing require prior approval from a Research Ethics Committee (REC). Therefore, this work does not have the clinical purpose of proving postural re-education, but rather to provide a solid technological foundation so that future clinical and ergonomic studies can be conducted under appropriate safety conditions.

V. IMPLEMENTATION CONSIDERATIONS

The proposed system was designed to transition from experimental validation to a dedicated commercial application. Its modular architecture based on MEMS inertial sensors allows the evolution from a bench prototype to low-power, highly portable devices without compromising biomechanical tracking fidelity.

A. Regulatory Alignment and Risk Management

To support future commercial evolution, the prototype's design was guided by medical device regulatory guidelines. The risk classification structures and Quality Management System (QMS) frameworks referenced the Brazilian Health Regulatory Agency (ANVISA) guidelines (RDC No. 751/2022 and RDC No. 665/2022). Risk identification followed the principles of the ISO 14971 standard, prioritizing firmware stability and physical circuit isolation. Furthermore, general electrical safety guidelines (IEC 60601 family) and usability engineering (IEC 62366) were used as design references for hardware layout and biofeedback delivery. For future stages involving continuous data collection in clinical cohorts, the firmware architecture will incorporate data encryption and privacy protocols in compliance with regulatory frameworks (such as the LGPD, the European MDR, and US FDA requirements).

B. Scalability and Occupational Integration

The architecture was structured in a scalable manner to allow integration into Internet of Medical Things (IoMT) ecosystems. The sensor data stream generates structured angular deviations in time series, making the dataset suitable for future Bluetooth Low Energy (BLE) transmission to mobile platforms and with Machine Learning classifiers for automatic activity recognition and adaptive postural threshold definition.

In occupational health, the device provides an objective tool aligned with ergonomic standards (such as the Brazilian Regulatory Standard NR-17). It enables integration into corporate Risk Management Programs (PGR) and Occupational Health Medical Control Programs (PCMSO) by generating continuous quantitative metrics—such as cumulative exposure time in non-neutral postures and biofeedback compliance rates—supporting evidence-based ergonomic interventions in clinical and workplace environments.

VI. Conclusion

Following systematic prototype validation, we conclude that the proposed architecture—composed of two MPU-6500 IMUs, an iterative calibration algorithm, and embedded processing via quaternion fusion—demonstrated satisfactory performance in estimating lateral trunk inclination (Z-axis / yaw). The system showed a strong correlation with the Kinovea optical reference method ($r = 0.90$), a mean absolute error of $0.61°$, and an RMSE of $0.69°$, attesting to good kinematic agreement.

Although an integration drift was empirically quantified in both the long-duration extended assays (240 minutes) and the four 80-minute validation collections (with the rate stabilizing at approximately $0.27°/\text{min}$), this effect was successfully neutralized using a software-embedded linear temporal compensation algorithm, reducing residual deviation to negligible levels. The consolidated results demonstrate that the prototype provides reliable and stable lateral postural tracking over time, establishing the technical foundation necessary to test active self-correction mechanisms with vibrotactile biofeedback.

As future perspectives, the next steps prioritize circuit miniaturization onto a Printed Circuit Board (PCB), the implementation of wireless communication, and the conducting clinical trials—preceded by approval from the Research Ethics Committee (REC)—with larger groups of participants. Additionally, the expansion of the kinematic algorithm for simultaneous mapping of all three postural axes (flexion/extension, lateral inclination, and axial rotation) is anticipated. This three-dimensional approach, associated with validation via multi-camera optical systems, will allow for the assessment of complex and combined deviations, essential for managing three-dimensional structural pathologies like scoliosis. Thus, the developed architecture provides a promising and low-cost technological foundation for the future of clinical and ergonomic assistance tools.

Acknowledgments

The authors declare the use of generative artificial intelligence tools during the development of this work. The *Pippit AI* tool (*ByteDance Pte. Ltd.*) was used to generate the base anatomical illustration and coordinate axes diagramming presented in Fig. 1. Additionally, *Claude* (*Anthropic*) was employed to assist in structural optimization and debugging of the microcontroller firmware's buffer management code. *ChatGPT* (*OpenAI*) was utilized to assist in the translation of the manuscript from Brazilian Portuguese to American English, as well as for linguistic refinement to enhance clarity, consistency, and adherence to academic writing standards. All scientific content, interpretations, analyses, and conclusions were independently verified and remain under the sole responsibility of the authors.

***Abstract*—Abstract—This study presents the development of a programmable walkway for generating visual and auditory cues for gait training. The prototype integrates two independently controlled addressable LED strips, an ESP32 microcontroller, and a mobile application that configures step length, cue size, transition time, movement direction, starting limb, and optional auditory signals. Preliminary laboratory tests verified communication among the components and execution of the programmed operating modes. These tests were qualitative and did not include instrumented measurements of spatial or temporal error, repeatability, electrical safety, or evaluation with people with Parkinson's disease. The results therefore demonstrate preliminary technical feasibility rather than clinical efficacy.**

Keywords— Assistive Technology, Gait Rehabilitation, Visual Cueing, Parkinson's Disease, Automation.

I. INTRODUCTION

Parkinson's disease (PD) affects 1 to 2 in every 1,000 people [1] and is the second most common neurodegenerative disease worldwide. PD is characterized by reduced dopamine availability in several structures of the central nervous system, such as the substantia nigra, putamen, and caudate nucleus, due to the death of neurons responsible for releasing this catecholamine. This physiological condition causes motor disturbances, such as muscle discomfort, postural instability, resting tremor, and bradykinesia [2]. Among these disturbances, gait dysfunction has the greatest impact on the quality of life of people with PD.

Gait alterations in patients with Parkinson's disease include reduced stride length and speed [3], [4], prolonged gait duration [5], [6], decreased dynamic stability [7], and reduced activation of the gastrocnemius and tibialis anterior muscles during the swing phase, compared with neurologically healthy individuals [8], [9]. These gait alterations are associated with a higher frequency of freezing of gait episodes and an increased risk of falls [10], which may even lead to death [11], [12].

Considering that these gait alterations increase the risk of falls, a growing number of studies have focused on identifying and mitigating gait disturbances in patients with Parkinson's disease (PD). Therefore, the development of assistive technologies capable of identifying gait alterations during daily activities and improving gait training/rehabilitation may contribute to enhancing the autonomy and mobility of patients with PD, reducing the risk of falls, and lowering the cost of PD treatment.

The development of assistive technologies to detect gait alterations in patients with Parkinson's disease (PD) during

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

daily activities, such as walking on the street, is an interesting approach to helping them improve their mobility. Currently, most studies aimed at detecting gait alterations in patients with PD are conducted in laboratories. Furthermore, the few studies on gait alteration detection conducted outside the laboratory are unable to provide users (i.e., patients with PD and/or healthcare professionals) with real-time feedback on movement changes.

Another approach to improving mobility in patients with Parkinson's disease is to optimize training/rehabilitation to mitigate the impact of the disease on gait. Studies have shown that patients with Parkinson's disease can improve walking speed and stride length with or without visual or auditory cues [13], [14]. Therefore, helping patients with Parkinson's disease develop this habit of active movement is a challenge for healthcare professionals.

The positive impact of visual cues on gait performance (speed, cadence, stride length, and stride width) is widely recognized and supported by substantial evidence [15], [16], [17], [18]. External visual cues serve to bypass and compensate for abnormal internal cueing mechanisms in the brain that contribute to deficits in motor planning and execution in patients with Parkinson's disease [19]. These strategies, provided during training/rehabilitation, can improve balance and gait speed [20].

Although the ESP32 microcontroller and addressable LED strips are commercially available, the technological contribution of this work lies in their integration into a single overground system that combines real-time mobile configuration, optional auditory cues, and independent bilateral control. The prototype allows step length, cue size, transition time, movement direction, and starting limb to be configured, and the right and left strips can generate different patterns. At this stage, these features define the proposed architecture; their quantitative performance and clinical effects remain to be evaluated.

Thus, this study aims to describe the development and preliminary qualitative functional verification of a programmable walkway for generating visual and auditory cues, intended for future investigation in individualized gait-training protocols for people with Parkinson's disease.

II. RELATED WORK

Visual cueing strategies applied to gait training range from fixed floor markings to projection-based systems, wearable devices, and interactive surfaces. Among the simplest approaches, Sidaway et al. [15] used transverse markings positioned along the walking path to guide step length. Similarly, Das et al. [17] used lines fixed to the floor to provide visual references during changes in direction. Although these solutions are accessible and easy to implement, they depend on the manual positioning of the cues and do not allow them to be dynamically modified during the activity.

Treadmill- and projection-based systems enable greater control of the cues. Schlick et al. [16] used an instrumented treadmill associated with the RehaWalk® system, in which the participants' footprints were projected onto the surface and synchronized with the treadmill speed. The shape of the footprints and the distance between the cues were adjusted according to the individual characteristics of the participants. However, this approach depends on a setup consisting of a treadmill, a pressure-sensitive platform, a projector, and specific software.

Other approaches seek to provide cues during movement through wearable devices. Chan et al. [21] developed footwear equipped with lasers, plantar pressure sensors, and inertial measurement units. The system alternately projects a line for the right foot and the left foot according to the gait phase detected by the sensors. Although it enables use outside a fixed setup, the authors reported limitations related to the projection distance of the cues. Janssen et al. [22], in turn, investigated the use of smart glasses to display virtual bars and staircases in augmented reality. This solution expanded the possibilities for cue presentation but presented usability limitations related to comfort, distraction, and partial obstruction of the visual field.

Interactive LED surfaces have also been developed for broader motor training applications. Van Delden et al. [23] presented an 8-m-long pressure-sensitive LED floor designed for personalized games for gait rehabilitation. Although it enables the generation of dynamic cues and the adaptation of activities, the system requires a dedicated interactive surface and was not specifically developed for people with Parkinson's disease.

Table I presents a comparison between the main characteristics of these approaches and the system proposed in this work.

TABLE I
COMPARISON OF THE TECHNICAL CHARACTERISTICS OF VISUAL CUEING STRATEGIES AND SYSTEMS APPLIED TO GAIT

Reference/ system	Visual cue	Cue adjustment	Bilateral control	Configuration interface	Auditory cue	Physical setup
Sidaway et al. [15]	Transverse blue tape strips on the floor	Spatial adjustment through manual positioning	No	No	No	Marked walkway
Schlick et al. [16] (RehaWalk®)	Footprints projected onto a treadmill	Individualized and synchronized with the treadmill	N.R.	RehaWalk® system	N.R.	Treadmill, projector, and instrumented platform
Das et al. [17]	Star-shaped adhesive tape lines	Fixed manual spatial adjustment to guide turns	No	No	No	Marked floor area
Chan et al. [21]	Lines projected by lasers attached to the footwear	Automatic activation according to gait phase	Automatic alternation between sides	Smartphone for data collection, not configuration	N.R.	Footwear with lasers, pressure sensors, and inertial units

Reference/ system	Visual cue	Cue adjustment	Bilateral control	Configuration interface	Auditory cue	Physical setup
Janssen et al. [22]	Three-dimensional bars and staircases in augmented reality	Position updated in real time and individualized spacing	Not applicable	Software running on a tablet	Metronome evaluated in a separate condition	Smart glasses, tablet, and inertial sensors
Van Delden et al. [23]	Interactive LED floor	Step length and width, speed, and duration via tablet	Partial: allows the affected limb to be specified	Tablet	Yes, through sound effects	Dedicated pressure-sensitive LED floor (8 × 1 m)
Proposed system	Addressable LED strips along the sides of the walkway	Step length, cue size, and transition time configurable in real time	Independent control of the right and left sides	Mobile application	Yes, with optional activation	Rubberized walkway with lateral LED strips

Note: N.R. = characteristic not reported in the reviewed study. The comparison considers only the technical characteristics described in the references and does not establish clinical superiority among the approaches.

Unlike the approaches analyzed, the proposed system combines two independently controlled LED strips, a mobile application for real-time configuration, wireless communication, and optional auditory cues in an overground walkway. The contribution of this work lies in integrating these features into a single configurable platform. The comparison presented in Table I is limited to the technical characteristics reported in the cited studies and does not establish superior performance or clinical effectiveness.

III. MATERIALS AND METHODS

A. Walkway

The walkway was designed as a research prototype for generating configurable visual cues along an overground path. Two lateral addressable LED strips allow programmed changes in spatial and temporal settings, including cue position, step length, and progression timing. These settings are intended to support future investigation of structured gait-training protocols; the present study does not evaluate their clinical adequacy or effects. Figure 1 presents a design drawing of the walkway.

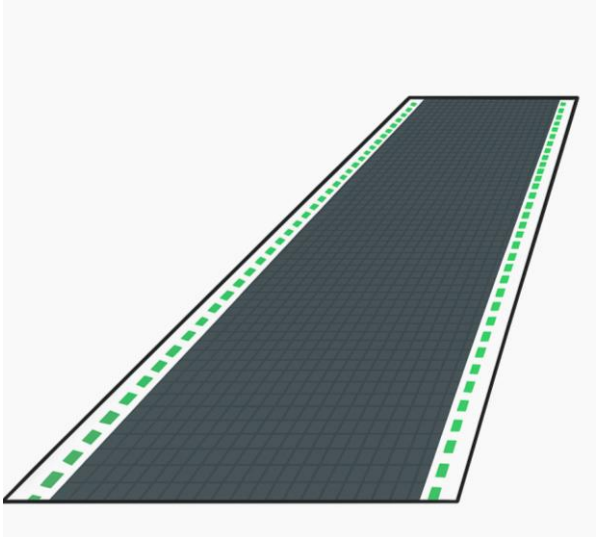

Fig. 1 Walkway Project

The walkway prototype includes two 5-m-long addressable WS2811 LED strips with 300 LEDs, 12 V, IP20, VLX, and RGB lighting, as well as a 5-m-long, 43-cm-wide non-slip rubber runner. The main objective of the device is to provide an

accessible and adjustable platform that can be easily integrated into the clinical context, expanding external rehabilitation strategies for people with gait disorders, particularly those with Parkinson's disease. Figure 2 presents the prototype that has already been constructed.

Fig.2 Completed Walkway Prototype

With the completion of the walkway prototype, as shown in Figure 2, it was possible to begin the coding stage of the parameters previously defined for the research project.

B. Walkway Code

The firmware developed for the walkway was designed to provide configurable control of the visual cues used in gait training. The architecture organizes the functions into independent modules, each responsible for updating the LEDs, managing configurable parameters, communicating with the microcontroller, and synchronizing the auditory signals. This modular structure allows the system to maintain temporal stability even in dynamic operating modes, ensuring the spatial consistency of the light pattern along the walkway.

Operational control is based on a state machine that manages transitions between different operating states, such as configuration, execution, and pause. Each treatment mode—unidirectional movement, forward-and-backward movement, or alternating limb movement—is handled as a specific set of rules that define the progression of the stimulation, movement limits, and application rhythm. Therefore, clinical parameters such as step length, rhythm, and activation time are translated into discrete positions on the LED strip, enabling the faithful reproduction of different gait patterns.

Visual behavior is updated in a continuous cycle. The firmware calculates the position of the activated LEDs, checks the limits of the available channel areas, and applies safety mechanisms to prevent overlap or incorrect activation. The system can also optionally synchronize the auditory signal emitted by a buzzer, a feature that expands the multimodal potential of the intervention by integrating auditory stimulation into the treatment protocol.

The control logic is implemented using procedural programming, with functions organized according to their responsibilities, thereby ensuring clarity, ease of maintenance, and the future scalability of the system. This approach provides the flexibility required for clinical adjustments, such as cue color, progression rate, number of repetitions, and independent selection of each side of the gait path, allowing healthcare professionals to customize training programs according to the patient's movement needs. Therefore, the firmware provides a configurable platform for preliminary experimental investigation, while its stability, reliability, and clinical suitability still require dedicated evaluation.

Figure 3 presents a small diagram illustrating the overall architecture of the project. The mobile application sends clinical parameters to the ESP32 via Wi-Fi, and the ESP32 runs the firmware responsible for generating the light patterns. The state machine translates these parameters into visual cues displayed on the left and right LED strips. A power supply ensures a stable power supply for the entire system, enabling the safe and repeatable execution of the gait training program.

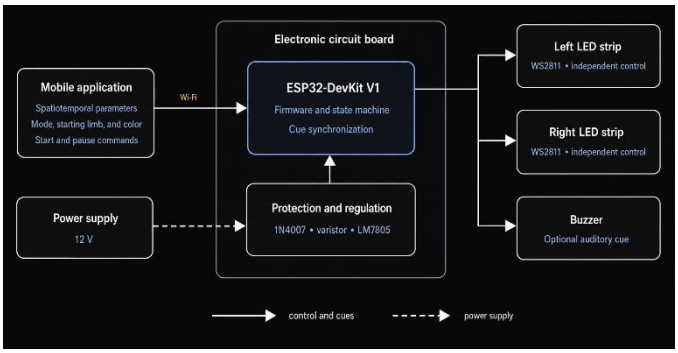

Fig. 3 Walkway Diagram

C. Walkway board

The electronic board developed for the walkway was designed as an integrated and low-cost prototype capable of meeting all the functional requirements of the visual cueing system for gait training. The hardware centralizes control in the ESP32-DevKit V1 module, which is responsible for processing the effect modes, communicating with the mobile application, and managing the signals sent to the LED strips. The board incorporates a protection stage consisting of 1N4007 diodes, a varistor, and an LM7805 voltage regulator for basic circuit protection and voltage regulation. Formal electrical safety and hardware reliability tests have not yet been conducted. The interface with the strips is implemented using BSS138 MOSFETs and BC548 transistors, which isolate the microcontroller and meet the requirements of the data channels. Figure 4 shows the completed board.

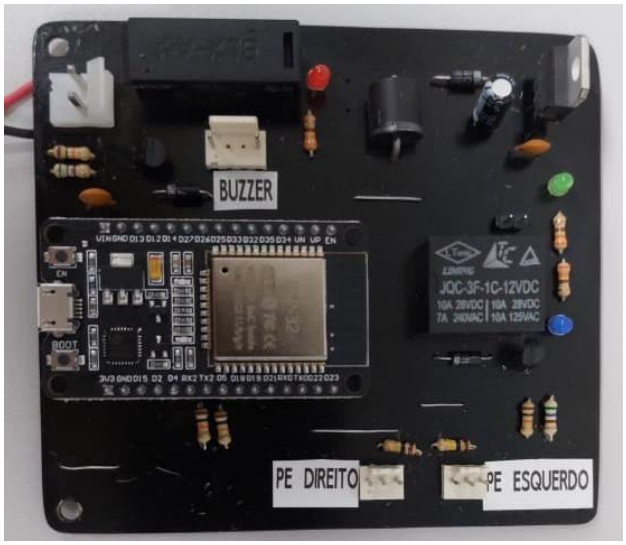

Fig. 4 Completed Walkway Circuit Board.

Figure 5 shows the enclosure housing the board, which was modeled and 3D-printed using PLA (polylactic acid). The enclosure contains the power button, the DB8 connector for the LED strips, the audio output located next to the LED strip connector, the ESP32 reset button, the ESP32 microcontroller connector, and the power connector.

Fig. 5 Walkway Hardware Enclosure

In addition, indicator LEDs, configuration jumpers, and dedicated connectors facilitate system diagnostics and maintenance, while the integrated buzzer circuit enables auditory signaling synchronized with the visual cues. Thus, the platform was designed not only to be functional, but also portable, modular, and scalable, allowing for the future development of the prototype and its adaptation to different clinical gait rehabilitation protocols.

D. Walkway Application

A mobile application was developed to control and configure the luminous walkway used as a gait rehabilitation and training tool. The application was designed to operate in conjunction with an ESP32 microcontroller connected to the local network via Wi-Fi, allowing the visual and auditory cues provided to the patient during the test to be configured in real time. In Figure 6, the main interface presents a set of modules designed for communication with the ESP32, test initialization, and the configuration of general parameters or parameters specific to each LED strip. The application displays the microcontroller's IP address and provides a Connection Test command, which verifies the responsiveness of the embedded system before the experimental protocols are executed.

The Both Strips configuration screen allows the parameters applied to both sides of the walkway to be adjusted simultaneously. The available variables include: LED status (ON/OFF); lighting color (selected via a drop-down menu); step length (cm); foot size (cm); transition time or activation time (s); total walkway length (m); operating mode (One-way, right foot; One-way, left foot; Out-and-back, left foot; Out-and-back, right foot); buzzer activation; and sound type (high-pitched, double, scale, or triple).

These parameters correspond to essential biomechanical variables for gait training, allowing cadence, rhythm, and the spatial positioning of the visual cues to be adjusted according to the user's individual characteristics.

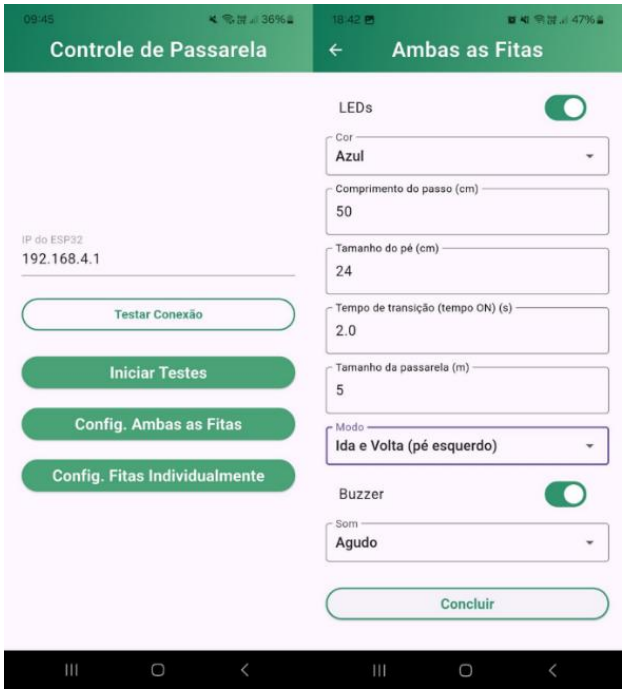

Fig. 6 On the left, the application's home screen; on the right, the configuration screen for both LED strips

Figure 7 illustrates, in addition to the combined configuration mode for both strips, a section dedicated to the independent configuration of each side of the walkway—the left and right strips. Although each strip has the same adjustment settings as the Both Strips configuration mode, it includes one additional option: "Enable Strip," which determines whether the healthcare professional will work with a specific side of the walkway. When a strip is disabled, all associated settings are automatically locked, ensuring configuration integrity and preventing incompatible settings during the therapeutic protocol. This functionality allows the healthcare professional to select only the side required for treatment, providing greater precision in controlling the visual cues according to the clinical objectives of gait training.

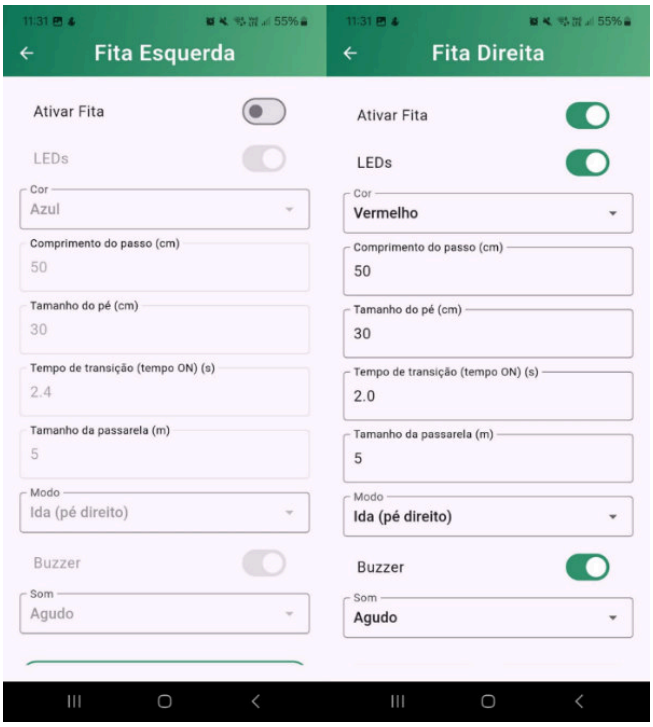

Fig. 7 On the left, the individual configuration screen for the left LED strip; on the right, the configuration screen for the right LED strip

Preliminary functional tests were conducted by selecting different configurations through the mobile application and observing the execution of the programmed commands, including LED-strip activation, movement direction, starting-limb selection, independent bilateral control, and optional buzzer operation. These tests were intended to verify component integration and basic system operation. No predefined quantitative protocol, calibrated instruments, or repeated-measurement analysis was used at this stage. Therefore, the procedure is characterized as a preliminary qualitative functional evaluation rather than a quantitative technical validation.

IV. Results

The preliminary tests showed that the ESP32, power supply circuits, driver transistors, addressable LED strips, firmware, and mobile application operated as an integrated system and executed the selected commands. The intended LED strips, movement direction, starting-limb option, and optional auditory cue were observed during the tests. Because no quantitative protocol or calibrated instruments were used, these observations do not establish spatial or temporal accuracy, repeatability, audiovisual synchronization, long-term stability, or hardware reliability.

A. Bench testing and validation of the hardware and device programming

Exploratory tests with laboratory members were conducted only to demonstrate the operation of the system. No gait outcomes were collected. Therefore, these preliminary observations indicate the execution of the implemented functions but do not demonstrate clinical effectiveness or readiness for use with patients.

Figure 8 shows a test of the walkway code with a laboratory member at the beginning of a session configured to start with the left foot.

Fig. 8 Walkway Code Test Starting with the Left Foot.

Figure 9 shows the beginning of a session configured for the laboratory member to start with the right foot.

Fig. 9 Walkway Code Test Starting with the Right Foot

It should be noted that the preliminary tests of the walkway, conducted with laboratory members, were intended exclusively to evaluate the operation of the device's hardware and software. At this stage, aspects related to component integration, the execution of programmed commands, and compliance with the previously established technical parameters were assessed. Therefore, these procedures did not constitute clinical testing and did not involve people with Parkinson's disease.

The prototype was sent to the Human Movement Research Laboratory (MOVI-LAB), at São Paulo State University (UNESP), Bauru campus, for operational testing and feedback from researchers and rehabilitation professionals. This stage aims to assess the operation of the system, the suitability of the configured gait parameters, and the usability of the interface. Based on this feedback, the necessary technical adjustments will be made before testing with people with Parkinson's disease. Such testing will only begin after completion of this stage and approval by the appropriate institutional ethics committee. Therefore, the present study does not include clinical data or results involving the target population.

It should also be noted that the prototype presented corresponds to the first stage of a broader project that includes the development of additional complementary devices. In the

future, these devices will be integrated into the walkway, enabling a more comprehensive and accurate collection of data related to the gait of participants with Parkinson's disease.

V. CONCLUSION

This work presented the initial development of a programmable walkway for generating visual and auditory cues for gait training. The prototype integrates addressable LED strips, an ESP32 microcontroller, and a mobile application for configuring cue parameters and independently controlling the right and left sides. Preliminary qualitative tests demonstrated the integrated execution of the implemented functions. However, the study did not include quantitative performance measurements or clinical testing involving people with Parkinson's disease. Therefore, the conclusions are limited to the preliminary functional feasibility of the prototype. Future work will include additional technical evaluation, feedback from rehabilitation professionals, the necessary safety assessments, and subsequent studies involving the target population, in compliance with institutional and ethical requirements.

***Abstract*—Stroke is one of the leading causes of motor disability and requires rehabilitation strategies capable of promoting neuroplasticity and supporting functional recovery. Among these strategies, physical practice, Action Observation (AO), and Motor Imagery (MI) have been increasingly investigated because of their potential to engage motor-related neural networks involved in motor learning and recovery. This work presents the development of a system composed of a sensorized cycle ergometer integrated with a serious game for post-stroke rehabilitation. The system employs Hall-effect sensors to monitor pedaling activity and an ESP32 microcontroller to acquire and transmit real-time data to a virtual environment developed in the Unity game engine. The serious game was designed to enable both direct interaction through pedaling and the presentation of visual stimuli aimed at promoting motor imagery and action observation. The results of the implementation demonstrated the technical feasibility of integrating hardware and software components and the system's ability to generate quantitative data for clinical monitoring. The proposed solution shows potential as a low-cost platform for motor rehabilitation and future clinical evaluation studies.**

***Index Terms*—stroke, cycle ergometer, serious game, rehabilitation, motor imagery**

I. Introduction

Stroke is one of the leading causes of long-term motor disability worldwide, and persistent motor impairments often require rehabilitation strategies capable of promoting motor relearning and neuroplasticity [1], [2]. Contemporary neurorehabilitation emphasizes combining repetitive, task-oriented practice with interventions that engage motor-related neural networks involved in motor planning, action representation, and sensorimotor integration [3].

Among these interventions, Action Observation (AO) and Motor Imagery (MI) have been extensively investigated as complementary strategies to conventional rehabilitation. AO consists of observing another individual performing a motor task, whereas MI refers to the internal simulation of a movement without overt muscular execution [4], [5].

Neurophysiological studies using transcranial magnetic stimulation, electroencephalography, and functional neuroimaging have demonstrated that both approaches recruit partially overlapping cortical and subcortical motor networks, including premotor, supplementary motor, parietal, and primary motor regions, although through partially distinct neural mechanisms [6], [7]. When combined with repetitive physical practice, AO and MI may enhance motor learning, sensorimotor integration, and functional recovery after stroke [8].

Technological resources such as virtual reality, serious games, and sensor-based rehabilitation systems have emerged as promising tools for implementing intensive, engaging, and objective rehabilitation programs [9]. These technologies enable real-time monitoring of motor performance while providing enriched visual feedback, facilitating the integration of physical exercise with cognitive-motor rehabilitation strategies.

In this context, this work presents the development of a rehabilitation platform integrating a sensorized cycle ergome-

ter with a serious game for post-stroke rehabilitation. The proposed system enables real-time acquisition of pedaling data, motion-based interaction with a virtual environment, and quantitative performance monitoring. Furthermore, the platform was designed to provide complementary active and observation training modes, allowing repetitive lower-limb exercise to be combined with visual feedback, Action Observation, and guided Motor Imagery within a single technological environment. This multimodal approach provides a flexible framework for future investigations of technology-assisted rehabilitation strategies following stroke.

II. Sensorized cycle ergometer

The cycle ergometer is a stationary device widely used in the rehabilitation of individuals affected by stroke, enabling the performance of cyclic and repetitive movements involving both the upper and lower limbs. Depending on the therapeutic goals and the patient's motor abilities, the device can be employed in passive, active, or resistive exercise modalities. Studies have shown that its use may contribute to improvements in range of motion, muscle strengthening, physical conditioning, and the prevention of muscle atrophy, while also supporting functional recovery and increasing patient confidence throughout the rehabilitation process [10].

For the development of the prototype, a portable cycle ergometer equipped with time monitoring and pedal revolution counting was used, allowing subsequent comparison and analysis of the results obtained. The device features an adjustable resistance mechanism that allows variations in intensity of exercise and can be used for both lower-limb and upper-limb training.

The measurement of the angular velocity of the cycle ergometer was made using a pair of Hall effect sensors. These electronic devices are capable of detecting magnetic fields and converting them into electrical signals. Their operating principle is based on the Hall effect, a phenomenon in which an electrical potential difference is generated when an electric current flows through a semiconductor material subjected to a perpendicular magnetic field. This potential difference, known as Hall voltage, is used to detect the passage of magnetic elements and determine rotational events.

To generate the magnetic fields, two permanent magnets were fixed at equally spaced positions on the rotating mechanism of the cycle ergometer. The use of two magnets enables the identification of the pedal rotation direction while also increasing the temporal resolution of the measurements. During the movement of the device, the passage of the magnets in front of the sensors generates electrical pulses, which are used to calculate both the rotational speed and the direction of movement.

Signal processing was performed using an ESP32 microcontroller, selected due to its high computational performance, low cost, integrated wireless connectivity, and ease of programming. Integration between sensors and the microcontroller enables real-time data acquisition and transmission to a computer, supporting interaction with the developed serious game as well as data storage for subsequent analysis.

The data acquisition system was configured with a sampling interval of 200 ms, which, according to bench tests, provided smooth and responsive avatar movement within the virtual environment. However, low pedaling cadences represent a potential challenge, as longer intervals between consecutive pedal events could compromise the responsiveness of the system. To mitigate this issue, two permanent magnets were installed on the rotating mechanism of the cycle ergometer, increasing the number of detectable events per revolution and improving temporal resolution, particularly at low rotational speeds. Data transmission between the ESP32 and the computer was performed at a baud rate of 115,200 bps, ensuring reliable real-time communication while minimizing latency and reducing processor overhead.

After signal acquisition and processing, the ESP32 firmware calculated several kinematic parameters from the detected Hall sensor events, including elapsed time between consecutive events (ms), angular velocity (rpm), linear velocity (m/s), and pedaling direction (clockwise or counterclockwise). These parameters were then transmitted to the computer in real time via USB serial communication, allowing their use both for controlling the serious game and for recording quantitative performance data for subsequent analysis.

To attach the data acquisition system to the cycle ergometer, a dedicated mounting structure was designed and manufactured using 3D-printing technology. Fig.1 illustrates the structure developed to position the sensors and other electronic components.

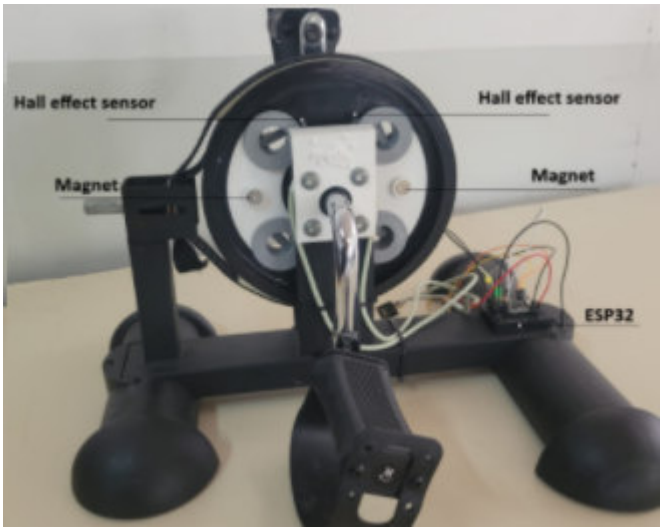

Fig. 1. Prototype developed.

III. Serious Game Developed

The concept of serious games was introduced by Abt in 1970, defining them as games with explicit educational purposes beyond entertainment [11]. [12] expanded this definition by describing serious games as computer-based applications

that combine elements of the game with specific objectives in areas such as education, training, and healthcare. Although entertainment is an important component, these systems are designed for applied and measurable outcomes. In the healthcare domain, serious games have been widely used as therapeutic support tools, contributing to increased patient engagement and enabling more motivating exercise practice compared to conventional approaches [13].

The developed serious game incorporates two distinct interaction modes. In the first mode, users control the game elements through movements performed on the cycle ergometer. The signals captured by the Hall-effect sensors are processed to determine pedal speed in real time, and this information is used as a control parameter within the application. In this way, the user's motor performance directly influences the game dynamics, providing an interactive experience and enhancing engagement during the therapeutic activity.

The second mode consists of the visual presentation of movements performed in different cadences that serve as stimuli for observation and reproduction. This approach aims to stimulate mechanisms related to motor imagery and activation of the mirror neuron system, encouraging users to follow or mentally simulate the observed movement. During activity, performance data are continuously recorded and stored, enabling the generation of reports for clinical monitoring and comparison between user's performance and the prescribed stimuli.

Based on the identified functional and therapeutic requirements, a Game Design Document (GDD) was proposed, with the following structure:

- Objective Description: An endless-running serious game developed to support therapeutic interventions through game-based therapy.
- Game Type: Serious game for motor rehabilitation supported by a sensorized cycle ergometer.
- Target Audience: Individuals undergoing post-stroke rehabilitation.
- Platform: Computer-based application connected to a sensorized cycle ergometer equipped with Hall-effect sensors and an ESP32 microcontroller.
- Game Mechanics: The character continuously moves forward automatically.
- General Characteristics: The game environment must be procedurally generated to provide an infinite path while the player remains active. Additionally, the system must support real-time integration with data acquired from the cycle ergometer, using the user's pedaling activity as the primary control mechanism for gameplay.
- Setting: The game is set in an urban environment. As the player progresses, different areas of the city are explored, providing environmental variety while preserving the overall urban setting.

An endless runner gameplay style was selected due to its simple and intuitive mechanics, allowing users to focus on the pedaling task without the need to learn complex controls. In addition, the continuous progression of the game establishes a direct relationship between pedaling cadence and avatar movement, facilitating real-time interaction with the rehabilitation device. The visual stimuli were designed to provide a continuous representation of cyclic lower-limb movements synchronized with the rehabilitation task, enabling users to observe movement-related cues while interacting with the virtual environment. This design was intended to support action observation and facilitate motor imagery processes, both of which have been associated with motor learning and functional recovery in post-stroke rehabilitation.

The serious game was developed in the Unity game engine using the `C#` programming language. Fig. 2 illustrates the development environment, highlighting the game objects. To create the effect of an "infinite city" during the prototyping phase, a modular city section was developed and used as the basic building block of the game environment (Fig. 3). This section was dynamically instantiated whenever necessary to extend the scenario and automatically destroyed after leaving the player's field of view. This approach enabled the creation of a virtually endless urban environment while maintaining low computational resource consumption. Furthermore, the adopted architecture facilitates future expansion of the game world through the addition of new city sections without requiring modifications to the core generation logic. Fig. 4 presents the avatar pedaling through the urban environment.

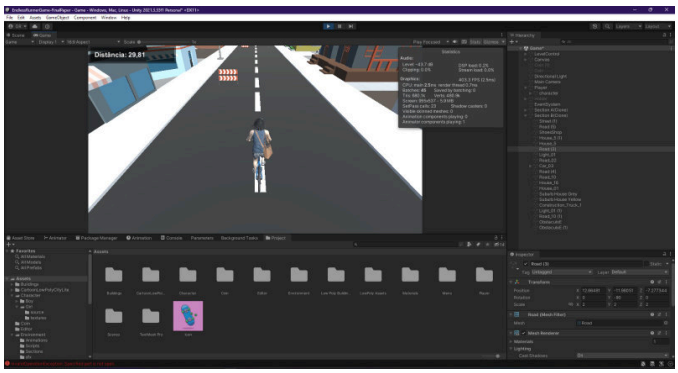

Fig. 2. Development environment.

IV. Proposed System Architecture

Fig. 5 shows the proposed system architecture, which integrates a sensorized cycle ergometer, an ESP32-based acquisition system, and a serious game platform to support post-stroke rehabilitation. The patient's pedaling activity is captured through Hall-effect sensors, processed by the ESP32 microcontroller, and transmitted to a computer in real time via USB serial communication. Communication between the ESP32 and the Unity application was implemented using the .NET SerialPort class available in the System.IO.Ports namespace. The serious game uses these data to provide interactive feedback, while session information is stored in a database for subsequent analysis and the generation of clinical reports. Table I summarizes the main technical specifications

Fig. 3. Urban environment section developed in the Unity game engine.

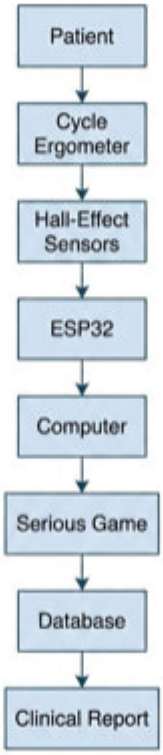

Fig. 5. Proposed system architecture.

TABLE I
TECHNICAL SPECIFICATIONS OF THE PROPOSED SYSTEM.

Component	**Specification**
Sensor	Hall-effect sensor
Microcontroller	ESP32
Sampling interval	200 ms
Communication	USB Serial
Baud rate	115200 bps
Computed parameters	Time (ms), rpm, m/s, direction
Game engine	Unity
Programming language	C#

of the proposed system, including the sensing, processing, communication, and game development components.

V. Discussion and Future Work

Recent studies suggest that post-stroke rehabilitation approaches may benefit from multisensory stimulation [10]. In this context, the proposed system integrates an instrumented cycle ergometer, a real-time data acquisition module, and a serious game into a single rehabilitation platform. This integration combines physical exercise with interactive visual stimuli, creating an environment that supports motor training while incorporating therapeutic approaches based on motor imagery and mechanisms associated with the mirror neuron system.

Bench tests demonstrated the feasibility of integrating the different components of the system, allowing real-time interaction between the user and the virtual environment. These results indicate that the proposed platform has potential for biofeedback applications in motor rehabilitation programs. The adopted configuration, including a 200 ms sampling interval, two magnetic markers, and a communication rate of 115,200 bps, provided stable real-time interaction between the cycle ergometer and the virtual environment during bench tests.

Several studies have highlighted the importance of sensor-based technologies for monitoring kinematic parameters during post-stroke rehabilitation [14], [15], [16]. In this context, the use of Hall-effect sensors combined with an ESP32 microcontroller provided a flexible, low-cost solution to monitor pedaling activity and transmit data in real time. The adopted

architecture also enables the future integration of additional sensors and physiological monitoring devices, which may further expand the applicability of the system in rehabilitation settings. Furthermore, the ability to automatically record quantitative performance data can support clinical follow-up and objective assessment of patient progress over time, representing an advantage over conventional rehabilitation approaches that often rely on subjective evaluations. Action Observation (AO) refers to observing another individual performing a motor action, whereas Motor Imaging (MI) involves the internal simulation of a movement without overt muscular execution [17].

Although distinct, both approaches involve partially overlapping cortical and subcortical motor networks, including premotor, supplementary motor, parietal, and primary motor regions, and have been extensively investigated as complementary strategies to promote motor learning and functional recovery after stroke [18], [19], [20]. Previous studies suggest that visual observation may not directly facilitate cortical activation but may serve as a precursor to motor imagery, which is considered one of the main mechanisms underlying cortical facilitation and motor relearning [21], [22]. In this context, the proposed platform was designed to combine a sensorized cycle ergometer with a serious game that supports both active and observational training modes. In active mode, the user controls the virtual environment by pedaling, promoting repetitive motor practice and real-time visual feedback. In the observation mode, the system presents pedaling movements in predefined cadences, allowing users to observe and mentally simulate the task. By integrating physical exercise, action observation, and motor imagery-related stimuli on a single platform, the proposed system may provide a technological framework for investigating rehabilitation strategies to enhance motor recovery after stroke. Although the system was designed to support motor imagery and action observation strategies, the present study did not include specific neurophysiological or behavioral assessments to verify the induction of these mechanisms.

Despite the promising characteristics of the proposed system, some limitations should be considered. The current study focused exclusively on the development and implementation of the prototype, without performing usability assessments or validation with healthy individuals and post-stroke patients.

Consequently, no conclusions can be drawn regarding the clinical effectiveness of the platform or its impact on functional recovery. Future work will involve experimental validation of the system, including usability studies, user engagement evaluations, and clinical investigations with post-stroke patients. In addition, adaptive game mechanics, personalized rehabilitation protocols, and integration with complementary physiological sensors may be explored to further enhance the therapeutic potential of the platform.

VI. Conclusion

This work presented the development of a system composed of a sensorized cycle ergometer integrated with a serious game for post-stroke rehabilitation. The proposed solution enables the real-time acquisition of pedaling data through Hall-effect sensors and an ESP32 microcontroller, allowing user interaction with a virtual environment while providing resources designed to stimulate motor practice, motor imagery, and mechanisms associated with the mirror neuron system.

The implementation results demonstrated the technical feasibility of integrating hardware and software components, as well as the potential of the platform for rehabilitation applications. In addition, the system demonstrated the capability to generate quantitative data that may support clinical monitoring and patient performance assessment. Future work will include usability testing and validation studies involving both healthy individuals and post-stroke patients in order to evaluate the effectiveness of the proposed tool as a support resource for therapeutic interventions and functional recovery.

***Abstract*—This study presents the development of a low-cost wearable orthosis prototype for non-invasive skin temperature monitoring as a potential strategy for diabetic foot prevention. The system was designed using an Arduino Uno microcontroller, LM35 temperature sensors, light-emitting diodes (LEDs), and an elastic support structure. The prototype acquires temperature data from two monitoring points and calculates the temperature difference between them, activating a visual warning when the predefined threshold of 2.2 °C is reached or exceeded. The electronic architecture and embedded algorithm were developed and functionally evaluated through simulations in the Tinkercad platform. The simulation tests verified temperature signal acquisition, data processing, differential temperature calculation, and the activation of the visual alert system according to the programmed decision logic. The results demonstrate the preliminary functional feasibility of the proposed circuit and algorithm in a simulated environment. However, laboratory calibration, experimental testing under real-use conditions, and clinical validation in individuals with diabetes mellitus are still required. The prototype provides a preliminary foundation for future improvements involving sensor distribution, ergonomic optimization, wireless communication, and clinical validation.**

I. Introduction

Diabetes mellitus (DM) is one of the fastest-growing chronic diseases worldwide and represents a major public health challenge due to its high prevalence, increasing incidence, and associated healthcare costs. According to the International Diabetes Federation (IDF), approximately 537 million adults were living with diabetes in 2021, and this number is projected to reach 643 million by 2030 and 783 million by 2045, reflecting the growing burden of the disease on healthcare systems worldwide [1].

Among the various chronic complications of diabetes, diabetic peripheral neuropathy (DPN) is one of the most prevalent and debilitating conditions. It affects peripheral nerve function, resulting in reduced pain perception, loss of protective sensation, and impaired thermal sensitivity, particularly in the lower extremities. Consequently, patients become more susceptible to unnoticed trauma, repetitive mechanical stress, ulcer formation, infections, and lower-limb amputations, significantly compromising quality of life while increasing healthcare expenditures [2].

Diabetic foot syndrome is considered one of the most severe complications of diabetes mellitus and remains a leading cause of hospitalization and disability among diabetic patients. The development of plantar ulcers is often preceded by localized inflammatory processes that produce increases in skin temperature before visible tissue damage becomes clinically apparent. Therefore, continuous monitoring of plantar skin temperature has emerged as a promising strategy for the early detection of inflammatory changes and the prevention of ulcer formation [3].

Several clinical studies have demonstrated that a temperature difference greater than 2.2°C between corresponding regions of both feet is strongly associated with an increased risk of ulcer development. Consequently, bilateral skin temperature monitoring has become an important non-invasive biomarker for the early identification of diabetic foot complications, enabling preventive interventions before irreversible tissue damage occurs [4].

Recent advances in wearable biomedical technologies have enabled the development of portable monitoring systems capable of continuously assessing physiological parameters outside clinical environments. These devices have attracted considerable attention due to their potential to support home

healthcare, remote patient monitoring, and telemedicine. In particular, wearable sensors integrated into orthotic devices have shown promising results for continuous plantar temperature monitoring while maintaining user comfort and mobility [5].

Despite these technological advances, many commercially available monitoring systems remain expensive and inaccessible, especially in low- and middle-income countries. Furthermore, several existing solutions rely on proprietary technologies, complex sensor arrays, or sophisticated manufacturing processes, limiting their widespread adoption in public healthcare systems and educational environments. Consequently, there is an increasing demand for affordable, reliable, and reproducible biomedical devices capable of assisting in the early detection of diabetic foot complications.

Open-source electronic platforms, such as Arduino, have become attractive alternatives for rapid biomedical prototyping due to their low cost, flexibility, ease of programming, and extensive development community. Combined with precision temperature sensors, these platforms enable the development of wearable monitoring systems that are reliable, scalable, and suitable for both research and educational applications while maintaining reduced implementation costs [6].

In this context, a low-cost wearable orthosis based on an Arduino Uno microcontroller and LM35 temperature sensors was developed for continuous monitoring of skin temperature in individuals with diabetes mellitus. The system was designed to automatically calculate the temperature difference between two monitored regions and provide an immediate visual warning whenever the temperature difference reached or exceeded the predefined threshold of 2.2°C, indicating the need for medical evaluation. The developed device demonstrates the feasibility of using low-cost electronic components to build assistive technologies for preventive diabetic foot monitoring, contributing to the early detection of thermal alterations associated with inflammatory processes. Furthermore, the prototype highlights the potential of open-source hardware platforms in Biomedical Engineering by providing an affordable, reproducible, and scalable solution that can be further integrated with remote monitoring and telemedicine technologies.

The main contribution of this work is the development and functional validation of a low-cost wearable orthosis for continuous skin temperature monitoring based on clinically established thermal thresholds. The developed system demonstrates the feasibility of integrating accessible hardware and embedded monitoring algorithms into wearable biomedical devices, contributing to the early prevention of diabetic foot complications and providing a foundation for future developments in connected healthcare and telemedicine.

II. Materials and Methods

This study is characterized as applied and exploratory research focused on the development and preliminary functional evaluation, through computer simulation, of a wearable orthosis prototype for non-invasive skin temperature monitoring. The methodology was organized into four main stages: literature review, definition of system requirements and prototype architecture, software and circuit development, and functional testing through simulation in the Tinkercad environment.

Fig. 1. Prototype Development Workflow.Author (2026)

A. Literature Review

Initially, a literature review was conducted to provide a foundation for the prototype's development and to identify technologies used to prevent complications associated with type 2 diabetes mellitus. Bibliographic searches were carried out across recognized databases and scientific portals—including the PubMed, Scopus, and LILACS using combinations of keywords such as diabetes mellitus, diabetic foot, diabetic neuropathy, skin temperature, temperature monitoring, wearable devices, orthosis, and Arduino.

Scientific articles, clinical studies, and technical publications were selected based on their focus on plantar temperature monitoring, the use of sensors for diabetic foot prevention, and the development of wearable devices for monitoring patients with diabetic neuropathy. Analyzing these studies made it possible to identify existing technological solutions, their limitations, and potential improvements for developing a low-cost device aimed at the early monitoring of thermal changes.

Furthermore, the literature review provided the basis for selecting the prototype's electronic components and for adopting a thermal difference threshold of 2.2°C—a value widely cited in the literature as an indicator of inflammatory processes and a risk factor for ulcer development in patients with diabetes.

B. Prototype Development

Following the literature review and the definition of the system requirements, a functional prototype of a wearable orthosis was developed to monitor skin temperature variations associated with diabetic foot complications. The prototype was designed with an emphasis on low cost, ease of assembly, and reproducibility, enabling future improvements and clinical adaptations.

The proposed physical structure consisted of an elastic support concept designed to accommodate the electronic components and enable future contact between the temperature sensors and the skin. At this stage, however, ergonomic

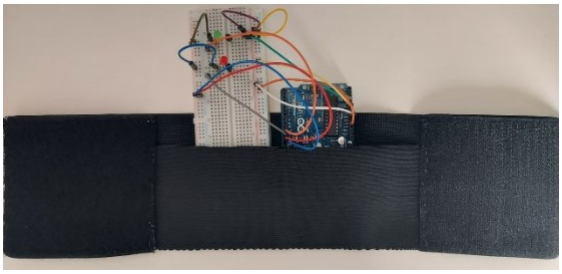

Fig. 2. Temperature sensors.Source: Author (2026)

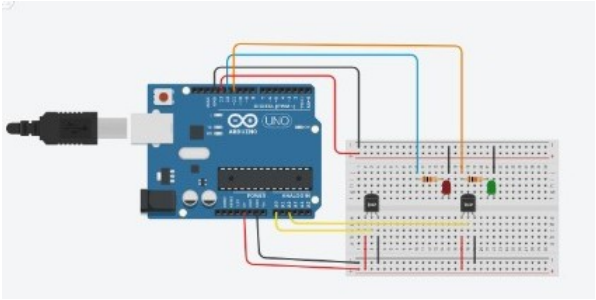

Fig. 3. Arduino Prototype. Source: Author (2026)

comfort, sensor fixation, skin contact stability, and suitability for prolonged use were not experimentally evaluated.

The Arduino Uno was selected due to its open-source architecture, ease of programming, low cost, and widespread use in biomedical engineering educational and research projects.

The sensors were positioned to allow simultaneous acquisition of temperature values from two monitoring points. The analog signals generated by the sensors were transmitted to the Arduino Uno, where they were converted into digital values and processed by the embedded algorithm. Based on these measurements, the system calculated the temperature difference (T) between the monitored regions.

To provide an intuitive user interface, two LEDs were incorporated into the prototype. Under normal operating conditions, when the calculated temperature difference remained below the predefined threshold, the green LED remained activated, indicating the absence of significant thermal alterations. Conversely, when the temperature difference reached or exceeded 2.2 °C, the green LED was turned off and the red LED was activated, providing an immediate visual warning that medical evaluation was recommended. This threshold was established according to findings reported in the literature regarding early detection of inflammatory processes associated with diabetic foot.

During the development phase, the electronic circuit was initially assembled on a breadboard to facilitate component replacement, functional verification, and iterative modifications without permanent soldering. The complete system was subsequently integrated into the orthosis structure.

C. Software Development

The embedded software was developed using the Arduino Integrated Development Environment (Arduino IDE), employing the C++ programming language for implementation of the temperature monitoring algorithm. The software was designed to perform continuous acquisition, processing, and analysis of the temperature signals generated by the LM35 sensors, enabling real-time monitoring of thermal variations associated with diabetic foot complications.

Initially, the algorithm configures the input and output ports of the Arduino Uno microcontroller, defining the analog pins connected to the LM35 sensors and the digital pins responsible for controlling the visual alert system through the LEDs. After the initialization stage, the program continuously acquires the analog voltage values generated by each sensor. The objective of this study was to develop and preliminarily evaluate, through computer simulation, a low-cost Arduino-based wearable orthosis prototype for non-invasive skin temperature monitoring, using bilateral temperature difference as a parameter for the preliminary identification of thermal asymmetries potentially associated with diabetic foot complications.

TABLE I
FUNCTIONAL TESTS OF THE PROPOSED WEARABLE ORTHOSIS

Test	Expected Response	Observed Response
LM35 temperature	Correct acquisition	Correct
Arduino processing	Program execution	Correct
LED indication	Visual activation	Correct
System operation	Continuous execution	Correct

The software was validated through simulations performed in the Tinkercad environment, where different temperature values were applied to the sensors to verify the correctness of signal acquisition, temperature conversion, differential calculation, and activation of the alert system. The simulation stage confirmed the proper execution of the embedded algorithm and demonstrated the feasibility of the proposed monitoring strategy before implementation in the physical prototype.

III. Results and Discussion

The simulation-based evaluation demonstrated the preliminary functional feasibility of the proposed monitoring system. The Tinkercad simulations verified the integration of the Arduino Uno microcontroller, LM35 temperature sensors, and LED-based visual alert system. The functional tests confirmed the expected execution of the programmed logic, including temperature signal acquisition, data processing, calculation of the temperature difference between the simulated monitoring points, and activation of the corresponding visual indicator.

Functional tests confirmed that the embedded software accurately acquired analog signals from the temperature sensors, converted them into temperature values, calculated the temperature difference between the monitored regions, and activated the appropriate visual indicator according to the predefined decision logic. As summarized in Table I, all evaluated functions—including sensor data acquisition, signal processing, LED activation, and continuous system operation—performed as expected throughout the simulations.

The decision algorithm adopted a temperature difference threshold of 2.2 °C, based on the bilateral comparison of corresponding anatomical regions of the feet. Therefore, this threshold should not be interpreted as an isolated absolute temperature value or applied indiscriminately to different anatomical locations. In future experimental and clinical applications, the sensors should be positioned at equivalent anatomical sites on both feet, with a standardized strategy for maintaining consistent skin contact and measurement conditions.

Another important aspect of the proposed device is its affordability and simplicity. The combination of the Arduino Uno platform and LM35 temperature sensors enabled the development of a reproducible and cost-effective wearable system using commercially available electronic components. According to Martín-Vaquero et al., open-source hardware platforms have become an attractive alternative for developing wearable biomedical devices because they reduce implementation costs while maintaining satisfactory performance for research and educational applications [9]. This characteristic is particularly relevant for low- and middle-income countries, where access to commercial plantar temperature monitoring systems may be limited.

The use of the Tinkercad simulation environment also proved valuable during the development process by enabling preliminary validation of the electronic architecture, embedded software, and interaction between sensors and output devices before physical implementation. This approach reduces prototyping costs, facilitates debugging, and improves system reliability during the early stages of biomedical device development.

Despite the preliminary functional results, important limitations should be acknowledged. First, the proposed system was evaluated exclusively through computer simulation and has not yet undergone laboratory calibration or experimental and clinical validation involving individuals with diabetes mellitus. Second, the prototype concept incorporates only two temperature sensors, limiting the number of anatomical regions that can be monitored simultaneously. In future versions, a larger number of sensors should be distributed bilaterally at anatomically corresponding plantar regions, particularly at sites associated with a higher risk of ulceration. In addition, the present study did not experimentally evaluate sensor positioning, skin-contact stability, measurement accuracy, environmental temperature effects, user movement, long-term sensor stability, ergonomic comfort, or dimensional suitability for routine use. These factors may influence temperature measurements and must be investigated before any clinical application of the proposed technology.

Future studies should focus initially on the construction and refinement of the physical prototype, including reduction of its dimensions and optimization of the arrangement of electronic components to improve compactness, comfort, and suitability for routine use. The number of temperature sensors should also be increased, with bilateral distribution at anatomically corresponding plantar regions, particularly at areas associated with a higher risk of ulceration. Sensor positioning should be standardized to ensure equivalence between corresponding regions of both feet and consistent contact with the skin.

The LM35 sensors should subsequently undergo calibration using certified reference instruments, followed by experimental tests under controlled and real-use conditions. These studies should evaluate measurement accuracy, repeatability, environmental temperature effects, sensor stability, movement-related interference, skin-contact conditions, and ergonomic comfort. Finally, experimental and clinical validation involving individuals with diabetes mellitus will be necessary to investigate the clinical applicability of the proposed monitoring strategy. Wireless communication technologies, such as Bluetooth or Wi-Fi, may also be incorporated in subsequent versions to enable remote monitoring and integration with mobile health and telemedicine applications.

Overall, the obtained results demonstrate the functional feasibility of the proposed wearable orthosis and indicate that low-cost open-source technologies can provide an effective foundation for developing assistive biomedical devices aimed at the early prevention of diabetic foot complications. Although further experimental and clinical validation is required, the proposed system represents a promising approach for future wearable health monitoring applications.

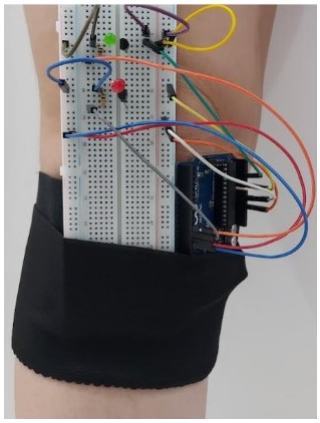

Fig. 4. Temperature Monitoring in Diabetic Foot Prevention.Source: Autor (2026)

IV. FINAL REMARKS

This study presented the development of a low-cost Arduino-based wearable orthosis prototype for non-invasive skin temperature monitoring, aimed at supporting future strategies for diabetic foot prevention. The proposed system integrates an Arduino Uno microcontroller, LM35 temperature sensors, and a visual alert mechanism based on the temperature difference between two monitored points.

The simulation results obtained in the Tinkercad environment demonstrated the preliminary functional feasibility of the electronic architecture and embedded decision algorithm, including temperature signal acquisition, data processing, differential temperature calculation, and activation of the visual alert according to the predefined 2.2 °C threshold.

However, the findings should be interpreted within the scope of a simulation-based preliminary study. No laboratory calibration, experimental testing under real-use conditions, or clinical validation involving individuals with diabetes mellitus was performed. Therefore, the present results do not establish the diagnostic or clinical effectiveness of the proposed device.

Future developments should include the construction and miniaturization of the physical prototype, calibration of the temperature sensors, expansion and standardized bilateral distribution of sensing points, optimization of skin contact and ergonomic characteristics, and evaluation under controlled and real-use conditions. Clinical studies involving individuals with diabetes mellitus will subsequently be necessary to determine the applicability and clinical relevance of the proposed monitoring strategy.

Therefore, the main contribution of this study is the preliminary demonstration of the feasibility of integrating low-cost electronic components and an embedded decision algorithm for bilateral temperature-difference monitoring in a wearable orthosis concept. The proposed architecture provides a basis for subsequent technological development and validation of a more compact, comfortable, and clinically applicable system.

Abstract*—Introduction: Foot drop is a clinical condition derived from neurological injuries characterised by weakness of the muscle tibialis anterior, responsible for ankle dorsiflexion, having as consequence a reduced walking speed, asymmetric gait and increased energy expenditure. Lower limb exoskeletons have been developed to support functional rehabilitation, using sensors to identify gait phases and motors to provide movement assistance, mostly using servomotors, force-sensitive resistors (FSRs) and inertial measurement units (IMUs).The objective of this work is to develop an ankle exoskeleton combining FSR and IMU information to assist ankle dorsiflexion movement while in the swing phase of gait. Method: The device was developed with wearability in mind. The sensors were positioned on the foot: the FSR was secured to the heel by a 3D-printed structure made from flexible filament, which is placed inside the user's shoe; and the IMU sensor was positioned, using a fabric structure, on the foot tip. For the motor, a shin guard was modelled and 3D-printed, also using flexible filament, to ensure greater adaptability to different body types and to keep the motor in place whilst the cable moves. An Arduino Uno and a 7.4V 2,7A battery are used for control and power supply; during the user's walk, these are housed in a knee brace made from neoprene fabric. Results: The wearable exoskeleton developed is capable of recognising the swing phase of the gait, activating the motor and pulling the cable connected to the foot, which in turn assists with dorsiflexion and improves walking. Discussion: Exoskeleton design varies in the literature, particularly with regard to the number and positioning of sensors and the method used to provide assisted dorsiflexion. In this study, both sensors were placed on the foot to improve device wearability and data accuracy. Pressure sensing can be carried out on the calcaneus or the forefoot, depending on the method of gait analysis, while gyroscopes can be positioned on the anterior and posterior aspects of the calf or on the ankle's axis of rotation. Ankle movement can be provided by rigid insoles, which may limit foot propulsion, or cable-based systems, both driven by a rotary motor or servomotor. Conclusions: The sensors, in the chosen quantities and positions, are successfully capable of recognising the swing phase of the gait and activating the servomotor, which, in turn, is able to lift the foot and follow the gait. Further studies are still needed and are ongoing to demonstrate the effectiveness of this exoskeleton in rehabilitation.

***Index Terms*—Exoskeleton, foot drop, gait, force sensing resistor (FSR), inertial measurement unit (IMU).**

This study was supported by institutional funds provided by the Graduate Program in Neuroengineering of the Edmond and Lily Safra International Institute of Neuroscience, Santos Dumont Institute.

I. Introduction

Neurological conditions that can develop to physical impairment are increasingly common today. Stroke and spinal cord injury are among the main causes of motor impairment

acquired in adulthood [1]. In these two cases of neurological injury, a proportion of survivors experience some impairment of lower limb motor function, leading to complications, particularly with regard to gait and mobility. Between 20% and 30% of stroke survivors develop motor impairments such as foot inversion and a lack of dorsiflexion [3]. The latter leads to a gait disorder known as foot drop, in which the individual has insufficient strength to lift their foot during the swing phase of the gait, leading to complications [2].

Foot drop conditions are becoming increasingly common amongst the general population, highlighting the growing number of patients with these conditions who require assistance. An increased risk of falls, contusions and fractures are the main concern for this population due to impaired mobility. It is therefore essential to develop accessible and innovative technologies to support conventional rehabilitation therapies.

Walking is a fundamental activity that brings benefits to an individual's health and well-being [4]. Impairments affecting the lower limbs, usually resulting from either mechanical or neurological injuries, can lead to gait complications, such as a reduced step length and chronic pain, which also have consequences for an individual's mental health and quality of life [5]. Among the motor impairments that develop following a stroke or spinal cord injury, one of the most common is foot drop, which involves an inability to dorsiflex the ankle during the swing phase of the gait cycle – the phase in which the foot is not in contact with the ground. This condition can lead to an asymmetrical gait, reduced walking speed and increased energy waste during walking [6].

As a result of impaired gait, negative effects are observed on an individual's self-esteem, social participation and psychological well-being, mainly due to reduced confidence when walking as a result of an increased risk of falls. This can lead to even more complex problems such as social isolation, anxiety, depression and even mortality [7].

In the literature, wearable assistive devices, such as active orthoses and exoskeletons, emerge as a promising technological tool in the field of neurorehabilitation, contributing to improvements in gait parameters, functional mobility and motor relearning [8], [9]. The use of these technologies, including in home environments, allows for high-intensity, task-specific and repetitive training, which leads to a greater chance of motor recovery [10]. The operating principle of these devices is based on two main points: firstly, the recognition of the gait phase via sensors—in most cases, Force Sensitive Resistors (FSRs) and Inertial Measurement Units (IMUs)—and secondly, the activation of the motor to perform the movement [11], [12]. However, there is no consensus on the optimal number and positioning of sensors for gait recognition, nor on the best method for activating the system.

The aim of this study is to develop an ankle exoskeleton to assist in dorsiflexion, using FSR and IMU sensors in association in order to recognise the gait phase, and a servomotor to assist movement during the swing phase.

II. Methods

A. Sensors

We used one FSR 402 (Interlink Eletronics, California, USA) and one IMU accelerometer and gyroscope, MPU6050 (Invensense Inc, California, USA) to detect the gait phases, more specifically the swing phase.

The FSR is located on the heel of the user and was fixated with a 3D printing structure (Fig. 1). To design the heel structure, a scan was taken of one of the researchers' feet, which was then resized and 3D-printed using flexible filament TPU 95 to improve comfort and adaptability to different shoes and sizes. This structure prevents the sensor from moving and ensures it remains fixed in the desired position for collecting data from the heel. Without it, the sensor moves around inside the shoe and the foot pressure data is no longer accurate.

Fig. 1. Heel Structure

The chosen position for the IMU sensor was the front of the foot. This allows it to detect the foot's inclination, enabling accurate detection of plantar flexion and dorsiflexion. The sensor was secured in the desired position using fabric. The researchers adjusted a fabric and Velcro structure that wraps around the foot and holds both the sensor and the motor-associated rod, which is responsible for holding and pulling the cable on the feet.

The data from the two sensors is used to generate the drive commands for the motor.

B. Motor

We used a DSServo DS3230 Pro 30kg Waterproof Servo (MK Racing, Salzburg, Austria), that works with 4.8 ˜ 6.8V. The battery used, 7.2V and 2,7A, can provide up to 7 hours of autonomy in normal experimental use conditions of the servomotor.

The motor operates based on information from the sensors. Two conditions must be satisfied for the motor to activate, as shown in (Fig. 2). These are:

- The foot must be off the ground. It indicates that the user is on the swing phase of the gait. This information is provided by the FSR sensor located in the heel.
- The foot must be in plantar flexion. This information is provided by the IMU sensor, located in the forefoot.

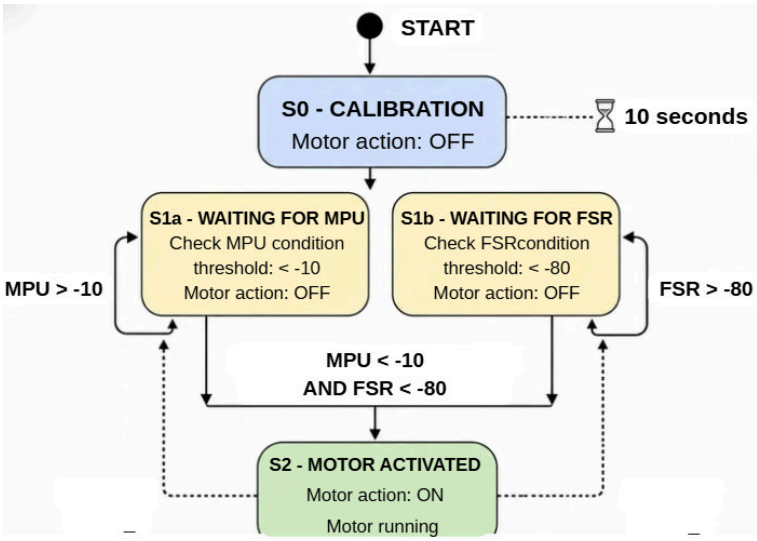

Fig. 2. Finite State Machine

An Arduino Uno microcontroller was used, connected to a printed circuit board (PCB), to establish the link between the data received by the sensors and the command sent to operate the motor.

The code was programmed in C++ to read the sensors, with the necessary calibration performed each time the user started the system. Calibration must be carried out with the user's foot on the floor so that both the pressure between the foot and the volunteer's footwear and the angle between the toe of the footwear and the floor can be measured. A parameter of 10° difference from the calibrated value was used to identify dorsiflexion via the IMU, and a pressure variation of 80 or greater between the current and calibrated values was used to recognise when the foot was off the ground by the FSR.

The motor is positioned on the user's anterior tibia. To this end, a shin guard was designed and 3D-printed both to protect the volunteer's skin and to prevent the motor from falling off or slipping down when activated.

Given the fact that the servomotor we purchased has a rotation of 180°, it was necessary to create a structure that would increase the rotation diameter so that more cable could be pulled at the same angle. We created a pulley that serves both to achieve the required diameter of 2.5 cm and to hold the Bowden cable in place so that it does not slip during operation (Fig. 3). To make it easier to fit the pulley to the motor, we also created a support structure that connects the two parts using screws (Fig. 4). Both structures were 3D-printed using PLA filament, with a gyroid shape and 85% infill to ensure resistance against forces of compression, contraction and shear.

C. Wearable structure

1) Foot/ankle: The design of the footwear component arose from the need to position the accelerometer sensor in the desired location and to attach the cable that would pull the foot to perform the assisted dorsiflexion movement.

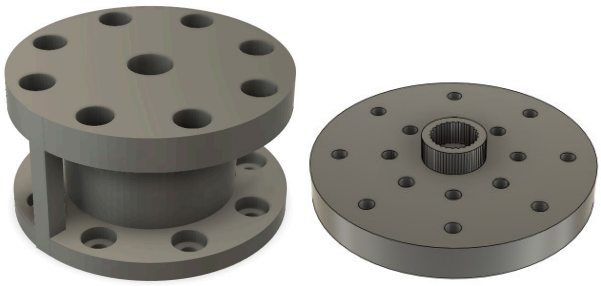

Fig. 3. Pulley and support structure

Fig. 4. Pulley and support structure on servomotor

In this way, two horizontal strips were sewn onto a vertical strip on the foot (Fig. 5). The sensor is located on the top strip. To facilitate the fitting of the device between volunteers, two rods were modelled and 3D-printed in order to adapt the length of the cable to each volunteer's leg.

Fig. 5. Foot structure

The cable adjustment mechanism was designed with two rods, one with a positive fit and the other with a negative fit, which is 3 mm shorter on each side to ensure a secure fit, thereby allowing up to 7 cm of variation in cable length between volunteers (Fig. 6). This structure was printed using PLA filament with a high infill rate (85%) to ensure its integrity.

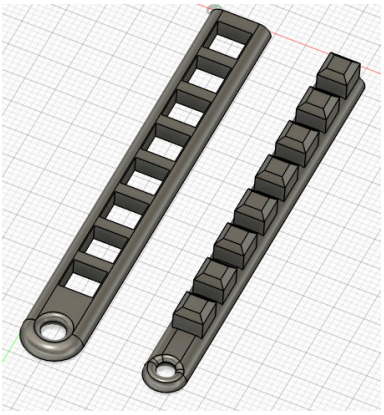

Fig. 6. Rods for cable adjustment

2) Knee: The system was planned and designed for both the battery and the Arduino + PCB assembly to be positioned on the side of the volunteer's affected thigh. To this end, a structure similar to a knee brace was developed, with Velcro strips on the outer sides of the thigh to attach the components to be secured in place (Fig. 7). The knee brace was made from neoprene fabric and also serves to provide support and stability for the shin guard.

Fig. 7. Knee structure

3) Schin: The main challenge in designing the exoskeleton was securing the motor in a position close to the foot in such a way that it did not compromise the user's comfort or the efficiency of the cable-pulling mechanism. With a view to achieving this goal of stabilization and protection, a total of six different versions of the shin guard were developed. The main changes were related to the height required to reduce the impact of the pull on the user's leg, sufficient width to prevent lateral displacement of the sensor while still accommodating users' different body types, and the motor's fit within the shin guard. The last version of the shin guard was 3D printed in flexible filament to allow better comfort for the users and shown to attend the project necessities (Fig.8).

Through sustainability tests, it was observed that the motor operates most efficiently when the pulley is positioned on the outer side and pointing downwards. In this way, the pulling action prevents the foot's inversion and reduces the impact of the reaction torque on the user's leg. For this reason, once the final and desired specifications for the shin guard had been established, an identical but mirror-image model was created for the other leg, so that the motor is correctly positioned for both affected sides.

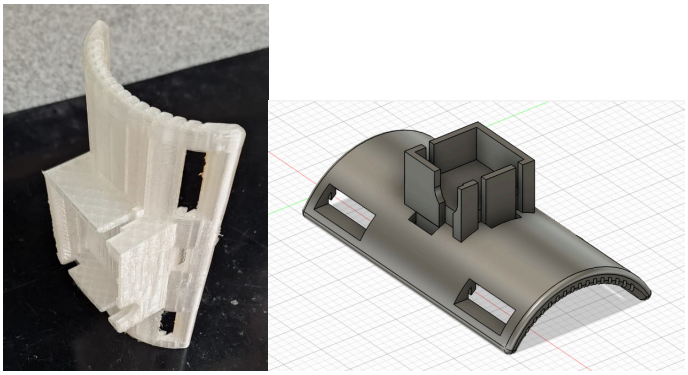

Fig. 8. Schin Guard

4) Safety Button : To ensure user protection, an ergonomic safety button has been added to the device; it is easy to grip and operate. Pressing this button automatically stops the system, so that the motor ceases to apply force to pull the foot and can release more cable to prevent the volunteer's foot from being pulled.

D. Clinical trials

The exoskeleton developed was used on volunteers with foot drop, in accordance with a protocol approved by the Ethics Committee of the Santos Dumont Institute (CAAE 89045425.3.0000.0129). The intervention consisted of 30 minutes of exoskeleton-assisted walking for 4 days over 4 consecutive weeks, amounting to a total of 16 walking sessions.

For metric purposes, gait assessments were carried out on the Zeno Walkway and Qualisys Motion Capture platforms before and after the intervention, and under conditions with and without the exoskeleton. The volunteers were instructed to walk on the platform at a self-selected speed.

Based on this assessment, data relating to the volunteer's gait cycle were obtained, specifying the average total duration of the cycles, as well as the total percentage of the swing and stance phases.

III. Results

As an outcome, we developed a wearable lower-limb exoskeleton to assist the dorsiflexion of the foot in patients with foot drop (Fig. 9). The exoskeleton developed is capable of recognizing the swing phase of the gait of the affected limb using information obtained from the sensors. Once the gait phase in which the foot is dropped is recognized, the device provides dorsiflexion assistance by integrating sensor data with the motor, cable, and rod system (Fig 10).

The device was designed to be adaptable to different users, so that all wearable components — the foot, knee brace, and shin brace — can be used by individuals of different body types without compromising the exoskeleton's function.

Fig. 9. Exoskeleton

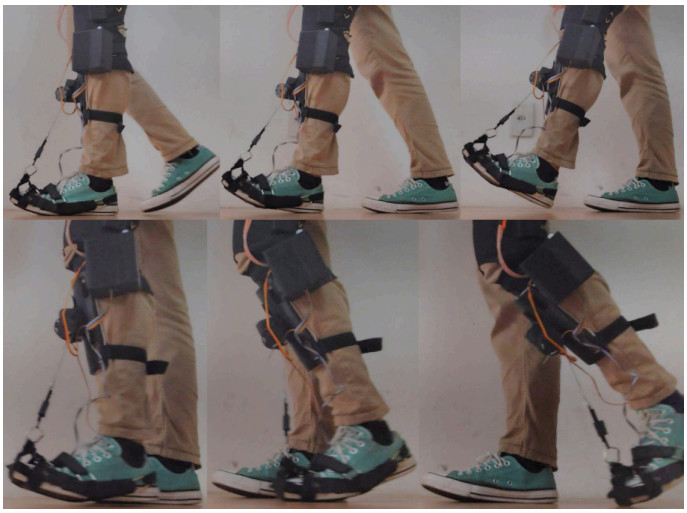

Fig. 10. Gait phases assisted by exoskeleton

The motor has been positioned on the shin in such a way that, even after 30 minutes of activity, it remains securely in place – neither rotating nor sliding down – and continues to lift the foot effectively. This positioning has allowed for the use of shorter cables, which do not become loose with each step. The foot structure housing the IMU sensor and the rod, although being slightly displaced after a long walk, continues to accurately record inclination information and does not compromise the dorsiflexion assistance. The heel structure, which houses the FSR sensor, is comfortable, adaptable to different shoe sizes and ensures that the sensor does not move while walking. Finally, the Arduino and battery are secured to the external side of the thigh via the knee brace structure; their placement does not interfere with walking nor does it compromise the system's operation. When asked, the volunteers reported feeling no discomfort with the noise generated by the motor. Some volunteers reported that the motor noise helped synchronize the execution of the step.

Thus, the developed exoskeleton is capable of assisting with gait in patients with foot drop.

A. Clinical trials

The developed device was tested on volunteers with foot drop and has demonstrated accuracy in detecting the swing phase of the gait in steps. Using the code developed, we can also adjust the walking speed in order to better suit each volunteer's gait, with the aim of promoting a progressively more symmetrical gait.

Using the Zeno Walkway platform, observations were made regarding gait cycle time, both overall and separately for the paretic and unaffected legs. Based on this, reductions in time were observed when comparing walking after the intervention with walking before the intervention, for both conditions—with and without the exoskeleton. The data are set out in the table below.

TABLE I
GAIT CYCLE AND SWING TIME ACCORDING TO VOLUNTEER, TIME, AND CONDITION.

Volunteer	Time	Condition	Gait Cycle Time (sec.)_ Geral	Swing Time (sec.)_ Geral	Gait Cycle Time (sec.)_ Left	Swing Time (sec.)_ Left	Swing Time (sec.)_ Right
1	pre	with	1.520	367	1.515	208	519
1	post	with	1.407	334	1.406	177	491
1	pre	without	1.541	400	1.547	260	540
1	post	without	1.438	369	1.438	213	540
2	pre	with	1.371	474	1.378	475	473
2	post	with	1.252	424	1.255	418	431
2	pre	without	1.462	533	1.458	501	570
2	post	without	1.352	475	1.357	497	453

Gray cells: difference greater than 10% between pre- and post-intervention measurements.

For volunteers 1 and 2, the gait cycle time and swing phase time were reduced during walking after the intervention compared with walking before the intervention. Volunteer 1 (impairment in the right leg), as highlighted in the first four lines, showed a 10 per cent reduction in the overall swing phase and a 17 per cent reduction when considering only the unaffected leg, both when using the exoskeleton. During unassisted walking, Volunteer 1 showed a 22 per cent reduction in the swing phase of the unaffected leg.

Volunteer 2 (affected left leg) had their results shown in the last four lines, with a 10 per cent reduction, when using the exoskeleton, in the overall gait cycle time, a 12 per cent reduction in the overall swing phase, a 10 per cent reduction in the gait cycle time of the affected leg, 13 per cent in the swing phase of the affected leg and 10 per cent in the swing phase of the unaffected leg. As for unassisted walking, the volunteer showed a 12 per cent reduction in the overall swing phase time and a 25 per cent reduction in the swing phase time of the unaffected leg.

In the same optical, the researchers observed, during the interventions with the volunteers, a reduction in compensatory

movements, such as hip and knee elevation, longer strides and greater symmetry between the paretic and unaffected sides.

IV. Discussion

We have developed an ankle exoskeleton to assist with dorsiflexion, which demonstrated satisfactory accuracy in recognising the swing phase of gait in patients with foot drop. Once the swing phase of the gait is recognised, the system sends a command to activate the motor, which is capable of assisting with the dorsiflexion movement, a function that is impaired in this group of individuals. The device was tested during 30-minute walks conducted in volunteers with drop foot and maintained both step recognition and dorsiflexion assistance throughout the entire test period.

The production of the exoskeleton required low costs for the researchers and the institution; a FSR, an IMU, a 2.7A battery, an Arduino Uno, a 30kgF motor and neoprene fabric were purchased, in addition to the parts produced using 3D printing.

The use of exoskeletons in gait rehabilitation has already been widely discussed in the literature. However, the methods for performing assisted dorsiflexion have not yet been standardized. There are, essentially, two factors that differ in relation to exoskeletons developed to assist dorsiflexion. These are: the number and location of the sensors used; and the method of promoting ankle rotation.

Reference [13] used load cells on the anterior and posterior calf associated with gyroscopes on the ankle joint to built soft exoskeletons and detect gait events. Reference [14] used FSRs placed under the heel and in the front part of the foot and an IMU, located on the ankle axis, to compose an exoskeleton ankle robot. Reference [17] used an IMU and an insole with 4 FSRs to activate dorsiflexion and plantarflexion in a pneumatic exoskeleton. Even using different sensors, locations and methods to promote joint movement, both devices were able to promote rehabilitation in patients.

In our project we used a lower number of sensors, one IMU located on the toe and one FSR fixed on the heel with a 3D printed flexible structure, and the authors observed that those were enough for recognizing the gait phases and providing the motors activation

In the same vein, the choice of actuators varies according to their location and the intended movement assistance. Reference [6] developed a system in which the motor is positioned at the back of the hip and foot movement is achieved via Bowden cables, attached to a knee pad and secured to a spiral end connection. As a result, the device created by the authors was able to facilitate dorsiflexion in patients with foot drop. Reference [17] developed artificial pneumatic muscles to assist dorsiflexion and plantaflexion movements. Reference [16] developed the ExoRoboWalker with servomotors associated with a rigid insole to promote dorsiflexion and plantarflexion.

In our device, we positioned the motor on the shin. This positioning was essential for providing assisted dorsiflexion during long walks without the device shifting out of place, thus ensuring the volunteer's comfort. The positioning of the pulley on the lower outer side of the shin guard also served to prevent foot inversion, a common condition in people with foot drop. The placement of the motor on the shin aids rehabilitation due to the improved fit of the device between volunteers, and facilitates the use of the device in activities of daily living since the cable is shorter during the gait phases.

Beyond the advantages related to design and positioning, the accuracy demonstrated by the device during testing, together with the low cost of the instrumentation used, reinforces its potential as an accessible rehabilitation tool. Housing all sensors and the motor on the shin and foot also resulted in a compact, easy-to-don design, which facilitates its use both in supervised rehabilitation sessions and in unsupervised activities of daily living, favouring adherence to treatment.

Reference [15], with the aim of assisting dorsiflexion and eversion of the foot, uses Bowden cables to perform the movement and load cell sensors to detect the events. In another design, the ExoRoboWalker was developed using rotational motors and potentiometers to control motor rotation; when coupled with a rigid insole, it is responsible for the movement of lifting the foot [16].

Although the improvements observed during the interventions - such as reduced compensatory movements, longer strides and greater symmetry between the paretic and unaffected sides - are encouraging, they were so far based on the researchers' observation during the sessions. Further analyses will be carried out, using validated tools such as the Zeno Walkway and Qualisys systems, in order to objectively quantify the gait differences already observed.

Gait cycle time is an important variable for determining walking patterns, and a reduction in this measure is indicative of improvements in functional gait parameters, such as speed, stride length and symmetries [18]. In our study, we observed a reduction in gait cycle time with the exoskeleton following the assisted walking interventions, indicating that its use has potential for rehabilitation and functional recovery. Walking without the exoskeleton following the intervention also showed a reduction in gait cycle time, indicating that functional improvement is maintained even without the assisted dorsiflexion provided by the device.

The analysis was carried out considering only one of the parameters provided by the Zeno platform. Further kinetic and kinematic analyses are currently being carried out. Future studies include conducting assisted walking interventions for patients with foot drop, followed by analysis of movement kinematics and kinetics, as well as assessments of clinical functionality regarding balance, strength, and spasticity.

V. Conclusion

We can conclude that the developed exoskeleton is able to effectively recognize the swing phase of gait in patients with foot drop. The sensors, in the quantities and positions previously described, were capable of accurately determining the swing phase of the gait and, as a result, reliably activating the motor to provide assisted dorsiflexion and aid the patient's walking. Throughout testing, the device maintained consistent

accuracy in gait phase recognition and dorsiflexion assistance, all achieved with low-cost and accessible instrumentation. Positioning the sensors and motor on the shin and foot resulted in a comfortable and adaptable design, which may facilitates its use both in supervised rehabilitation sessions and in unsupervised activities of daily living, reinforcing the device's potential as a practical and reliable rehabilitation tool. The reduction in gait cycle time following the interventions suggests that the exoskeleton intervention has the potential to facilitate functional walking rehabilitation. The reduction in gait cycle time when walking without the exoskeleton suggests that the benefits of the exoskeleton intervention are maintained even without movement assistance. Further analyses, using validated tools such as the Zeno Walkway and Qualisys systems, are needed to objectively quantify the gait improvements already observed and to further determine the effectiveness of the exoskeleton in rehabilitation and activities of daily living for patients with foot drop.

Abstract—**This paper presents the development of the PULSEGRID prototype, an interactive floor system designed for cognitive and motor activities based on the reproduction of audiovisual sequences. The equipment consists of four interactive blocks identified by different colors when illuminated, addressable LED lighting, infrared sensors, an audio system, a numerical display, and an ESP32 microcontroller. Interaction occurs when the system presents a sequence of lights and sounds that must be reproduced by the user by touching or stepping on the corresponding blocks. An Android application connected via Bluetooth enables the adjustment of stimulus duration, the interval between sequences, the maximum response time, and the number of stages in the activity. PULSEGRID was conceived as an adaptable platform for research in biomedical engineering, motor activities, special education, and studies involving neurodivergent individuals. Its configuration enables working memory, attention, reaction time, motor planning, and visuospatial orientation to be combined in a full-body activity. Previous studies indicate that motor interventions and active games show promising results regarding motor skills and executive functions in children with neurodevelopmental disorders. However, technical evaluations, usability testing, and clinical studies are still required to validate the acceptability and potential functional effects of the equipment.**

Keywords—**Biomedical Engineering, Exergame, Neurodivergence, Cognitive-Motor Stimulation, Interactive Floor.**

I. INTRODUCTION

The development of interactive technologies applied to health has enabled new approaches to the assessment, stimulation, and rehabilitation of cognitive and motor functions. Among these technologies are active video games, also referred to as exergames, in which body movements are used as interaction commands [1].

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior — Brasil (CAPES) — Finance Code 001.

Unlike games controlled exclusively by buttons or screens, exergames may require body displacement, postural adjustments, spatial orientation, and coordination among visual, auditory, and motor stimuli. These characteristics make it possible to integrate physical activity and cognitive demands within the same task [2].

This approach may be particularly relevant for neurodivergent individuals, including people with autism spectrum disorder, attention-deficit/hyperactivity disorder, and developmental coordination disorder. However, these populations are highly heterogeneous, making it necessary to adapt stimulus intensity, activity speed, and the time available for response [3].

Autistic children may exhibit differences in balance, bilateral coordination, motor planning, and movement execution [4]. Differences in sensory processing may also influence how visual, auditory, and bodily stimuli are perceived and translated into motor responses [5].

Studies involving structured physical activity have shown promising results regarding motor proficiency and components of executive functioning in autistic children [6]. Exergame-based interventions have also been investigated in children with neurodevelopmental disorders, particularly because they combine movement, attention, motivation, and immediate feedback [7], [8].

In this context, PULSEGRID was developed as an interactive floor system composed of four response regions. The system presents visual and auditory sequences that must be memorized and reproduced by the user by touching the corresponding blocks. This study aims to present the architecture, operation, and potential applications of PULSEGRID as an adaptable technological platform for cognitive and motor activities.

II. MATERIALS AND METHODS

This study is part of a broader research project conducted collaboratively by the Instrumentation and Biomedical Engineering Laboratory (LIEB) and the Movement and Medical Technologies Laboratory (LAMOTEM), approved by the Research Ethics Committee of the Federal University of Mato Grosso do Sul (UFMS), under CAAE no. 71042323.7.0000.0021. However, the stage reported in this paper is restricted exclusively to the conceptual, hardware, firmware, and software development of the PULSEGRID platform. No participants were recruited, no experimental intervention was conducted, and no human data were collected or analyzed during this stage of technological development. Future usability investigations and clinical studies involving participants will be conducted according to the procedures established in the approved research protocol.

A. PULSEGRID Architecture and Physical Structure

PULSEGRID was designed as a whole-body interactive system in which the user responds to presented stimuli through four blocks positioned on the floor. Each block corresponds to a color—yellow, blue, red, or green—and acts simultaneously as a visual stimulation element and a system input area, as shown in Fig. 1.

Fig. 1. PULSEGRID platform.

The PULSEGRID structure was built from MDP panels, with the surface divided into four independent blocks arranged in a 2 × 2 matrix configuration. Each block consists of an acrylic panel bordered by aluminum angle profiles, which provide finishing, protect the edges, and support the installation of addressable LED strips. Positioned along the inner sides of the blocks, these strips illuminate the acrylic panels and enable individual visual identification of each interaction area.

User interaction is detected by a set consisting of an infrared emitter and receiver installed face-to-face at the midpoints of two opposite sides of each block. This arrangement establishes a transverse optical barrier across the respective interaction area. When the user touches or steps on the block, interruption of the infrared beam is identified by the system as an input. The assembly is completed by screws, spacers, supports, and electrical wiring, which secure the components and integrate the mechanical structure with the lighting and detection systems.

PULSEGRID operates by presenting a sequence of stimuli that progressively expands. Initially, the system activates one of the blocks through light and sound stimuli. The user must then touch or step on the corresponding block. After the entire sequence is reproduced correctly, a new element is added and the user must reproduce the complete sequence again. This process continues until the previously configured number of stages is completed, an incorrect response occurs, or the maximum response time is exceeded.

B. Control Module

PULSEGRID uses an ESP32 microcontroller as its central processing unit, responsible for integrating the sensors, visual and auditory systems, and Bluetooth communication with the mobile application. The main electronic components are integrated into a control module connected to the platform by cable (Fig. 2).

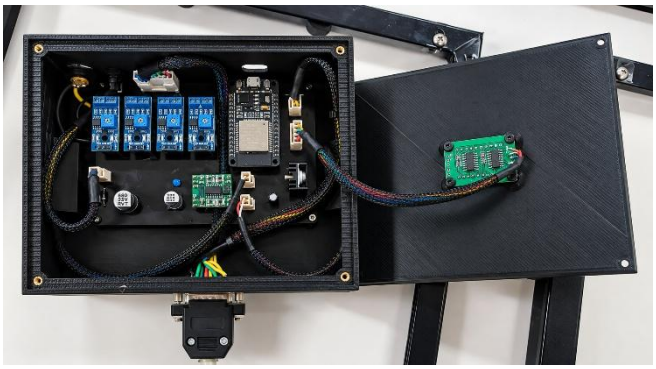

Fig. 2. Internal view of the PULSEGRID electronic control module.

The control module contains a main circuit board (motherboard) integrating the ESP32 microcontroller; the two-digit seven-segment display module; the infrared sensor modules; the PAM8304 amplifier module; the PCM5102A audio digital-to-analog converter (DAC) module with an I²S interface; and all connectors for the remaining components. The motherboard was designed using KiCad® software and fabricated at LIEB using a small CNC milling machine, enabling all components to be integrated and organized within a compact structure.

C. *Detection System and Visual Stimulation System*

The equipment uses one infrared sensor module for each block. The emitter and receiver were positioned face-to-face at the midpoints of opposite sides (Fig. 3), forming an optical barrier along the beam crossing the central region of the block. When the user's hand or foot interrupts this beam, the sensor's electrical signal changes, and this variation is detected and processed by the ESP32 microcontroller.

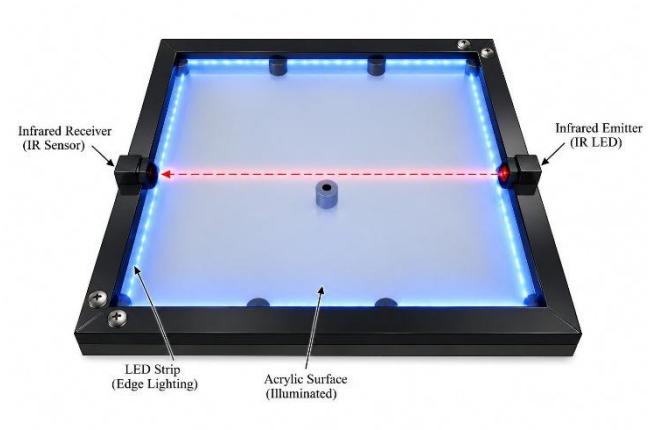

Fig. 3. Illustration of a PULSEGRID block.

To encourage touching the block, in addition to the auditory stimulus, PULSEGRID's visual response is produced by an LED strip containing 72 addressable LEDs (Fig. 3), individually controlled by the ESP32 and distributed so as to form four colored floor blocks. Thus, the visual stimulation system is used to indicate the blocks included in the sequence, guide the user during the activity, and signal the start, correct response, error, and victory conditions.

D. *Auditory Stimulation System*

PULSEGRID's auditory stimulation is digitally synthesized by the ESP32 and transmitted to an external digital-to-analog converter through the I²S protocol. The resulting analog signal is then sent to a stereo amplifier and reproduced through 5 W loudspeakers.

Each block is assigned a characteristic sound frequency, establishing an association among spatial position, color, and sound. The frequencies were defined based on the musical notes C6, E6, G6, and C7, which correspond, respectively, to a harmonic relationship formed by the tonic, major third, perfect fifth, and upper octave (Table I). This arrangement was adopted to provide greater musical coherence to the auditory stimuli generated during sequence playback.

TABLE I
SOUND FREQUENCIES ASSOCIATED WITH THE PULSEGRID BLOCKS

Color	Frequency	Approximate note	Musical relation
Green	1046 Hz	C6	Tonic
Red	1318 Hz	E6	Major third
Blue	1568 Hz	G6	Perfect fifth
Yellow	2092 Hz	C7	Upper octave

The system also uses specific sound effects to indicate the start of the activity, correct responses, errors, and completion of the sequence. The simultaneous presentation of visual and auditory stimuli provides informational redundancy, allowing the user to identify each block both by its color and by its characteristic sound. However, this multimodal configuration may be made adjustable in future protocols, allowing visual-only, auditory-only, and audiovisual conditions to be evaluated separately.

E. *Embedded System Firmware*

The firmware was developed based on a state-machine architecture that organizes the different stages of system operation and coordinates command execution according to the active state. This architecture comprises the following states: initialization of peripherals and the communication interface; standby mode, in which the system waits for a touch on one of the blocks or receipt of a command from the application; sequence generation and storage; playback of visual and auditory stimuli; acquisition and verification of the user's response; sequence expansion after its complete and correct reproduction; error or timeout signaling; execution of victory stimuli; and return to standby mode for the start of a new activity.

The control architecture also manages settings received while an activity is in progress. When a change is sent by the application while a sequence is running, it remains pending and is applied only after completion of the current activity. Thus, changes to execution times or difficulty level do not unexpectedly interfere with the sequence in progress.

To filter rapid signal fluctuations, the firmware performs temporal confirmation of sensor activation before considering the input valid. This procedure is intended to reduce improper detections associated with electrical noise and brief beam interruptions during incomplete movements. The effectiveness of this treatment in reducing false activations should be quantified in specific tests.

F. *Mobile Application*

The PULSEGRID application was developed for Android devices using MIT App Inventor© and communicates with the ESP32 via Bluetooth. As illustrated in Fig. 4, its interface allows the user to start the activity, transmit configuration parameters, and restore the system's default settings.

Fig. 4. Main interface of the PULSEGRID application.

The interface allows four parameters to be adjusted: transition speed between stages; duration of the visual and auditory stimuli; maximum time allowed for the user to touch the block; and level, corresponding to the number of stages required to complete the activity.

The application also receives status messages from the ESP32 indicating whether the settings were applied, whether an activity is already in progress, or whether a communication failure occurred. These adjustments make it possible to adapt activity speed, response time, and difficulty level according to the user's characteristics and performance.

G. System Operational Flow

The system's decision-making logic was structured according to the flowchart shown in Fig. 5.

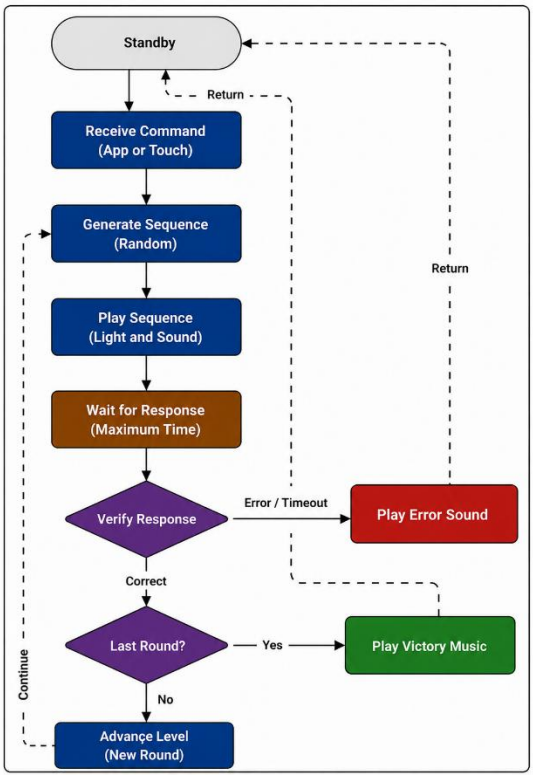

Fig. 5. PULSEGRID flowchart.

When the equipment is powered on, the ESP32 initializes the sensors, lighting system, audio system, display, memory, and Bluetooth communication interface. After initialization, the system enters standby mode, in which the blocks remain available to start the activity. A session can be started by touching any of the blocks or by pressing the Play button in the mobile application.

After the start command is received, the system generates the first element of the sequence. The corresponding block is illuminated and its associated sound is reproduced for the interval defined by the light-and-sound duration parameter. After the stimulus is presented, the equipment enters the response-waiting state. The user must touch the corresponding block within the configured maximum response time. The infrared sensor detects interruption of the beam and transmits the resulting signal to the ESP32.

The detected response is then compared with the stored sequence element. When the response is correct, the system records the successful input and proceeds with the activity. An incorrect response triggers error feedback, whereas the absence of a response within the established interval ends the attempt due to timeout.

After the complete sequence is reproduced correctly, a new element is added. The system then presents the expanded sequence in its entirety, progressively increasing working-memory and motor-planning demands. When the number of stages defined in the application is reached, the equipment executes the victory pattern. After successful completion, an incorrect response, or a timeout, the system automatically returns to standby mode.

Preliminary bench functional verification included sequence generation and playback, input detection, progression after correct reproduction, error and timeout signaling, and return to standby mode. Transmission of settings by the application, status messages, and application of pending changes after completion of the activity were also verified. This verification was qualitative, without measurement of latency, repeatability, or false-trigger rate.

III. RESULTS AND DISCUSSION

Development resulted in a functional PULSEGRID prototype composed of four interactive blocks, infrared sensors, addressable LEDs, an audio system, a numeric display, an ESP32-based control unit, and an application for Android® devices. Preliminary bench tests indicated integrated operation of these components while executing the proposed activity. The system generated, stored, and reproduced pseudorandom sequences of visual and auditory stimuli, while the sensors detected activations performed on each block. The temporal confirmation implemented in the firmware was used to filter rapid signal variations before responses were recognized. However, its effectiveness in reducing unintended activations was not quantified at this stage.

Correct reproduction of the entire sequence allowed progression to the next stage, whereas incorrect responses or expiration of the available time triggered error signaling. The lighting identified the blocks in the sequence and signaled the start, error, and successful completion of the activity. The audio system reproduced the characteristic sounds of each block and the effects associated with these conditions, while the numeric display indicated progression through the stages.

At the end of each attempt, the equipment automatically returned to standby mode.

Bluetooth communication between the ESP32 and the application made it possible to configure the transition speed between stages, stimulus duration, maximum response time, and activity level, corresponding to the number of stages required for completion. The application also received messages regarding application of settings, the existence of an activity in progress, and possible communication failures. Changes received during an activity remained pending until it ended, preserving the parameters of the sequence in progress.

These results indicate the feasibility of integrating the components and functions planned for the prototype under the evaluated bench conditions. The available adjustments make it possible to modify the pace of the activity, the time allowed for response, and the number of elements to be memorized, establishing a basis for future evaluations with users of different profiles.

From an operational standpoint, infrared-barrier detection does not require cameras, wearable devices, or handheld controllers, which may facilitate platform setup and use in certain environments. However, the tests presented were limited to preliminary functional verification of the components and activity execution. Technical validation should include measurements of sensor response time, detection consistency during repeated activations, false-trigger frequency, communication delay, and stability during prolonged operation.

Usability evaluations and studies with participants will also be required to verify comprehension of the instructions, comfort, acceptance, and suitability of the tasks for different user profiles. Therefore, the results of this stage demonstrate the preliminary operation of the prototype, while its possible cognitive and motor benefits remain questions for future investigations.

IV. Potential Applications and Perspectives

The proposed activity combines sequence memorization with the identification and activation of blocks at different positions. Depending on the adopted interaction mode, the task may involve attention, sequential memory, visuospatial orientation, and motor planning. When performed with the feet, it may also require body displacement, weight transfer, and balance during movement. These characteristics describe the expected demands of the activity, whose effects on user performance still need to be investigated.

To expand the possibilities for adaptation to individual sensory characteristics, future versions may include independent adjustments of light intensity and volume, as well as the option to disable auditory stimuli. Evaluation of these features should consider ease of stimulus perception, comfort during interaction, and understanding of the task.

A. Autism Spectrum Disorder

The association among audiovisual stimuli, memorization, and movement allows PULSEGRID to be considered as a platform for investigating complementary activities aimed at autistic children and adolescents. Studies using active video games, also referred to as exergames, present findings that motivate this investigation, although they are not yet conclusive. Edwards et al. reported the feasibility of an active sports game intervention targeting object-control skills [7]. Miranda et al., in a randomized crossover study with nine autistic children, observed reduced reaction time in an inhibitory-control task after an exergame session, without consistent improvement in response accuracy [9].

The small sample size and assessment of the effects of a single session limit the generalizability of these results. Even so, the studies provide a basis for investigating tasks that combine movement and cognitive demands. In PULSEGRID, sequence presentation, user response, and result signaling follow a defined organization. Future studies may evaluate whether this organization supports understanding of the activity and its acceptance by users, taking into account individual differences in sensory and motor characteristics.

B. Attention-Deficit/Hyperactivity Disorder

The combination of physical exercise and cognitive tasks has been investigated as a complementary approach for children with attention-deficit/hyperactivity disorder (ADHD). In a randomized clinical trial, Benzing and Schmidt reported effects of an exergame program on executive functions and motor skills, highlighting the importance of adapting games to the population being studied [8].

In PULSEGRID, the need to wait until sequence presentation has ended before responding makes it possible to explore tasks related to inhibitory control, understood as the ability to suppress premature or inappropriate responses. The progressive increase in sequence length expands the amount of information to be maintained and reproduced, while choosing among the four blocks involves identifying positions and selecting responses. These characteristics may guide studies of attention, working memory, and response control. Quantitative analysis of reaction time will additionally depend on the implementation and validation of a feature for recording this measure.

C. Coordination and Motor Planning Difficulties

The arrangement of the four blocks makes it possible to propose tasks with different movement directions and response positions. Depending on the protocol, interaction may involve laterality, weight transfer, dynamic balance, and precision in positioning the feet or hands. In the current version, the positions and distances between blocks are fixed, while activity pace, response time, and number of stages can be adjusted through the application.

Reproducing sequences in reverse order represents a possible extension of the tasks, but requires adaptation of the operating logic. Use of the platform in clinical or rehabilitation contexts should be investigated through specific protocols, with professional supervision and activities compatible with participants' conditions.

D. Interaction and Cooperative Activities

Interactive platforms may also offer shared activities between participants. Nekar et al. evaluated a multiplayer augmented-reality system with cognitive and motor tasks in 14 autistic children. The study reported feasibility and good acceptance, but highlighted the need for randomized trials with larger samples [10]. As a development perspective, PULSEGRID may incorporate activities in which two users reproduce alternating parts of a sequence or perform a task together. Recognition of simultaneous responses and programmed alternation between participants will depend on adaptations to the firmware and sensor-signal processing.

The use of the floor as an interaction space was also explored by Panceri et al., who integrated serious games projected onto the floor with a socially assistive robot in activities involving autistic children and children with Down

syndrome. The pilot study demonstrated the technical feasibility of this form of interaction [11], providing a reference for the development of activities that use physical space as part of the task.

More broadly, studies on physical activity and exergames contribute to the rationale for the proposed applications. Prieto et al., for example, reported improvements in fundamental motor skills after a parent-mediated physical activity intervention [12]. These findings justify further investigation, but cannot be attributed directly to PULSEGRID because they were obtained with other interventions, protocols, and populations.

V. CONCLUSIONS

This study presented the conceptual and technological development of PULSEGRID, an interactive floor system controlled by an ESP32 and composed of four blocks equipped with sensors, addressable lighting, auditory feedback, a numeric display, and a mobile application.

The architecture enables the development of progressive activities that associate visual and auditory stimuli with bodily responses. Adjustment of stimulus duration and speed, response time, and number of stages makes the system potentially adaptable to users with different motor, cognitive, and sensory characteristics.

From a biomedical engineering perspective, PULSEGRID can serve as a research platform for the development and evaluation of cognitive-motor tasks, with the potential to support future acquisition of objective performance measures. Its main characteristics include a modular structure, relatively low component cost, whole-body interaction, and remote configuration.

Although studies of motor interventions and exergames have reported promising findings in autistic individuals and people with ADHD, this evidence does not demonstrate the effectiveness of PULSEGRID. Technical tests, usability evaluations, and controlled clinical studies are still needed to determine its safety, acceptability, and potential functional effects.

CONFLICT OF INTEREST

The authors declare that there is no conflict of interest.

***Resumo*—A disponibilidade de próteses personalizadas ainda constitui um desafio nos serviços públicos de reabilitação. Este trabalho descreve a aplicação de um fluxo de manufatura digital no desenvolvimento de próteses transradiais passivas para uma participante de 64 anos, com amputação esquerda e preservação de aproximadamente metade do antebraço. A demanda consistia em um dispositivo predominantemente estético, compatível com o uso cotidiano e com a atividade de costura. O fluxo compreendeu escaneamento tridimensional, tratamento da malha, modelagem do soquete, prototipagem por extrusão de material, ajustes presenciais e desenvolvimento de um terminal baseado no modelo Kwawu. Aproximadamente dez versões do soquete em TPU foram avaliadas durante quatro visitas. A configuração final utilizou duas abas sobre os epicôndilos para promover retenção supracondilar, sem cintas adicionais. Foram fabricadas duas próteses completas com o mesmo modelo de soquete e diferentes conexões roscadas. A primeira conexão apresentou menor estabilidade e escape do acoplamento; na segunda, o aumento das dimensões e do comprimento da rosca melhorou a estabilidade durante o reposicionamento do terminal. As próteses apresentaram massas totais de 395 g e 488 g. Após a entrega, a participante relatou perceber a nova prótese como mais leve que a prótese mecânica anteriormente fornecida pelo sistema público e informou utilizar o terminal como apoio passivo durante a costura. Os resultados demonstram a viabilidade inicial do fluxo e a aceitabilidade preliminar dos dispositivos, mas não constituem validação clínica ou funcional, pois não foram empregados instrumentos padronizados, ensaios mecânicos ou acompanhamento prolongado.**

***Index Terms*—manufatura digital, impressão 3D, prótese transradial, tecnologia assistiva, engenharia de reabilitação**

I. Introdução

A amputação de membro superior produz efeitos que ultrapassam a perda segmentar, podendo limitar atividades cotidianas e ocupacionais, modificar a participação social e repercutir sobre a percepção corporal [1], [2]. Nas amputações transradiais, a preservação da articulação do cotovelo mantém possibilidades relevantes de adaptação protética; ainda assim, a ausência da mão compromete tarefas que dependem de preensão, manipulação de objetos e coordenação bimanual [3].

As próteses de membro superior podem responder a objetivos distintos, como compensar limitações funcionais, apoiar atividades específicas ou recompor a aparência corporal. As próteses passivas podem ser estáticas ou ajustáveis; nas soluções de finalidade predominantemente estética, não há restituição de preensão ativa, e o benefício esperado relaciona-se

sobretudo à recomposição do contorno do membro e, conforme as prioridades da pessoa, à confiança e à participação social [2], [4]. Por isso, o dispositivo deve ser definido e avaliado de acordo com sua finalidade e com as prioridades da pessoa, sem equiparar uma prótese estética a um dispositivo destinado à restauração motora [1].

Independentemente do tipo de prótese, sua aceitação e seu uso continuado são influenciados por conforto, funcionalidade, adequação do encaixe, peso, aparência, confiabilidade e facilidade de colocação e retirada. Encaixe inadequado, dor ou desconforto, peso excessivo e incompatibilidade entre o dispositivo e as necessidades individuais são fatores frequentemente associados à insatisfação e ao abandono protético [1], [3], [5]. Como cada membro residual apresenta características anatômicas próprias, a personalização deve abranger o encaixe, a forma externa e o contexto de uso, e não somente medidas lineares ou a escala do dispositivo.

Nos processos convencionais, o encaixe também é individualizado, mas sua fabricação costuma depender de moldes físicos, etapas manuais e ajustes sucessivos. Embora esses procedimentos possam produzir dispositivos adequados, eles demandam trabalho especializado e não geram, por si, um registro digital reutilizável da anatomia e das modificações realizadas no projeto [6].

Os fluxos de manufatura digital integram aquisição tridimensional da anatomia, modelagem computacional e manufatura aditiva. Essa integração permite registrar dados anatômicos, modificar geometrias específicas para cada pessoa, documentar versões e parâmetros de fabricação e produzir novos protótipos sem reiniciar o processo a partir de um molde físico [6]–[8]. Essas possibilidades técnicas, entretanto, não garantem superioridade clínica. A literatura ainda aponta heterogeneidade dos resultados, validação clínica limitada e necessidade de avaliar ajuste, conforto, materiais, durabilidade, segurança e desfechos funcionais [8], [9].

Em serviços públicos, a incorporação desse tipo de fluxo depende de sua compatibilidade com os recursos locais, da qualificação da equipe, da articulação multiprofissional e da continuidade das etapas de avaliação, adaptação e acompanhamento [7], [8]. O presente estudo dá continuidade e aplica, em contexto assistencial, um fluxo digital previamente estruturado no âmbito do Programa de Extensão Mão3D e do Laboratório de Órteses e Próteses 3D da UNIFESP, baseado em biomodelos digitais, modelagem computacional iterativa e manufatura aditiva para o desenvolvimento de próteses passivas personalizadas [10].

A demanda assistencial foi encaminhada, antes do início do desenvolvimento, pela Prefeitura de São José dos Campos, por meio da Unidade de Reabilitação, e consistia na produção de uma prótese predominantemente estética e compatível com a atividade de costura da participante. O trabalho foi realizado em parceria entre o Núcleo de Saúde Digital da UNIFESP, o PET-Saúde Digital, o Programa de Extensão Mão3D, o Laboratório de Órteses e Próteses 3D (LO&P3D/UNIFESP) e a Unidade de Reabilitação da Prefeitura de São José dos Campos. Assim, o objetivo deste trabalho foi descrever a aplicação do fluxo de manufatura digital no projeto e na fabricação de uma prótese transradial passiva, de finalidade predominantemente estética, considerando a anatomia do membro residual e a demanda ocupacional apresentada.

II. Materiais e Métodos

A. Delineamento, contexto assistencial e participante

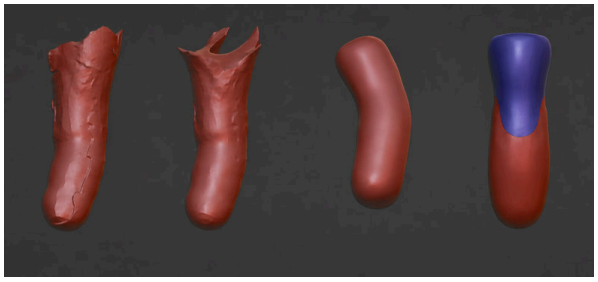
Trata-se de um estudo aplicado e descritivo, de desenvolvimento tecnológico, conduzido como estudo de caso único, com resultados de natureza qualitativa, no contexto da Unidade de Reabilitação da Prefeitura de São José dos Campos (UR/SJC). A participante, de 64 anos, recebeu diagnóstico de sarcoma no membro superior esquerdo em 2007. Segundo seu relato, a manifestação inicial foi caracterizada por dores intensas e contínuas. A condição resultou em amputação transradial esquerda, com preservação de aproximadamente metade do antebraço. A participante possuía experiência anterior com uma prótese mecânica fornecida pelo SUS.

Os resultados foram registrados de forma descritiva a partir da interação direta da participante com os protótipos e com as próteses completas durante as provas presenciais, os ajustes e o uso inicial dos dispositivos. Foram consideradas as observações da equipe, as modificações efetuadas ao longo do processo iterativo e os relatos da participante sobre encaixe, estabilidade, aparência e utilização do terminal durante a costura.

Os dados quantitativos restringiram-se a informações técnicas, como o número aproximado de versões e visitas e as massas dos dispositivos; não foram aplicados instrumentos padronizados nem realizada análise estatística inferencial.

O protocolo de pesquisa foi registrado no Sistema CEP/Conep sob o CAAE 96891226.0.0000.5505. A participante assinou o Termo de Consentimento Livre e Esclarecido e autorizou a publicação das informações e imagens relacionadas ao caso.

B. Origem da demanda e definição dos requisitos



A demanda foi encaminhada pela Prefeitura de São José dos Campos, por meio da Unidade de Reabilitação, antes do início do desenvolvimento. A solicitação consistia em uma prótese predominantemente estética e compatível com a atividade de costura da participante. A partir dessa demanda, foram definidos como requisitos a compatibilidade do soquete com o membro residual, a configuração estética da prótese e sua adequação à atividade informada. A proposta não incluiu mecanismo de preensão ativa.

C. Digitalização e modelagem do soquete

A primeira atividade presencial foi o escaneamento tridimensional do membro residual, realizado na Unidade de Reabilitação por integrantes da área da saúde da equipe. Foi utilizado um escâner EINSTAR (Shining 3D, Hangzhou, China). A malha anatômica obtida foi manipulada e refinada digitalmente mediante correções geométricas, fechamento de superfícies e suavização.

(a)

(b)

Figura 1. Etapas iniciais do fluxo digital: (a) escaneamento tridimensional na Unidade de Reabilitação; (b) estágios de tratamento e refinamento das malhas digitais. Fonte: acervo do projeto.

A Fig. 1 documenta a aquisição tridimensional e o tratamento inicial das malhas digitais.

O soquete foi modelado sobre a malha anatômica no Blender (Blender Foundation, Amsterdam, Países Baixos, versão 3.6 LTS), por meio de ferramentas de escultura digital. Sobre a malha foi criada uma máscara superficial com a geometria do soquete. Na região proximal, foram modeladas duas abas para realizar contato sobre os epicôndilos umerais e promover a retenção ou suspensão supracondilar do soquete.

D. Prototipagem e ajustes presenciais

Foram produzidas aproximadamente dez versões de teste do soquete. As versões selecionadas foram fabricadas em TPU por extrusão de material. Após a sessão de escaneamento, foram realizadas quatro visitas presenciais destinadas às provas e aos ajustes do soquete. Em cada prova, foram observadas a compatibilidade dimensional, a retenção sob tração manual, a facilidade de colocação e retirada, o contato das abas sobre os epicôndilos, a presença de dor ou desconforto relatado e a condição da pele quanto a marcas, irritação ou lesões. As modificações identificadas nessas visitas foram incorporadas às versões digitais subsequentes.

E. Modelagem do terminal, fabricação e montagem

Depois da definição do encaixe, o terminal estético e a conexão roscada foram desenvolvidos a partir do modelo original Kwawu [11]. Os arquivos foram parametrizados no OpenSCAD e posteriormente ajustados no Blender. O terminal passou por ajustes geométricos para esta aplicação, e a geometria negativa da rosca foi incorporada à extremidade distal do soquete.

As versões selecionadas do soquete e o terminal estético foram fabricados em TPU por extrusão de material, enquanto o componente da conexão roscada foi fabricado em PETG pelo mesmo processo. Foram empregados velocidade aproximada de 10 mm/s, temperatura do bico de 240 °C, três paredes e preenchimento de 25% com padrão *gyroid*. A fabricação foi realizada sem suportes. Após a fabricação, os componentes foram submetidos a acabamento e montagem.

A Fig. 2 reúne uma etapa de prova do soquete e os componentes empregados na montagem roscada.

Foram fabricadas duas próteses completas. Posteriormente, foram realizadas duas visitas destinadas à entrega e à avaliação inicial dessas próteses. Desse modo, o processo presencial compreendeu uma sessão de escaneamento, quatro visitas de teste e ajuste do soquete e duas visitas de entrega das próteses completas.

III. Resultados e Discussão

A. Atendimento aos requisitos da demanda

A prótese utilizada anteriormente pela participante era percebida como pesada e rígida. Embora ela conseguisse costurar com o dispositivo, relatou dificuldade para executar a atividade, interferência da prótese na movimentação e impossibilidade de utilizá-la confortavelmente por períodos prolongados. A demanda para o novo desenvolvimento compreendeu uma configuração predominantemente estética, com menor peso percebido, aparência compatível com suas preferências e possibilidade de utilização em atividades cotidianas e durante a costura. Peso, conforto, funcionalidade e compatibilidade com as necessidades individuais são fatores relacionados à aceitação e ao abandono protético [1], [3], [5].

O dispositivo desenvolvido permaneceu classificado como prótese passiva, sem mecanismo de preensão ativa. Durante o desenvolvimento, entretanto, o reposicionamento angular do terminal foi incorporado como possibilidade de adaptação à tarefa. Essa distinção deve ser mantida: o dispositivo não substitui a função motora da mão, mas pode atuar como apoio passivo em atividades específicas [4].

B. Desenvolvimento iterativo do soquete

Foram produzidas aproximadamente dez versões do soquete em TPU. Como não houve registro sistemático individual de todas as impressões, esse número deve ser apresentado como estimativa. O processo de ajuste ocorreu durante quatro visitas presenciais, nas quais os problemas identificados foram incorporados às versões digitais subsequentes. O registro e a modificação de geometrias entre versões integram as possibilidades dos fluxos de manufatura digital [6]–[8].

Na primeira visita, constatou-se incompatibilidade dimensional entre o modelo impresso e o membro residual. O problema foi atribuído à ausência de calibração adequada na aquisição inicial, e um novo escaneamento foi realizado. Na segunda visita, o soquete ainda apresentava folga excessiva. As regiões proximais destinadas ao contato sobre os epicôndilos não apresentavam concavidade suficiente, motivo pelo qual as

(a)

(b)

Figura 2. Prototipagem e montagem: (a) prova de uma versão intermediária do soquete; (b) terminal estético e componente distal roscado. A configuração em (a) é anterior ao sistema final sem cintas. O painel (b) foi aprimorado por inteligência artificial a partir de fotografia do acervo.

abas foram deslocadas para o interior e sua geometria foi acentuada. Na terceira visita, o encaixe estava próximo da configuração desejada e foram realizados ajustes geométricos localizados. Na quarta visita, foi definida a geometria final.

O soquete final utilizou exclusivamente as duas abas sobre os epicôndilos como sistema de retenção, sem cintas ou faixas adicionais. Durante a verificação manual, o dispositivo não se desprendeu sob manipulação habitual. Sua retirada exigia tração deliberada por outra pessoa ou um movimento rotacional intencional realizado pela participante. A colocação e a retirada foram consideradas fáceis. A participante não relatou dor durante as provas, e não foram observadas marcas, irritação ou lesões na pele. Como o tempo de permanência durante os testes foi curto, esses achados não representam avaliação prolongada de conforto.

A definição do encaixe final baseou-se na retenção verificada por tração manual e no retorno fornecido pela participante. O resultado demonstra a viabilidade inicial da suspensão supracondilar empregada, mas não substitui avaliações estruturadas de pressão, conforto e estabilidade durante uso prolongado [3], [5].

C. Terminal estético e conexão roscada

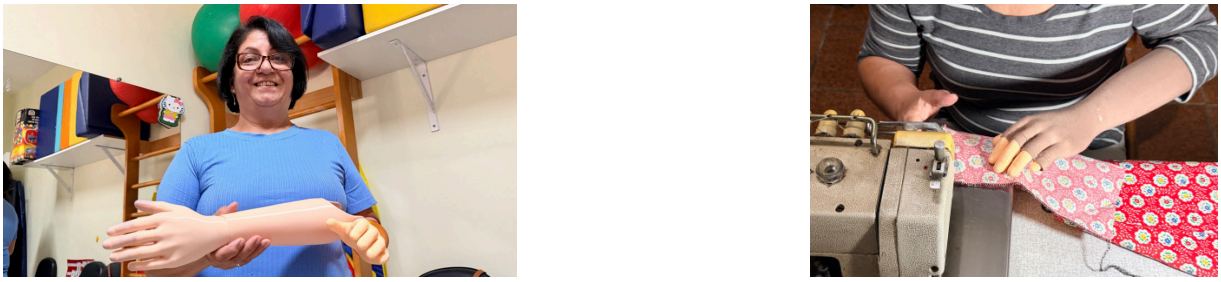
O terminal estético foi desenvolvido a partir do modelo Kwawu citado na metodologia [11]. Por solicitação da participante, os dedos foram discretamente reduzidos e o polegar foi aumentado, buscando aproximar as proporções do terminal das características observadas em sua mão contralateral. A participante também participou da escolha da cor, que constituiu o principal aspecto de personalização estética relatado durante essa etapa.

Foram produzidas duas próteses completas utilizando o mesmo modelo final de soquete. A principal diferença entre elas esteve na conexão roscada. Na primeira prótese, a rosca apresentava dimensões menores e menor comprimento de engate. Embora a participante tenha avaliado positivamente a possibilidade de rotacionar o terminal, essa primeira conexão era mais frágil, podia escapar do acoplamento e limitava a estabilidade das posições selecionadas.

Na segunda prótese, as dimensões e o comprimento da conexão foram ampliados. O maior engate entre os componentes aumentou a estabilidade do terminal durante o reposicionamento e reduziu a ocorrência de escape da rosca. Essa configuração foi adotada como solução definitiva. O terminal podia ser reposicionado angularmente mediante afrouxamento da conexão, rotação até a orientação desejada e novo aperto.

As duas próteses foram entregues à participante. A primeira unidade foi mantida como dispositivo secundário e passou a ser utilizada pela participante durante a hidroginástica. Esse uso foi uma decisão espontânea da participante e não foi acompanhado por ensaio de estanqueidade ou certificação de impermeabilidade; portanto, o estudo não permite afirmar que o dispositivo seja à prova d'água. A segunda prótese, com a conexão ampliada, passou a ser utilizada preferencialmente em atividades sociais e cotidianas.

D. Fabricação das próteses completas



Na primeira prótese, o soquete apresentou massa de 258 g e tempo de impressão de 36 h, enquanto o conjunto terminal apresentou massa de 137 g e tempo de impressão de 19 h 30 min. A massa total calculada foi de 395 g, com tempo acumulado de impressão de 55 h 30 min.

Na segunda prótese, o soquete apresentou massa de 240 g e tempo de impressão de 34 h, enquanto o conjunto terminal apresentou massa de 248 g e tempo de impressão de 33 h. A massa total calculada foi de 488 g, com tempo acumulado de impressão de 67 h.

A maior massa do conjunto terminal da segunda prótese coincidiu com a ampliação da conexão roscada. Como a massa da rosca não foi medida separadamente, não é possível atribuir quantitativamente a diferença observada apenas a essa modificação. Como não foram registrados o consumo total de material e o custo direto de fabricação, não devem ser apresentadas afirmações quantitativas sobre economia. Também não foi realizada comparação objetiva de massa com a prótese mecânica anteriormente fornecida pelo SUS; qualquer referência à maior leveza deve ser apresentada como percepção da participante.

E. Entrega e percepção inicial de uso

A primeira visita de entrega ocorreu com a disponibilização da prótese dotada da conexão roscada menor. Após o uso inicial, a participante relatou instabilidade e escape da conexão, embora tenha aprovado a possibilidade de reposicionar angularmente o terminal. Esse retorno motivou o aumento das dimensões e do comprimento da rosca.

(a) (b)

Figura 3. Dispositivos finais e uso inicial: (a) as duas próteses completas, com a mesma geometria de soquete e conexões roscadas distintas; (b) utilização do terminal como apoio passivo na condução do tecido durante a costura. Fotografias: Claudio Vieira/Prefeitura de São José dos Campos, reproduzidas com autorização.

Na segunda visita de entrega, foi disponibilizada a prótese com a conexão modificada. Essa configuração apresentou maior estabilidade e foi confirmada como versão definitiva. A versão definitiva permaneceu com a participante desde o final de maio de 2026.

Em relato público posterior à entrega, a participante descreveu a nova prótese como mais leve que a prótese mecânica anteriormente fornecida pelo SUS e informou utilizá-la em atividades cotidianas e durante a costura [12]. Durante essa atividade, o reposicionamento do terminal permitiu utilizar a mão como apoio passivo para sustentar, orientar e conduzir o tecido. A participante também expressou satisfação com a aparência e indicou intenção de continuar utilizando o dispositivo.

A Fig. 3 apresenta as duas próteses completas e o uso do terminal como apoio passivo durante a costura.

Esses relatos são compatíveis com os requisitos identificados no início do desenvolvimento e constituem evidência preliminar de aceitabilidade e utilidade percebida. Entretanto, foram obtidos por observação não padronizada e por entrevista jornalística, sem aplicação de escalas validadas de conforto, satisfação ou desempenho ocupacional. Não devem, portanto, ser interpretados como demonstração de eficácia funcional.

F. Limitações

O trabalho apresenta as limitações inerentes a um estudo de caso único. Não foram realizados ensaios mecânicos, avaliação controlada de desempenho, comparação com métodos convencionais ou aplicação de instrumentos padronizados de conforto, satisfação e função. As provas presenciais do soquete tiveram duração curta, e o acompanhamento após a entrega ainda não permite avaliar durabilidade, integridade dos materiais ou uso continuado em longo prazo [8], [9].

O número de versões do soquete é aproximado, pois não houve registro sistemático de cada impressão e de todas as alterações geométricas. Os relatos de uso cotidiano e costura são subjetivos e não foram acompanhados por medição ergonômica ou análise quantitativa da atividade. Assim, os resultados demonstram a aplicação inicial do fluxo, o refinamento iterativo do encaixe e a aceitabilidade preliminar das próteses, mas não validam um protocolo clínico ou produtivo generalizável.

IV. Conclusão

O fluxo de manufatura digital possibilitou desenvolver aproximadamente dez versões de teste do soquete e fabricar duas próteses transradiais passivas completas para uma participante atendida pelo SUS. A prototipagem iterativa permitiu corrigir a incompatibilidade dimensional inicial, aprimorar o contato sobre os epicôndilos e obter retenção supracondilar sem cintas adicionais. A personalização do terminal baseado no modelo Kwawu e a ampliação da conexão roscada na segunda prótese responderam, respectivamente, às preferências estéticas da participante e à necessidade de maior estabilidade durante o reposicionamento da mão.

Após a entrega, a participante relatou perceber a nova prótese como mais leve que a prótese mecânica anteriormente fornecida pelo SUS e informou utilizar o terminal como apoio passivo durante a costura. Esses achados indicam aceitabilidade inicial e compatibilidade do dispositivo com a demanda apresentada, mas não demonstram eficácia funcional. A generalização dos resultados é limitada pelo estudo de caso único, pelo curto período de acompanhamento e pela ausência de ensaios mecânicos, instrumentos padronizados e avaliação quantitativa do desempenho ocupacional.

Agradecimentos

Os autores agradecem à Unidade de Reabilitação da Prefeitura de São José dos Campos, ao Núcleo de Saúde Digital da Universidade Federal de São Paulo, ao PET-Saúde Digital e ao Laboratório de Órteses e Próteses 3D pelo apoio técnico e institucional.

***Abstract*—A acessibilidade digital é um fator fundamental para a inclusão social de pessoas com deficiência, especialmente aquelas com limitações motoras severas, que frequentemente encontram barreiras no uso de dispositivos convencionais de interação computacional. Neste contexto, este trabalho apresenta o desenvolvimento de duas interfaces homem-máquina de baixo custo voltadas à ampliação do acesso a recursos digitais por meio da utilização de múltiplos sensores. O primeiro protótipo utiliza sensores inerciais e eletromiografia de superfície (EMG) para realizar o controle do cursor e a execução de comandos de clique, respectivamente. Os resultados obtidos demonstraram a viabilidade da integração dos sensores e da estratégia de fusão de sinais adotada, permitindo a conversão de movimentos residuais e contrações musculares em comandos digitais. Como complemento, foi desenvolvido um software de treinamento em formato de jogo sério utilizando a biblioteca Pygame, destinado à calibração do sistema e à adaptação do usuário ao dispositivo. O segundo protótipo, baseado em acionamento capacitivo e estrutura modelada em três dimensões, encontra-se em fase de desenvolvimento, apresentando resultados preliminares promissores em sua modelagem e implementação. Os resultados indicam que a combinação de diferentes tecnologias de sensoriamento constitui uma alternativa viável para o desenvolvimento de dispositivos assistivos acessíveis, contribuindo para a ampliação da autonomia, da inclusão digital e da participação social de pessoas com deficiência motora.**

***Index Terms*—tecnologia assistiva, fusão de sinais, mobilidade reduzida**

I. Introdução

Em uma sociedade cada vez mais conectada e dependente de recursos tecnológicos, a inclusão digital tornou-se um fator essencial para a participação plena dos indivíduos em atividades educacionais, profissionais e sociais. Apesar dos avanços tecnológicos observados nas últimas décadas, ainda persistem desafios significativos relacionados à acessibilidade digital, especialmente para pessoas com limitações motoras. Barreiras tecnológicas, econômicas e de usabilidade dificultam o acesso a dispositivos computacionais convencionais, comprometendo a autonomia e a qualidade de vida desses usuários [1].

Os dispositivos de entrada tradicionalmente utilizados para interação com computadores, como teclados e mouses convencionais, foram desenvolvidos considerando predominantemente usuários sem restrições motoras. Consequentemente, muitas pessoas com comprometimentos motores severos encontram dificuldades para realizar tarefas simples em ambientes digitais, uma vez que os equipamentos disponíveis comercialmente nem sempre oferecem a sensibilidade, a personalização ou a adaptabilidade necessárias para converter movimentos de baixa amplitude e intensidade em comandos digitais precisos e confiáveis [2].

As limitações de acesso às tecnologias digitais impactam diretamente a inclusão social, educacional e profissional desses indivíduos. A dificuldade de interação com sistemas computacionais reduz oportunidades de comunicação, aprendizado, trabalho e entretenimento, além de restringir a independência funcional e a participação ativa na sociedade [3]. Nesse contexto, o desenvolvimento de tecnologias assistivas capazes de ampliar a acessibilidade digital representa uma importante estratégia para promover autonomia e inclusão.

Diante desse cenário, este trabalho propõe o desenvolvimento de interfaces homem-máquina baseadas na integração de múltiplas tecnologias de aquisição de sinais, incluindo eletromiografia de superfície (EMG), sensores capacitivos, chaves de fim de curso e sensores inerciais. A utilização combinada desses dispositivos busca explorar diferentes formas de interação, permitindo que usuários com distintos níveis de comprometimento motor possam acessar recursos computacionais por meio de movimentos residuais ou sinais musculares voluntários. Além disso, a abordagem proposta prioriza soluções de baixa complexidade, baixo custo e elevada capacidade de adaptação às necessidades individuais dos usuários [4], [5].

Para validar essa proposta, foram desenvolvidos dois protótipos de mouse acessível destinados a pessoas com diferentes graus de limitação motora. Ambos os sistemas têm como objetivo substituir ou complementar dispositivos convencionais de entrada, transformando sinais captados pelos sensores em comandos digitais capazes de controlar aplicações computacionais. O primeiro protótipo utiliza predominantemente sinais eletromiográficos para o acionamento dos comandos, enquanto o segundo incorpora sensores inerciais e outros mecanismos de interação, ampliando as possibilidades de uso e adaptação às características funcionais de cada usuário.

Como complemento ao desenvolvimento do hardware, foi implementado um software de treinamento e validação em formato de jogo sério, permitindo que os usuários realizem o processo de aprendizado de forma lúdica e progressiva. Essa ferramenta possibilita a calibração dos parâmetros do sistema, o ajuste dos níveis de sensibilidade e a avaliação do desempenho dos métodos de acionamento, contribuindo para uma experiência de uso mais intuitiva e personalizada.

Dessa forma, o objetivo deste trabalho é desenvolver e avaliar estratégias de interação digital baseadas na combinação de múltiplos sensores,como eletromiográficos, capacitivos, mecânicos e inerciais, para a construção de interfaces homem-máquina acessíveis. Busca-se, por meio da implementação e comparação de dois protótipos, identificar soluções de baixo custo, alta adaptabilidade e elevado potencial de aplicação como tecnologia assistiva, contribuindo para a ampliação da acessibilidade digital e da autonomia de pessoas com severas limitações motoras.

II. Materiais e Métodos

Este trabalho caracteriza-se como uma pesquisa aplicada, com enfoque no desenvolvimento de tecnologias assistivas voltadas à promoção da acessibilidade digital para pessoas com limitações motoras. A proposta consiste na concepção e implementação de interfaces homem-máquina capazes de converter diferentes sinais fisiológicos e mecânicos em comandos digitais, utilizando componentes de baixo custo e ampla disponibilidade comercial.

Os principais materiais empregados no desenvolvimento dos protótipos foram: Sensor inercial MPU-6050, composto por acelerômetro e giroscópio de três eixos; Shield de eletromiografia (EMG) Olimex para aquisição de sinais musculares de superfície; Microcontrolador ESP32-S2 Mini para processamento dos sinais e comunicação com o computador.

A metodologia adotada foi estruturada em quatro etapas principais, descritas a seguir.

A. Revisão bibliográfica

Inicialmente, realizou-se uma revisão da literatura com o objetivo de identificar o estado da arte relacionado ao desenvolvimento de dispositivos de tecnologia assistiva e interfaces homem-máquina para pessoas com limitações motoras. Foram analisados trabalhos envolvendo diferentes formas de interação baseadas em sinais musculares, sensores inerciais e outros métodos alternativos de acionamento, buscando compreender as soluções existentes, suas limitações e oportunidades de melhoria.

B. Estudo e seleção dos sensores

Na segunda etapa, foi conduzida uma análise comparativa entre diferentes tecnologias de sensores com potencial aplicação em dispositivos assistivos. Foram avaliados sensores eletromiográficos, capacitivos, indutivos, inerciais e chaves mecânicas de fim de curso, considerando critérios como sensibilidade, robustez, facilidade de integração, custo e adequação aos diferentes níveis de comprometimento motor dos usuários. A partir dessa análise, foram selecionados os sensores mais adequados para a implementação dos protótipos propostos.

C. Desenvolvimento e integração dos protótipos

A terceira etapa compreendeu o desenvolvimento dos dispositivos e a integração entre hardware e software. O primeiro protótipo foi implementado utilizando o microcontrolador ESP32-S2 Mini e os sensores selecionados, empregando a linguagem CircuitPython para aquisição, processamento e interpretação dos sinais captados. A estratégia adotada baseia-se na fusão de sinais provenientes de diferentes sensores, permitindo o reconhecimento de comandos destinados ao controle

do cursor e à execução de ações equivalentes às de um mouse convencional. Os testes funcionais preliminares do Protótipo 1 foram realizados em ambiente de laboratório controlado. A aquisição do sinal EMG via Shield Olimex operou sob taxa de amostragem de 1 kHz, com eletrodos de superfície dispostos no músculo bíceps braquial e limiar de detecção (threshold) ajustado via software após normalização da amplitude do sinal. A movimentação inercial pelo MPU6050 foi aferida registrando-se a resposta de deslocamento do cursor em pixels/segundo em relação aos ângulos de inclinação (pitch e roll). As rotinas de teste integradas ao jogo Pygame registraram a estabilidade da comunicação I2C/CircuitPython e o tempo de resposta entre o evento muscular/inercial e a resposta visual na tela.

O segundo protótipo encontra-se em fase de desenvolvimento e modelagem mecânica. Nesta etapa, está sendo utilizado o software CAD SolidWorks para o projeto estrutural e a definição da arquitetura do dispositivo, visando à futura implementação física e validação experimental.

D. Desenvolvimento do software de treinamento e validação

Como complemento ao desenvolvimento do hardware, foi implementado um software de treinamento utilizando a biblioteca Pygame. O sistema foi concebido na forma de um jogo sério, permitindo a calibração dos sensores, a adaptação dos parâmetros de sensibilidade e o treinamento progressivo dos usuários. Além de auxiliar no processo de aprendizagem da utilização do dispositivo assistivo, o software possibilita a realização de testes funcionais e a demonstração técnica dos protótipos desenvolvidos.

III. Protótipo 1

O desenvolvimento do primeiro protótipo foi dividido em quatro etapas principais: implementação do controle de movimentação do cursor por meio do sensor MPU6050, desenvolvimento do sistema de clique utilizando sinais eletromiográficos (EMG), criação de um software para calibração e treinamento do usuário e integração dos subsistemas. O segundo protótipo foi estruturado em três etapas: modelagem mecânica, desenvolvimento da programação embarcada e integração dos sistemas.

A. Sensor MPU6050

O sensor MPU6050 foi selecionado por integrar um acelerômetro e um giroscópio de três eixos em um único dispositivo, apresentando baixo custo, ampla disponibilidade comercial e facilidade de integração com sistemas embarcados. Para este trabalho, utilizou-se exclusivamente a funcionalidade de acelerometria para o controle do deslocamento do cursor do mouse nos eixos X e Y.

A comunicação entre o sensor e o microcontrolador foi realizada por meio do protocolo I2C, reduzindo a quantidade de conexões necessárias e simplificando a montagem do circuito. A estratégia de aquisição e processamento dos dados foi implementada utilizando a linguagem CircuitPython embarcada no microcontrolador.

Por meio da medição das acelerações nos três eixos espaciais, foi possível mapear os movimentos realizados pelo usuário e convertê-los em deslocamentos correspondentes do cursor na interface gráfica. Os testes realizados demonstraram que o sensor apresentou estabilidade e sensibilidade adequadas para a aplicação proposta, permitindo um controle contínuo e intuitivo do cursor.

B. Sensor EMG

O sensor de eletromiografia foi empregado para a execução dos comandos de clique do mouse. Para sua utilização, foi integrado ao Shield EMG Olimex, responsável pelo condicionamento e amplificação dos sinais musculares adquiridos. A combinação entre os dois dispositivos mostrou-se adequada para a aplicação proposta devido à sua simplicidade de utilização, acessibilidade financeira e facilidade de integração com sistemas embarcados.

A aquisição dos sinais foi realizada utilizando um microcontrolador Arduino Uno conectado ao Shield Olimex, sendo a leitura efetuada por meio da entrada analógica A0. Para garantir o funcionamento adequado do sistema, foi necessário posicionar corretamente os eletrodos sobre o músculo monitorado. O eletrodo de referência foi fixado em uma região sem atividade muscular significativa, enquanto os eletrodos de medição foram posicionados ao longo do ventre muscular.

A Figura 1 apresenta um exemplo do sinal eletromiográfico obtido durante os testes realizados no músculo bíceps braquial. Observa-se a presença de um pico associado à contração muscular voluntária, utilizado como evento de acionamento do sistema.

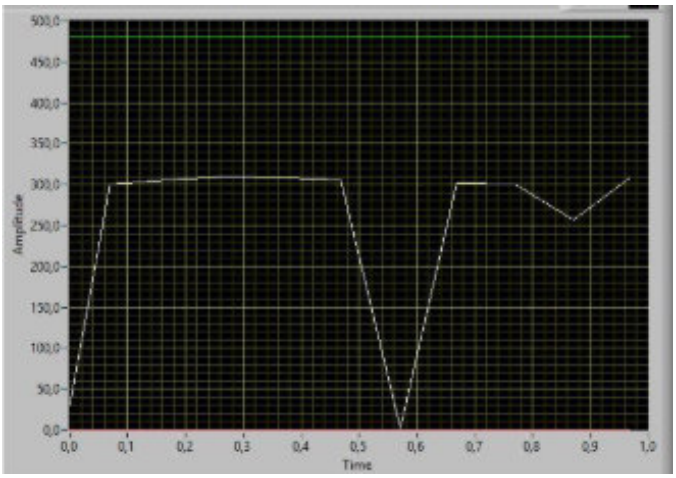

Fig. 1. Leitura do sinal eletromiográfico durante uma contração muscular.

Para a identificação automática dos comandos de clique, foi definido um limiar de detecção. Quando a amplitude do sinal ultrapassa esse valor pré-estabelecido, o sistema interpreta a ocorrência como um comando válido de clique. O limiar pode ser ajustado tanto por meio de um potenciômetro quanto por software, permitindo a adaptação do dispositivo às características musculares e limitações específicas de cada usuário.

Os resultados obtidos demonstraram que a estratégia adotada foi capaz de detectar de forma consistente as contrações musculares voluntárias, possibilitando sua conversão em comandos digitais de maneira simples e eficiente.

C. Software de treinamento

Como complemento ao desenvolvimento do hardware, foi implementado um software de treinamento utilizando a biblioteca Pygame. O sistema foi concebido na forma de um jogo sério inspirado no gênero shoot 'em up, no qual o jogador controla uma nave espacial com o objetivo de eliminar inimigos e evitar colisões com projéteis adversários.

A principal finalidade da ferramenta é auxiliar o usuário durante o processo inicial de adaptação ao dispositivo, além de permitir a calibração dos parâmetros de sensibilidade dos sensores utilizados. A abordagem lúdica busca aumentar o engajamento do usuário durante o treinamento, tornando o processo de aprendizagem mais intuitivo e motivador.

O jogo foi projetado para ser controlado exclusivamente pelo protótipo desenvolvido. Os movimentos da nave são realizados a partir dos deslocamentos captados pelo sensor MPU6050, que controlam a posição do cursor nos eixos horizontal e vertical. Já os comandos de clique, obtidos por meio do sensor EMG, ativam um escudo temporário que torna a nave invulnerável por um curto intervalo de tempo.

A dinâmica do jogo segue o modelo de progressão contínua, em que a dificuldade aumenta gradativamente com o avanço das fases, por meio do aumento da velocidade e da quantidade de inimigos presentes na tela. Além disso, níveis específicos incluem o enfrentamento de chefes (bosses), exigindo maior precisão e controle por parte do usuário.

A Figura 2 apresenta a interface gráfica desenvolvida para treinamento e validação do sistema. Os testes realizados demonstraram o correto funcionamento da comunicação entre o protótipo e o software, permitindo a utilização do jogo como ferramenta de treinamento, calibração e demonstração tecnológica.

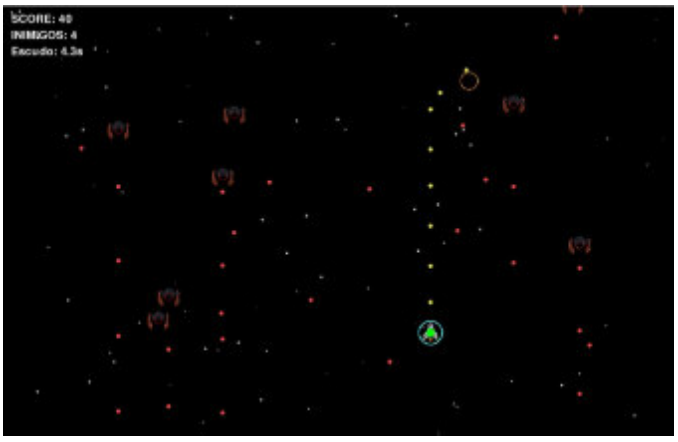

Fig. 2. Software de treinamento desenvolvido em Pygame.

D. Integração dos sistemas

Após a validação individual dos sensores, realizou-se a integração entre o MPU6050 e o sistema de aquisição de sinais EMG em um único protótipo funcional, conforme ilustrado na Figura 3.

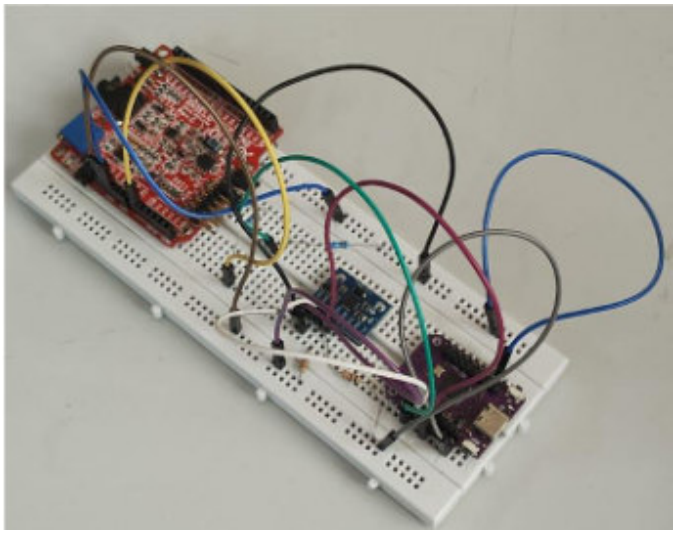

Fig. 3. Protótipo integrado desenvolvido.

Nessa configuração, o sensor MPU6050 foi responsável pelo controle do deslocamento do cursor, enquanto o sensor EMG foi utilizado para a geração dos comandos de clique. A integração dos sistemas permitiu validar o funcionamento conjunto dos componentes, demonstrando a viabilidade da arquitetura proposta para aplicações de acessibilidade digital.

Os testes preliminares indicaram que a comunicação entre os módulos ocorreu de forma estável, possibilitando a conversão dos movimentos e contrações musculares em comandos computacionais. Os resultados obtidos evidenciam o potencial da combinação de sensores inerciais e eletromiográficos para o desenvolvimento de interfaces homem-máquina acessíveis, de baixo custo e adaptáveis a diferentes níveis de comprometimento motor.

A abordagem multimodal proposta alinha-se às tendências de tecnologias assistivas de baixo custo [6]. Dispositivos baseados exclusivamente em EMG oferecem precisão para acionamentos binários, porém podem induzir à fadiga muscular quando utilizados por períodos prolongados [7]. Ao combinar o EMG apenas para a função discreta de clique e o MPU6050 para o deslocamento contínuo do cursor, a presente solução minimiza a carga muscular exigida. Por outro lado, soluções que empregam unicamente rastreamento inercial ou ocular [8] enfrentam desafios operacionais em usuários com tremores involuntários. A integração da filtragem digital e o ajuste de limiar flexível no ESP32-S2 reduzem falsos positivos causados por ruídos de movimento.

IV. Protótipo 2

Com o objetivo de ampliar as possibilidades de interação para usuários com diferentes níveis de comprometimento mo-

tor, foi desenvolvido um segundo protótipo baseado em acionamento capacitivo. Diferentemente do primeiro dispositivo, que utiliza sinais eletromiográficos para a execução dos comandos de clique, esta proposta busca explorar uma interface de toque capaz de detectar contatos de baixa intensidade, permitindo sua utilização por indivíduos que preservam movimentos residuais limitados. Além de reduzir a complexidade do sistema, essa abordagem contribui para o desenvolvimento de uma solução de baixo custo, fácil implementação e elevada adaptabilidade, ampliando o conjunto de tecnologias assistivas disponíveis para promoção da acessibilidade digital.

A. Modelagem

A estrutura mecânica do segundo protótipo foi desenvolvida por meio de modelagem tridimensional utilizando software CAD. O processo de desenvolvimento ocorreu de forma iterativa, permitindo sucessivos refinamentos no projeto para otimizar a disposição interna dos componentes eletrônicos, a ergonomia e a usabilidade do dispositivo.

O modelo final, apresentado na Figura 4, consiste em uma interface vestível no formato de anel, projetada para acomodar os elementos eletrônicos necessários ao acionamento por toque capacitivo. Além de garantir a proteção física dos componentes, a estrutura foi concebida para proporcionar conforto durante o uso prolongado e facilitar a interação de usuários com limitações motoras.

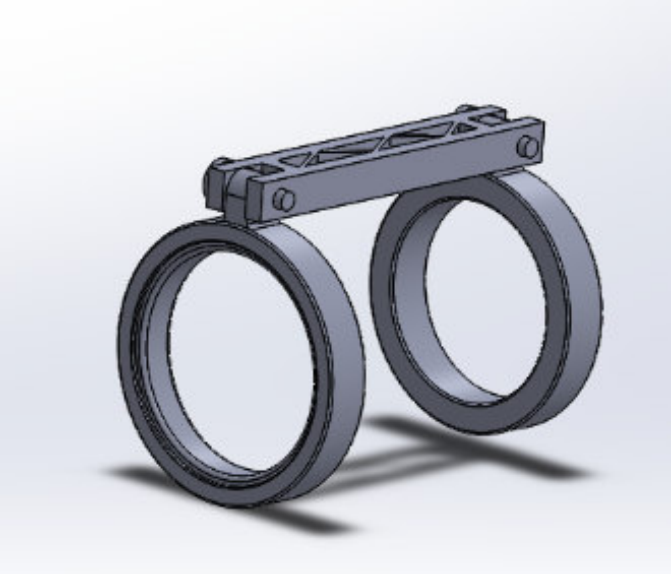

Fig. 4. Modelo tridimensional do protótipo baseado em sensor capacitivo.

B. Programação

O sistema de acionamento foi desenvolvido utilizando o microcontrolador ESP32-S2 Mini, explorando sua capacidade nativa de leitura capacitiva. Essa característica permitiu implementar uma interface de toque sem a necessidade de circuitos adicionais de condicionamento de sinal, reduzindo a complexidade e o custo do dispositivo.

A programação foi realizada em CircuitPython, utilizando a biblioteca Adafruit HID para a emulação de dispositivos de entrada do tipo mouse e teclado. O limiar de detecção capacitiva foi definido experimentalmente por meio de testes sucessivos, buscando maximizar a sensibilidade ao toque e, simultaneamente, minimizar a ocorrência de acionamentos indevidos provocados por ruídos elétricos ou interferências ambientais.

Os resultados obtidos demonstraram a capacidade do sistema em detectar toques intencionais de forma consistente, convertendo-os em comandos digitais utilizados para interação com o computador. Dessa forma, o protótipo apresenta potencial para atender usuários que possuem mobilidade residual limitada, mas que ainda conseguem realizar pequenos movimentos ou contatos físicos controlados.

C. Integração dos Sistemas

A etapa de integração envolveu a montagem do circuito eletrônico em protoboard para validação funcional dos componentes e dos algoritmos desenvolvidos. Foram utilizados cabos de extensão para posicionar a superfície sensível ao toque de forma independente da placa principal, proporcionando maior flexibilidade durante os testes e permitindo futuras adaptações ergonômicas do dispositivo. A Figura 5 apresenta a configuração eletrônica utilizada durante a fase de desenvolvimento.

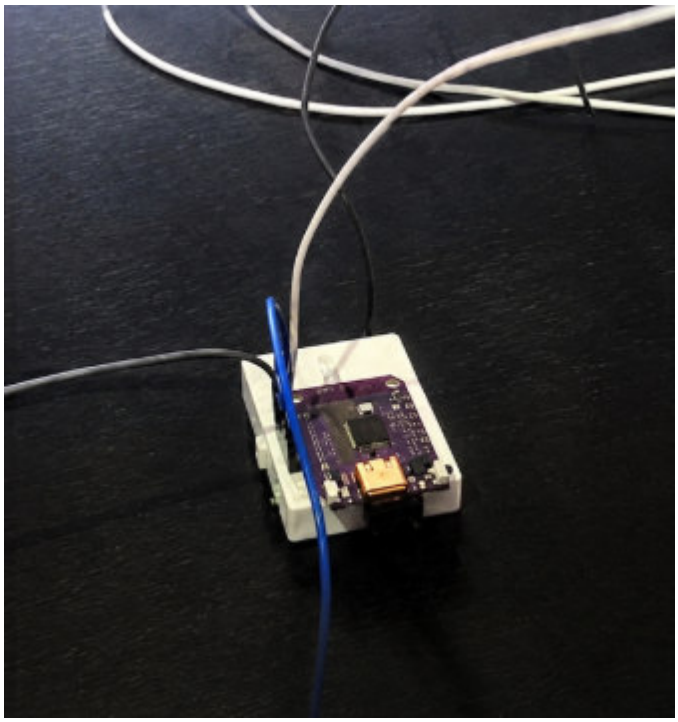

Fig. 5. Protótipo eletrônico baseado em acionamento capacitivo.

O ESP32-S2 Mini foi adotado como elemento central do sistema devido ao seu reduzido tamanho físico, baixo consumo de energia e conjunto de funcionalidades compatíveis com os

requisitos do projeto. Entre seus principais recursos destacam-se o suporte nativo ao padrão USB HID (Human Interface Device), permitindo que o dispositivo seja reconhecido diretamente pelo sistema operacional como um periférico de entrada, sem necessidade de instalação de drivers adicionais, e a comunicação via protocolo I²C para integração com sensores externos.

A arquitetura desenvolvida possibilita a incorporação de diferentes mecanismos de acionamento em uma única plataforma embarcada, favorecendo a criação de dispositivos assistivos compactos, de baixo custo e facilmente replicáveis. Atualmente, o protótipo encontra-se em fase de finalização, com a fabricação da estrutura física em andamento e a realização dos testes de validação funcional prevista para as próximas etapas do projeto.

Os resultados preliminares indicam a viabilidade do acionamento capacitivo. A Tabela I sintetiza a análise comparativa qualitativa entre a arquitetura do Protótipo 1 e a do Protótipo 2 com base nos testes de bancada e nas especificações de projeto.

TABLE I
COMPARAÇÃO QUALITATIVA ENTRE OS PROTÓTIPOS DESENVOLVIDOS.

Parâmetro	**Protótipo 1 (MPU+EMG)**	**Protótipo 2 (Capacitivo)**
Mecanismo de Clique	Contração muscular voluntária (EMG)	Toque por proximidade (Capacitivo)
Controle do Cursor	Inercial (Acelerômetro MPU6050)	Emulação direta / Comutação
Esforço Motor	Baixo a Médio (requer tônus muscular)	Mínimo (apenas contato residual)
Estágio Atual	Validado em bancada e integrado ao jogo	Validado em modelagem 3D e bancada eletrônica
Complexidade Eletrônica	Média (filtragem e condicionamento EMG)	Baixa (leitura nativa ESP32-S2)

V. CONCLUSÃO

Este trabalho apresentou o desenvolvimento e a avaliação de duas abordagens de Interface Homem-Máquina voltadas à acessibilidade digital de pessoas com limitações motoras. A utilização de componentes de baixo custo e código aberto viabilizou a construção de arquiteturas modulares e adaptáveis.

O Protótipo 1 (MPU6050 + EMG) teve sua viabilidade técnica comprovada por meio de testes funcionais de bancada e integração com um jogo sério em Pygame, demonstrando estabilidade na conversão de movimentos inerciais e eventos musculares em comandos digitais de navegação e clique. O Protótipo 2 (Capacitivo) teve sua viabilidade eletrônica e conceitual demonstrada nas etapas de modelagem 3D, programação embarcada e testes de sensibilidade ao toque, posicionando-se como uma alternativa promissora para usuários com mobilidade residual severamente reduzida.

Como trabalhos futuros, pretende-se concluir a fabricação da estrutura física do Protótipo 2, realizar testes de usabilidade com usuários reais e quantificar métricas exatas de desempenho (tempo de resposta, taxa de acerto de comandos e curva de aprendizado) para ambas as soluções.

AGRADECIMENTOS

Os autores agradecem ao Instituto Federal de Educação, Ciência e Tecnologia do Sudeste de Minas Gerais — Campus Juiz de Fora, e ao Programa de Educação Tutorial (PET), por meio da Pró-Reitoria de Ensino e do Ministério da Educação (MEC), cujas bolsas e recursos foram essenciais para apoiar as atividades de pesquisa e extensão aqui apresentadas.

***Abstract*—Stroke frequently results in persistent motor deficits that impair gait and functional independence. Neuromodulation strategies, such as repetitive transcranial magnetic stimulation (rTMS), combined with motor imagery (MI) and brain-computer interfaces (BCIs), have been investigated as approaches to enhance motor recovery. The aim of this study was to evaluate the effects of rTMS combined with MI on the peak electromyographic contraction of the tibialis anterior and rectus femoris muscles in post-stroke individuals. This pilot randomized, controlled, assessor-blinded clinical trial included 10 participants allocated to the Intervention Group (rTMS + BCI-mediated MI; $n = 5$) and the Control Group (BCI-mediated MI; $n = 5$). Electromyographic activity was assessed before and after two weeks of intervention using surface electromyography (sEMG). The Intervention Group showed increased mean peak electromyographic activation of both muscles, with the largest descriptive change observed in the tibialis anterior, whereas the Control Group showed reductions in mean activation. These findings indicate a preliminary favorable electromyographic response to the combined intervention, particularly in the tibialis anterior. Given the small sample size, baseline differences, and inter-individual variability, the results should be interpreted as exploratory. Larger randomized studies incorporating baseline-adjusted analyses and functional gait outcomes are required to determine the clinical relevance of these electromyographic changes.**

I. Introduction

Stroke is one of the leading causes of acquired disability in adults, often resulting in persistent motor deficits that impair gait, balance, and functional independence. Hemiparesis, present in approximately 80% of stroke survivors, is associated with reduced muscle recruitment, altered motor control, and limited mobility, significantly impacting the quality of life of affected individuals [1,2].

Motor recovery after stroke depends on the ability of the central nervous system to reorganize its neural connections through neuroplasticity mechanisms. In this context, techniques capable of modulating cortical excitability and promoting motor relearning have received increasing attention in neurorehabilitation. Among these, repetitive transcranial magnetic stimulation (rTMS) and motor imagery (MI) stand out as approaches associated with promoting cortical reorganization and improving motor function [3].

rTMS is a non-invasive neuromodulation technique that may help restore interhemispheric balance after stroke, thereby contributing to functional recovery. Complementarily, MI consists of the mental representation of movements without their physical execution, activating neural circuits similar to those recruited during the actual performance of motor tasks. When combined with brain-computer interfaces (BCIs), this strategy

enables the generation of real-time sensorimotor feedback, thereby enhancing neuroplastic processes [4-8].

Surface electromyography (sEMG) provides an objective approach for quantifying neuromuscular responses to rehabilitation interventions. Although previous clinical studies have investigated rTMS, motor imagery, BCI-based rehabilitation, and technology-assisted gait training after stroke, the neuromuscular effects of combining cortical neuromodulation with BCI-mediated motor imagery during locomotor training remain insufficiently characterized. In particular, limited evidence is available regarding changes in the electromyographic activation of specific lower-limb muscles following this multimodal approach. Therefore, the main contribution of this pilot study is the use of sEMG to objectively characterize changes in the activation of the tibialis anterior and rectus femoris following a combined rTMS and BCI-mediated motor imagery protocol. These muscles were selected because of their relevant roles in ankle dorsiflexion, lower-limb control, and gait. Accordingly, this study aimed to explore the preliminary effects of the combined intervention on peak electromyographic activation in post-stroke individuals.

II. Methodology

A. Study Design and Participants

This study was characterized as a pilot, randomized, controlled, assessor-blinded clinical trial conducted at the Physical Rehabilitation Center of Espírito Santo (CREFES in Vila Velha-ES, Brazil). The study was approved by the Research Ethics Committee of the Federal University of Espírito Santo (Approval No. 7.567.540), and all participants provided written informed consent prior to enrollment.

Individuals were eligible if they had a diagnosis of stroke, were over 18 years of age, presented with residual hemiparesis or hemiplegia, and had preserved cognitive and communication abilities. Participants were excluded if they had a history of epilepsy or seizures, previous craniectomy, intracranial metallic implants, or any contraindication to rTMS.

Following the baseline assessment, participants were randomly assigned to one of two groups: the Intervention Group (rTMS + MI) or the Control Group (MI). Participants were unaware of their group allocation, and all assessments were performed by a physical therapist who was blinded to the experimental groups.

B. Experimental Procedures

The Intervention Group received rTMS over the cortical representation of the tibialis anterior muscle, which had been previously identified through electromyographic mapping. Stimulation was delivered at an intensity corresponding to 100% of the motor threshold, five sessions per week for two consecutive weeks. The stimulation parameters were as follows: frequency of 10 Hz, 10 trains of stimulation, 100 pulses per train, and an inter-train interval of 50 seconds. In addition to rTMS, participants also underwent MI-based BCI (Fig. 1) three times per week for two weeks.

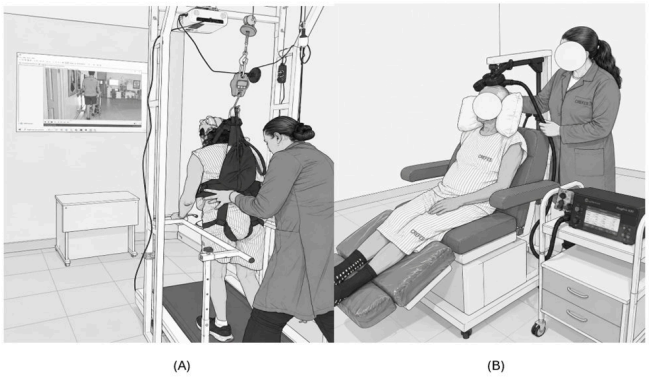

Fig. 1. Illustration of robotic treadmill gait training controlled by BCI combined with MI (A), and the application of rTMS (B). Images derived from the authors' original photographs, edited to remove elements unrelated to the procedure and to preserve participant anonymity.

During the training sessions, participants remained in an upright standing position on a body weight-supported treadmill. Brain activity was recorded using electroencephalography (EEG) with a 16-channel cap (OpenBCI). The brain signals generated during MI were processed by the BCI and used to control the treadmill, providing real-time sensorimotor feedback. Each BCI training session lasted 6 minutes.

The Control Group underwent only the BCI and treadmill training, using the same procedures and duration as the Intervention Group, but without prior application of rTMS.

C. Electromyographic Assessment

The electromyographic activity of the tibialis anterior and rectus femoris muscles of the affected lower limb was assessed before and after the intervention period using sEMG with the New MioTool system (Miotec, Brazil). For each muscle, three 8-second maximum voluntary contractions were recorded, with 12-second rest intervals between contractions. The outcome analyzed was the peak electromyographic activation. The values obtained in the pre- and post-intervention assessments were compared across time points and among the experimental groups.

III. Results

As aforementioned, ten individuals diagnosed with stroke were included and randomly assigned to two groups: the Intervention Group (n = 5) and the Control Group (n = 5). The sample had a mean age of 61.5 years and consisted of five men and five women. All participants had a diagnosis of systemic arterial hypertension (SAH). Regarding stroke etiology, 60% of the participants had experienced an ischemic stroke, whereas 40% had experienced a hemorrhagic stroke (Table 1), characterizing a clinically heterogeneous population that is nevertheless consistent with the epidemiological profile commonly observed in neurological rehabilitation programs.

The electromyographic analysis of the peak contraction of the rectus femoris and tibialis anterior muscles demonstrated distinct responses between the groups evaluated after the

TABLE I
SAMPLE CHARACTERIZATION

Sample Characteristics	
Average Age	61.5 Years
Men	50%
Women	50%
Hypertension	100%
Ischemic Stroke	60%
Hemorrhagic Stroke	40%

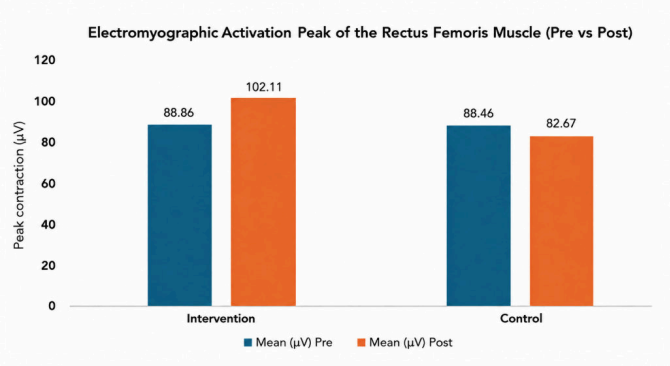

Fig. 2. Comparison of the mean peak of the electromyographic activation (μV) for the rectus femoris muscle in the Intervention and Control Group, before (Pre) and after (Post) the intervention period.

intervention period. Table 2 presents the results comparing the pre- and post-intervention time instants for both groups.

In the Intervention Group, an increase was observed in the mean electromyographic activity of the rectus femoris muscle, rising from 88.86 ± 74.20 μV at the initial assessment to 102.11 ± 102.46 μV at the final assessment (Fig. 2), representing a mean increase of 13.26 μV (+14.9%). Individually, three of the five participants showed an increase in peak muscle activation, one showed a decrease, and one maintained values similar to those observed at baseline. The calculated effect size was small (Cohen's dz = 0.30), indicating a modest pre–post change in peak electromyographic activation. Given the small sample size and substantial inter-individual variability, this finding should be interpreted descriptively.

For the tibialis anterior muscle, the Intervention Group showed a more pronounced increase in electromyographic activity. The mean peak of contraction increased from 46.70 ± 34.57 μV to 93.79 ± 61.72 μV after treatment (Fig. 3), corresponding to a mean increase of 47.09 μV (+100.8%). Four out of the five participants demonstrated increased muscle activation, whereas only one participant showed a reduction in electromyographic values at the end of the protocol. The effect size was moderate (Cohen's dz = 0.54); however, considering the small sample size and variability of the measurements, this result should be interpreted as a preliminary signal of increased electromyographic activation rather than evidence of treatment efficacy.

In contrast, the Control Group exhibited a different pattern. For the rectus femoris muscle, the mean peak electromyographic activation decreased from 88.46 ± 101.53 μV to 82.67 ± 65.24 μV, representing a mean reduction of 5.79 μV (-6.5%). Although one participant showed a marked increase in muscle activity, the remaining participants exhibited decreases or only minor changes, contributing to the overall reduction in the group mean. The effect size was negligible (Cohen's $d_z = -0.07$), indicating minimal pre–post change in peak electromyographic activation.

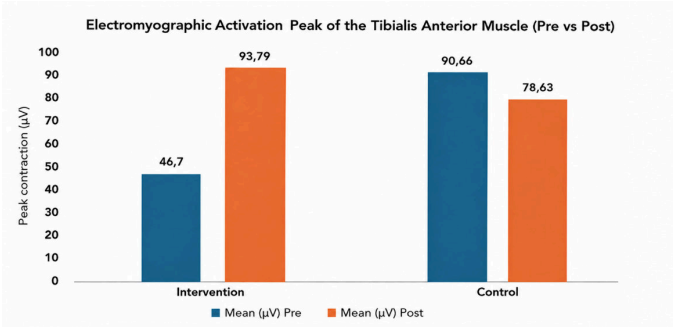

Fig. 3. Comparison of the mean peak of the electromyographic activation (μV) for the tibialis anterior muscle in the Intervention and Control Group, before (Pre) and after (Post) the intervention period.

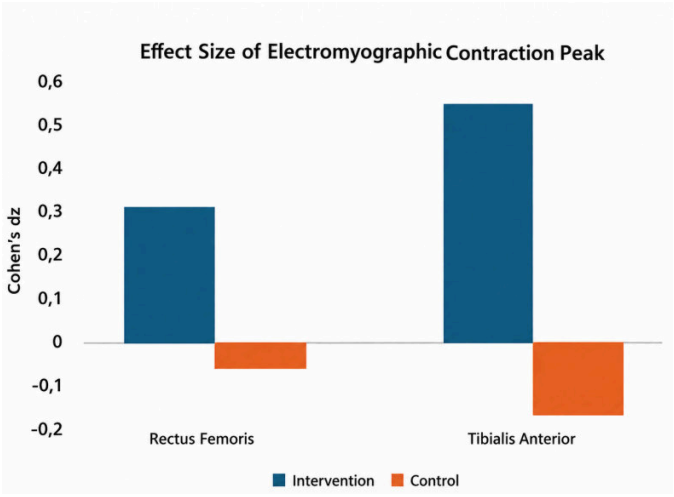

Fig. 4. Effect size (Cohen's d_z) of the pre–post intervention changes in the peak electromyographic activation of the rectus femoris and tibialis anterior muscles. The Intervention group showed positive effects ranging from small ($d_z = 0.30$) to moderate magnitude ($d_z = 0.54$), whereas the Control Group showed negative effects of trivial to small magnitude ($d_z = -0.07$ and $d_z = -0.16$, respectively), indicating greater muscle responsiveness in the group that underwent the intervention.

Similar findings were observed for the tibialis anterior muscle in the Control Group. Mean electromyographic activity decreased from 90.66 ± 126.64 μV to 78.63 ± 71.97 μV after the intervention period, corresponding to a mean reduction of 12.03 μV (-13.3%). Although two participants showed increased muscle activation, three demonstrated reduced peak electromyographic values at the end of the protocol. The observed effect size was small and negative (Cohen's $d_z = -0.16$), as shown in Fig. 4.

Descriptively, the groups showed different patterns of pre–

TABLE II
ELECTROMYOGRAPHIC OUTCOMES BEFORE AND AFTER THE INTERVENTION.

Assessed Muscle	**Group**	**Pre-intervention (μV) Mean $\pm$ SD**	**Post-intervention (μV) Mean $\pm$ SD**	**Δ Absolute (μV)**	**Δ (%)**	**Cohen's d_z**
Rectus Femoris	Intervention	88.86 $\pm$ 74.20	102.11 $\pm$ 102.46	+13.26	+14.92%	0.30
Rectus Femoris	Control	88.46 $\pm$ 101.53	82.67 $\pm$ 65.24	-5.79	-6.54%	-0.07
Tibialis Anterior	Intervention	46.70 $\pm$ 34.57	93.79 $\pm$ 61.72	+47.09	+100.84%	0.54
Tibialis Anterior	Control	90.66 $\pm$ 126.64	78.63 $\pm$ 71.97	-12.03	-13.27%	-0.16

Caption: SD = Standard Deviation; Δ = difference between the post- and pre-intervention time points; Cohen's d_z = within-group effect size for paired pre–post observations.

post change. The Intervention Group exhibited increases in mean peak electromyographic activation of both muscles, with the largest relative change observed in the tibialis anterior ($+100.8\%$), whereas the Control Group showed reductions in mean activation of the rectus femoris (-6.5%) and tibialis anterior (-13.3%). However, the baseline tibialis anterior values differed substantially between groups and showed considerable dispersion, particularly in the Control Group. Therefore, percentage changes should be interpreted cautiously and should not be considered direct evidence of between-group efficacy.

Overall, these findings indicate a preliminary favorable electromyographic signal following the combined rTMS and BCI-mediated MI intervention, particularly for the tibialis anterior. Given the pilot sample size, these results are primarily descriptive and hypothesis-generating.

IV. DISCUSSION

The present study investigated the effects of rTMS combined with MI on the electromyographic activation of the tibialis anterior and rectus femoris muscles in post-stroke individuals. The results demonstrated an increase in electromyographic activity peak in both muscles in the intervention group, whereas the Control Group showed a reduction in muscle activation at the end of the protocol. The most pronounced effect was observed in the tibialis anterior muscle, which exhibited a mean increase of more than 100% after the treatment period.

The principal contribution of this study lies not only in the multimodal combination of rTMS, BCI-mediated motor imagery, and locomotor training, but particularly in the use of sEMG to objectively examine the neuromuscular response of specific lower-limb muscles. Previous clinical investigations have primarily focused on motor, gait, balance, or global functional outcomes when evaluating neuromodulation and technology-assisted rehabilitation after stroke. In this context, the present study provides complementary physiological information by quantifying changes in muscle activation following the intervention. Thus, rather than establishing clinical efficacy, these findings contribute preliminary evidence regarding the neuromuscular response associated with this multimodal rehabilitation strategy.

Although the present study did not directly assess cortical reorganization or neuroplasticity, the observed electromyographic changes may be interpreted within the broader neurophysiological framework of rTMS-induced modulation of motor cortical excitability. Studies have shown that low-frequency rTMS applied over the contralesional hemisphere reduces excessive transcallosal inhibition exerted on the affected motor cortex, promoting the restoration of interhemispheric balance and functional recovery [9–11]. In the meta-analysis by Dionísio et al. (2018) [5], positive effects of rTMS on motor function in post-stroke individuals were observed, particularly when combined with conventional rehabilitation programs.

In addition to neuromodulation, MI plays an important role in activating neural circuits related to movement planning and execution. Evidence from neuroimaging studies demonstrates that MI recruits cortical areas similar to those activated during actual motor task execution, including the primary motor cortex, premotor cortex, and associative parietal areas. Thus, the combination of rTMS and MI may produce synergistic effects on neural plasticity by enhancing the recruitment of residual motor pathways after brain injury [12,13]. A systematic review conducted by Bai et al. (2020) [7] concluded that MI programs significantly improve motor function in post-stroke individuals, particularly when combined with sensorimotor feedback technologies.

The increase in tibialis anterior activation is potentially relevant from a clinical perspective because this muscle plays a fundamental role in ankle dorsiflexion during the swing phase of gait and contributes to adequate foot clearance. Impaired tibialis anterior activation after stroke may contribute to foot drop, altered gait patterns, reduced walking efficiency, and increased risk of falls. Therefore, the electromyographic changes observed in the present study provide a physiologi-

cally relevant signal that warrants further investigation. However, increased peak sEMG activation cannot be interpreted as evidence of improved gait performance. Walking speed, balance, ankle kinematics, functional mobility, and independence were not evaluated in the present study. Future trials should determine whether changes in tibialis anterior activation are associated with clinically meaningful improvements in outcomes such as gait speed, balance, walking capacity, and functional independence.

Several limitations should be considered when interpreting these findings. First, the very small sample size (n = 5 per group) substantially limits statistical power, increases the influence of individual responses and extreme values, and prevents definitive conclusions regarding between-group efficacy. Accordingly, the observed effect sizes and percentage changes should be considered exploratory estimates rather than confirmatory evidence. Second, the sample was clinically heterogeneous, including participants with both ischemic and hemorrhagic stroke, and potentially different levels of motor impairment. Such heterogeneity may contribute to variability in responsiveness to neuromodulation and rehabilitation. Third, the baseline electromyographic values of the tibialis anterior differed considerably between groups, and the large standard deviation observed in the Control Group indicates substantial inter-individual dispersion. Consequently, the relative percentage increase observed in the Intervention Group should be interpreted cautiously because it may be influenced by baseline imbalance. Finally, the intervention lasted only two weeks, limiting the interpretation of the findings to short-term neuromuscular responses. The study therefore cannot determine whether the observed electromyographic changes are sustained over time or translate into long-term functional improvement.

From a feasibility perspective, several lessons can be drawn from this pilot study. First, integrating rTMS with BCI-mediated motor imagery and treadmill-based locomotor training was feasible within a short rehabilitation protocol. Second, sEMG provided an objective and potentially sensitive measure for detecting individual neuromuscular responses that may not be captured by group-level clinical measures alone. Third, the marked inter-individual variability observed in the electromyographic responses highlights the importance of detailed participant characterization and individualized analysis in future neuromodulation trials. Finally, the baseline differences observed between groups reinforce the need for baseline-adjusted statistical approaches in subsequent larger randomized studies.

Important research gaps also remain. Future studies should investigate whether the electromyographic changes observed after combined rTMS and BCI-mediated motor imagery are accompanied by changes in cortical excitability and whether these physiological responses translate into clinically meaningful improvements in gait and mobility. Larger randomized trials should incorporate baseline-adjusted between-group analyses, longer intervention and follow-up periods, and standardized functional outcomes, including gait speed, balance, walking capacity, ankle dorsiflexion, and functional independence. Further investigation is also needed to identify clinical or neurophysiological characteristics associated with responsiveness to multimodal neuromodulation protocols.

Taken together, the present findings should be interpreted as preliminary and hypothesis-generating. They provide an exploratory signal that the addition of rTMS to BCI-mediated motor imagery and locomotor training may influence lower-limb electromyographic activation, particularly in the tibialis anterior, but larger and adequately powered trials are required to determine the magnitude, reproducibility, and clinical relevance of this response.

V. Conclusion

This randomized pilot study identified a preliminary pattern of increased peak electromyographic activation of the tibialis anterior and rectus femoris following a short-term intervention combining rTMS with BCI-mediated motor imagery and locomotor training. The most pronounced descriptive change was observed in the tibialis anterior, whereas the Control Group showed reductions in mean electromyographic activation over the same period.

These findings should be interpreted as exploratory rather than as evidence of clinical efficacy because of the small sample size, inter-individual variability, baseline differences, clinical heterogeneity, and short intervention period. The use of sEMG represents an important contribution of this study by providing an objective physiological measure of lower-limb neuromuscular response. Larger randomized trials incorporating baseline-adjusted between-group analyses, functional gait and balance outcomes, and longitudinal follow-up are required to determine whether these electromyographic changes are reproducible and translate into clinically meaningful improvements in post-stroke mobility.

Abstract— This work presents an intelligent embedded system for real-time evaluation of performance in handgrip exercises, based on a force-sensitive resistor (FSR) and embedded artificial intelligence. The device integrates a 3D-printed mechanical structure with an analog acquisition circuit, employing fourth-order polynomial calibration of the sensor, which achieved R^2 = 0.9976 across the available reference loads. The system performs local signal processing and extracts force-tracking and execution features, including curve error, area error, stability, slope error, initial force level, and final force level. These features are used as input to a lightweight neural network model to estimate exercise performance after its completion. Experimental results indicate predictive performance with $R^2 \approx 0.95$, while inference is performed locally on the embedded device at the end of each exercise. The embedded system provides both quantitative feedback, inferred by the neural network, and qualitative feedback based on patterns such as instability, improper force application, and imprecise execution. The proposed solution represents a portable and low-cost alternative for objective evaluation of handgrip exercises, with potential applications in rehabilitation, motor training, and functional monitoring.

Keywords— Embedded systems, Force sensors, Signal processing, Real-time systems.

I. INTRODUCTION

Handgrip strength is an important functional indicator widely used in the assessment of motor capacity, rehabilitation, and overall health and motor function monitoring [1], [2]. Isometric handgrip exercises have been shown to produce clinically significant reductions in blood pressure, with decreases of approximately 6–8 mmHg in systolic pressure after training [3].

However, studies report a lack of standardization in evaluation protocols, with inconsistencies in acquisition, intensity, and repetition, hindering cross-study comparisons [2], [4].

Recent rehabilitation systems have incorporated sensory feedback and machine learning techniques to improve force control and provide real-time evaluation [5], [6]. Nevertheless, many of these solutions still rely on high-cost equipment or subjective analysis, limiting their applicability in home-based settings.

Sensor-based approaches, particularly those using force-sensitive resistors (FSRs), enable low-cost solutions integrated with embedded systems; however, they are primarily focused on static force measurements [7]–[9].

In addition, traditional evaluation methods predominantly rely on maximum force measurements, disregarding the temporal dynamics of movement. Force-tracking tasks use reference signals over time, in which users continuously adjust the applied force, and performance is evaluated using error-based metrics [10], [11].

In this context, this work proposes an embedded system for dynamic performance evaluation in handgrip exercises. The proposed approach integrates signal acquisition, temporal feature extraction, and local inference based on an embedded multilayer perceptron (MLP) neural network. The results indicate predictive performance suitable for the intended application ($R^2 \approx 0.95$), with on-device operation on low-cost hardware.

The system integrates sensing using a force-sensitive resistor (FSR), temporal storage of the exercise signal, feature extraction, and score inference through embedded artificial intelligence in a fully autonomous system for training evaluation and feedback.

The main contribution is the development of a support tool for healthcare professionals in the prescription, monitoring, and evaluation of handgrip exercises, including both static and dynamic effort tasks ranging from 0 to 10 kgf with variable duration. The proposed tool can be configured for use in future studies and clinical applications.

II. SYSTEM OVERVIEW

A. Assembly and Hardware Architecture

Several approaches for measuring handgrip force have been proposed, including traditional dynamometers and FSR-based sensors [2].

Fig. 1 illustrates the mechanical design of the proposed device, in which an FSR 402 sensor is integrated into a handgrip structure designed to ensure uniform distribution of the applied force over its sensitive area. This design improves measurement repeatability and consistency in data acquisition using the ESP32 microcontroller (Microcontroller Unit, MCU), as well as the consistency of the feedback provided through a display and buzzer.

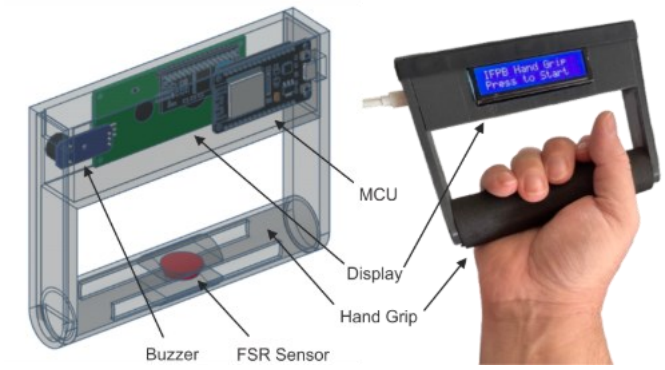

Fig. 1. Hardware layout and final construction of the handgrip device.

B. Signal Acquisition and Calibration

The FSR sensor exhibits nonlinear behavior, with resistance inversely proportional to the applied force [12], [13].

In this work, the analog signal is acquired using a resistive divider (1 kΩ pull-down) with an input voltage of 3.3 V. The signal is sampled by the 12-bit analog-to-digital converter (ADC) of the ESP32.

Due to sensor nonlinearity, a fourth-order polynomial calibration was adopted to convert ADC values into force. Calibration was performed experimentally using loads from 1 to 10 kgf with a precision scale as reference.

Based on the collected calibration data, a fourth-order polynomial model was fitted, achieving a coefficient of determination of $R^2 = 0.9976$, as shown in Eq. (1), where $x$represents the 12-bit ADC digital value:

$$F(x) = 5.04 \times 10^{-13}x^4 - 2.68 \times 10^{-9}x^3 + 3.86 \times 10^{-6}x^2 + 1.85 \times 10^{-3}x - 2.92 \quad (1)$$

The calibration procedure achieved a coefficient of determination of $R^2 = 0.9976$ across the available reference loads, indicating a strong fit of the adopted fourth-order polynomial to the calibration data. However, the present study did not calculate a separate absolute calibration error, and further validation using independent reference measurements is required to characterize measurement accuracy.

Fig. 2 shows the resulting calibration curve, highlighting the strong correlation between the experimental data and the fitted model.

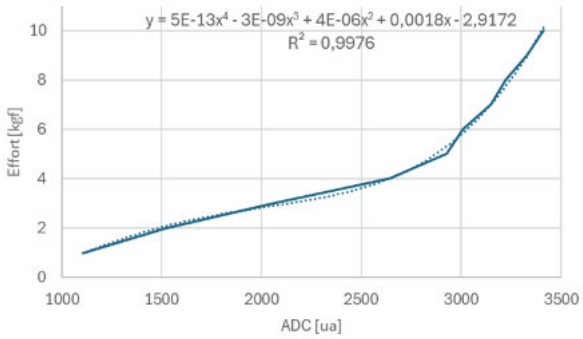

Fig. 2. Calibration curve of the FSR sensor with polynomial fitting.

C. System Workflow

The system operates in real time following a structured processing pipeline, as illustrated in Fig. 3, consisting of the following steps:

1. Continuous acquisition and ADC conversion of the force signal;
2. Application of a nonlinear fourth-order polynomial calibration;
3. Storage of the complete exercise in a temporal buffer;
4. Extraction of force-tracking and execution features;
5. Score inference using a feedforward neural network after exercise completion; and
6. User display (score and qualitative feedback).

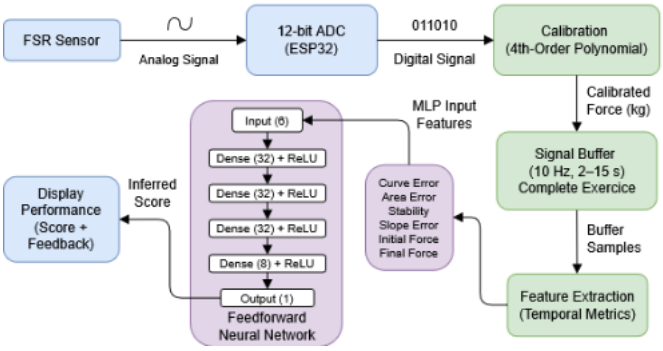

Fig. 3. Block diagram of the proposed system.

D. Exercise Protocol and Interface

Isometric handgrip exercise protocols typically involve sustained contractions at controlled force levels over time, usually defined as a percentage of the maximum voluntary contraction (MVC), organized into sets with different durations [14].

Force-tracking approaches use reference signals over time, in which users continuously adjust the applied force, and performance is evaluated based on error metrics between the target signal and the measured response [10], [11]. Different excitation profiles, such as ramp, constant, and periodic signals, allow the assessment of distinct force modulation behaviors.

Fig. 4 shows the system interface, including pre-exercise instructions (a) and real-time feedback (b).

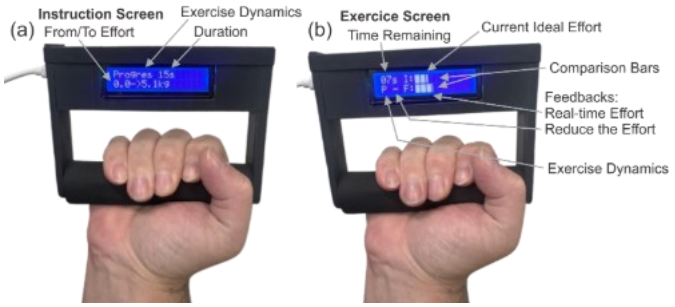

Fig. 4. Pre-exercise and real-time feedback interface: (a) Exercise instruction—15 seconds of progressive effort from 0 to 5.1 kgf. (b) Real-time feedback—Progressive exercise (P), remaining time (s), ideal force (I), applied force feedback (F), and guidance to reduce (−) or increase (+) effort.

The system was designed to support different isometric handgrip exercise profiles, allowing force parametrization over time. The operating range and duration of the exercises were defined considering low-intensity execution and real-time constraints, while remaining adaptable to specific applications and clinical requirements.

Three main profiles were defined:

- **Progressive (P):** gradual increase in force;
- **Static (S):** maintenance of force at a target level;
- **Regressive (R):** controlled reduction of force.

Exercises are performed within time windows ranging from 2 to 15 s, with force levels between 2 and 10 kgf. The profiles include progressive (0 to 2–10 kgf), constant (2–10 kgf), and regressive (2–10 kgf to 0) variations, enabling the analysis of force modulation during execution.

The interface provides real-time feedback on execution accuracy through two force bars: the upper bar (I) represents the ideal force, while the lower bar (F) indicates the user's applied force. Additionally, visual cues are provided: "–" suggests reducing effort, "+" increasing effort, and "*" indicates correct execution within the target range.

This approach integrates reference-based protocols and force-tracking tasks, enabling evaluation of both force control and trajectory tracking.

III. Signal Processing and Inference

A. Feature Extraction

Performance evaluation is based on features extracted from the executed force trajectory and its reference profile, describing force-tracking accuracy and execution dynamics. Six main metrics were defined: curve error, area error, stability, slope error, initial force level, and final force level.

The system is aligned with evaluation methods based on tracking error, in which performance is quantified by the difference between the executed signal and the reference trajectory over time [11].

To formalize these metrics, let $y[n]$ and $r[n]$ represent the measured and reference force signals at sample n, respectively. Let N denote the total number of samples, $F_{initial}$ and F_{final} the initial and final force levels of the reference trajectory, t_n the time associated with sample n, and T the target exercise duration.

For progressive and regressive exercises, in which the reference trajectory changes over time, the curve error is normalized by the absolute difference between the initial and final force levels, as follows:

$$\mathrm{E}_c^{dyn} = \frac{1}{N \mid F_{final} - F_{initial} \mid} \sum_{n=1}^{N} |y[n] - r[n]| \qquad (2)$$

where E_c^{dyn} denotes the curve error for dynamic exercises.

For static exercises, where the initial and final reference force levels are equal, the normalization is performed using the target force level with the offset adopted in the embedded implementation:

$$\mathrm{E}_c^{stat} = \frac{1}{N(F_{initial} + 0.1)} \sum_{n=1}^{N} |y[n] - r[n]| \qquad (3)$$

where E_c^{stat} denotes the curve error for static exercises.

The 0.1 term corresponds to the numerical offset used in the embedded implementation to avoid an excessively small normalization denominator.

Area error quantifies the relative deviation between the measured and reference areas under the force-time curves. The measured area is obtained using the trapezoidal rule, while the reference area is determined from the initial and final force levels and the target exercise duration:

$$E_a = \frac{\left| \sum_{n=2}^{N} \frac{y[n]+y[n-1]}{2} (t_n - t_{n-1}) - \frac{F_{initial}+F_{final}}{2} T \right|}{\frac{F_{initial}+F_{final}}{2} T} \qquad (4)$$

This metric represents the deviation in the total applied effort relative to the expected effort for the prescribed trajectory.

Stability is defined as a bounded measure of local force consistency based on the mean absolute variation between consecutive measured samples. The resulting variation is transformed into a stability score, such that larger values indicate more stable force application:

$$S = \frac{1}{1 + \frac{1}{N} \sum_{n=2}^{N} |y[n] - y[n-1]|} \qquad (5)$$

Thus, lower sample-to-sample variations result in stability values closer to one.

Slope error corresponds to the absolute difference between the global slope of the executed force trajectory and the slope prescribed by the reference trajectory:

$$E_s = \left| \frac{y[N] - y[1]}{t_N - t_1} - \frac{F_{final} - F_{initial}}{T} \right| \qquad (6)$$

The executed slope is calculated from the measured force variation over the elapsed execution time, whereas the reference slope is determined from the prescribed initial and final force

levels and the target duration. Because the slope is zero for an ideal static profile, slope error is primarily informative for progressive and regressive exercises.

The initial and final force levels define the boundary conditions of the reference trajectory. Specifically, $F_{initial}$corresponds to the prescribed force at the beginning of the exercise, whereas F_{final}corresponds to the prescribed force at the end of the target duration. The initial force level is defined as:

$$r(0) = F_{initial} \tag{7}$$

The final force level is defined as:

$$r(T) = F_{final} \tag{8}$$

These variables characterize the prescribed force profile rather than independent physiological measures. They determine whether the exercise begins, maintains, or ends at a given force level and therefore provide contextual information for interpreting the force-tracking metrics.

Unlike the measured force samples used in the error metrics, these two variables describe the boundary conditions of the prescribed exercise profile. In progressive exercises, the reference changes from a lower initial force level to a higher final force level; in regressive exercises, the opposite occurs; and in static exercises, the two levels are equal.

Together, these features provide a compact representation of force-tracking accuracy, local force consistency, execution rate, and the boundary conditions of the reference trajectory. This low-dimensional representation is suitable as input to an embedded machine-learning model.

B. Machine Learning Model

The extracted features are used as input to a feedforward neural network implemented in TensorFlow/Keras to model nonlinear relationships between force-tracking descriptors and the defined performance score.

Unlike approaches that directly process time series data, such as recurrent models (e.g., LSTM) [6], this work adopts a feature-based strategy, reducing the dimensionality of the problem and eliminating the need for full sequential processing.

The input vector consists of six variables: curve error, area error, stability, slope error, initial force level, and final force level. The architecture comprises four fully connected hidden layers with 32, 32, 32, and 8 neurons, respectively, utilizing ReLU activation functions, and a single linear output node, as illustrated in Fig. 3.

It is important to emphasize that this study represents an initial proof of concept focused on validating the proposed Edge AI architecture on a microcontroller. Therefore, to evaluate the system's operational viability and tracking capabilities without requiring prior ethical committee approval for human trials, a dataset of approximately 380 executions was generated using simulated data. These simulated profiles were designed to represent expected dynamic force variations with different performance levels. The target value (score) for these profiles was defined based on the deviation from the reference trajectory, considering factors such as stability, delay, improper force application, and interruptions.

For model training and evaluation, the dataset was randomly partitioned into 80% for model development and 20% for final testing using a fixed random seed. Within the training subset, 20% was further reserved for validation during training. Input and output normalization parameters were fitted exclusively using the training subset and subsequently applied to the validation and test data. The model was trained using the Adam optimizer and mean squared error (MSE) loss function and evaluated using MAE, RMSE, and R^2 on the held-out test subset. As an initial technological proposition, this simulated approach was used to evaluate the proposed embedded inference pipeline; future studies, pending ethics approval, will incorporate real user data for clinical validation.

After training, the model performs a single score inference at the end of each completed exercise. Additionally, a rule-based module provides qualitative feedback to the user.

C. Embedded Implementation

The trained model was converted to TensorFlow Lite format and integrated into the ESP32 as a binary array of approximately 45 kB. The system performs a single neural-network inference locally at the end of each completed exercise, after the force trajectory has been acquired and the features have been extracted. This architecture allows continuous force acquisition and feedback during exercise without requiring continuous neural-network inference or external communication.

Input and output normalization parameters are embedded within the system, ensuring consistency between training and inference.

The implementation follows the TinyML paradigm, enabling efficient execution of the model on resource-constrained devices and supporting portable and autonomous applications.

IV. Results

A. Model Evaluation Results

The model achieved the following predictive performance on the held-out test subset, with a mean absolute error (MAE) of 4.25, a root mean square error (RMSE) of 6.78, and a coefficient of determination of $R^2 = 0.946$. The results indicate a strong correspondence between the predicted and reference scores within the simulated test data.

Fig. 5 presents representative examples of model inference for different exercise profiles: (a) and (b) linear regressive exercises over 13.82 s, starting from 8.1 kgf to 0 kgf, separated into two plots to improve data visualization, with (a) emphasizing temporal deviations and (b) highlighting force amplitude errors; (c) a static exercise at 7.7 kgf for 6.82 s; and (d) a linear progressive exercise over 9.92 s, starting from 0 kgf to 8.31 kgf.

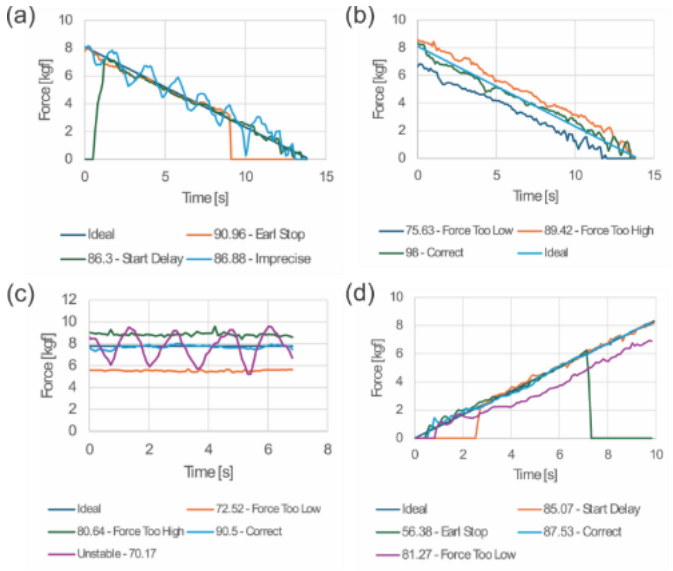

Fig. 5. AI inference results for exercises: (a) and (b) regressive from 8.1 kgf to 0 kgf in 13.82 s, displaying temporal deviations and force amplitude errors, respectively; (c) static at 7.7 kgf for 6.82 s; (d) progressive from 0 kgf to 8.31 kgf in 9.92 s.

The model distinguishes execution patterns, assigning scores consistent with observed behavior. In regressive cases (Fig. 5(a) and (b)), deviations such as early termination and delays (temporal errors) as well as inadequate force application (amplitude errors), reduce the score. In the static case (Fig. 5(c)), stability variations impact evaluation, while in the progressive case (Fig. 5(d)), delays and differences in force rate are reflected in the score.

Fig. 5 shows higher scores for executions close to the reference and lower scores for deviations such as instability and delays.

Overall, the neural network exhibits lower sensitivity to purely temporal deviations and higher sensitivity to amplitude-related errors for a given global error level. For instance, in the progressive exercise shown in Fig. 5(d), a delayed initiation (orange curve, score 85.07) has less impact on the score than early termination (green curve, score 56.38) for similar durations.

This behavior is consistent with the nature of progressive exercises, where force demand increases over time; thus, early termination may indicate insufficient strength development, whereas an initial delay may reflect minor instability in fine motor control at low force levels.

Similarly, in the regressive exercise shown in Fig. 5(a), an initial delay (green curve, score 86.3) is more penalized than early termination (orange curve, score 90.96), as the exercise requires an initial force level that must be properly established before reduction.

In the static exercise (Fig. 5(c)), the score reflects deviations below (orange curve, score 72.52) and above (green curve, score 80.64) the target force, proportional to the error magnitude. In contrast, unstable execution (purple curve, score 70.17) is more penalized, even when the global error is partially minimized, indicating the model's ability to capture distinct temporal patterns.

The results depend on the selected feature set and can be refined for specific clinical applications. The model is more sensitive to amplitude errors (area error) than to temporal deviations, while stability captures local variations not reflected in the global error. The initial and final force levels additionally encode the boundary conditions of the prescribed reference trajectory.

B. Discussion

Trajectory-based features enable the proposed model to represent force-tracking accuracy, local force consistency, execution rate, and reference-trajectory boundary conditions, providing a more comprehensive representation than static force-based measurements. Unlike methods focused on static measurement or grip classification [7], the system captures temporal dynamics through metrics such as curve error, area error, and stability, reflecting motor control and effort consistency and addressing limitations reported in the literature [2], [10], [11].

Furthermore, while several systems emphasize data acquisition and transmission [9], the proposed approach integrates acquisition, temporal processing, and local inference within a single architecture. Force acquisition and user feedback operate during exercise, while the neural network is invoked once after exercise completion, enabling autonomous on-device evaluation. The present study did not include a quantitative measurement of neural-network inference time on the ESP32. Although inference is executed only once after each completed exercise, future work should quantify execution time and its variability under different operating conditions.

The system supports multiple exercise profiles, allowing adaptation to different rehabilitation scenarios and integration with feedback-based applications and exergames [15], enhancing user engagement.

Embedded execution demonstrates the feasibility of low-cost intelligent systems for real-time functional assessment in clinical settings.

It is important to emphasize that the current study focuses on the technological validation of the proposed architecture. The inferred AI score is designed to evaluate a user's motor control and ability to follow a dynamic reference trajectory, rather than providing an absolute, clinically validated index. The calibration procedure achieved a coefficient of determination of $R^2 = 0.9976$ across the available reference loads, indicating a strong fit of the adopted fourth-order polynomial to the calibration data. However, the present study did not calculate a separate absolute calibration error, and further validation using independent reference measurements is required to characterize measurement accuracy.

While traditional dynamometers are widely used as reference instruments for static maximum grip strength assessment, this device aims to serve as a dynamic tracking and rehabilitation tool. No direct comparison with a reference dynamometer was performed in the present study. Similarly, repeatability across repeated executions was not quantitatively

characterized and should be investigated using repeated trials under controlled conditions. Future studies should therefore evaluate calibration accuracy, repeatability, and clinical validity using independent reference measurements, repeated trials, reference dynamometers, and real user data.

Future work will focus on configurable exercise profiles, quantitative characterization of inference time, independent calibration validation, comparison with reference dynamometers, repeatability assessment, and continuous model refinement using real user data, enabling more robust and potentially personalized rehabilitation strategies.

V. Conclusion

This work presented an intelligent embedded system for dynamic and static performance evaluation in handgrip exercises, integrating force sensing, signal processing, temporal feature extraction, and embedded artificial intelligence. The proposed approach enables on-device assessment with continuous force acquisition and feedback during exercise, while neural-network inference is performed once after exercise completion.

The model achieved an MAE of 4.25, an RMSE of 6.78, and an R^2 of 0.946 on the simulated held-out test subset. These results demonstrate the feasibility of the proposed embedded inference pipeline for dynamic force-tracking evaluation. However, the present study represents a technological proof of concept based on simulated data, and further validation with real users, independent reference measurements, repeatability analysis, and clinical protocols is required.

***Abstract*—Down syndrome (DS) and autism spectrum disorder (ASD) are genetic disorders that occur at infancy and could last for a life-time. Affected people have difficulty in performing motor activities such as engaging in communications, social interactions and sporting. Cycling is one such activity that DS and ASD children are slow in learning. Researchers in the literature had developed special techniques in aiding DS and ASD children learn to cycle. One such technique is the use of video games to enable ASD children learn and reduce weights. The research investigates the usefulness of computer games in aiding DS and ASD children in cycling. It is an area that has not received its required attention in the literature. Can cycling computer games reduce the learning curve of cycling by DS and ASD children? A computer game was developed to achieve the aim of the research. Results show that most ASD children performed above average, and that cycling computer games could reduce the learning curve of cycling by DS and ASD children.**

Keywords— cycling computer games, down syndrome, autism spectrum disorder, animation application, virtual reality, responsive app design

I. Introduction

Down Syndrome (DS) is a genetic condition that occurs when an infant has excess of chromosome 21 at birth. Some of the characteristics exhibited are retarded intellectual ability, pale facial features and feeble muscles (hypotonia) [1]. Autism Spectrum Disorder (ASD) is also a genetic disorder syndrome. It is a neuro-disorder that affects the social behaviour of people having it. People having ASD and DS exhibit restricted or repetitive behavioural patterns and interests. They are sometimes unable to effectively use body languages for communicating with others [2]. The rest of the work will refer to DS and ASD people as either ASD children or ASD people based on the context of use.

ASD people have difficulty in participating in sporting activities and social interactions. Due to the inherent dysfunctional traits that spontaneously exhibit themselves during physical activities such as sporting and social interactions, they sometimes shy away from socializing with people. As a consequence, they require motivation to learn and master an activity or engage in social interactions [2]. Participating in sporting activities and social interactions could improve the overall well-being of a person, in particular, they could improve the mood of ASD people and ignite their interests in socializing with people [3].

Bicycle Cycling is one such physical activity that is difficult for ASD children to learn. It is difficult for them to position themselves (hands and legs) on a bicycle and ride. Most times, instead of riding forward, the wheels roll backward, and it discourages them from riding. Researches such as [4], [5], [6] respectively had created various techniques on cycling to enable ASD children learn to cycle at their own pace. Findings from these articles show that with specialized techniques and lots of patience on the side of the trainers, they could learn to cycle faster than usual.

Furthermore, the use of computer software such as virtual reality and video games to encourage ASD children to learn and reduce weight had also been researched by [7], [8], [9], [10]. Findings from these researches show that encouraging them to play video games could improve their mood and enable them to learn and reduce weights.

The research investigates the usefulness of computer games in enabling ASD children learn to cycle. It tries to

answer the question: can cycling computer games reduce the learning curve of cycling by ASD children, or can cycling computer games improve the learning ability of ASD children in cycling? To investigate the question, a computer game was developed to enable them learn to cycle. In the game, an animated bicycle on-screen guides them as they ride a static physical bicycle. The animation is controlled by the physical bicycle. The game encourages them to continue to ride by counting the number of times they have won by reaching a certain level.

For the purpose of the research, a cycle is defined as a 360 degree turn of a bicycle pedal.

A round is defined as a completion of a game session. A round could contain any number of cycles as set by a player.

II. Game Interface Design

The interface design of the game follows the responsive app design approach [11]. The game is designed to be viewable on varied device screen sizes: televisions, computers and smartphones. This enables the user to install the game on his/her preferred device(s).

The smartphone view was designed to be viewable on virtual reality (VR) glasses. Players could place a smartphone in a VR headset and wear it to have an immersive experience while cycling. The remote control of the VR headset could be used to control the game. This could improve the mood of the player. The smartphone view is shown in fig. 2(a) while the computer view is shown in fig. 2(b) respectively.

A computer bicycle was designed to mimic a real-life bicycle. Also, a dinosaur was designed to mimic a player, as shown on fig 2(a) and (b) respectively.

An 'okay' emoji was also designed as shown in fig. 1(a). It displays on screen to show a player that the bicycle is rolling forward (clockwise) and that he/she is doing fine.

A 'warning' emoji was also designed as shown in fig 1(b). It displays on screen to show that the bicycle is cycling backward (anticlockwise), and that a player needs to cycle forward.

A counter interface was also designed as shown in fig. 1(c). It displays the number of cycles completed by a player. This encourages a player to continue cycling.

A 'winner' emoji was also designed as shown in fig. 1(d). it is displayed when a player reaches a winning level of cycling. A winning level depends on the maximum number of cycles set by a player.

Fig 1(a). Okay emoji

(b). Warning emoji

(c). Cycles counter

(d). Winner message

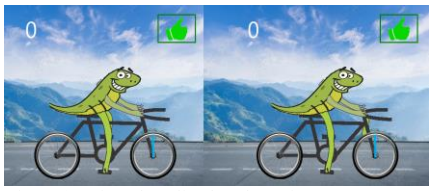

Fig 2(a). Virtual reality headset view

III. Circuitry and Casing Design

A circuit in package was designed to sense the angular position of the petal while a player is cycling. The BNO055 sensor was used to achieve the sensing of the angular position. The ESP32 microcontroller was used to retrieve the angle from the BNO055 sensor. The angle is then transmitted by the microcontroller via WIFI to a device where the game app is installed in order to animate the on-screen dinosaur and bicycle.

A. Circuitry Components

- **ESP32:** It is a microcontroller that is used for the programming of electronic components. It has both WIFI and Bluetooth technology that enables wireless connectivity and could be used to implement Internet of Things (IOT) applications [12].
- **BNO 055 Sensor:** It is a System in Package (SIP) Inertial Measurement Unit (IMU) sensor. It has a triaxial 14-bit accelerometer, a close-loop triaxial 16-bit gyroscope and a triaxial geo-magnetometer [13]. It was used to sense the pedal rotation angles of a bicycle.
- **Printed Circuit Board (PCB):** A PCB was used to connect various circuit components together to form an integrated circuit.
- **Battery:** A battery powered the circuitry.
- **Connector:** A two pin KK connector was used to connect the battery to the PCB.
- **Voltage Regulator:** It regulated the battery voltage to avoid overcharge.
- **Resistors:** a number of resistors were used to control the voltage entering a particular component.
- **Wires:** Jumper wires were used to connect the battery to the connector pins. They enable an easy removal of the battery for recharging.

The circuitry is shown in fig. 3.

B. Casing Design

A plastic casing was designed to safely package the circuitry and attach it to the pedal of a bicycle. It contains a battery section for holing a battery and a section for holding the circuitry. A metallic handle attaches the casing to the pedal of a bicycle. The casing could be attached to either the left or right pedal of a bicycle in order to read the pedal angle. The casing and the metallic handle are shown in fig. 4 (a), and the casing attached to a bicycle is shown in fig. 4 (b) respectively.

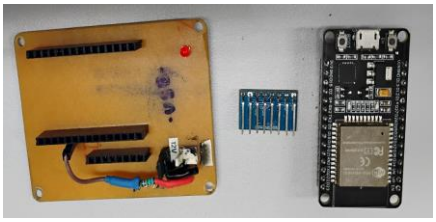

Fig 3. Circuitry

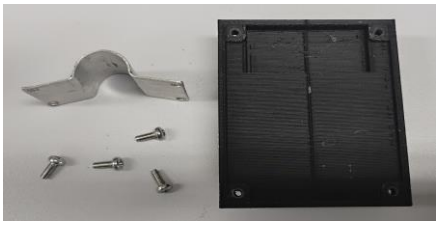

Fig 4 (a). Fabricated casing and handle

Fig 4 (b). Circuitry mounted on bicycle

IV. METHODOLOGY

When a player rides the physical bicycle, the ESP32 microcontroller gets the BNO055 sensor angle and sends it via WIFI to a device in real time. The game application on the device then retrieves the sensor angle and uses it to animate the legs of the on-screen dinosaur and the pedals and wheels of the on-screen bicycle to the angle position. Depending on the angle received, the on-screen dinosaur (legs) and bicycle (pedals and wheels) could either move clockwise (forward) or anticlockwise (backward) to the position of the angle. The 'okay' emoji is displayed for a successful clockwise movement and the 'warning' emoji is displayed for an anticlockwise movement.

In combination with the 'warning' emoji, a 'warning' sound is also played for a short period to notify a player that he/she is cycling backward. In combination with the 'okay' emoji, an 'okay' sound is also played for a short period to notify a player that he/she is back on track from riding backward.

Also, a count of number of successful cycles completed is displayed on-screen. The 'Winner' message is displayed when a player successfully completes a maximum number of cycles. A 'winner' sound is also played to indicate that a player has won. These gestures encourage a player to continue playing the game.

The microcontroller was programmed with Arduino sketch while the game app was developed with Qt C++.

A. Game Rules

- By default, maximum number of cycles (MC) is set to 10.
- A player can change the default MC and set his/her MC per round of play
- Backward cycles (BC) are wrong, and are subtracted from MC
- Forward cycles (FC) are counted for a player as successful cycles. It is calculated using equation 1
- A round ends when MC is reached
- Percentage Progress (*PP*) is measured as a percentage of FC over MC per round of play. It is calculated using equation 2.
- A player can play as many rounds in order to improve his/her cycling

$$FC = MC - BC \quad (1)$$

$$PP = \frac{FC}{MC}(100) \quad (2)$$

B. Game Diagram

C. Algorithm

1. Start game
2. While player is cycling
    a. Get angle from BNO055 sensor
    b. Animate on-screen dinosaur and bicycle to angle position
    c. Display 'okay' or 'warning' emoji based on angle
    d. increase number of cycles if a cycle is completed
    e. increase number of backward cycles if current angle is less than previous angle
    f. display 'Winner' message if maximum number of cycles is reached and go to step 4
3. go to step 2
4. stop

V. RESULTS AND DISCUSSION

A qualitative experiment was conducted on 20 ASD children between the age bracket of 6-12 years. The aim of the experiment was to determine the effectiveness of computer games at reducing the learning curve of cycling by ASD children.

The game was installed on both computers and smartphones. It was to check which device that is most effective in encouraging the children to play the game. The smartphone was put in a virtual reality headset and worn by a child to have an immersive experience while cycling.

The experiment was divided into pretraining and training sessions.

In the pretraining session, ASD children were introduced to the cycling game. They were taught to interact with the game by pressing the play button and cycling a physical bicycle.

After the game was introduced to the children, it was observed that they were excited to continue playing the game, and a training session was set. The aim of the training session was to observe the progress of the children as they played the game.

Ten consecutive rounds of 50 maximum cycles (MC) per round were achieved. In each round, the children were observed and forward cycles (FC) and backward cycles (BC) were recorded. The app automatically calculates the progress of a player by counting number of backward and forward cycles. Backward cycling meant wrong cycling and were subtracted from the overall 50 maximum cycles to get successful forward cycles. The forward cycles' function is illustrated in equation 1. The app also automatically calculates the percentage progress (*PP*) of a player in each round. The *PP* is shown in equation 2.

Table 1 shows the recorded observations as each child progressed during the training session. Row 1-20 represent the children while column 1-10 represent the forward cycles achieved by individuals during each training round.

Cumulative percentage progresses (CPP) were also calculated to determine the overall progress of each child during the ten sessions conducted. The C*PP* is illustrated in equation 3.

$$CPP = \frac{\sum_1^{10} FC}{\sum_1^{10} MC}(100) \quad (3)$$

Based on observations and the recorded data, it was seen that all children performed above average. Hence, it could be asserted that cycling computer games improve the mood of ASD children and reduces their training curve of cycling.

Table 1: cycling data

VI. CONCLUSION

The research investigated the usefulness of computer games in reducing the learning curve of ASD children in cycling. The literature indicates that video games had been developed to enable ASD children learn and lose weight, and that the efforts were averagely successful. A computer game was developed to aid the investigation. A circuitry in package was also designed and attached to a physical bicycle in order to read the angles of a pedal. Angles were read in real time as a player is cycling a physical bicycle. The read angle is then sent via WIFI to the game app in order to animate the on-screen dinosaur and bicycle. Twenty (20) ASD children participated in a training session that investigated the successful use of the game. It was observed that all children performed above average. Findings show that computer games improve the mood of ASD children and reduces their learning curve in cycling.

***Abstract*—Population aging is associated with declines in gait quality and functional mobility, motivating repeated and monitored walking practice in older adults. This descriptive longitudinal study characterized spatiotemporal gait behavior, functional mobility, and perceived usability during three months of supervised Serious Game-assisted self-paced treadmill training. Five sedentary older adults (four women and one man; mean age, 70.2 ± 3.0 years) completed 36 supervised sessions. Treadmill-derived walking speed, stride length, and stride frequency were summarized using participant-level medians from a predefined 30–90 s analysis window at baseline (Pre), monthly during training, and at three months (3M). Mean walking speed increased from 0.63 to 1.31 m/s, mean stride length from 0.64 to 0.93 m, and mean stride frequency from 1.01 to 1.42 strides/s. All participants showed higher values at 3M than at Pre, although the magnitude and spatiotemporal composition of change varied across participants. Mean instrumented Timed Up and Go duration decreased from 10.68 to 9.18 s, with shorter durations at 3M in all participants. Mean System Usability Scale score increased from 69.5 after Session 1 to 87.7 after Session 36, although participant-level SUS scores did not increase monotonically across the four administrations. These findings characterize participant-specific longitudinal gait, functional-mobility, and usability patterns within the integrated self-paced treadmill–Serious Game system. The descriptive design, small sample, absence of a control condition, and lack of direct overground assessment limit causal interpretation and overground generalizability.**

***Index Terms*—self-paced treadmill, walking speed, stride length, stride frequency, gait analysis**

I. Introduction

Population aging is associated with declines in mobility, gait quality, and functional independence, partly related to increasingly sedentary behavior and reduced habitual physical activity [1]–[3]. These changes are linked to an elevated risk of falls and to progressive declines in the strength, balance, and locomotor capacity required for daily activities [4]–[6]. Supervised exercise and gait-focused interventions are widely recommended to mitigate these declines [7], [8], highlighting the need for technologies that support repeated, monitored walking practice among older adults over extended periods.

Self-paced treadmills allow users to regulate their walking speed while preserving the controlled setting of treadmill-based protocols. Unlike fixed-speed systems, these platforms operate through a closed-loop interaction in which treadmill-belt speed is continuously adjusted in response to the user's behavior, thereby better accommodating self-selected locomotor patterns during repeated exposure [9].

Walking speed is often used as a global descriptor of locomotor performance, yet speed alone does not indicate how a given gait pattern is produced. Similar speeds may arise from different combinations of stride-length-related spatial behavior and stride-frequency-related temporal behavior. When the goal is to interpret change over repeated exposure, these descriptors become important because they help determine whether longitudinal speed increases are associated primarily with spatial adjustments, temporal adjustments, or a combination of both. Prior work has shown that spatiotemporal gait parameters vary

systematically with walking condition and speed, supporting the joint interpretation of speed and stride-related descriptors rather than speed alone [10], [11].

Overground and treadmill walking represent distinct assessment contexts. Treadmill walking enables repeated measurements over many gait cycles under controlled conditions, but it should not be considered directly equivalent to overground walking. Differences between treadmill and overground conditions have been reported in kinematics, kinetics, spatiotemporal variability, and sensory context [12], [13]. Self-paced control reduces an important limitation of fixed-speed treadmill walking by allowing participants to regulate their walking speed. Nevertheless, because treadmill-belt speed is continuously adjusted in response to user behavior, the participant and treadmill operate as a closed-loop system [14], [15]. Consequently, longitudinal changes may reflect both locomotor behavior and increasing familiarity with the self-paced control interface.

Despite growing interest in self-paced treadmill systems, the available literature remains focused primarily on controller validation and cross-sectional comparisons among overground, fixed-speed treadmill, and self-paced treadmill walking [14], [15]. Less is known about how gait behavior evolves during repeated supervised exposure to self-paced treadmills over longer periods in older adults. In particular, it remains unclear whether longitudinal changes in walking speed are associated mainly with spatial adjustments, temporal adjustments, or participant-specific combinations of both.

Beyond spatiotemporal gait parameters, the Timed Up and Go (TUG) test captures sit-to-stand transitions, walking, turning, and overall task duration, providing a complementary descriptor of functional mobility in older adults [16], [17]. Whether longitudinal changes in treadmill-derived gait descriptors coexist with changes in functional mobility over the same period remains unclear.

To address the identified gap, the present study examined repeated Serious Game-assisted self-paced treadmill walking in older adults [18]. The primary aim was to characterize participant-specific longitudinal patterns in treadmill-derived walking speed, stride length, and stride frequency across the three-month training period, from baseline to each monthly assessment, including differences in the spatial and temporal composition of change. The secondary aim was to describe concurrent changes in functional mobility over the same period. As a tertiary, exploratory aim, perceived usability of the integrated treadmill–Serious Game system was described using the System Usability Scale (SUS) across the training period.

II. Materials and Methods

A. Assistive Technology System

The training protocol used an integrated assistive-technology platform that combined self-paced locomotion on the UFES SmartTreadmill [9] with Serious Game-based visual guidance, concurrent upper-limb interaction, stereoscopic visualization, and physiological monitoring. The UFES Smart-Treadmill consisted of a commercial treadmill retrofitted with a closed-loop treadmill-belt-speed controller. An RPLiDAR A3 laser range finder tracked the participant's lower-limb position, and the resulting signal was processed using the Weighted-Frequency Fourier Linear Combiner and Fourier Linear Combiner methods to estimate walking speed in real time [9]. An E6B2-CWZ6C incremental encoder independently measured treadmill-belt speed for feedback control. Thus, the walking-speed estimate and treadmill-belt speed were obtained through separate sensing paths. The sensing architecture and associated self-paced control methods were previously developed and evaluated [9], [18]. Figure 1 illustrates the physical configuration of the platform.

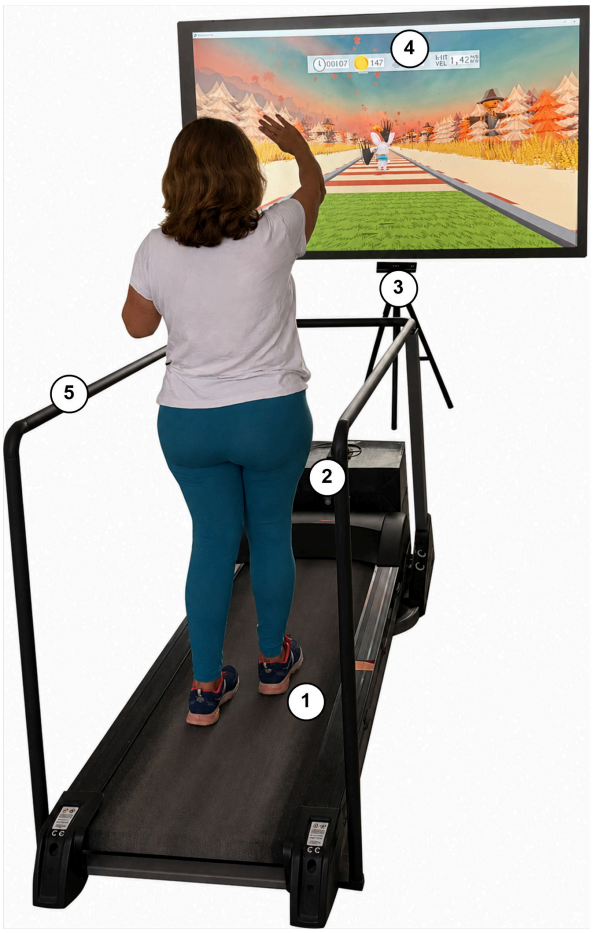

Fig. 1. Experimental setup of the integrated assistive-technology platform: (1) self-paced treadmill walking surface, (2) RPLiDAR A3 laser range finder, (3) Kinect V2 sensor, (4) Serious Game visual-feedback display, and (5) safety handrails.

The Serious Game was implemented in Unity and exchanged locomotion and control information with the treadmill controller in real time through a Robot Operating System-based architecture and WebSocket communication. This integrated treadmill–Serious Game application was previously

described [18]. A Microsoft Kinect V2 sensor provided markerless tracking for the concurrent upper-limb interaction task but did not contribute to gait sensing. A passive stereoscopic projection system displayed the virtual environment during treadmill walking. Heart rate (HR) was continuously monitored using a Polar H10 as a real-time safety measure and was not used as an input to the self-paced controller.

B. Serious Game Training Tasks

Training sessions took place within a virtual environment that changed across the three-month protocol. In the treadmill-integrated task, avatar progression was coupled to the participant's walking speed, and participants regulated their pace to remain within a visual target walking zone, receiving continuous feedback on their position relative to this zone. In the Kinect-integrated task, markerless upper-limb movements were used to collect target stimuli and avoid distractors while the treadmill-integrated task was performed concurrently. The simultaneous execution of both tasks constituted the motor-cognitive dual-task condition implemented by the Serious Game. Every 5 min, the Dynamic Difficulty Adjustment (DDA) mechanism independently adjusted the upper speed limit of the target walking zone and the number of target stimuli for the subsequent interval according to task performance. This upper speed limit also constrained the maximum treadmill-belt speed for the subsequent interval, while the self-paced controller continued to regulate belt speed in response to participant motion within that limit.

C. Participant Information

Participants were recruited by convenience sampling from a university program for older adults at the Federal University of Espírito Santo. The inclusion criteria were: age 60–80 years; cardiologist clearance for exercise participation; independent ambulation without an assistive device; low physical activity level according to the International Physical Activity Questionnaire (IPAQ) [19]; body mass index between 18.5 and 29.9 kg/m^2 [20]; nonsmoking status; no structured exercise during the preceding three months; no previous virtual-reality experience; and no cognitive impairment, vestibular disorder, or monocular vision, with cognitive status assessed using the Mini-Mental State Examination [21]. A minimum attendance of 80% of the scheduled training sessions was required for inclusion in the longitudinal analysis.

Of 68 older adults who contacted the research team, 47 expressed interest in participating. Of these, 42 did not meet the eligibility criteria, and the remaining five were enrolled in the study. The enrolled cohort comprised five sedentary older adults (P1–P5; four women and one man), with a mean age of 70.20 ± 3.03 years, height of 1.57 ± 0.05 m, body mass of 63.20 ± 4.55 kg, and body mass index of 25.76 ± 1.18 kg/m^2. All participants walked independently without assistive devices and completed the 36 scheduled sessions, with no attrition.

D. Study Design and Supervised Training Protocol

This descriptive, exploratory longitudinal study was conducted at the Human-Centered Systems Laboratory of the Federal University of Espírito Santo. The protocol was approved by the Research Ethics Committee of the Federal University of Espírito Santo (approval no. 6,294,101; CAAE: 70158523.2.0000.5542), and all participants provided written informed consent before enrollment.

Eligibility screening and participant characterization were completed together with a familiarization session introducing the treadmill, visualization system, and interaction procedures, during an initial laboratory visit. The pre-intervention assessment (Pre) was conducted during the following laboratory visit. Data collected during familiarization were not included in the longitudinal analysis.

The supervised training phase comprised 36 Serious Game-assisted sessions on the self-paced treadmill, scheduled three times per week. Session duration was 20, 25, and 30 min in months 1, 2, and 3, respectively. HR and symptom status were monitored throughout each training session under continuous supervision, whereas resting blood pressure was assessed during the protocol-defined safety screening. Training was not initiated or was interrupted in response to clinically relevant symptom worsening (e.g., dizziness, dyspnea, chest pain, or excessive fatigue), postural instability, abnormal HR or resting blood-pressure findings, or participant request.

Longitudinal assessments were conducted in dedicated sessions separate from the supervised training sessions, before the training phase (Pre) and after the first (1M), second (2M), and third (3M) months. During each assessment, participants walked on the self-paced treadmill at a comfortable self-selected pace, and the corresponding gait recordings were

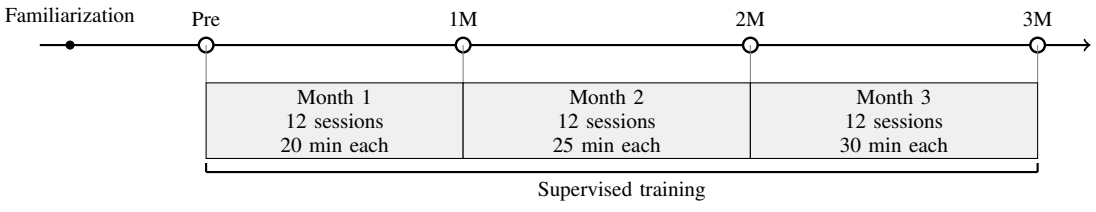

Fig. 2. Longitudinal schedule relevant to the present gait analysis. A familiarization visit, which also included eligibility screening and participant characterization, preceded the baseline assessment (Pre). Supervised training comprised 36 Serious Game-assisted sessions, scheduled three times per week and organized into three monthly blocks of 12 sessions. Session duration was 20, 25, and 30 min in months 1, 2, and 3, respectively. Longitudinal assessments (open circles) were conducted at Pre and after each month (1M, 2M, and 3M).

retained for the present analysis. The study schedule is summarized in Fig. 2.

E. Data Analysis

Gait data collected at Pre, 1M, 2M, and 3M were processed using the previously described treadmill-processing procedure [9] and analyzed descriptively. This procedure provided walking speed, stride length, and stride frequency. The reported walking speed represented the participant's walking-speed estimate rather than treadmill-belt speed. All three variables were interpreted as treadmill-derived descriptors rather than direct measurements of overground gait.

At each assessment, the participant was the unit of longitudinal analysis. Samples from the predefined 30–90 s window were used to derive participant-level summaries after excluding the gait-initiation and gait-termination segments. Each gait variable was summarized as the median of the samples within that window, and group values were calculated as the mean and standard deviation (SD) of the five participant-level medians. Samples within an assessment window were not treated as independent longitudinal observations. Given the exploratory design and sample size, longitudinal interpretation focused on participant-level trajectories across all four assessments.

To address the secondary aim, functional mobility was assessed using an instrumented Timed Up and Go (TUG) test [16], [17]. The assessment was performed using a Baiobit wearable inertial sensor system (BTS Bioengineering, Garbagnate Milanese, Italy), positioned over the lower trunk/pelvic region using the manufacturer-provided belt. Participants stood from a chair, walked 3 m, turned, returned to the chair, and sat down. TUG total duration was obtained directly from the Baiobit report. For each assessment, the first recording classified as valid by the system was retained. Group TUG duration was presented as mean (SD).

As an exploratory measure, system usability was assessed using the Brazilian Portuguese version of the SUS after Sessions 1, 12, 24, and 36 [22]. Standard SUS scoring was applied: for odd-numbered items, one was subtracted from the response; for even-numbered items, the response was subtracted from five; and the adjusted item scores were summed and multiplied by 2.5, yielding a total score from 0 to 100.

Session 1 served as the initial usability reference. Sessions 12, 24, and 36 marked the ends of the three monthly training blocks and preceded the 1M, 2M, and 3M assessments, respectively. SUS administrations were separate from the gait and TUG assessments. Participant-level SUS change was calculated as the Session 36 score minus the Session 1 score, and group values were presented as mean (SD).

Pre-to-3M percentage changes were calculated as

$$\Delta x(\%) = \frac{x_{3\mathrm{M}} - x_{\mathrm{Pre}}}{x_{\mathrm{Pre}}} \times 100. \tag{1}$$

Participant-level changes were calculated from the corresponding gait medians and retained TUG values. Group changes were calculated as mean (SD) across participants. Changes in stride length and stride frequency were compared descriptively to characterize spatial, temporal, or combined patterns.

III. Results

Figure 3 shows participant-level values of treadmill-derived walking speed, stride length, and stride frequency across Pre, 1M, 2M, and 3M. Table I reports the corresponding participant-level medians and group summaries. Mean participant-level Pre-to-3M percentage changes were 123.9% (SD: 61.9%) for walking speed, 54.3% (SD: 32.2%) for stride length, and 45.0% (SD: 32.2%) for stride frequency. All participants had higher 3M than Pre values for all three

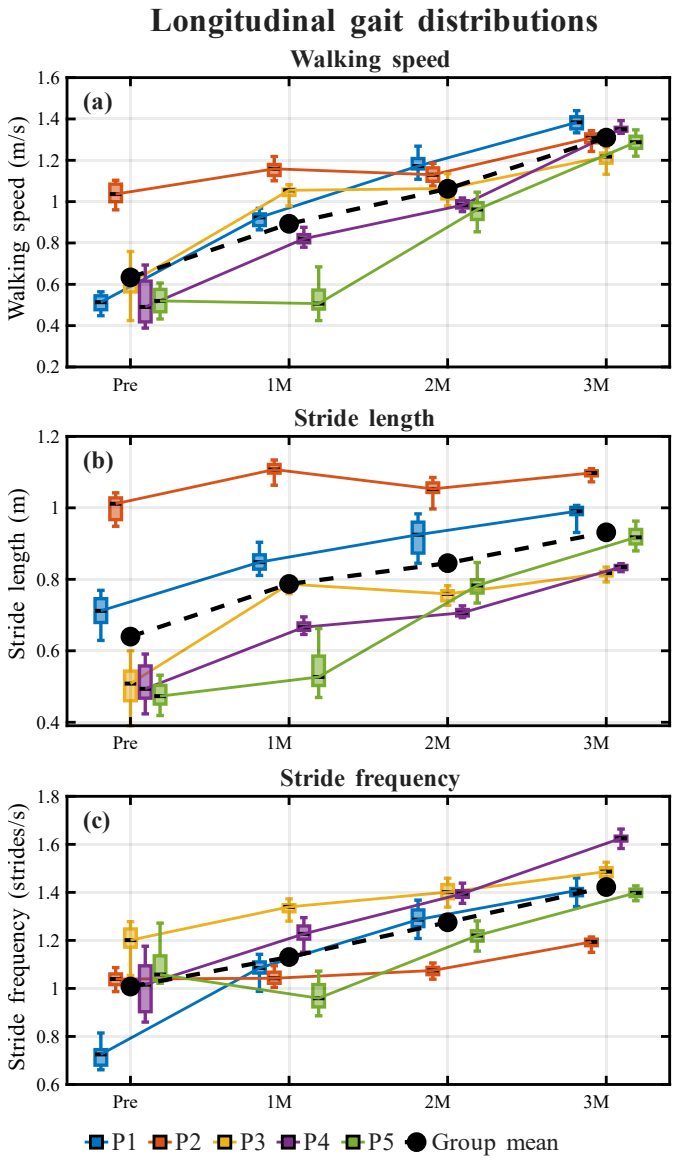

Fig. 3. Distributions of treadmill-derived walking speed (a), stride length (b), and stride frequency (c) at Pre, 1M, 2M, and 3M. For each participant and assessment, boxes show the interquartile range, center lines the median, and whiskers the 5th–95th percentiles of samples within the predefined window. Colored lines connect participant-level medians, and the black dashed line shows their arithmetic mean at each assessment. Participant-level values are reported in Table I.

TABLE I

PARTICIPANT-LEVEL MEDIANS OF TREADMILL-DERIVED WALKING SPEED, STRIDE LENGTH, AND STRIDE FREQUENCY AT PRE, 1M, 2M, AND 3M, WITH PRE-TO-3M PERCENTAGE CHANGES. VALUES ARE DISPLAYED TO TWO DECIMAL PLACES; PERCENTAGE CHANGES AND GROUP SUMMARIES WERE CALCULATED FROM UNROUNDED PARTICIPANT-LEVEL MEDIANS AND MAY THEREFORE NOT BE EXACTLY REPRODUCIBLE FROM THE PRINTED VALUES. BOTTOM-ROW ASSESSMENT VALUES ARE MEAN (SD) ACROSS PARTICIPANTS, WHEREAS BOTTOM-ROW PERCENTAGE CHANGES ARE MEAN (SD) OF PARTICIPANT-LEVEL CHANGES.

	Walking speed (m/s)					Stride length (m)					Stride frequency (strides/s)

TABLE II

INSTRUMENTED TIMED UP AND GO (TUG) TOTAL DURATION AT PRE, 1M, 2M, AND 3M. NEGATIVE PERCENTAGE CHANGES INDICATE SHORTER TUG DURATION AT 3M THAN AT PRE. BOTTOM-ROW DURATIONS ARE MEAN (SD) ACROSS PARTICIPANTS, WHEREAS THE BOTTOM-ROW PERCENTAGE CHANGE IS THE MEAN (SD) OF PARTICIPANT-LEVEL CHANGES.

	Instrumented TUG total duration (s)				
Participant	Pre	1M	2M	3M	Δ Pre–3M (%)
P1	8.59	6.88	8.55	6.28	-26.90
P2	10.39	10.70	10.31	10.04	-3.40
P3	11.40	12.24	12.82	9.92	-13.00
P4	11.44	11.89	9.98	8.88	-22.40
P5	11.56	12.16	10.08	10.76	-6.90
Mean (SD)	10.68 (1.26)	10.77 (2.26)	10.35 (1.55)	9.18 (1.75)	-14.51 (9.99)

descriptors, although participant-level values did not increase monotonically across all four assessments. P2 showed the smallest changes in walking speed (+26.3%), stride length (+8.5%), and stride frequency (+14.9%), whereas the largest changes were observed in P4 for walking speed (+175.2%), P5 for stride length (+93.9%), and P1 for stride frequency (+94.1%).

The percentage changes in stride length and stride frequency differed across participants. P1 and P2 showed larger percentage increases in stride frequency than in stride length, whereas P3 and P5 showed larger percentage increases in stride length. P4 showed substantial increases in both components, with stride length increasing by 69.0% and stride frequency by 60.0%. Thus, the higher walking speeds observed at 3M were not accompanied by a uniform spatial or temporal pattern across participants.

Mean participant-level TUG duration decreased by 14.5% from Pre to 3M (Table II). All five participants had shorter durations at 3M, with reductions ranging from 3.4% in P2 to 26.9% in P1. Intermediate TUG durations did not decrease monotonically, with transient increases at 1M or 2M in some participants.

Mean SUS score increased by 18.2 points (SD: 15.7) from Session 1 to Session 36 (Table III), and all five participants had higher scores at Session 36 than at Session 1. P2 and P5 showed the smallest increases (+3.0 points each), whereas P4 showed the largest increase (+40.0 points). Participant-level perceived-usability changes were heterogeneous, and

TABLE III

SYSTEM USABILITY SCALE (SUS) SCORES AT FOUR TRAINING-SESSION LANDMARKS: THE INITIAL SESSION AND THE ENDPOINTS OF THE THREE 12-SESSION MONTHLY BLOCKS. Δ SUS DENOTES THE SESSION 36 MINUS SESSION 1 CHANGE. BOTTOM ROW: MEAN (SD) ACROSS PARTICIPANTS.

P4	60.0	85.0	100.0	100.0	+40.0
P5	75.0	75.0	80.0	78.0	+3.0
Mean (SD)	69.5 (6.7)	77.6 (4.9)	87.6 (8.3)	87.7 (10.5)	+18.2 (15.7)

SUS scores did not increase monotonically across the four administrations.

IV. Discussion

This study showed that treadmill-derived walking speed, stride length, and stride frequency increased from Pre to 3M in all five participants, although the magnitude and spatiotemporal composition of change differed markedly across participants. The concurrent reduction in TUG duration provided complementary functional-mobility context. Overall, the findings indicate participant-specific spatial and temporal organization rather than a uniform pattern of change during the supervised training period.

These findings reinforce the need to interpret walking speed together with stride-related spatial and temporal descriptors. Higher walking speeds can be achieved through longer strides, higher stride frequency, or combined changes in both components [10], [11]. Previous work involving older adults has similarly shown that faster walking may be supported by different combinations of step length and step time [23]. These findings were therefore consistent with participant-specific spatiotemporal patterns rather than with a single common organization for achieving a higher final walking speed.

For descriptive context, Hollman et al. reported sex- and age-stratified overground means of 1.12–1.22 m/s for gait speed, 1.18–1.39 m for stride length, and 102–114 steps/min (0.85–0.95 strides/s) for cadence in healthy adults aged 70–79 years [24]. These subgroup means are not clinical thresholds and are not directly equivalent to treadmill-derived measurements. In the present study, walking speed was below the lowest Hollman subgroup mean in all participants at Pre and at or above the highest subgroup mean in all participants at 3M. Stride length remained below the lowest subgroup mean at both Pre and 3M. Stride frequency was above the highest subgroup mean in four participants at Pre and in all participants at 3M. Thus, higher final treadmill-derived walking speeds co-occurred with shorter strides and higher stride frequencies than the published overground subgroup means. Together with the participant-level percentage-change patterns, these descriptive contrasts are consistent with heterogeneous spatial and temporal organization across participants [23]; they do not indicate gait normalization or treadmill–overground equivalence.

The participant-specific patterns should be interpreted within the closed-loop context of self-paced treadmill walking, in which treadmill-belt speed responds continuously to participant behavior [14], [15]. The platform also combined locomotion-related visual guidance, concurrent upper-limb interaction, and DDA within the dual-task Serious Game [18]. Because changes in DDA settings over time were not analyzed, whether task adjustment contributed to the observed gait heterogeneity cannot be determined.

The SUS results provided complementary context for the participant-specific gait changes during the same training period. Mean SUS scores increased from 69.5 points after Session 1 to 87.7 points after Session 36, with intermediate group means of 77.6 and 87.6 points after Sessions 12 and 24, respectively (Table III). At the participant level, P2 combined a small SUS increase (+3.0 points) with the smallest changes in all three gait descriptors, whereas P4 combined the largest SUS increase (+40.0 points) with substantial changes across the three gait descriptors, including the largest increase in walking speed. In contrast, P5 showed the same small SUS increase as P2 but the largest increase in stride length. These descriptive concordances and discordances should not be interpreted as evidence of an association or causal influence between perceived usability and the observed gait patterns. The SUS reflected overall perceived usability of the integrated treadmill–Serious Game system rather than isolated treadmill-control difficulty.

Mean TUG duration decreased from 10.68 s at Pre to 9.18 s at 3M, corresponding to a descriptive reduction of 14.5%. All participants had shorter durations at 3M, although intermediate TUG durations varied and Pre-to-3M reductions ranged from 3.4% in P2 to 26.9% in P1. Thus, the observed treadmill-derived gait changes co-occurred with shorter TUG durations in an overground functional task, but the descriptive design does not establish transfer or a training effect.

Several limitations must be considered. The sample included only five participants recruited by convenience; therefore, the study does not support population-level inference, and the findings should be interpreted as participant-specific observations within this cohort rather than as estimates applicable to the broader older-adult population. The restrictive eligibility criteria further limit representativeness, particularly for older adults with cognitive, vestibular, visual, or mobility impairments. No control or comparison condition was included. The descriptive design therefore does not allow the observed changes to be separated from familiarization with the self-paced controller, repeated task exposure, spontaneous variability, measurement variability, or other time-related influences. The gait variables were treadmill-derived descriptors obtained from a predefined 30–90 s analysis window and summarized using participant-level medians. They should not be interpreted as direct overground gait measurements; therefore, transfer of the observed spatiotemporal changes to overground walking cannot be established. In addition, the Pre-to-3M percent changes summarize the overall baseline-to-final contrast but do not fully represent the heterogeneous gait behavior observed at 1M and 2M, as shown in Fig. 3.

Future studies should include larger samples, control or comparison conditions, and direct overground assessments. Prespecified longitudinal models that preserve the participant-level data structure would help evaluate whether the observed findings generalize beyond this cohort and experimental environment.

V. Conclusion

Across the three-month supervised training period, all five participants had higher treadmill-derived walking speed, stride length, and stride frequency at 3M than at Pre, but the magnitude and spatiotemporal composition of change differed across participants. These differences describe heterogeneous

participant-specific locomotor patterns. Shorter TUG durations at 3M co-occurred with these treadmill-derived gait changes, and mean SUS score was higher at Session 36 than at Session 1, although participant-level SUS scores did not increase monotonically across the four administrations. Together, these findings characterize longitudinal patterns in gait, functional mobility, and usability within the integrated self-paced treadmill–Serious Game system.

Given the descriptive design, five-participant sample, absence of a control condition, and lack of direct overground gait assessment, causal interpretation is not supported and generalizability beyond this cohort and experimental environment is limited. Larger controlled studies incorporating direct overground assessments and prespecified longitudinal analyses are needed to evaluate the functional relevance and generalizability of these findings.

***Abstract*—This paper presents GESTUS, a proof-of-concept assistive technology system for human-computer interaction operated exclusively by a conventional webcam and aimed at individuals with severe motor restrictions. The system integrates MediaPipe, image preprocessing, 3×3 grid gaze calibration, automatic interface scanning, blink-based selection, and speech synthesis. We evaluate eight preprocessing techniques combined with five interpolation methods across three facial luma ranges, with and without glasses. Configurations using the median filter reached the highest average separability among centroids while staying above 33 FPS. Classification accuracy on frames temporally separated from calibration inverts this ranking: the Gaussian filter leads with an accuracy of 0.559, κ of 0.504, and top-2 of 0.752, whereas the median filter drops to seventh of eight, showing that centroid separability does not predict classification performance. Per-session z-score standardization of the attributes raises accuracy to 0.613 at no extra cost, and 92.0% of predictions fall on the correct cell or an immediate neighbor. Because the error is predominantly local and rejection improves reliability, the interface can operate in a conservative regime that favors reliability over coverage. The exploratory analysis was done with one participant and without usability evaluation.**

***Index Terms*—Assistive Technology, Augmentative and Alternative Communication, Eye Tracking, Proof of Concept, Computer Vision, MediaPipe, OpenCV.**

I. Introduction

People with reduced mobility from amyotrophic lateral sclerosis (ALS) or the sequelae of a stroke face substantial barriers with technology, since conventional input devices such as keyboards, mice, and touchscreens are often unsuitable. Augmentative and Alternative Communication (AAC) brings together strategies to complement or replace speech, with effectiveness documented in both clinical and home settings [1]–[3]. Computer vision offers one route into this space, making it possible to build contact-free interfaces based on eye tracking and blink detection. GESTUS is a non-invasive assistive system of this kind, operated by a conventional webcam.

The computer vision stage uses MediaPipe together with image processing techniques to extract in real time the features needed to drive the interface [4]. The MediaPipe Face Landmarker supplies facial landmarks, facial expression scores (*blendshapes*), and geometric information about the face [5], all of which matter for representing facial geometry from monocular video [6].

This paper asks whether a usable ocular signal for discrete control can be extracted from a conventional webcam and which preprocessing decisions are most promising. We describe the architecture, image processing, and communication interface of GESTUS and measure how preprocessing and interpolation affect the separability of nine gaze directions, classification accuracy on a temporally separated test set, and real-time throughput. No claim of clinical efficacy, usability, or equivalence to dedicated eye trackers is made. The contributions are four: (i) reproducible integration of calibration, gaze classification, scanning, blink detection, and speech synthesis in a webcam-only application; (ii) systematic screening of 40 preprocessing and interpolation configurations under varying facial luma and glasses, assessed by both separability and temporal-split accuracy; (iii) instrumentation for future evaluation with users; and (iv) a low-cost classifier modification, per-session attribute standardization, that raises accuracy at no extra computational cost.

II. Related Works

A. AAC Tools and Access Methods

Among established AAC solutions, the closest functional reference for GESTUS is Jabbla's Mind Express 5, which organizes vocabulary into grids of selectable cells and accepts several access methods—touch, mouse, joystick, switches, head tracking, and eye tracking—while extending gaze control to the Windows environment for typing, scrolling, and mouse-equivalent actions [7]. GESTUS sets out to reproduce exactly this arrangement, in which a single input channel serves both cell-based communication and control of the operating system. What differs is the hardware it assumes: commercial gaze access depends on a dedicated tracking module, and eye-typing systems are reported to cost between $5,000 and $10,000 depending on configuration [8], a decisive barrier in low-income settings.

Scanning access, in which cells are highlighted in sequence and the user confirms with a single voluntary gesture, is the classical alternative when motor control cannot support direct pointing [3]. It trades spatial precision for time: the communication rate drops, but the motor demand falls to binary activation. GESTUS pairs this strategy with an unusual trigger—a deliberate blink via webcam—and with synthesized speech, placing it between low-cost printed communication boards and commercial suites tied to specific hardware.

B. Gaze-Based Assistive Interfaces

Work on gaze interaction for users with severe motor impairment differs in three main respects: the sensor it requires, the granularity of the signal it extracts, and how far it has been validated with the target population.

Several systems remove dedicated hardware from the equation. Chhimpa et al. [9] present real-time, low-cost eye tracking with no mandatory calibration; Kumar et al. [10] drive a cursor from facial landmarks with OpenCV; Deepika and Murugesan [11] combine cursor movement with blink selection; and Buhagiar et al. [12] explore gaze-driven web navigation. GESTUS shares this premise but departs from [9] in keeping a short nine-point calibration stage: the 3×3 grid needs references for diagonal regions, and a per-session baseline absorbs variation in positioning and lighting between uses.

Granularity involves a recurring trade-off between spatial precision and robustness. Blink-To-Live [8] pushes this to the limit by discarding position altogether and encoding voice-synthesized commands with four facial gestures on a smartphone. Jain et al. [13] take the opposite route, with typing driven by continuous eye analysis. GESTUS sits between the two: the 3×3 grid retains enough precision for cursor control, while automatic scanning supports communication without direct pointing and eases the burden of sustained fixation (Section II-C).

Validation is where SpeakFaster [14] sets the highest bar. Combining gaze typing with language models that expand abbreviated text, it saved 57% of motor actions in simulation and, in laboratory and field trials with two ALS users experienced in gaze typing, achieved text-entry rates 29% to 60% above the baselines. That work shows how far the evaluation of gaze-based AAC extends beyond the sensor, into interaction and language.

Taken together, the reviewed systems cover the individual pieces GESTUS depends on: webcam-only capture, blink confirmation, and gaze-driven pointing. What we did not find was a low-cost combination of them serving both cell-based communication and cursor control, as the commercial suites in Section II-A do with dedicated hardware. GESTUS explores that combination, and this article characterizes the image pipeline that supports it.

C. Challenges and Obstacles of Gaze Interaction

The literature documents several obstacles that shape the design of systems like GESTUS. The main one is the *Midas touch* problem: because gaze is at once the channel for inspection and for command, the system cannot tell reading apart from an intention to act [15], and a second signal must express that intention. The most common strategy is dwell time, usually between 500 and 1000 ms [16], which trades slowness and sustained fixation against unintended selections as the interval is shortened or lengthened. The alternative is an explicit gesture such as a voluntary blink, which separates pointing from confirmation unambiguously, at the cost of the discomfort of repeated blinking and the risk that spontaneous blinks are read as commands [15], [17]. GESTUS uses the explicit gesture and handles that risk with the duration thresholds of Section III-E.

Visual fatigue and sustained effort are a second obstacle, and they matter especially in neurodegenerative disease, where holding a fixation is costly. The automatic scanning module is a design decision aimed at this problem: the highlight moves through the cards on its own, gaze is no longer the pointing channel, and all that remains for the user is the confirmation gesture. This reduces cumulative fixation time shifting the cost from spatial precision to waiting.

A third obstacle is how sensitive appearance-based approaches are to capture conditions. Methods that estimate gaze in visible light are affected by non-uniform illumination, shadows, reflections on corrective lenses, and reduced contrast between iris, pupil, and sclera, which degrades accuracy in uncontrolled environments relative to infrared trackers [18]; failures are more frequent in low luminance, particularly among users with visual correction [19]. Two decisions in GESTUS respond to this: adaptive, iterative percentage thresholding of the ocular region, which readjusts the threshold according to the local intensity distribution, and enhancement techniques applied before ocular extraction, evaluated in Section III-B across facial luma ranges.

III. Materials and Methods

A. Overview, Architecture, and Study Delimitation

GESTUS is a Python application organized under the MVC pattern. It uses OpenCV and MediaPipe for computer vision,

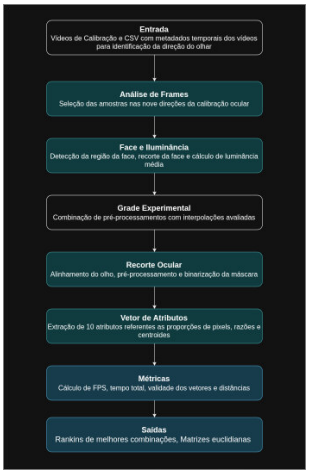

Fig. 1: Exploratory analysis workflow used to compare facial luma, preprocessing techniques, interpolations, feature vectors, Euclidean distances, and processing cost.

PyAutoGUI for cursor control, and gTTS for speech synthesis. This paper covers the technical integration and the choice of preprocessing, binarization, and interpolation settings for the visual pipeline. Clinical evaluation is future work: the data come from a single participant with no independent replication, and the focus here is the technical proof of concept.

B. Exploratory Analysis and Experimental Protocol

The analysis covers 40 configurations, combining 8 preprocessing methods with 5 interpolation methods ($8 \times 5 = 40$). OpenCV lists six interpolation options, but linear and bilinear follow the same execution path in two-dimensional resizing and produce identical results, so they are counted once. The aim is a comparative baseline across capture conditions, enhancements, and ocular metrics that can inform the choice of real-time pipeline (Fig. 1).

The experimental set contains six videos recorded by a single participant, one for each combination of the three lighting conditions with and without glasses. Each video lasts 82.0 s, with 2,460 frames at 30 FPS and a resolution of 640×480. For each configuration, 1,080 frames per video were analyzed, evenly distributed across the nine directions of the 3×3 grid (120 samples per direction), giving 6,480 unique frames and 259,200 processing records in total. There was no independent experimental replication: each combination of illumination and glasses was represented by a single video.

The recordings used a Bison Electronics camera with automatic exposure and gain. The facial luma we report therefore describes the resulting image rather than the ambient illuminance, which partly compresses the variation between capture conditions. The participant stayed 45–50 cm from the lens. Processing ran on a Lenovo IdeaPad (i5-13420H, 24 GB RAM) with Ubuntu 24.04.4, Python 3.12.13, OpenCV 4.13.0, and MediaPipe 0.10.33.

C. Image Processing Pipeline

RGB frames are processed with MediaPipe to identify the face, landmarks, and *blendshapes*. The system then crops the face, resizes it to 384×384 pixels, applies the enhancement, and extracts the eyes in grayscale. Ocular tilt is corrected by aligning the interocular axis with the horizontal through an affine transformation, using $\theta = \arctan 2(y_R - y_L,\, x_R - x_L)$; this keeps the anatomical correspondence between the processed bands stable even with the head tilted. Binarization uses inverted thresholding, assigning 255 to segmented dark pixels:

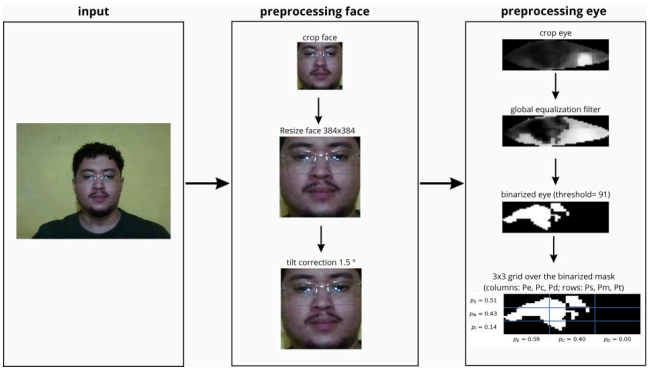

Fig. 2: Image processing pipeline steps on a real frame from the semi-lit session with glasses ($\overline{Y'} = 83.3$), using global equalization and nearest-neighbor interpolation. Top row: original 640×480 frame, facial crop, resizing to 384×384, and 1.5° tilt correction. Bottom row: grayscale ocular crop, applied enhancement, binary mask obtained by Eq. (1) with threshold 59, and division into bands with the segmented pixel proportions p_E, p_C, p_D, p_S, p_M, and p_I that make up the feature vector.

$$B(x,y) = \begin{cases} 255, & I(x,y) \le \tau, \\ 0, & I(x,y) > \tau, \end{cases} \qquad \tau^* = \arg\min_{\tau} \left| P_{\text{seg}}(\tau) - P_{\text{alvo}} \right|. \tag{1}$$

The second expression defines the iterative percentage mode, in which the threshold is adjusted until the proportion of segmented pixels approaches a predefined target (66.0% with a tolerance of 0.5%, an initial threshold of 14, and at most 255 iterations). The pipeline also supports fixed thresholding, Otsu's method [20], and local adaptive thresholding [21], which is the system's main defense against mask degradation in low light.

Fig. 2 shows the full chain on a real frame from the semi-lit session with glasses. The final panel makes the effect of capture conditions on the feature vector visible: a specular reflection on the lens introduces a high-intensity region in the right portion of the ocular crop which, after inverted binarization, is left unsegmented, giving $p_D = 0.00$ against $p_E = 0.59$. The asymmetry comes from an optical artifact rather than from gaze direction, and it shows the mechanism by which corrective lenses degrade classification; Section IV-E quantifies the effect.

1) Preprocessing Techniques: The main criterion is not visual quality but the effect on the *binary mask*. Since the ten attributes of the vector are area proportions and coordinates computed over that mask, the technique has to stabilize the segmented contour and preserve the contrast between the dark region and the sclera. The comparison measured directional

separability, mask stability, frame rate (FPS), and total processing time.

The eight techniques differ in the support of the operation. Point transformations map each intensity independently of its neighborhood and change the histogram from which τ is computed, without altering the local geometry of the contour; contrast operations redistribute intensities from global or local statistics; and spatial filters act on a neighborhood and directly affect the regularity of the segmented edge.

- *No preprocessing*: baseline; the crop goes straight to binarization.
- *Global equalization* [21]: takes the cumulative intensity distribution as the mapping function, expanding the dynamic range and amplifying noise in the eyelid shadows.
- *CLAHE* (*Contrast Limited Adaptive Histogram Equalization*) [22]: block-based equalization (8×8) with histogram clipping (clip 2.0); on a small ocular crop it accentuates eyelashes and reflections.
- *Gamma correction* [23]: point transformation $I' = 255\,(I/255)^{\gamma}$ with $\gamma = 1.5$, which shifts the midtones and with them the threshold that satisfies the target proportion.
- *Single-scale Retinex* [24]: estimates the illumination by Gaussian convolution ($\sigma = 30.0$) and subtracts it in the logarithmic domain, attenuating non-uniform illumination and shadows.
- *Bilateral filter* [25]: weighted average over spatial and intensity kernels ($d = 5$, $\sigma_{\text{color}} = \sigma_{\text{space}} = 50$); smooths homogeneous regions while preserving the iris–sclera transition.
- *Gaussian filter* [26]: 5×5 linear low-pass convolution with continuous response; attenuates high-frequency contour noise at the cost of isotropic blurring.
- *Median filter* [27]: replaces each pixel with the median of its 5×5 neighborhood; removes impulse noise without blurring edges, but, being an order filter, produces quantized jumps in the output, a property we return to in Section IV-C.

2) Interpolation and Resizing: The detected face is resized to 384×384 pixels, which standardizes the scale before ocular extraction. Faces in 640×480 frames at 45–50 cm occupy between 180 and 260 pixels, so this stage acts in practice as an *upscaling*, with scale factors between 1.5 and 2.1.

Five numerically distinct strategies were evaluated [28]. They differ in the support of the reconstruction kernel, that is, in the number of source samples that contribute to each destination pixel.

- *Nearest neighbor*: zero order; copies the closest sample without averaging. It is the fastest and creates no new intensities, at the cost of pixelation.
- *Area*: average of the source pixels covered by the projection of the destination pixel; avoids aliasing when downscaling, but degenerates to nearest neighbor when *upscaling* [28], which explains how close the two are in Table I.
- *Linear/bilinear*: first order over 4 neighbors, interpolating along one axis and then the other; in two-dimensional resizing both resolve to the same procedure and are counted once.
- *Bicubic*: cubic polynomials over 16 neighbors (4×4); a smoother result at a higher per-pixel cost.
- *Lanczos*: windowed sinc kernel over 64 neighbors (8×8); sharper, but prone to ringing near high-contrast edges and the slowest of the five (Table II).

Interpolation has little effect on accuracy: the ten attributes are first-order statistics over the mask, and upscaling only estimates values without adding spatial detail. Preprocessing, by contrast, changes the intensity distribution on which τ is computed, and dominates the result.

3) Facial Luma and Lighting Ranges: The mean digital luma of the face converted to RGB is computed over the region Ω_f with BT.709 coefficients [29]: $Y' = 0.2126R' + 0.7152G' + 0.0722B'$ and $\overline{Y'} = N^{-1} \sum_{(x,y)\in\Omega_f} Y'(x,y)$, with N the number of valid pixels. The sessions were split *a posteriori* from the six observed values (Fig. 6) into three ranges: dark ($40 \le \overline{Y'} < 70$), medium ($70 \le \overline{Y'} < 90$), and bright ($90 \le \overline{Y'} \le 110$).

Facial illuminance (lux) is not the same as the flux emitted by the source (lumen), since incidence varies with geometry. With no luxmeter available, the study used mean digital luma $\overline{Y'}$ as an approximate substitute, aware that it depends on camera exposure. A formal photometric measurement correlated with $\overline{Y'}$ is part of the validation protocol planned for future work.

4) Feature Vector and Euclidean Distance: After binarization, the ocular region is divided into three vertical bands (left, center, right) and three horizontal bands (top, middle, bottom). For each band Ω_i we compute the proportion of segmented pixels within the valid area of the mask, $p_i = |\Omega_i|^{-1} \sum_{(x,y)\in\Omega_i} \mathbf{1}[B(x,y) = 255]$, with $\mathbf{1}[\cdot]$ the indicator function. The feature vector has ten components:

$$\mathbf{v} = [p_E, p_C, p_D, p_S, p_M, p_I, r_H, r_V, c_x, c_y], \tag{2}$$

where $r_H = (p_D - p_E)/(p_D + p_E + \epsilon)$ and $r_V = (p_I - p_S)/(p_I + p_S + \epsilon)$ summarize the horizontal and vertical displacement of the segmented pixels, and c_x, c_y are the normalized centroid coordinates. A vector counts as valid only when all ten attributes are present and numeric. In the experiments the vector is extracted from the left eye, which keeps the analysis consistent with the channel used for content selection in the interface and avoids doubling the dimensionality; a comparison between the left eye, the right eye, and both concatenated is planned for the multiparticipant study. The system also records the eyelid height of each eye, given by the Euclidean distance between landmarks 159 and 145 (left) and 386 and 374 (right), used as an auxiliary reference in blink detection.

Classification compares the current vector with a calibrated mean vector $\bar{\mathbf{v}}_d$ for each direction d, and the estimated direction is the nearest reference:

$$D(\mathbf{v}, \bar{\mathbf{v}}_d) = \sqrt{\textstyle\sum_{i=1}^{10} (v_i - \bar{v}_{d,i})^2}, \quad \hat{d} = \arg\min_d D(\mathbf{v}, \bar{\mathbf{v}}_d). \tag{3}$$

In the comparative analysis, the same metric produces distance matrices between the mean vectors of distinct directions, $M_{a,b} = D(\bar{\mathbf{v}}_a, \bar{\mathbf{v}}_b)$; higher off-diagonal means indicate greater separability between centroids. Separation between centroids is not, however, equivalent to classification accuracy, a point we return to in Section IV-C.

Accuracy is evaluated with a per-session temporal split. For each combination of video and direction the frames were ordered: the first 30 (one second) form the calibration for the threshold and $\bar{\mathbf{v}}_d$, mimicking initialization, and the remaining 90 form the test set. Centroids are extracted separately for each session, since GESTUS recalibrates on every use and sessions under different illumination should not be pooled. Each test frame is then labeled by its nearest centroid through Eq. (3), which mimics real operation.

The temporal split avoids reusing calibration frames, but it does not imply statistical independence: consecutive frames from the same session share participant, camera, positioning, and environmental conditions. The six sessions are the only experimental units available, so we do not report aggregated confidence intervals; Table IV gives the per-session accuracy of the best configuration instead, which is more transparent at $n = 6$.

D. Initialization and Operation Flows

Initialization (Fig. 3) loads the services and MediaPipe. With the user looking at the center, the system iteratively adjusts the binarization threshold to reach the target proportion of pixels and records the mean eyelid height, the reference for blinks. Gaze is then calibrated by capturing a ten-dimensional vector for each of the nine points on the screen. Unlike strictly calibration-free approaches [9], this brief stage gives the mapping of the diagonal regions its robustness.

Continuous operation (Fig. 4) involves detection, enhancement, and ocular binarization for attribute extraction and eyelid measurement. Blink detection combines the MediaPipe blendshapes with the calibrated relative height, and to avoid false positives the system requires ocular dominance: a one-eyed blink is confirmed only if the other eye stays below the threshold. Closing both eyes triggers suspension. The spatial classifier may later give way to supervised models.

E. Functionalities and Definition of Temporal Thresholds

Fig. 5 shows the main screens. Card-based communication organizes the vocabulary into categories covering family, actions, needs, pain and body, feelings, an intensity scale, numbers, the alphabet, yes/no answers, and questions. The categories come directly from the boards of the Alternative Communication Notebook for COVID-19 Patients with Reduced Mobility, produced by the Occupational Therapy Department at UFRJ [30]: the *what I would like to do* board, for instance, gave rise to the actions category. Adopting this lexicon anchors the interface in vocabulary already organized by occupational therapists around the needs of hospitalized patients without functional speech [2], [3]. The validation protocol includes

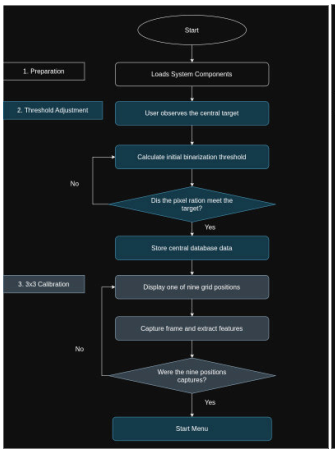

Fig. 3: Initialization and 3×3 grid calibration workflow.

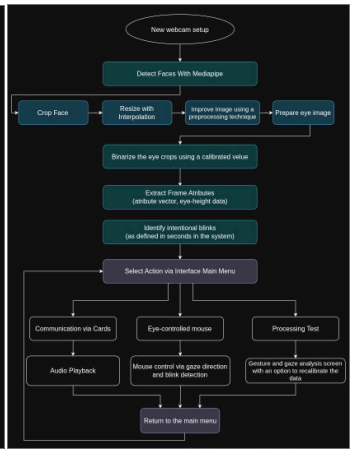

Fig. 4: GESTUS real-time processing workflow.

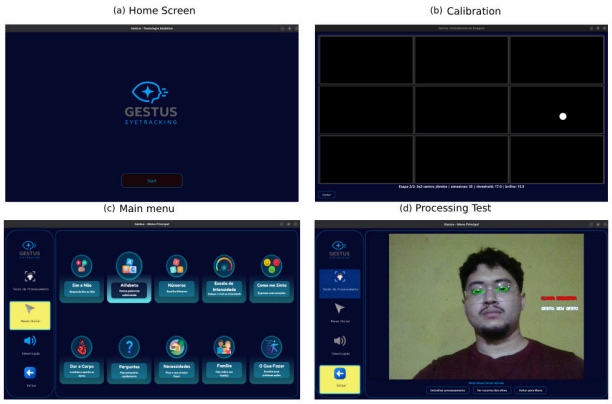

Fig. 5: GESTUS screens: (a) initial screen; (b) calibration; (c) main menu; and (d) processing test.

professionals from HUWC and PROTECS/UFC in adapting the vocabulary and in the evaluation with users and caregivers.

Automatic scanning advances the card highlight at a fixed interval, so the user only has to blink deliberately to confirm the selection and have it read aloud. During scanning, the left eye selects the content of the grid and the right eye moves through the options, which reduces ambiguity. In mouse control, cardinal and diagonal gaze directions move the cursor along the corresponding axes, and closing both eyes for 3 s suspends or resumes detection.

The temporal thresholds were anchored in the literature on eyelid kinematics and then tuned in an internal pilot. A single blink lasts mostly between 100 and 400 ms, with a mean for endogenous blinks near 334 ms ($\pm$67 ms) [31], while a *voluntary* blink is substantially longer at 572 ± 25 ms [32]. We therefore placed the 0.5 s threshold for a single click *above* the usual limit for spontaneous blinks and inside the voluntary range, which reduces false commands from reflex blinks [15]. The thresholds of 1 s (double click) and 3 s (suspension) give larger margins to actions whose reversal cost is higher, consistent with usual dwell values [16]. Future evaluation will measure their effect on execution time, response time, and hit rate to support per-user calibration.

Fig. 6: Representative frames of the six sessions in the *center* direction with ocular landmarks, across the three facial luma ranges and with and without glasses, annotated with the respective $\overline{Y'}$: low light (59.0 and 60.3), medium light (81.2 and 83.3), and high light (93.2 and 95.9).

TABLE I: Mean Euclidean separability among centroids: six configurations with highest separability (six sessions from a single participant).

Preprocessing	Interpolation	Mean	SD	Min.	Max.
Median	Linear/Bilinear	0.8975	0.3185	0.1554	1.7560
Median	Nearest Neighbor	0.8961	0.3060	0.1374	1.7797
Median	Area	0.8955	0.3169	0.1533	1.7560
Bilateral	Linear/Bilinear	0.8929	0.3159	0.1554	1.7448
Bilateral	Area	0.8887	0.3139	0.1543	1.7421
Bilateral	Nearest Neighbor	0.8881	0.2989	0.1443	1.7566

IV. Preliminary Results and Discussion

The implemented prototype includes threshold calibration, nine-point gaze calibration, the communication menu, automatic scanning, audio playback, gaze classification, eye-controlled mouse operation, and blink detection based on blendshapes and eyelid geometry. The results below correspond to the technical evaluation of that prototype.

A. Facial Luma and Capture Conditions

The observed luma values were used descriptively to group the six sessions into three ranges, since ocular segmentation is affected by shadows, reflections on glasses, saturation in bright areas, and reduced contrast between iris, pupil, and sclera. The six sessions separate cleanly: $\overline{Y'} = 59.0$ and 60.3 (low light), 81.2 and 83.3 (medium light), and 93.2 and 95.9 (high light), as in Fig. 6. Throughout the text the conditions are referred to both by qualitative label and by $\overline{Y'}$. Since $\overline{Y'}$ derives from the image itself, it should not be read as photometric illuminance.

B. Separability, Computational Cost, and Accuracy

Table I lists the configurations with the highest mean Euclidean distance between centroids. The median and bilateral filters lead, while CLAHE/Lanczos records the smallest separation (0.3969). Because the gaps between the leading configurations are small, they were not tested for significance and the ranking is reported descriptively.

Table II compares the fastest and slowest combinations for each luma range, which matters because a technique with good separability may be expensive to compute. The vector validity rate was 100% in every condition, confirming that all ten attributes were extracted. The fastest options (Retinex or no preprocessing) are not the ones with the highest separability (median and bilateral). Among the best in separability, however, the median filter with bilinear, nearest-neighbor, or area interpolation stayed above 33 FPS, which is compatible with capture at 30 FPS. Section IV-D details the spatial structure of the error.

TABLE II: Fastest and slowest combinations per facial luma range.

Luma Range	Fastest	FPS	Slowest	FPS
Low ($\overline{Y'} \approx 60$)	Retinex/Linear	41.89	Gaussian/Lanczos	34.64
Medium ($\overline{Y'} \approx 82$)	No prep./Linear	40.15	Median/Lanczos	35.16
High ($\overline{Y'} \approx 95$)	No prep./Nearest	39.35	Gaussian/Lanczos	30.71

TABLE III: Nine-direction classification accuracy on a temporal test set separated from calibration (six sessions of a single participant).

Preprocessing	Interpolation	Accuracy	F1	κ	Top-2
Gaussian	Nearest Neighbor	0.5588	0.5555	0.5037	0.7519
Bilateral	Nearest Neighbor	0.5576	0.5542	0.5023	0.7473
Gaussian	Bilinear	0.5508	0.5472	0.4947	0.7529
Median	Nearest Neighbor	0.5287	0.5250	0.4698	0.7371
CLAHE	Nearest Neighbor	0.4510	0.4495	0.3824	0.6753

The distance between centroids measures how far apart the class prototypes are, but it is insensitive to the dispersion of the samples around each prototype. To check whether the ranking holds, the same 40 configurations were re-evaluated by classification accuracy on a test set temporally separated from calibration, following the protocol of Section III-C4.

C. Separability Does Not Predict Accuracy

Comparing the two criteria produces the most relevant finding of this analysis. The median filter, which leads on separability with a mean distance of 0.8975, falls to seventh among the eight techniques when the criterion is accuracy, at 0.5287. The Gaussian filter, absent from the top six on separability, leads on accuracy with 0.5588 (Table III).

The inversion occurs because distance assesses only how far apart the prototypes are, ignoring intraclass dispersion. One hypothesis is that the median filter, being an order filter, produces quantized jumps in the contour and creates centroids that are distant but unstable, unlike Gaussian smoothing, which softens the boundary and reduces dispersion in a way that improves accuracy. CLAHE, operating on 8×8 blocks, amplifies unwanted structures such as eyelashes and reflections under inverted binarization, which accounts for its low performance (mean of 0.4663 across interpolations). Since interpolation has only a marginal effect (0.530 to 0.538), preprocessing dominates the result: separability between centroids does not predict accuracy and should not guide the choice of pipeline on its own.

D. Error Structure

Although κ is only moderate (0.504) [33], the structure of the error is local. In the 3×3 grid, predictions falling on the correct cell or an immediate neighbor (Chebyshev distance ≤ 1) reach 0.920, so only 8.0% of failures land in distant regions. Among the errors, 82% are adjacent and 43.8% carried the correct class as the second candidate (top-2 of 0.752), which will make later disambiguation easier. Corner directions have a higher top-2 (0.821) because they have fewer

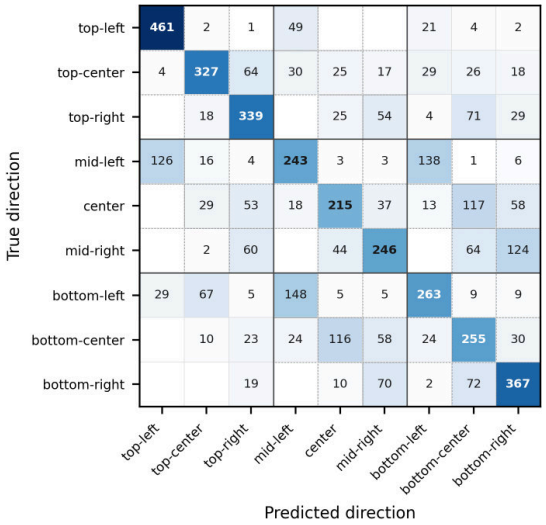

Fig. 7: Confusion matrix of the best configuration (Gaussian/nearest neighbor), aggregated over the six sessions: 540 test frames per direction, 4,860 in total. Cells report counts; blank cells indicate zero. Thick lines delimit the bands of the 3×3 grid; off-diagonal mass concentrates in cells adjacent to the true direction.

TABLE IV: Accuracy of the best configuration (Gaussian/Nearest Neighbor) across six sessions, over 810 test frames per session.

Session	Glasses	$\overline{Y'}$	Accuracy
Low light	No	60.3	0.6568
Low light	Yes	59.0	0.5765
Medium light	No	81.2	0.6111
Medium light	Yes	83.3	0.4333
High light	No	93.2	0.5333
High light	Yes	95.9	0.5420
Aggregated six sessions			**0.5588**

neighbors, while the *center* suffers more confusion (top-1 of 0.398), which makes it well suited as a resting dead zone.

The error is therefore local and structured rather than randomly dispersed. Fig. 7 confirms the pattern: off-diagonal mass concentrates in neighboring cells, with reciprocal confusions between mid-left and bottom-left (138 and 148 frames) and between center and bottom-center (117 and 116), both vertically adjacent pairs in the grid. The distinction matters for the application: in gaze-controlled mouse operation an error to an adjacent cell produces a small displacement that later frames can correct, whereas an error to the opposite cell would move the cursor against the user's intention.

E. Variation by Capture Condition

Aggregating the six sessions hides substantial variation, detailed in Table IV. Stratifying the test set of the best configuration, accuracy ranges from 0.4333 in the semi-lit condition with glasses ($\overline{Y'} = 83.3$) to 0.6568 in the poorly lit condition without glasses ($\overline{Y'} = 60.3$), an amplitude of 22.4 percentage points that exceeds any difference observed between preprocessing configurations. Corrective lenses lower accuracy from 0.6004 to 0.5173, a drop of 8.3 points consistent with the degradation reported in the presence of specular reflections [18], [19] and illustrated in Fig. 2. The effect of illumination ran counter to expectation: the poorly lit condition gives the highest accuracy (0.6167), the semi-lit the lowest (0.5222), and the lit condition an intermediate value (0.5377).

Two hypotheses could account for this. Neither was tested, and they are not mutually exclusive. Thresholding compensates for global drops in light but does not resolve reflections on lenses and sclera under high luminance. Beyond that, the automatic adjustments of the camera may have preserved ocular contrast in the dark condition while saturating areas in the bright one. Separating the two causes will depend on photometric records fixed in lux in future validations.

F. Rejection and Distance Metric

In assistive interfaces, incorrect commands impose a correction cost on the user. Adopting the normalized margin $m(\mathbf{v}) = [D(\mathbf{v}, \bar{\mathbf{v}}_{d_{(2)}}) - D(\mathbf{v}, \bar{\mathbf{v}}_{d_{(1)}})]/[D(\mathbf{v}, \bar{\mathbf{v}}_{d_{(2)}}) + D(\mathbf{v}, \bar{\mathbf{v}}_{d_{(1)}})]$ and rejecting decisions below a threshold, accuracy rises from 0.559 at full coverage to 0.692 at 50% coverage and 0.808 at 20%. Incorrect classifications then drop from 44.1% to 30.8% and 19.2%. This fraction is not the final rate of false commands, since scanning and temporal aggregation are evaluated later. At 30 FPS, discarding 50% of the frames still leaves 15 decisions per second, enough for cursor control. The margin threshold calibrates the trade-off between responsiveness and reliability without modifying the extractors.

Because the ten attributes have heterogeneous scales (proportions, ratios, and coordinates), Euclidean distance imposes distorted weights. Z-score standardization corrects the distortion at no extra computational cost, raising mean accuracy from 0.533 to 0.579. The best configuration (Gaussian/Nearest) reached an accuracy of 0.613 (κ of 0.565) and a top-2 of 0.797. Although 0.613 is still preliminary for uninterrupted frame-by-frame classification, the practical viability of the interface rests on the spatial adjacency of the error (Section IV-D) and on margin-based rejection.

G. Limitations of the Technical Evaluation

The main methodological limitation is the absence of a comparison with a dedicated infrared eye tracker. Since GESTUS classifies nine discrete regions instead of estimating a continuous point, conventional validation metrics—mean angular error, precision, and data loss rate [34]—do not apply directly. This affects only the absolute interpretation of the results; the relative comparison still holds, as the internal comparison of the 40 configurations follows the same protocol and temporal split throughout. It is not possible, however, to separate the portion of error due to the pipeline from the portion originating in label imprecision, which assumes static fixation on the target. Synchronous recordings from webcam and tracker will make that decomposition possible. Other limiting factors include camera resolution, user positioning and distance, involuntary head movement, and the distinction between natural and command blinks [10], [11], [18], [19].

V. Conclusion and Future Work

This paper presented GESTUS, a proof of concept for assistive technology that supports human-computer interaction

through eye movement and deliberate blinks using only a standard webcam, integrating nine-point calibration, image processing with MediaPipe, gaze direction classification, card-based communication with scanning, speech synthesis, and cursor control.

The experiment addressed two questions. On the pipeline, mean distance between centroids ignores intraclass dispersion and does not work as a sole criterion: the median filter led on separability but fell to seventh on accuracy. On webcam-based extraction, standardizing the attributes raised accuracy to 0.613 at no extra cost. That value is still preliminary for operational robustness, but the interface remains viable because of the local structure of the error, with 92.0% of predictions on the correct or an adjacent cell, and because it can run conservatively, reaching 0.808 accuracy once low-margin decisions are rejected.

Without an external tracker, pipeline error cannot be separated from label imprecision. The 22.4 percentage point amplitude between sessions also exceeds the gains from preprocessing, which indicates that standardizing capture conditions affects performance more than refining the algorithm. The accuracy and κ reported here describe one participant's ocular anatomy, iris pigmentation, and capture conditions, and do not generalize.

Future work follows two lines. The technical line covers expansion to multiple participants with sampling stratified by the Fitzpatrick scale, photometric control of illumination with a luxmeter at the plane of the face, evaluation of different cameras and of head movement, and comparison with a reference eye tracker in synchronous recording. For the evaluation with users, the protocol approved by CEP/HUWC-UFC (Opinion no. 8,491,889) covers 10–12 participants without motor limitation and 10–12 with severe motor impairment, measuring execution and selection time, hit rate, false command rate, cursor stability, fatigue, and satisfaction. Those results will support per-user calibration of the temporal thresholds and the replacement of the classifier with supervised models.

Acknowledgment: The authors thank UFC, PROTECS, and GESTUS collaborators for their support.

Abstract*—This study aimed to map the routines, barriers, and suggestions for improvement in early mobilization in intensive care units (ICUs) from the perspective of physical therapists, within a Design Science Research (DSR) framework. A qualitative, exploratory-descriptive study was conducted with 20 physical therapists from six Brazilian cities through semistructured video interviews. Data were analyzed using Bardin's Content Analysis, resulting in 66 codes grouped into 19 thematic categories across four research questions. Results indicate that clinical stability and hemodynamic safety criteria guide the prescription of therapeutic exercise, consistent with international guidelines. However, the absence of formalized protocols, fragmented documentation, limited equipment, and gaps in interprofessional collaboration represent significant barriers. Participants suggested the development of structured protocols, digital monitoring platforms, assistive devices, and multiprofessional communication tools. The contributions of this study encompass the systematized mapping of gaps, barriers, and problems that may guide innovation proposals in biomedical engineering aimed at early rehabilitation. These findings provide an empirical basis for biomedical engineering recommendations, representing the immersion phase of the DSR cycle toward innovative solutions for early rehabilitation in Brazilian ICUs.

Keywords*—early mobilization; intensive care unit; physical therapy; Design Science Research; Design Thinking; biomedical engineering

I. INTRODUCTION

Care and treatment in the Intensive Care Unit (ICU) have evolved significantly in recent years, moving beyond the paradigm of deep sedation and prolonged bed rest toward approaches that improve clinical outcomes, including a focus on early mobilization and physical rehabilitation, with the goal of reducing the risk of post-intensive care sequelae [1].

Functional decline during ICU hospitalization can be prevented through interventions involving physical activity and early mobilization practices. Although guidelines for physical activity in the ICU exist, the timely identification of patients eligible for these interventions remains a challenge, and a variety of obstacles to their implementation persist [2].

Evidence on early exercise for the prevention of ICU-acquired muscle weakness (ICUAW) points to heterogeneity in implementation across different units, stemming from factors such as excessive workload, insufficient staffing, limited time, inadequate training, and the absence of standardized protocols [3].

The implementation of early mobilization in ICUs remains inconsistent and faces barriers at multiple levels, notably a lack of familiarity with the scientific literature, underestimation of the incidence of ICUAW, the absence of routine assessment for mobilization, and the perception that mobility is not a care priority [4].

Although the benefits of early mobilization are widely documented, its systematic implementation remains inconsistent across different healthcare contexts and systems, highlighting a persistent gap between available scientific knowledge and actual clinical practice [3].

In recent years, technological solutions have been increasingly incorporated into intensive care settings to support clinical decision-making, but few are specifically designed for early mobilization or physical therapy practice; most target other domains of critical care, such as hemodynamic monitoring and sedation control [5]. This absence of practice-oriented technological support reinforces the need to investigate, in depth, the problems and gaps that hinder the implementation of early mobilization before proposing new solutions.

Research grounded in Design Science Research (DSR) enables researchers to construct, evaluate, and theorize solutions, differing from traditional methods by initially focusing on the identification of complex problems. The design science paradigm seeks to expand the limits of human and organizational capabilities through the creation of new and innovative artifacts [6].

Given the importance of early rehabilitation in the ICU for functional prognosis and the reduction of complications during hospitalization. This study aimed to map the complexity of physiotherapy practice in the intensive care setting, with an emphasis on early mobilization, by identifying problems and gaps in the care process from the perspective of intensive care physical therapists, with a view to informing the subsequent development of practice-oriented solutions tailored to the reality of intensive care units. Problem identification is a critical first step in guiding the development of effective solutions in rehabilitation engineering, as it ensures that subsequent design efforts are grounded in the real needs.

The contributions of this study encompass the systematized mapping of gaps, barriers, and problems that may guide innovation proposals in biomedical engineering aimed at early rehabilitation.

II. METHODOLOGY

This is an exploratory-descriptive qualitative study situated within the field of Design Science Research applied to healthcare specifically in the context of intensive care.

This study corresponds to the initial phase of the research process, focused on problem identification and awareness, which precedes the design and evaluation of technological artifacts. The findings obtained at this stage are intended to inform and guide the subsequent search for practice-oriented solutions capable of addressing the barriers identified in the early mobilization care process.

The research was carried out with intensive care physiotherapists, where participants were recruited through invitations sent via messaging applications and social media, targeting professionals working in the field of intensive care physical therapy.

A non-probabilistic sampling technique known as snowball sampling [7] was adopted, whereby each participant was invited to refer others with similar characteristics. This study included the participation of 20 intensive care physical therapists. Although the literature does not specify a minimum sample size for qualitative research, this number exceeds the data saturation parameters suggested by [8], which indicate that saturation can be achieved with 6, 12, or 17 participants, reinforcing the adequacy of the sample for the purposes of this study.

The inclusion criteria were: being a licensed physiotherapist with at least one year of ICU experience, including day and night shift staff affiliated with public and private intensive care units. No exclusion criteria were established.

After providing free and informed consent, participants completed an identification questionnaire, followed by semi-structured interviews conducted via Google Meet between March and May 2026. The interviews were recorded and transcribed. Each participant's speeches were tabulated in an Excel spreadsheet for subsequent Content Analysis. All interviews were conducted by the same researcher to ensure consistency in data collection. The interview guide was structured as presented in Table 1.

TABLE I. SEMI-STRUCTURED INTERVIEW GUIDE

No.	Topic	Guiding Question
Q1	Prescription criteria	What criteria do you use when prescribing therapeutic exercise for patients in the ICU? What most influences your decision?
Q2	Assessment tools and protocols	Does the unit where you work have specific tools or protocols for assessing, recording, and monitoring exercise progress in the ICU? How are these tools used in practice?
Q3	Frustrations with the current process	Is there anything that frustrates you about the current process of implementing therapeutic exercise in the ICU?
Q4	Suggestions for improvement	If you could suggest something to improve the applicability of therapeutic exercises in the ICU, what would it be?

Q = Question - Source: prepared by the author (2026)

Data from the identification form were analyzed using descriptive statistics with the aid of JASP software. Categorical variables were expressed as absolute and relative frequencies (n; %), while continuous variables were expressed as mean and range.

Content analysis, as proposed by Bardin [9], was applied following three phases: pre-analysis, exploration of the material, and treatment of the results/inference/interpretation. In the pre-analysis phase, the interview recordings were fully transcribed and read repeatedly (floating reading) to allow familiarization with the content and identification of preliminary patterns. The interview transcripts were organized and tabulated in an Excel spreadsheet, with coding and categorization performed manually by a single researcher (first author), who conducted all interviews.

Sample size was defined a priori based on the literature on data saturation in qualitative research [8] and was subsequently corroborated empirically: during the final interviews, no new codes emerged, and participants' responses increasingly converged around previously identified patterns, indicating that thematic saturation had been reached.

In the exploration of the material stage, the transcripts were coded through the identification of recording units, understood as text segments carrying meaning relevant to the phenomenon under investigation. These units were extracted, grouped, and classified according to their thematic and conceptual proximity, giving rise to initial codes. The codes were subsequently submitted to successive rounds of analysis and refinement, being aggregated into subcategories and, later, into broader thematic categories. The categorization process observed the criteria of homogeneity, relevance, exclusiveness, objectivity, and productivity established by Bardin.

Finally, in the treatment of results, inference, and interpretation stage, the thematic categories were analyzed in light of the study's objectives and its four guiding research questions (P1–P4). As a complementary strategy for organizing and presenting the data, the frequency of occurrence of codes and subcategories was calculated, allowing the recurrence of themes across the interviews to be identified. For each category, representative recording units were selected to illustrate the meanings attributed by participants and to lend transparency to the interpretive process. The results were discussed in dialogue with the scientific literature on early mobilization in intensive care units, promoting theoretical triangulation and broadening the understanding of the phenomenon under investigation.

The study was approved by the Research Ethics Committee under Opinion No. 8,061,868, in accordance with the ethical principles governing research involving human subjects.

III. RESULTS

Twenty physical therapists from six Brazilian municipalities were interviewed. Juazeiro do Norte accounted for the largest portion of the sample (n=9; 45%), followed by Fortaleza and Crato (n=3 each; 15%), Recife and Quixeramobim (n=2 each; 10%), and Brasília (n=1; 5%). The mean duration of professional training was 10.9 years (range: 2–20 years), while the mean duration of practice specifically in intensive care physical therapy was 8.8 years (range: 1.5–15 years).

Most participants worked in public hospitals (n=13; 65%), while the remainder were affiliated with private institutions (n=7; 35%); all worked on an on-call shift basis.

Content analysis yielded 66 codes grouped into 19 thematic categories, organized according to the four thematic

topics described below. For each of the study's four guiding research questions, the table presents the thematic category identified through content analysis, the frequency of occurrence of that category that is, the number of times the theme appeared in participants' statements and a representative recording unit, corresponding to an excerpt of speech that concretely illustrates the meaning attributed by participants to that category, thereby lending greater transparency and clarity to the interpretation of the data.

A. Clinical Decision-Making and Therapeutic Exercise Prescription in the ICU

Physical therapists identified hemodynamic stability as the primary factor in clinical decision-making for the prescription of therapeutic exercise in the ICU, followed by the use of standardized assessment tools, institutional protocols, and the patient's ability to cooperate with and accept the proposed interventions (Table II).

It should be noted that the frequency reported in each table corresponds to the number of recording units coded within each category, rather than the number of distinct participants who addressed that theme. As a single participant could generate more than one recording unit within the same category — for instance, when a given criterion was mentioned at different moments throughout the interview — frequencies may exceed the total sample size (n=20). This distinction is consistent with Bardin's content analysis framework, in which the recording unit, not the respondent, constitutes the base unit of quantification.

TABLE II. CRITERIA FOR PRESCRIBING THERAPEUTIC EXERCISE IN THE ICU (QUESTION 1)

Category	Freq.	Representative recording unit
Hemodynamic stability	23	*"Hemodynamic stability as defined by the mobilization protocol [...] FiO2 below 40, P/F greater than 200, Hb above 7, no active bleeding, low-dose vasoactive drugs, heart rate below 110, no arrhythmias. (F15)"*
Application of functional scales	9	*"We assess muscle strength, the IMS scale, to determine the degree of functionality. And the trunk control test, along with muscle strength tests, to define the level of mobilization. (F20)"*
Institutional protocol criteria	3	*"We use our mobilization protocol. Patients who are not eligible are placed on the red list; those on green or yellow are assessed and a decision is made. (F10)"*
Patient cooperation	4	*"We check whether the patient is fit to receive care, whether they consent—the code of ethics is also important—and we verify vital signs and level of consciousness. (F7)"*

Participants identified by code (F1–F20); Number of times the theme appeared in participants statements.Source: Research data

B. Tools and Protocols for Exercise Progression

The four categories identified in theme 2 are described in Table III. It is noteworthy that the first three categories showed a frequency of 20 recording units, a value numerically equivalent to the total number of participants which reflects the number of times the code was identified in the material, and not necessarily the number of distinct physical therapists who addressed these aspects.

TABLE III. TOOLS AND PROTOCOLS FOR EXERCISE PROGRESSION IN THE ICU (QUESTION 2)

Category	Freq.	Representative recording unit
Existence and formalization of protocols	20	*"The protocol has three stages: red, when mobilization is not possible at all; yellow, with caution; and green, when mobilization can proceed without contraindication. We use the patient's IMS. (F15)"*
Recording tools	20	*"We have daily progress notes and a daily mobilization goal that must be met. If not met, there must be a documented justification. This is recorded in the medical chart and on the monitoring form. (F17)"*
Assessment tools	20	*"We assess the MRC and IMS daily—these are the two main tools: the strength scale and the functional progression scale, showing where the patient is at a given moment and where we want them to be. (F5)"*
Progression and continuity dynamics	8	*"Since each ICU has a daily physical therapist, we use progression markers—this is today's goal—and the daily therapist ensures continuity of care. (F12)"*

Participants identified by code (F1–F20); Number of times the theme appeared in participants statements.Source: Research data

C. Frustrations with the Implementation of Early Mobilization

When reporting their frustrations, three categories emerged with equal frequency (n=7): collaboration and recognition from the interdisciplinary team, lack of equipment and assistive devices, and absence of workflow and guidance on procedures. These findings reveal multifactorial frustrations encompassing human, structural, and organizational factors (Table IV).

TABLE IV. FRUSTRATIONS IN THE PROCESS OF IMPLEMENTING THERAPEUTIC EXERCISE IN THE ICU (QUESTION 3)

Category	Freq.	Representative recording unit
Collaboration and recognition by the interdisciplinary team	7	*"Early mobilization is not carried out by the physical therapist alone—it is an interdisciplinary process and the team needs to understand that. (F8)"*
Lack of equipment and assistive devices	7	*"What is frustrating is the lack of even the most basic conditions: ankle weights, dumbbells, resistance bands, exercise balls, and bedside sitting chairs. (F14)"*
Staffing levels	3	*"Here we have one physical therapist for every [several] patients—all in very serious condition. The shift is hectic, and sometimes we could do more, but the staffing levels do not allow it. (F11)"*

Category	Freq.	Representative recording unit
Absence of workflow and guidance on procedures	7	*"Continuity only works when there is a resident. What is frustrating is the inconsistency—if there were a mandatory protocol to follow, it would be different. (F3)"*
Bureaucracy in record-keeping and inadequate follow-up	2	*"The bureaucratic part is very repetitive—we record the same information in different tools: incident reports, progress notes, and shift handoffs. (F6)"*

Participants identified by code (F1–F20); Number of times the theme appeared in participants statements.Source: Research data

D. Suggestions for Improving the Physical Therapy Routine

The categories that emerged from the participants' suggestions are directly related to the frustrations identified in the previous section. The highest-frequency category, "standardization and structured documentation" (n=13), encompasses suggestions ranging from protocols guiding clinical practice to the incorporation of the International Classification of Functioning (ICF) into clinical practice (Table V).

TABLE V. SUGGESTIONS FOR IMPROVING THE APPLICABILITY OF THERAPEUTIC EXERCISES IN THE ICU (QUESTION 4)

Category	Freq.	Representative recording unit
Standardization and structured documentation	13	*"It would be an individualized prescription based on functional assessments, with specific therapeutic goals, periodic reassessments, and load progressions. (F2)"*
Assistive devices and assistive technology	7	*"I would provide stretchers that keep the patient in an upright position. The basics are also missing: ankle weights, dumbbells, resistance bands, and appropriate sitting chairs. (F15)"*
Daily physical therapist and supervision	4	*"With the daily physical therapist, we had daily follow-up—this greatly improved functional progress and the continuity of therapeutic goals. (F5)"*
Culture of mobilization	3	*"There are still limitations in physical therapist training—they are too focused on mechanical ventilation, with gaps when it comes to therapeutic exercise. (F6)"*
Communication and integration with the multidisciplinary team	5	*"Brief meetings with the team—physician, nurse, and technician—to explain the importance of mobilization and introduce the ICF into the physiotherapy diagnosis. (F10)"*

Participants identified by code (F1–F20); Number of times the theme appeared in participants statements.Source: Research data

IV. DISCUSSION

This study is situated within the immersion phase of the DSR cycle, characterized by the systematic identification of problems, meaningful engagement with the professionals involved, and the mapping of contextual needs—elements that are essential for the development of innovative and technologically relevant artifacts.

The criteria reported by physical therapists for the prescription of therapeutic exercise align with the safety domains established in the literature. The "hemodynamic stability" category (n=23) corresponds directly to the cardiovascular, respiratory, and neurological criteria systematized through expert consensus [10]. This alignment suggests that, even in the absence of formalized protocols (n=3), physical therapists base their clinical decision-making on parameters consistent with international safety recommendations, albeit in an unsystematic manner.

The use of the ICU Mobility Scale (IMS) and the Medical Research Council Scale (MRC) was identified as the second most frequent category (n=9) for guiding therapeutic exercise prescription. A multicenter observational study demonstrated that the IMS score at ICU discharge is independently associated with 90-day survival [11]. However, no explicit correspondence was identified between the scores obtained on these scales and the type of exercise actually prescribed, suggesting that these tools serve a predominantly classificatory function—characterizing the patient's level of muscle strength and functional capacity—without constituting formal prescription guidelines. Brazilian researchers are advancing in this direction by proposing a framework that integrates IMS scores with CBDF (Brazilian Classification of Physical Therapy Diagnoses) diagnoses and progressive therapeutic plans based on corresponding clinical interventions [12].

Findings regarding protocol existence reveal institutional heterogeneity: ten participants reported the absence of a mobilization protocol, and eight described an implemented protocol. Protocols employing standardized safety guidelines have been shown to increase early exercise rates in the ICU [13]. The absence of a common language among assessment tools hinders longitudinal patient follow-up and is associated with worse clinical outcomes and longer hospital stays [12].

Collaboration among the multidisciplinary team emerged both as a source of frustration and as a solution proposed by participants. It is recommended that the ICU multidisciplinary team assess patients, develop individualized rehabilitation programs, and promote shared decision-making, as interdisciplinary collaboration is central to the safe and effective implementation of early exercise [13].

Regarding staffing, the European Society of Intensive Care Medicine recommends one specialist physical therapist per five ICU beds, with 24-hour, 7-day coverage [14], while Brazil's RDC No. 7/2010 establishes a minimum of one physical therapist per ten beds, with coverage across morning, afternoon, and evening shifts, totaling 18 daily hours of physical therapy care [15]. Although the reported staffing levels generate dissatisfaction, they remain within the parameters established by current Brazilian regulations.

The availability of appropriate equipment is a structural prerequisite for the progressive implementation of therapeutic exercise. Electrical stimulation combined with a cycle ergometer has demonstrated benefits regarding muscle strength, cross-sectional muscle area, ventilator-free days, cognitive function, delirium, and quality of life [16]. Emerging technologies such as robot-assisted mobilization and virtual reality expand this horizon, offering promising opportunities for rehabilitation in the ICU setting with the potential to reduce risks and staffing requirements during mobilization [17]. The European expert guideline on positioning and early mobilization incorporated specific recommendations for devices and robotics, formally

recognizing the role of these technologies in the rehabilitation of critically ill patients [18].

The findings reveal significant internal consistency between the identified gaps, reported frustrations, and proposed solutions. Recognizing and thoroughly understanding the problems in a given area is an indispensable prerequisite for directing relevant and contextually appropriate interventions [6].

The study presents limitations, such as the geographical factor with the majority of participants hailing from the Northeast region, specifically the state of Ceará, and the use of snowball sampling, where participants tend to refer colleagues with similar routines. Furthermore, it reflects only the perspective of the physiotherapists, excluding the intensive care unit's interdisciplinary team. In addition, the content analysis was conducted by a single researcher, which may represent a limitation regarding triangulation and cross-validation of the coding process.

V. DESIGN REQUIREMENTS FOR BIOMEDICAL ENGINEERING

Following the Content Analysis of the interviews, classes of problems were identified based on the thematic categories of frustration and suggestions for improvement reported by the participating physical therapists, with the most frequently occurring ones listed in Table IV, which highlight the main gaps experienced in the clinical practice of early mobilization in the ICU. From these needs, design requirements were derived to guide the development of future solutions, without prescribing, at this stage of the research, the specific technology or format of the solution, as shown in Table VI.

TABLE VI. SYNTHESIS OF IDENTIFIED NEEDS AND CORRESPONDING DESIGN REQUIREMENTS

Problem	Corresponding design requirement
Absence of workflows and guidance on procedures	Interoperability and communication between systems; Creation of protocols and conduct guidelines
Collaboration and recognition from the multidisciplinary team	Facilitating interdisciplinary communication; Ensuring clarity in shift handoffs regarding mobilization / mobilization level
Insufficiency of equipment and technologies to support mobilization	Equipment designed for quick setup and operation within the confined physical space of an ICU bed. Equipment capable of supporting progressive levels of mobilization (from passive to active-resisted exercise), accompanying the patient's functional evolution.
Excessive bureaucracy without effective data	Automation of process steps
Lack of objective measures in patient assessment	Objective assessments and metrics for ICU mobilization

Source: Research data

VI. CONCLUSION

The data produced in this study indicate that the main problems identified by physical therapists in the process of implementing therapeutic exercise in the ICU are concentrated in four areas: the absence of formalized institutional protocols and structured documentation tools that ensure the continuity and progression of interventions across shifts; the insufficiency of equipment and devices to support mobilization; weaknesses in collaboration and integration within the multidisciplinary team; and an inadequate ratio of professionals to patients. These findings provide direction for the subsequent stages of the design cycle, in which the perceptions and suggestions of the participating physical therapists may inform the development, implementation, and evaluation of innovative solutions aimed at improving the applicability of early mobilization in Brazilian ICUs.

AI USAGE DECLARATION

The written content, analysis, interpretation, and discussion of the results were carried out exclusively by the authors. During the preparation of the manuscript, the authors used the artificial intelligence tool Claude to assist with grammar, improve the writing, and verify the text's compliance with the journal's template structure. The authors critically reviewed all suggestions and bear full responsibility for the content presented.

ACKNOWLEDGMENT

The authors would like to thank the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) for the financial support provided for the development of this research.

Abstract*—Stroke remains one of the leading causes of long-term disability worldwide, frequently resulting in persistent impairments in motor performance, mobility, independence, and quality of life. Digital rehabilitation technologies, including virtual reality, serious games, and exergames, have emerged as promising strategies for enhancing rehabilitation by integrating task-oriented training, real-time feedback, and interactive environments that increase patient engagement and practice intensity. This systematic review aimed to synthesize current evidence on applying these technologies in post-stroke rehabilitation, comparing studies by methodological design (randomized controlled trials, pilot studies, and mixed methods/feasibility studies) and technological modality. We conducted a systematic search in PubMed, Scopus, Embase, Web of Science, and IEEE Xplore, following PRISMA 2020 guidelines and registering the protocol in PROSPERO. Seventeen studies met the eligibility criteria and were analyzed regarding their technological characteristics, intervention protocols, and functional outcomes. Overall, most studies reported favorable effects of digital technologies on motor function, balance, mobility, activities of daily living, and quality of life, although not all included a control group. Most interventions used markerless motion capture systems, combined with real-time visual feedback and task-oriented exercises. Studies also frequently reported high usability, motivation, and treatment adherence, although they measured these outcomes with different instruments, limiting direct comparisons between these secondary outcomes and the primary clinical outcomes. The methodological quality and risk of bias of the 17 included studies were assessed using the Joanna Briggs Institute (JBI) critical appraisal tools, revealing substantial heterogeneity in methodological rigor, particularly regarding the blinding of participants and therapists and allocation concealment; no meta-analysis was performed. Substantial heterogeneity in technological platforms, intervention protocols, study designs, and outcome measures limits the strength of conclusions about the clinical effectiveness of these technologies. Collectively, the findings suggest that digital rehabilitation technologies are promising complementary tools that may support motor learning and experience-dependent neuroplasticity, although the included studies did not directly measure these mechanisms, while also promoting more engaging and personalized rehabilitation. Heterogeneity among studies, predominantly small sample sizes, and the lack of long-term follow-up still limit the ability to draw robust conclusions. Future studies should prioritize standardized study protocols, individualized reporting of sample size, duration, and comparator groups, and comprehensive outcome measures to strengthen the clinical evidence and guide the development of intelligent rehabilitation systems.

Keywords—Stroke; Serious Game; Rehabilitation; Functional Recovery; Therapeutic Engagement; Virtual Reality; JBI.

I. INTRODUCTION

Stroke remains among the leading causes of mortality and long-term disability worldwide, representing a major public health challenge due to its clinical, social, and economic impact. Although advances in acute-phase treatment have contributed to reduced mortality, a significant proportion of survivors are left with persistent motor, sensory, cognitive, and perceptual deficits, compromising functional independence, performance in activities of daily living (ADLs), social participation, and quality of life. In this context, rehabilitation plays a fundamental role in promoting functional recovery after stroke [1–4].

Functional recovery after stroke is strongly influenced by the central nervous system's capacity to reorganize and adapt; this ability stems from neuroplasticity mechanisms that depend on experience and environment. Experimental and clinical evidence shows that this reorganization is favored by interventions based on intensive, repetitive, task-oriented, and functionally meaningful practice, combined with the provision of adequate feedbackprinciples considered fundamental to motor learning and neurorehabilitation [5–8]. However, implementing these principles in conventional rehabilitation still faces several challenges. Limited therapy time, low practice intensity, and a progressive decline in patient motivation frequently compromise treatment effectiveness, especially in the chronic phase of stroke, when spontaneous neurological recovery is already considerably reduced [4,5].

In this scenario, digital rehabilitation technologies have emerged as promising tools for enhancing neurological rehabilitation. These technologies encompass a wide range of interactive systems, including virtual reality (VR), serious games, exergames, motion capture systems, and other computational platforms geared toward rehabilitation [9–13]. While serious games are digital applications developed for objectives beyond entertainment, such as education, training,

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

or health, exergames are a subcategory characterized by the need for body movement to interact with the virtual environment [9–11]. By integrating physical activity with gamification elements, these technologies can increase repetitions, motivation, engagement, and treatment adherence characteristics particularly relevant to rehabilitation after stroke [12,13].

Furthermore, these technological resources offer therapeutic environments that incorporate principles essential to motor learning. Most systems provide real-time visual or multimodal feedback, task-oriented exercises, automatic difficulty-progression mechanisms, and continuous performance monitoring, allowing training to be tailored to each individual's functional capacities. These features favor active patient participation, facilitate error correction during task execution, and increase practice intensity, creating conditions favorable to experience-dependent neuroplasticity and functional recovery [5,6,12,14].

Previous studies show that digital rehabilitation technologies can improve motor function, balance, gait, upper-limb performance, and functional independence after stroke, especially when used alongside conventional physical therapy [13,15]. However, important challenges remain. Studies vary widely in the technological platforms used, intervention protocols, training intensity, and assessment instruments, which hinders direct comparisons. Moreover, most research focuses on evaluating outcomes related to body functions and structures, while aspects such as activity, participation, quality of life, motivation, usability, and user experience remain underexplored.

Thus, this systematic review aimed to synthesize the available evidence on the application of digital rehabilitation technologies, including virtual reality, serious games, exergames, and other interactive systems, in the rehabilitation of individuals after stroke. It also sought to characterize the main technological aspects of these interventions and analyze their effects on different functional outcomes, comparing studies by methodological design and technological modality, thereby providing evidence to support both clinical decision-making and the development of new technologies for neurological rehabilitation.

II. Methods

A. Study Design

This study consists of a systematic literature review conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA 2020) recommendations and registered in the International Prospective Register of Systematic Reviews (PROSPERO) under number CRD420261338426.

B. Procedures

Articles published up to March 2026 were included, and the systematic literature search was conducted in the following databases: PubMed (https://www.ncbi.nlm.nih.gov/pubmed), Scopus (https://www.scopus.com), Embase (https://www.embase.com), Web of Science (https://login.webofknowledge.com/), and IEEE Xplore (https://ieeexplore.ieee.org). The search terms used were: (“stroke” OR “post-stroke”) AND (“serious games” OR “video games” OR exergames OR “game-based rehabilitation”) AND (rehabilitation OR physical therapy OR neurorehabilitation) AND (“activities of daily living” OR functionality OR “functional recovery” OR engagement OR adherence OR motivation). The full search syntax for each database is available at https://drive.google.com/drive/folders/1ZRlrZIrXLnQtFtQTJx893XhbSIQBe5wy?usp=drive_link. The search was conducted on March 12, 2026, and the results obtained were synthesized and used in the present review.

Keyword selection for the database searches followed the PICOS framework. Population (P): individuals diagnosed with stroke (ischemic or hemorrhagic); Intervention (I): serious games, exergames, or digital games for therapeutic purposes; Comparison (C): conventional physical therapy, conventional rehabilitation, control group, or pre- and post-intervention comparison; Outcomes (O): improvement in overall functionality and activities of daily living and, as secondary outcomes, therapeutic engagement, motivation, and treatment adherence. We included all study types except systematic reviews, meta-analyses, preprints, and conference proceedings.

We initially organized data extracted from the different databases into separate Microsoft Excel spreadsheets and then merged them into a single spreadsheet to identify and remove duplicate articles. We then exported the studies to the Rayyan platform (https://www.rayyan.ai/), which we used to organize the screening process, manage study selection, and ensure reviewer blinding. We screened titles and abstracts according to the established inclusion and exclusion criteria. Studies involving adults diagnosed with stroke undergoing interventions based on serious games, exergames, or digital games for physical therapy rehabilitation were included, provided they assessed outcomes related to functionality, motor performance, balance, gait, and functional independence, and were conducted in an outpatient setting; as a secondary outcome, studies assessing adherence or therapeutic engagement were also considered.

Studies were excluded if they: (1) were conducted in animals; (2) involved other neurological conditions, such as Parkinson's disease, traumatic brain injury, multiple sclerosis, or cerebral palsy; (3) used virtual reality without a game-based component; (4) were systematic reviews, meta-analyses, protocols, case studies, conference abstracts, or preprints; (5) did not include assessments of functionality or therapeutic engagement; (6) were conducted in intensive care units or exclusively at home; or (7) were conducted via telerehabilitation or without professional guidance. After initial screening, we assessed potentially eligible articles in full text using the same inclusion and exclusion criteria. To improve selection reliability, four reviewers independently and blindly assessed all titles, abstracts, and full texts in two pairs (Reviewer 1 and Reviewer 2; Reviewer 3 and Reviewer 4), with each pair responsible for all records at their respective stage. In cases of disagreement, an external researcher managed and resolved conflicts.

C. Assessment of Methodological Quality and Risk of Bias

Three reviewers independently assessed the methodological quality and risk of bias of the included studies; in cases of disagreement, a fourth reviewer broke the tie. We used Joanna Briggs Institute (JBI) critical appraisal tools selected according to each study's design. For randomized controlled trials and randomized controlled pilot trials, we applied the JBI Critical Appraisal Checklist for Randomized Controlled Trials (13 items), addressing randomization,

allocation concealment, blinding, baseline similarity between groups, complete follow-up, and intention-to-treat analysis. For non-randomized or single-arm studies, and for mixed-methods and feasibility studies without a control group, we applied the JBI Critical Appraisal Checklist for Quasi-Experimental Studies (9 items), marking items related to between-group comparison as not applicable when no control group was present. Each item was judged as "yes," "no," "unclear," or "not applicable," with no summary score used, as recommended by JBI. We resolved disagreements between raters by consensus or, when necessary, by consulting an additional reviewer. Table I summarizes judgments per study; Tables II and III present item-by-item judgments for each of the two critical appraisal tools. We excluded no study on methodological quality; instead, we used this assessment when interpreting the strength of the evidence discussed in Section IV.

Table I - Summary of the JBI critical appraisal by included study

Alhwoaimel et al. [21]	Y	Y	NA	N	N	NA	Y	Y	Y	Include
Bouatrous et al. [29]	U	NA	NA	N	N	U	Y	Y	N	Single-arm study (n=11) — partial checklist

Color legend: green = Yes; red = No; yellow = Unclear; gray = Not applicable. Item legend (JBI Quasi-experimental, 9 items): 1) Clear cause-and-effect relationship; 2) Comparable and similar participants; 3) Comparable care/treatment other than the intervention; 4) Presence of a control group; 5) Multiple pre/post measurements; 6) Complete follow-up/losses described; 7) Outcomes measured in the same way; 8) Reliable measurement of outcomes; 9) Appropriate statistical analysis.

Bouatrous et al. [29] (Multimedia Systems, 2023;29:3385–3402, doi:10.1007/s00530-023-01180-0): the article addresses a subjective usability/feasibility assessment in a single arm, with 11 stroke patients, no control group, and no repeated pre/post measures—only the descriptive application of the SUS (System Usability Scale) and the IMI (Intrinsic Motivation Inventory), with no inferential statistical test reported. Because there is no comparison (neither between groups nor pre/post), the JBI checklist for quasi-experimental studies is only partially applicable to this design; items 2 and 3 were marked as "Not applicable" for this reason.

III. Results

The initial search strategy identified 529 articles from the selected databases. After removing duplicates, 347 studies remained. During initial screening, we excluded 180 studies based on title assessment and 90 based on abstract review. We included 77 articles for full-text review after title and abstract screening. Of these, we excluded 60 full texts: 48 for not meeting the established eligibility criteria and 12 because we could not retrieve the full text, resulting in 17 studies included in the review. Fig. 1 shows the entire process.

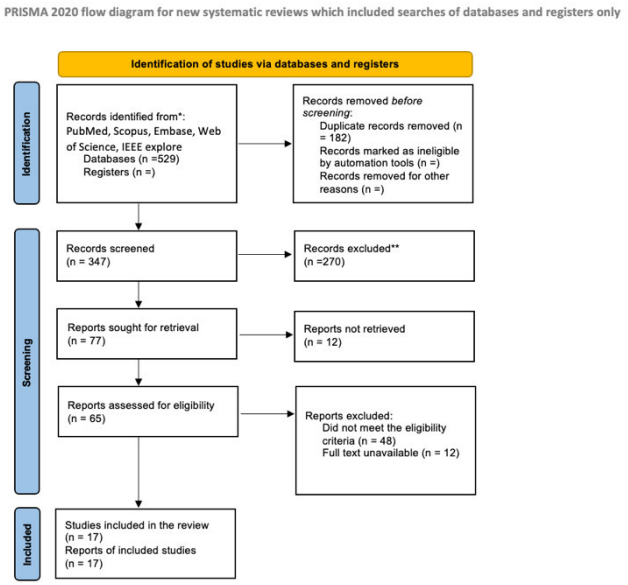

Fig. 1. Flow diagram of the identification, screening, eligibility, and inclusion process for studies in the systematic review, prepared in accordance with the PRISMA 2020 recommendations.

A. Characteristics of Participants in the Included Studies

The included studies included 10 to 120 participants, totaling 648 participants. Among studies that reported sex distribution, 203 participants were female and 347 were male. Participants' mean age ranged from 51 to 68 years. Overall, the samples were predominantly composed of individuals with chronic-phase ischemic stroke. However, some studies also included participants with hemorrhagic stroke in the subacute phase, while others did not specify the type of stroke or the time since the event. These findings highlight heterogeneity in the clinical characteristics of the included populations, which should be considered when interpreting the results.

B. Characteristics of the Interventions

Most interventions used motion capture technologies, predominantly featuring upper-limb rehabilitation and balance training. The therapeutic dose varied considerably across studies, ranging from 3 to 30 sessions, with session durations of 30 to 80 minutes. In virtually all trials, the experimental intervention was compared with conventional physical therapy.

C. Characteristics of the Technological Interventions and Comparison by Technological Modality

Table I presents the main characteristics of the technological interventions employed in the included studies, describing the platform used, the type of interaction between the user and the system, the available feedback mechanisms, and the therapeutic goals of each intervention. Analyzing these aspects helps us understand how different digital technologies have been applied to post-stroke rehabilitation and identify trends in the development of exergames, serious games, and virtual reality systems aimed at functional recovery. Motion-capture-based systems with real-time visual feedback and motor-practice-oriented tasks predominated. Less frequently, studies identified features such as auditory feedback, multisensory stimuli, and adaptive difficulty-adjustment mechanisms, reflecting different strategies for optimizing user–system interaction and promoting motor learning during rehabilitation.

TABLE IV. TECHNOLOGICAL CHARACTERISTICS OF THE DIGITAL INTERVENTIONS USED IN THE INCLUDED STUDIES

Author (Year)	Technology	Feedback	Mechanics	Adaptation
Kostekçi et al. (2024)	Leap Motion Controller ('CatchaPET' and 'LeapBall' software). Optical system featuring 3 infrared emitters and 2 cameras for markerless hand/finger tracking.	Visual	Immediate visual feedback focused on manual dexterity.	Sensitivity adjustment based on captured finger movements.
Huber et al. (2022)	Dividat Senso. Pressure-sensitive force platform with three-sided safety handrails positioned in front of an eye-level screen.	Visual	Serious games based on motor and cognitive challenges with level progression.	Automatic adaptive progression based on the patient's accuracy and response time.
Aguilera-Rubio et al. (2020)	Unity3D Game Engine integrated with the Leap Motion optical sensor.	Visual	Gamified motor challenges based on goals with level progression and scoring.	Customization of reaching range and virtual workspace according to patient deficits.
Alhwoaimel et al. (2024)	Valedo® System (Hocoma AG). 3 wireless inertial sensors (IMUs) attached to the trunk via straps for non-invasive angle and velocity measurement.	Visual & Auditory	Therapeutic exercises integrated into serious games with goals and difficulty levels.	Initial calibration of the patient's active trunk range of motion.
Cinnera et al. (2021)	Riablo™ (CoRehab). System composed of 5 inertial sensors (IMUs) and a wireless force platform connected via Bluetooth (50 Hz).	Visual & Auditory	Serious balance and coordination games with real-time audiovisual feedback of posture.	Initial postural calibration based on individual Center of Pressure (CoP).
Ali et al. (2018)	ArmAble™ Device. Mechanized, gamified upper limb training system tracking shoulder, elbow, forearm, and hand movements.	Visual, Acoustic & Haptic	Interactive games focused on functional repetition with incremental challenge levels.	Adjustable weight support and resistance settings to assist movement.
Vélez-Guerrero et al. (2021)	Oculus Quest 2 VR headset integrated with 'Blexer' software ('Phiby's Adventure' game), tracked by a Microsoft Kinect 360 v1 sensor.	Visual	Four immersive minigames performed in a standing (orthostatic) posture.	Tailoring of specific virtual scenarios monitored by the therapist.
Amin et al. (2021)	Oculus Quest 2 VR headset with native hand tracking executing APK-format games developed in Unity3D.	Visual	Direct real-time immersive interaction with virtual targets using the user's hands.	Real-time spatial kinematic mapping adapted to the user's hands.
Korkusuz et al. (2023)	Microsoft Xbox 360 Kinect™ sensor positioned at 250 cm coupled to a TV screen. Games: 'Skicross' and 'Bounty Super G'.	Visual	Skiing and reward-collecting tasks involving knee flexion/extension and weight-bearing.	Initial familiarization/calibration phase and encouragement through an accumulated reward system.
Chong Li et al. (2023)	CARS System developed in ARKit (iPhone XR). Device attached to the hand via a fingerless glove-style sleeve.	Visual	Interaction with 3D virtual targets generated by augmented reality directly on the mobile screen.	Ergonomic, adaptive glove-sleeve to secure the phone and compensate for weak grip.
Anwar N et al. (2020)	Nintendo Wii console with wireless controllers (Nunchucks) and Wii Balance Board platform. Games: Wii Sports and Cooking Mama.	Visual & Auditory	Sports and cooking simulation focused on balance gain and dual-tasking with level progression.	Native gameplay adjustments according to patient's physical tolerance.
Bouatrous A et al. (2022)	Leap Motion Controller connected via USB to a computer for stereo 3D tracking of phalanges and finger bones.	Visual	Serious games for fine finger rehabilitation with three-dimensional geometric tracking.	Sensor positioned upside down over the arm, allowing desktop support against gravity.
Eichinger F et al. (2021)	Load cells acting as dynamometers integrated into a leg extension machine ('mim Pong SG' game) and an upper limb device.	Visual	Interactive exergame controlled by the patient's maximum voluntary isometric force.	Initial baseline force calibration and adjustable hip (110°) and knee (60° or 90°) angles.
Anwar et al. (2021)	Nintendo Wii home console integrated with the Nintendo Wii Fit biofeedback platform.	Visual	Weight-shifting and postural control exercises guided by native serious games.	Difficulty progression adjusted based on stability scores.
Marda M, Thorat K (2023)	Virtual Reality headset displaying an ecosystem of ten immersive serious games.	Visual	Gamified functional tasks of high immersion based on progressive levels.	Custom selection of the minigame catalog according to the therapeutic goal of the day.
Térémetz M et al. (2019)	Polhemus Fastrak electromagnetic system (4 sensors, 33 Hz) for kinematics + wireless accelerometers (hand dorsum and sternum) + Nintendo Wii.	Visual	Functional training monitored by comprehensive 3D biomechanical analysis of the trunk and arm.	Mandatory prior familiarization with the games and magnetic placement under the table to compute compensations.
Huber et al. (2021)	Dividat SENSO device consisting of a platform with 20 sensors under 5 sub-platforms for CoP analysis.	Visual, Auditory & Tactile	Cognitive-motor exergames focused on reaction time and mobility with safety handrails.	Automatic variation algorithm for speed and complexity of cognitive stimuli.

To complement the study-design analysis, the 17 included studies were also grouped by the main technological modality employed (Table I), allowing direct comparison of studies that used similar systems.

Optical hand and finger tracking (Leap Motion). Three studies used Leap Motion optical sensors for contactless hand and finger tracking: Kostekçi et al. (2024) (CatchaPET and LeapBall software), Aguilera-Rubio et al. (2020) (games developed in Unity3D), and Bouatrous et al. (2023) (adaptive exergame for hand rehabilitation). All three studies focused on distal upper-limb (hand/finger) rehabilitation. Kostekçi et al. and Aguilera-Rubio et al., both randomized trials with a comparator group, reported partially divergent results regarding between-group superiority: the former found an advantage for the video game group in FMA-UE, WMFT, and the kitchen subitem of the DHI, while the latter found no between-group difference in most outcomes, only a long-term within-group improvement. Bouatrous et al., in turn, correspond to a single-arm study with no comparator group, in which only usability (SUS: 71.81) and motivation (IMI: 6.09–6.58) indices were reported (see Section III-D).

Immersive virtual reality with headset (Oculus Quest 2). Three studies used Oculus Quest 2 immersive virtual reality headsets: Peláez-Vélez et al. (2021) ('Blexer' software, 'Phiby's Adventure' game, with Kinect sensor), Amin et al. (2021) (native hand tracking, games in Unity3D/APK), and Marda & Thorat (2023) (ecosystem of ten immersive serious games). All three studies reported significant improvement in favor of the experimental group: Peláez-Vélez et al. in MI, TCT, Tinetti, BBS, and functional gait; Amin et al. in all outcomes assessed (FMA-UE, ARAT, BBT, MBI, SAQOL); Marda & Thorat in mobility (POMA), balance (BBS), and independence (BI), suggesting that the immersion provided by VR headsets may favor consistent gains in motor function and balance within this sample of studies. The JBI critical appraisal confirmed that both Amin et al. and Marda & Thorat correspond to randomized controlled trials (see Supplementary Table 3), allowing them to be compared directly with Peláez-Vélez et al., conducted as a randomized controlled pilot trial; none of the three reports, however, describes in detail the method used to generate the randomization sequence or allocation concealment, an aspect considered in the risk-of-bias assessment of these studies.

Commercial video game consoles (Nintendo Wii). Three studies used the Nintendo Wii console: Anwar N et al. (2020) (Wii Sports and Cooking Mama, with wireless controllers), Anwar et al. (2021) (Wii Fit biofeedback platform), and Térémetz et al. (2019) (Wii combined with the Polhemus Fastrak electromagnetic system for kinematic analysis). All three randomized controlled trials reported significant improvements in balance (BBS) and/or motor function in groups that used the Wii, and Térémetz et al. also reported no increase in compensatory trunk movements during training, a relevant safety finding for using commercial video games in post-stroke rehabilitation.

Motion capture systems with depth camera (Kinect). The Microsoft Kinect sensor was used as the primary technology in Korkusuz et al. (2023) (in the games 'Skicross' and 'Bounty Super G', with a focus on dynamic balance and knee hyperextension) and, in combination with a VR headset, in Peláez-Vélez et al. (2021, already described in the immersive VR group). Korkusuz et al. reported superiority of the experimental group in dynamic balance, knee control, and activities of daily living, in a single-blind randomized controlled trial.

Inertial sensor (IMU) platforms for trunk and balance. Two studies used inertial sensor (IMU) systems positioned on the trunk: Alhwoaimel et al. (2024) (Valedo system, Hocoma AG) and Martino Cinnera et al. (2021) (Riablo system, CoRehab). Both aimed at trunk and balance training; the two studies reported positive results but with different designs: Cinnera et al., a randomized controlled pilot trial, reported clinical improvement on all scales assessed, with a postural difference (CoP) favoring the experimental group; Alhwoaimel et al., a feasibility study without a control group, reported positive psychosocial impacts, but without the possibility of comparison with a control group.

Force platforms and postural biofeedback. The Dividat Senso/SENSO system, a pressure-sensitive force platform with safety handrails, was used in two studies from the same research group: Huber et al. (2022, randomized controlled trial, PEMOCS protocol) and Huber et al. (2021, feasibility study). The feasibility study (2021) preceded the controlled trial (2022) and reported significant improvement only in the TUG mobility outcome, with moderate effect sizes for cognitive functions; the subsequent controlled trial, in turn, found no between-group difference in the primary outcome (MoCA) but identified superiority of the experimental group in complex outdoor gait parameters, illustrating how a feasibility study can inform the design of a subsequent controlled trial on the same platform.

Augmented reality on a mobile device. Chong Li et al. (2023) was the only included study to use smartphone-based augmented reality (CARS system, developed with ARKit for

iPhone XR, with a fingerless glove-sleeve). In a randomized controlled trial comparing the CARS system with conventional occupational therapy, the CARS group outperformed conventional therapy specifically in FMA-UE and ARAT, with no between-group difference in the other outcomes assessed (balance, mental status, and functional independence).

Dedicated mechatronic and haptic devices. Two studies used dedicated mechatronic devices, without relying on commercial optical or inertial sensors: Ali et al. (2018) (ArmAble device, with visual, acoustic, and haptic feedback) and Eichinger et al. (2021) (load cells integrated into the 'Mim-Pong' game). Ali et al., in a multicenter randomized controlled trial, reported significant improvement in the experimental group in FM-UE and ARAT; Eichinger et al., in a non-randomized study without a control group, reported significant pre-post improvement and a correlation between game performance and the patient's pinch/grip strength.

D. Results and Outcomes Found

The 17 included studies presented distinct methodological designs, which directly influence the strength of the evidence for each finding. In this section, results are presented grouped by study design: randomized controlled trials, randomized controlled pilot studies, mixed-methods/feasibility studies, and the study with a non-randomized design, followed by a comparison of how intervention time, sample size, and the presence (or absence) of a comparator group influenced the reported findings. No meta-analysis was performed; the effects described here therefore reflect a narrative synthesis of individual study results rather than a pooled effect estimate.

Randomized controlled trials. Eleven of the 17 studies corresponded to larger-scale randomized controlled trials, comparing the experimental group with a control group or a conventional intervention: Kostekçi et al. (2024), Huber et al. (2022), Aguilera-Rubio et al. (2020), Ali et al. (2018, multicenter), Amin et al. (2021), Korkusuz et al. (2023), Chong Li et al. (2023), Anwar N et al. (2020), Anwar et al. (2021), Marda & Thorat (2023), and Térémetz et al. (2019). Results within this group were heterogeneous regarding between-group statistical significance: some studies reported significant differences favoring the experimental group in motor and functional outcomes (Ali et al., FM-UE and ARAT; Korkusuz et al., dynamic balance and knee control; Chong Li et al., FMA-UE and ARAT; Anwar N et al. and Anwar et al., BBS and FMA; Amin et al., significant within- and between-group improvement in all outcomes assessed—FMA-UE, ARAT, BBT, MBI, SAQOL; Marda & Thorat, superiority of the experimental group in mobility (POMA), balance (BBS), and independence (BI)), while others found no between-group difference in the primary outcome, with improvement occurring only within each group over time (Huber et al., 2022, in MoCA; Aguilera-Rubio et al., in all outcomes except ARAT subitem D). Térémetz et al. reported no unwanted compensatory movements and improvement over time, with no between-group difference observed in Table II.

Randomized controlled pilot studies. Two studies were randomized controlled pilot trials: Martino Cinnera et al. (2021) and Peláez-Vélez et al. (2021), characterized by smaller samples and a primary goal of testing feasibility and estimating parameters for a larger-scale trial. Both reported significant improvement favoring the experimental group (Cinnera et al.: clinical improvement on all scales assessed, with a favorable post-training postural difference (CoP) for the experimental group; Peláez-Vélez et al.: superiority of the experimental group in MI, TCT, Tinetti, BBS, and functional gait classification). Although the results are positive, the pilot nature of these studies, with typically small samples, limits generalization until larger, confirmatory trials confirm the effects.

Mixed-methods and feasibility studies. Two studies adopted feasibility designs without a control group: Alhwoaimel et al. (2024), explicitly a mixed-methods feasibility study, and Huber et al. (2021), a feasibility study of cognitive-motor exergames. Because they did not include a comparator group, these studies do not allow inferences about the relative efficacy of an alternative intervention; their results mainly reflect indicators of recruitment, retention, adherence, and within-group pre-post change. Although Aimel et al. reported positive psychosocial impacts (PIADS) and three participants with mild frustration, Huber et al. (2021) reported significant improvement only in TUG, with moderate effect sizes for visual attention and mental rotation, and a dropout rate above the planned threshold.

Study with a non-randomized design. Only Eichinger et al. (2021) remains in this category: the authors themselves explicitly described the study as a non-randomized controlled trial with an experimental group and a control group, but without random allocation. The other three studies initially grouped here because their design was not specified in the title were reclassified after the JBI critical appraisal: Amin et al. (2021) and Marda & Thorat (2023) were confirmed as randomized controlled trials (see previous paragraph), and Bouatrous et al. (2023) actually corresponds to a single-arm study (subjective assessment of usability and motivation, with no control group and no repeated pre/post measures), and should therefore not be interpreted as a comparative efficacy study (see Supplementary Table 4).

Comparison across designs: impact of time, sample size, and comparator group. Overall, the studies with an active comparator group (conventional physical therapy, occupational therapy, or another control intervention), present in most of the randomized controlled trials and in both pilot studies, were the only ones able to report between-group statistical differences, making it possible to distinguish the specific effect of the digital technology from a possible spontaneous improvement or one associated with the therapeutic attention received by both groups. The feasibility studies, by contrast, did not include a control group and therefore reported only within-group (pre-post) changes, which precludes attributing the observed gains specifically to the technology tested. Regarding sample size, a small sample was reported as an explicit limitation in at least six of the 17 studies (Aguilera-Rubio et al.; Alhwoaimel et al.; Martino Cinnera et al.; Peláez-Vélez et al.; Anwar et al., 2021; Marda & Thorat), concentrated mainly in the pilot and feasibility studies which is expected given the very purpose of these designs, but also reinforces that their findings should be interpreted as exploratory. Regarding intervention time, the data show, in aggregate, a range of 3 to 30 sessions and 30 to

80 minutes per session across the 17 studies; Supplementary Table 1 details the specific sample and comparator-group values for each study.

Table V Comparative summary of interventions, study designs, and outcomes by included study

Study Information			**Intervention and Outcomes**		
Study (Author, Year)	***Technology / Intervention***	***Study design***	***Sample (N)***	***Comparator group***	***Direction of observed effect (summary)***
Kostekçi et al. (2024)	Leap Motion Controller (CatchaPET/LeapBall) — optical hand/finger capture	Randomized controlled trial (RCT)	30	Manual rehabilitation group and use of a triple-coordination device	Within-group improvement in both groups; between-group analysis favored the video game group in FMA-UE, WMFT, and the DHI kitchen subscale
Huber et al. (2022)	Dividat Senso — pressure-sensitive force platform	Randomized controlled trial (RCT)	46	Conventional physical therapy and weekly telephone calls to maintain contact with the research team	No between-group difference in the primary outcome (MoCA); experimental group superior in complex outdoor gait parameters
Aguilera-Rubio et al. (2020)	Unity3D + Leap Motion optical sensor	Randomized controlled trial (RCT)	36	Functional tasks	No between-group difference (except ARAT subitem D); long-term within-group improvement in the experimental group
Alhwoaimel et al. (2024)	Valedo System (Hocoma AG) — inertial measurement units (IMUs) on the trunk	Feasibility study (mixed methods), no control group	10	No control group	Positive psychosocial impacts (PIADS: competence 1.7; adaptability 1.6; self-esteem 1.8)
Martino Cinnera et al. (2021)	Riablo (CoRehab) — inertial sensors + wireless platform	Randomized controlled pilot trial (RCT)	21	Conventional balance training	Clinical improvement on all scales; post-training difference favoring the SB group in postural assessment (CoP)
Ali et al. (2018)	ArmAble — mechanized and gamified device for the upper limbs	Multicenter randomized controlled trial (RCT)	120	Training in functional daily tasks with the upper limb	Significant improvement in the experimental group in FM-UE (2 and 6 weeks) and ARAT (6 weeks)
Peláez-Vélez et al. (2021)	Oculus Quest 2 + "Blexer" software ("Phiby's Adventure" game)	Randomized controlled pilot trial (RCT)	24	Conventional physical therapy	Experimental group significantly superior to control in MI, TCT, Tinetti, BBS, and functional gait classification
Amin et al. (2021)	Oculus Quest 2 with native hand tracking (games in APK/Unity3D)	Randomized controlled trial (RCT)	52	Conventional physical therapy	Significant within- and between-group improvement, with greater gains in the experimental group across all outcomes
Korkusuz et al. (2023)	Kinect Xbox 360 ("Skicross" and "Bounty Super G" games)	Single-blind randomized controlled trial (RCT)	25	Conventional physical therapy	Experimental group superior in dynamic balance, knee control, and ADLs; control group improved in only some outcomes
Chong Li et al. (2023)	CARS system developed in ARKit (iPhone XR)	Randomized controlled trial (RCT)	30	Conventional occupational therapy	CARS group outperformed conventional therapy in FMA-UE and ARAT; no between-group difference in BS, MMT, or BI
Anwar N et al. (2020)	Nintendo Wii (Wii Sports and Cooking Mama) with wireless controllers	Randomized controlled trial (RCT)	68	Conventional physical therapy	Significant improvement favoring the VR group in BBS and motor FMA; no differences in sensitivity
Bouatrous et al. (2023)	Leap Motion (USB) — 3D stereo tracking of hand phalanges/bones	Single-arm study (usability/feasibility assessment), no control group	11	No control group	High usability and motivation (SUS 71.81; IMI 6.09–6.58); single-arm study, with no comparison to a control group
Eichinger et al. (2021)	Load cells (dynamometer) integrated into the "Mim-Pong" game	Non-randomized study (as reported by the authors), no control group	24	No control group	Significant pre-post improvement in the experimental group; game performance correlated with pinch/grip strength
Anwar et al. (2021)	Nintendo Wii Fit — biofeedback platform	Randomized controlled trial (RCT)	68	Conventional physical therapy	Significant improvement in balance (BBS) and the motor subscales of the FMA-LE in the VR group
Marda & Thorat (2023)	VR headset with an ecosystem of 10 immersive serious games	Randomized controlled trial (RCT)	32	Task-oriented training and conventional exercises	Experimental group significantly superior to control in mobility (POMA), balance (BBS), and independence (BI)

Study Information			Intervention and Outcomes		
Study (Author, Year)	*Technology / Intervention*	*Study design*	*Sample (N)*	*Comparator group*	*Direction of observed effect (summary)*
Térémetz et al. (2019)	Polhemus Fastrak electromagnetic system + Nintendo Wii	Blinded randomized controlled trial (RCT)	40	Conventional physical therapy	No increase in compensatory trunk movements after Wii training; paretic arm acceleration increased significantly over time
Huber et al. (2021)	Dividat SENSO — cognitive-motor exergames	Feasibility study, no control group	10	No control group	Significant improvement only in TUG; moderate effect sizes for visual attention and mental rotation

TABLE VI. STUDY CHARACTERISTICS, MAIN OUTCOMES, AND REPORTED LIMITATIONS

Author (Year)	Assessed Outcomes	Main Results (p < 0.05)	Experience / Usability / Adherence	Reported Limitations
Kostekçi et al. (2024)	FMA-UE, WMFT, MMDT, DHI.	Significant intragroup improvements in both groups. Intergroup analysis favored the VG (Video Game) group for FMA-UE, WMFT, and the kitchen subscore of the DHI.	Excellent overall acceptability; no limiting adverse events reported.	Wide age range of participants, introducing high baseline functional and recovery variability.
Huber et al. (2022)	SIS 3.0, TMT, Stroop, NBT, MRT, TUG, 10MWT, OWA, MoCA.	No significant intergroup differences in the primary outcome (MoCA). The experimental group was superior in complex spatiotemporal outdoor gait parameters.	Adherence rate of 89.8% and compliance of 89.1%. High motivation and satisfaction reported.	Limited variety of games; complex motor instructions provided verbally without in-game feedback; female underrepresentation.
Aguilera-Rubio et al. (2020)	Grip Strength, BBT, ARAT, DASH.	No significant intergroup differences, except for ARAT sub-section D. Intragroup analysis showed significant long-term improvements in the experimental group.	Adherence and satisfaction were very high. The controlled clinical environment provided a strong sense of safety.	Lack of stratification by baseline motor impairment level; small sample size limits generalizability.
Alhwoaimel et al. (2024)	PIADS, recruitment, retention, adherence, safety, qualitative interviews.	Positive psychosocial impacts on the PIADS (competence: 1.7; adaptability: 1.6; self-esteem: 1.8).	High motivation driven by the playful nature of the system. Three participants reported minor frustration.	Small and heterogeneous sample size; lack of a control group; inability to customize game settings.
Cinnera et al. (2021)	BBS, CNS, BI, RMI, NIHSS, stabilometry (CoP).	Clinical improvement across all scales. Significant post-training difference in postural assessment: reduced CoP path length (eyes open) in the SB vs. UC group.	Significantly higher participation (PRPS) in the SB group (5.82) vs. UC group (4.92).	Non-parametric statistical approach due to small sample size; baseline differences in stroke side and onset.
Ali et al. (2018)	FM-UE, ARAT.	Significant improvements in the EG for FM-UE at 2 and 6 weeks, and for ARAT at 6 weeks.	High retention and adherence rates to the proposed home-based training protocol.	Short intervention period; lack of comprehensive sensory assessment; daily real-world hand use not monitored.
Vélez-Guerrero et al.	Daniels, MAS, MI, TCT.	EG was significantly superior to CG in MI, TCT, Tinetti, BBS, and functional gait	Home-based training adherence	Small sample size; prior clinical treatments and rehabilitation history
(2021)	Tinetti, BBS, Sagunto Scale.	classification.	of 89.1% (EG) vs. 85.8% (CG).	were not evaluated.
Amin et al. (2021)	FMA-UE, ARAT, BBT, MBI, SAQOL.	Significant improvements within and between groups. The EG demonstrated significantly greater improvements in all outcomes.	Excellent tolerability and no reports of physical discomfort during training sessions.	Single-center study; lack of a mid-to-long-term follow-up assessment.
Korkusuz et al. (2023)	FRT, TUG, computerized gait analysis, BI.	EG showed superior improvements in dynamic balance, knee control, and ADLs. CG improved in dynamic balance and knee control but not in ADLs.	High levels of overall satisfaction and system usability reported by patients.	Absence of a follow-up assessment to monitor the retention of therapeutic gains.
Chong Li et al. (2023)	FMA-UE, ARAT, MMT, Brunnstrom, MMSE, Cognitive Games, BI.	The CARS group significantly outperformed conventional OT in FMA-UE and ARAT. No intergroup differences in BS, MMT, or BI.	High general satisfaction (4.27) and system control usability (4.67). Highly recommended for homecare.	Unmonitored compensatory movements; non-blinded therapists; uniform-sized training gloves.
Anwar N et al. (2020)	BBS, FMA-UE.	Significant post-treatment differences in BBS and motor FMA in favor of the VR group. No differences in sensation.	Interactive games were reported as engaging and fun, whereas conventional therapy was described as tedious.	Slow technological familiarization; limited clinical outcome scales; lack of long-term follow-up.
Boustrous A et al. (2022)	Finger ROM, SUS, IMI.	SUS score: 71.81 (acceptable). IMI subscale scores ranged from 6.09 to 6.58 (out of 7).	High perceived interest, enjoyment, and choice. Good scores for effort and utility.	Difficulty in 3D motion perception within the virtual space, especially for patients with cognitive deficits.
Eichinger F et al. (2021)	FMAS, MMSE, Mim-Pong performance, MVIC.	Game performance score correlated strongly with pinch and grasp strength. Significant pre-to-post improvements in the EG.	High patient engagement recorded natively via in-game telemetry.	Non-randomized study design; small sample size; lack of standardized fatigue or motivation scales.
Anwar et al. (2021)	BBS, FMA-LE.	Significant improvements in balance (BBS) and motor subscales of the FMA-LE in the VR group.	High adherence rate with good compliance to the training protocol.	Single-center study design, limiting the generalizability of the therapeutic effects.
Marda M, Thorat K (2023)	POMA, BBS, BI.	EG showed significantly superior improvements in mobility (POMA), balance (BBS), and independence (BI) compared to CG.	VR-based training was perceived as more dynamic and engaging than conventional task-oriented training.	Restricted sample size; lack of rigorous standardization of the home/extraclinical environment.
Térémetz M et al. (2019)	BI, AST, Bell's Neglect, FMA, ARAT, BBT, trunk kinematics.	No increase in compensatory trunk movements after Wii training. Paretic arm acceleration increased significantly over time.	Excellent physical tolerability; no muscle soreness or joint discomfort reported.	Lack of clinical assessments of real-world daily activities; absence of a dose-matched control group.
Huber et al. (2021)	FBW, VAS, Gait parameters, TUG, TMT A/B, BREQ-3.	Significant improvement only in TUG. Moderate effect sizes observed for visual attention and mental rotation.	Feasibility parameters met, though the dropout rate was higher than the planned threshold.	No control group; sample biased toward high-functioning and highly educated individuals; missing data.

Abbreviations & Outcomes Legend:
• FMA-UE: Fugl-Meyer Assessment - Upper Extremity • WMFT: Wolf Motor Function Test • MMDT: Minnesota Manual Dexterity Test • DHI: Duruöz Hand Index • SIS 3.0: Stroke Impact Scale • TMT: Trail Making Test (A/B) • NBT: N-Back Test • MRT: Mental Rotation Test • TUG / TUG-Cogn: Timed Up and Go (Simple / Cognitive) • 10MWT: 10-Meter Walk Test • OWA: Outdoor Walking Assessment • MoCA: Montreal Cognitive Assessment • BBT: Box and Block Test • ARAT: Action Research Arm Test • DASH: Disabilities of the Arm, Shoulder and Hand • PIADS: Psychosocial Impact of Assistive Devices Scale • BBS: Berg Balance Scale • CNS: Canadian Neurological Scale • BI / MBI: Barthel Index / Modified Barthel Index • RMI: Rivermead Mobility Index • NIHSS: National Institutes of Health Stroke Scale • CoP: Center of Pressure • MAS: Modified Ashworth Scale • Mt: Matricity Index • TCT: Trunk Control Test • FRT: Functional Reach Test • MMT: Manual Muscle Testing • MMSE: Mini-Mental State Examination • SUS: System Usability Scale • IMI: Intrinsic Motivation Inventory • MVIC: Maximum Voluntary Isometric Contraction • POMA: Performance-Oriented Mobility Assessment • AST: Apraxia Screen of TULIA • EG / CG: Experimental Group / Control Group • VG / VR: Video Game / Virtual Reality

E. Secondary Outcomes: Usability, Motivation, and Adherence

To assess clinical outcomes, studies used different scales; Table II shows the scales in more detail. User experience assessments generally indicated good acceptance of the systems across the 17 studies; some used validated instruments to quantify usability and motivation, such as the System Usability Scale (SUS), the Intrinsic Motivation Inventory (IMI), and the Psychosocial Impact of Assistive Devices Scale (PIADS) (Table II), while most reported only session adherence rates (percentage of protocol completion) or non-standardized satisfaction scales. Because completing scheduled sessions does not necessarily reflect greater therapeutic engagement, interpret these findings on usability, motivation, and adherence separately from the clinical outcomes discussed in Section III-D, and with due caution. The most frequently reported limitations included small samples, clinical heterogeneity, lack of long-term follow-up, and limited intervention personalization (Table II).

IV. DISCUSSION

The studies included in this review showed that digital technologies, such as virtual reality, serious games, and exergames, can improve different aspects of functional recovery after stroke. Despite heterogeneity among the platforms used, therapeutic protocols, and assessment instruments, most studies reported improvements in outcomes related to motor function, balance, functional mobility, performance in day-to-day activities, and quality of life.

This trend should, however, be interpreted with caution: because no meta-analyses were performed, these findings do not provide a robust, generalizable estimate of the effect of digital technologies, but rather reflect a pattern observed consistently across heterogeneous individual studies, many with small samples. In addition, the methodological assessment using the JBI tool identified potential risks of bias, related mainly to the lack of blinding of participants and therapists, the lack of description of allocation concealment, and, in some studies, loss to follow-up.

Even so, these findings align with recent evidence in the literature, which indicates that virtual reality is a promising complementary strategy to conventional physical therapy, especially when used to increase the intensity and duration of practice during rehabilitation [13,15].

The observed benefits can be understood in light of the principles of experience-dependent neuroplasticity. According to Kleim and Jones [5], neural adaptations are favored by interventions that promote intensive, repetitive, specific, and functionally relevant practice—principles that, at least in part, were present in the design of the technological interventions included in this review (Table I). However, the included studies assessed clinical and functional outcomes (e.g., strength, balance, mobility) and did not directly measure indicators of neuroplasticity or cortical reorganization (e.g., functional neuroimaging or transcranial magnetic stimulation). Thus, the relationship between the effects observed in this review and the motor learning and cortical reorganization mechanisms proposed by Kleim and Jones [5] constitutes a plausible theoretical inference rather than a direct demonstration made by the analyzed studies.

Fig. 2. Proposed conceptual model explaining the contribution of digital technologies to functional recovery after stroke.

Fig. 2 summarizes the conceptual model proposed based on this review's findings, showing how the characteristics of digital technologies can favor motor learning and neuroplasticity processes, culminating in functional recovery after stroke.

Another important aspect identified in this review was the predominance of systems based on markerless motion capture and real-time visual feedback. These features enable greater interaction between the user and the virtual environment, supporting immediate movement correction and task progression based on patient performance. Some studies also incorporated auditory feedback, multisensory stimuli, and adaptive mechanisms for automatic difficulty adjustmentfeatures that can increase motivation and personalize training. From a Biomedical Engineering perspective, these results show a growing trend toward intelligent systems that integrate movement monitoring, real-time processing, and individualized therapeutic adaptation. By definition of this review's eligibility criteria, all included virtual reality interventions featured a game-based component (serious games or exergames), since virtual reality studies without this component were excluded (exclusion criterion 3, Section II-B). Thus, the findings discussed here apply specifically to gamified interventions and should not be generalized to non-gamified virtual reality approaches, which this review did not address.

Another frequent finding among the included studies was participants' high acceptance of the technologies (Table II). Several studies reported good usability, high satisfaction, and greater motivation during the interventions, although they measured these differently using validated usability and motivation instruments in some cases and adherence rates or qualitative reports in others, which limits direct comparisons (Table II). Although often considered secondary outcomes, these factors can influence treatment adherence and the intensity of therapeutic practice. Strategies such as gamification, goal setting, rewards, and immediate feedback make training more engaging and favor continuity of rehabilitation, especially in individuals with chronic sequelae, for whom maintaining motivation represents one of the main clinical challenges [8,10].

Despite the promising results, this review has important limitations in both the available literature and the review process itself. Notable limitations in the literature include small sample sizes, heterogeneity of protocols and technological platforms, diverse study designs (including controlled trials and a feasibility study without a control group), and a lack of standardization of assessment instruments. It is particularly worth noting that Bouatrous et al. (2023) corresponds to a single-arm study focused on assessing usability and motivation, with no control group and no repeated pre/post measures, and should be interpreted as a usability/feasibility study rather than as comparative evidence of clinical efficacy, contrary to what the title of the original publication might suggest. In addition, few studies conducted long-term follow-up, which limits understanding of whether functional gains are maintained after the interventions end.

Regarding the review process, the authors identified limitations in assessing methodological quality. Although most studies are experimental and have results favorable to interventions with serious games, exergames, and virtual reality, the critical appraisal using the JBI tool (Supplementary Tables 2–4) found limitations related to the lack of blinding of participants and therapists, the lack of description of allocation concealment, and, in some studies, the absence of a control group and the conduct of multiple pre- and post-intervention assessments.

These limitations make comparisons between studies difficult and reinforce the need for multicenter clinical trials with standardized protocols regarding study design, individualized reporting of sample size and duration, and systematic assessment of risk of bias.

Overall, the evidence analyzed suggests that virtual reality, serious games, and other digital technologies should not be understood merely as technological resources, but also as tools capable of implementing fundamental principles of neurorehabilitation. By promoting task-oriented training, real-time feedback, greater practice intensity, and high engagement, these technologies favor motor learning and neuroplasticity mechanisms that can contribute to more comprehensive functional recovery after stroke.

V. Conclusion

This systematic review found evidence that digital technologies, including virtual reality, serious games, and exergames, are promising strategies for rehabilitating individuals after stroke. Overall, most interventions showed gains across functional domains, including motor function, balance, mobility, performance in day-to-day activities, and quality of life, and indicated good acceptance, motivation, and treatment adherence among participants. These findings suggest that these technologies have therapeutic potential, not only as technological innovations but also as ways to operationalize motor learning principles such as intensive training, task-oriented practice, and real-time feedback, although, as discussed, the included studies did not directly measure the underlying neuroplastic mechanisms. However, heterogeneity among studies, predominantly small sample sizes, diverse methodological designs, and methodological quality limitations identified by the JBI critical appraisal still

limit the ability to draw robust, generalizable conclusions about the clinical effectiveness of these technologies.

The results indicate that digital technologies can contribute to more comprehensive functional recovery, although the literature remains predominantly focused on motor and functional outcomes, with less attention to measures of social participation and quality of life. In this context, it is recommended that future studies adopt more standardized protocols regarding study design, individually report sample size, intervention duration, and the comparator group used, incorporate systematic assessment of methodological quality and risk of bias from the study-design stage onward, and, whenever possible, conduct meta-analyses stratified by study type and technological modality. Furthermore, developing intelligent, adaptive, user-centered systems offers an opportunity to improve clinical efficacy and strengthen the application of digital technologies in post-stroke rehabilitation.

ACKNOWLEDGMENT

The authors thank the Federal Institute of Education, Science and Technology of Southeast Minas Gerais – Juiz de Fora Campus for its contribution to their academic and professional development, as well as for the educational support and institutional resources provided throughout this work.

Carta Resposta aos Revisores

Inspiratory Muscle Training Using a Harmonica in the Postoperative Period of Coronary Artery Bypass Grafting

Programa de Pós-Graduação em Tecnologia em Saúde (PPGTS) – PUCPR

Prezados Revisores,

Agradecemos a leitura e as críticas construtivas. Gostaríamos de esclarecer que o presente estudo não realizou e nem teve como objetivo avaliar a correlação entre o *MIP* e a distância percorrida no TC6M, e que o objetivo deste estudo é analisar a viabilidade da gaita de boca como um dispositivo de uso para o treinamento da musculatura inspiratória para que, no próximo passo, seja realizado um ensaio clínico randomizado comparando um grupo controle com o grupo intervenção. Ajustamos o texto para melhor compreensão do leitor.
Abaixo, apresentamos as respostas aos apontamentos de ambos os revisores. Em itálico mostramos o comentário do revisor e em seguida a resposta.

Revisor 1

Apontamento 1 – Correlação de MIP e TC6M
Comentário do revisor:

> *O artigo reporta correlação entre MIP e distância percorrida no TC6M, mas não ficou claro qual teste de correlação foi usado (Pearson? Spearman?), o coeficiente encontrado e o tamanho de efeito. Dado o tamanho pequeno da amostra, essa correlação seria apenas exploratória/hipótese geradora.*

Resposta dos autores:

Gostaríamos de agradecer o comentário por completo e apenas esclarecer que o presente estudo não realizou e nem teve como objetivo avaliar a correlação entre o *MIP* e a distância percorrida no TC6M. Trata-se de um estudo de viabilidade cujo objetivo foi comparar os momentos pré e pós-intervenção para cada desfecho de forma independente (*MIP* por meio do teste de Wilcoxon e TC6M por meio do teste t pareado). Ajustamos o texto na Discussão e Conclusão para garantir que

nenhuma inferência estatística de correlação bivariada seja transmitida ao leitor. Além disso, adicionamento a magnitude do efeito entre os resultados de *MIP* e TC6M. Para testar a normalidade da distribuição dos dados, foi utilizado o teste de Shapiro–Wilk. Foi confirmada a distribuição normal para o teste de caminhada de 6 minutos antes e após a intervenção. A variável que não mostrou normalidade nos dados foi a pressão inspiratória máxima antes da intervenção, e para essa variável foi utilizado o teste correspondente não-paramétrico. Para testar o efeito pré e pós-intervenção da *MIP*, foi aplicado o teste de Wilcoxon dos Postos Sinalizados. Para avaliar a magnitude do efeito do teste de Wilcoxon, utilizou-se o coeficiente de correlação de Rosenthal. Em todos os casos, adotaram-se os critérios de Cohen (1988) para a classificação da força de associação, classificados em pequeno (próximo a 0,10), moderado (próximo a 0,30) e grande (próximo ou acima de 0,50).

Referência: Cohen J (1988) Statistical power analysis for the behavioral sciences, 2nd edn. Erlbaum, Hillsdale, New Jersey.

Revisor 2

Apontamento 1 – Tipo de estudo

Comentário do revisor: *A avaliação inclui 13 pacientes e não utiliza um grupo controle submetido à fisioterapia convencional, o que impede determinar se as melhorias observadas decorreram do uso da gaita ou da recuperação esperada após a cirurgia e das demais intervenções realizadas no período. Incluir um grupo controle e realizar um estudo randomizado comparando a gaita com dispositivos convencionais de treinamento muscular inspiratório.*

Resposta dos autores:

Gostaríamos de agradecer os comentários construtivos. Para deixar mais claro, este estudo é de viabilidade da gaita de boca como um dispositivo de uso para o treinamento da musculatura inspiratória para que, no próximo passo, seja realizado

um ensaio clínico randomizado, ou seja, não foi comparado um grupo controle com um grupo intervenção porque o presente estudo é de viabilidade apenas.

Apontamento 2 – Pressão de ar na Gaita de Boca

Todos os participantes utilizaram a mesma abertura da gaita, sem individualização da resistência de acordo com a capacidade inspiratória, e os próprios autores informam que não foi possível determinar a resistência ideal para o treinamento. Adicionar diferentes níveis de carga definidos a partir da MIP e acompanharia também adesão e segurança durante as sessões.

Resposta dos autores:

Concordamos e agradecemos a crítica construtiva. A ideia futura é adaptar a Gaita de boca para saber a pressão inspiratória na abertura correta. A gaita de boca possui nas aberturas iniciais uma resistência menor, notas mais graves com espaços maiores para a passagem do ar, enquanto aberturas finais possuem maior resistência, com um espaço menor para a passagem do ar e notas mais agudas. Dado que as aberturas da gaita irão gerar notas diferentes, quanto mais agudo, mais força é necessária para fazer a nota, ou seja, maior a resistência (Bahnson, 1998).

A ideia inicial era definir o nível de resistência pela Pimáx que o paciente apresentasse, medida pelo manovacuômetro. Uma Pimáx de 20 a 30 cmH_2O iniciaria na abertura de número 1 (grau mais baixo, mais fácil), de 30 a 40 cmH_2O na abertura de número 4 (grau baixo, nível médio), e >40 cmH_2O na abertura de número 6 (grau médio, nível difícil). Entretanto, os participantes conseguiram atingir na avaliação uma Pimáx >40 cmH_2O, sendo portanto fixado na abertura de número 6.

Este protocolo foi elaborado em colaboração de uma musicoterapeuta e a partir de estudos envolvendo o uso da gaita na DPOC (Alexander & Wagner, 2011, Hart *et al*., 2020; Lewis *et al.,* 2022), com as devidas adaptações para a população e contexto deste estudo

Como este estudo foi somente de viabilidade, com um tempo mais breve, não foi possível estabelecer o critério de quanto de pressão de ar entra ou sai

exatamente da gaita de Boca, mas futuramente pode ser realizado para dar maior consistência a um futuro ensaio clínico randomizado.

***Abstract*—Physical mobility is a determining factor for pediatric cognitive and psychosocial development. Although motorized wheelchairs promote essential independence, their adoption for early childhood frequently faces two structural barriers: the high acquisition cost and the profound clinical insecurity associated with autonomous control via a traditional joystick, which is inadequate for the motor maturity of this age. This article presents the development of an Evolutionary Prototyping Experimental Platform classified at Technology Readiness Level 4 (TRL 4) [1], whose focus does not lie on the mechanical construction of the vehicle, but rather on the implementation of a wireless communication architecture via Bluetooth that enables the absolute transfer of control to the caregiver. The study details the resolution of complex embedded integration problems, notably the mitigation of electromagnetic interference (EMI) and voltage drops on the radio frequency bus, as well as the elimination of race conditions between the physical and virtual joysticks. Technical feasibility was validated in the laboratory using an application developed in MIT App Inventor [2] and an Arduino microcontroller. The results demonstrate stability in the transmission of serial packets in inductive environments and the effective logical blocking of local pediatric control, ensuring a latency of less than 500 ms. It is concluded that the adoption of a remote priority control system enables operational safety, establishing a replicable and low-cost technological basis for future clinical phases.**

***Index Terms*—Assistive Technology, Bluetooth Communication, Caregiver Control, Race Condition, Signal Integrity, Arduino.**

I. Introduction

A. Pediatric Mobility and the Control Paradigm

Mobility is an essential factor for the autonomy and quality of life of people with reduced mobility [3]. Independent movement contributes directly to participation in social and educational environments. In the specific case of children, locomotion plays an even more critical role, as it is intrinsically linked to neuromotor and spatial perception development [4]. Deprivation of autonomous exploration in the first years of life can result in significant delays in learning and problem-solving. Furthermore, considering the physical profile of children up to 5 years old, whose weight and development standards are cataloged by the World Health Organization (WHO) [5], mechanical suitability must be rigorous to safely support the child's structure.

The evolution of wheelchairs to motorized versions represented a therapeutic milestone. However, prescribing this technology for young children faces complex operational and physical safety challenges. Standard commercial chairs are predominantly controlled by an analog joystick, which requires fine motor coordination and rapid decision-making [3]. For children in early childhood, this complexity represents an imminent risk of collisions. Rehabilitation professionals frequently postpone the prescription of the equipment until the child reaches cognitive maturity, creating a clinical paradox. Allied to this, the cost of pediatric models, which exceed the R$ 10,000.00 mark in the national market [6], makes acquisition unfeasible for families dependent on the public health system. Research focused on low-cost open-source hardware [7], [8], [9] highlights the need for open platforms; however, most of these works keep steering autonomy restricted to the user, failing to address the supervision aspect.

B. The Challenge of Wireless Integration in Inductive Environments

To reduce clinical insecurity, the introduction of a remote control interface operated by the caregiver emerges as the most appropriate technological response. The Bluetooth protocol stands out for its wide adoption in mobile devices and low power consumption. However, implementing a wireless communication architecture in an electric wheelchair is not a trivial task from an embedded systems engineering perspective.

A motorized wheelchair is, by definition, an extremely hostile electrical environment. The presence of high-power Direct Current (DC) motors generates intense current consumption peaks during starting inertia, causing abrupt voltage drops on the power bus. Furthermore, switching inductive loads generates strong Electromagnetic Interference (EMI) noise, which propagates through the motherboard's ground planes [10]. Radio frequency modules, such as those based on the Bluetooth standard, are highly sensitive to these variations,

frequently resulting in the corruption of serial data packets or involuntary reboots of the transmitter module.

Besides the electrical challenges, the coexistence of two means of control — the physical (local) joystick and the virtual (remote) joystick — creates a classic failure scenario in computer science: the race condition [11]. If both controls send translation or rotation commands in the same microcontroller clock cycle, the system logically collapses, generating unpredictable states in the mechanical actuators.

C. Study Objective

The present work presents the development of an Evolutionary Prototyping Experimental Platform, classified on the Technology Readiness Level 4 scale (TRL 4, Proof of Concept in the laboratory, or PoC) [1]. The primary focus of this study is to detail the architectural solutions adopted to enable the use of the Bluetooth protocol in the control of a pediatric wheelchair. The article describes electrical noise mitigation techniques to ensure wireless module stability and the implementation of a finite state machine focused on resolving command conflicts, ensuring the safe and immediate transfer of control to the child's caregiver.

II. Related Works

The quest for financial accessibility has driven the creation of academic prototypes based on off-the-shelf components. Gross and Lermen [7] developed a motorized wheelchair using the Arduino Uno coupled to DC motors. Along the same lines, Barcelos et al. [8] proposed a control and motorization system, and Santos and Machado [9] proposed a similar mechanical system for motorizing wheelchairs for children up to 9 years old. Although they prove financial viability, both works keep the navigation interface restricted to the traditional physical joystick, without providing for external intervention by the caregiver.

The use of mobile devices acting as wireless interfaces is a growing trend. Kim et al. [12] designed a smartphone platform integrated with a Tongue Drive System. In parallel, Dasgupta et al. [13] demonstrated the stability of the Arduino-Bluetooth-Smartphone technological triad in the control of electromechanical actuators, evaluating the integrity of wireless serial data packets. However, their focus lies on providing control methods for the adult user themselves, discarding the figure of an external caregiver actively acting on the priority of the control loop.

In the literature focused on pediatric rehabilitation, Guerette et al. [3] and Rodby-Bousquet and Hägglund [4] analyze the profound impact of electric mobility on the socialization of children with motor disabilities. Both studies reinforce that early prescription is vital, but reiterate the latent need for systemic safety adaptations that minimize immediate accident risks.

Table I consolidates the literature review and positions the present article, seeking the resolution of hardware and software conflicts to actually integrate the Bluetooth architecture focused exclusively on the minor's caregiver control.

TABLE I
COMPARISON OF SOLUTIONS IN THE LITERATURE AND PROTOTYPING STATE

Work	Pediatric Focus	Low Cost	App	Caregiver Control
Gross [7]	No	Yes	No	No
Barcelos [8]	Yes	Yes	No	No
Santos [9]	Yes	Yes	No	No
Kim [12]	No	No	Yes	No
Proposed (TRL 4)	Yes	Yes	Yes	Yes

III. Materials and Methods

A. Overview of the Network and Control Architecture

The platform was designed under the Master-Slave communication paradigm. The mobile application acts unconditionally as the maximum authority (Master) in the network hierarchy. Digital commands are transmitted via the Bluetooth Classic protocol (IEEE 802.15.1, operating in the 2.4 GHz ISM band) to the Arduino Uno microcontroller (Slave). The microcontroller processes the instruction matrix, electronically overrides the local physical joystick inputs when necessary, and converts movement intentions into Pulse Width Modulation (PWM) signals that are delivered to the power driver modules for differential drive of the traction motors.

B. Power Sizing and EMI Mitigation in the Bluetooth Module

Component selection was based on financial accessibility and ease of replacement. The differential drive is performed by two 12V brushed DC motors [14]. To supply the high current demand, which can reach momentary peaks of up to 25A, the traditional low-capacity L298N drivers were replaced by robust industrial IBT-2 modules, which use BTS7960 H-bridges [15]. The system is powered by a single 12V lithium battery. The small number of batteries used is justified by the fact that the project is in the bench prototype testing phase. The internal recharging circuit in the laboratory used the XL4015 current regulator module adjusted to 14.5V/3A.

One of the most severe problems faced during the development of this Proof of Concept (PoC) was finding a way to ensure that the HC-05 Bluetooth module would not lose power or signal coherence when the motors were subjected to maximum torque. Initially, by connecting all components to the standard Arduino regulator, it was noticed that the system was a constant victim of abrupt voltage drops (voltage sags). Whenever the motors started moving, a high level of electromagnetic noise and harmonics propagated through the circuit. This phenomenon manifested empirically in the test debugging serial terminal: strange characters and corrupted packets flooded the serial monitor whenever the motor spun, proving the direct electrical conflict.

As an architectural solution, the unified power supply was abandoned. The power bus was strictly segregated from the battery root. The B+ and B- power pins of the IBT-2 modules

were connected directly to the lithium battery terminals, passing only through a high-current mechanical SPST switch. In a totally isolated parallel manner, the use of an LM2596 step-down regulator converter dedicated exclusively to the logic loop was adopted. Connected in parallel to the battery, the LM2596 was calibrated to reduce the voltage to a continuous 6V (ideal level for the Vcc input of the Bluetooth module). This physical isolation topology prevented the motor interference and the primary voltage sag from dropping the stability of the HC-05 module's radio frequency carrier, ensuring that the serial receiving terminal operated with integral data packets.

C. Embedded Software Development and Analog Filters

The main microcontroller's control firmware was written in C/C++. To ensure comfortable driving, the internal registers TCCR0B and TCCR1B were altered to modify the prescaler of the hardware timers (Timers 0 and 1). This manipulation increases the generated PWM signal frequency (exceeding the factory 490 Hz), eliminating the high-pitched acoustic noise from the coils and providing stabilized electrical torque at low rotation.

The treatment of the virtual joystick signal required rigorous mathematical calibration. Knowing that the 10-bit Analog-to-Digital Converter (ADC) has a resting center at 512, a software deadband was implemented. The microcontroller was instructed to ignore the user unless the signal read on the X and Y axes deviates from the center in absolute value by more than 80 units. This logical barrier prevents parasitic electrical noise from translating into spurious movements.

D. The Race Condition and Caregiver Hierarchy

The virtual remote control panel, operated exclusively by the adult, was developed on the MIT App Inventor platform [2]. For the execution and validation of the interface and remote communication, the application was operated from a Motorola G86 5G smartphone running the Android version 16 operating system. The interface (Fig. 1) features a connection button, a playful directional virtual joystick, a boolean toggle switch called "Physical Lock" (Trava Física), used to block the physical joystick signals, and a button to call the latency display.

During the initial integration tests, a critical computer science problem was detected: the simultaneous use conflict factor (Race Condition). When the wheelchair's physical joystick and the application's virtual joystick were activated at the same time, the microcontroller received concurrent directional vectors in the same instruction (e.g., child pulling backwards, and application commanding to the right). The inability to process the desired state generated severe mechanical juddering in the H-bridges and placed the system in a dangerously undefined state.

To solve this conflict, in addition to prioritizing the virtual joystick command, there was an urgent need to activate a lock for the physical joystick in the application itself, strictly preventing the child from controlling the wheelchair alone in open

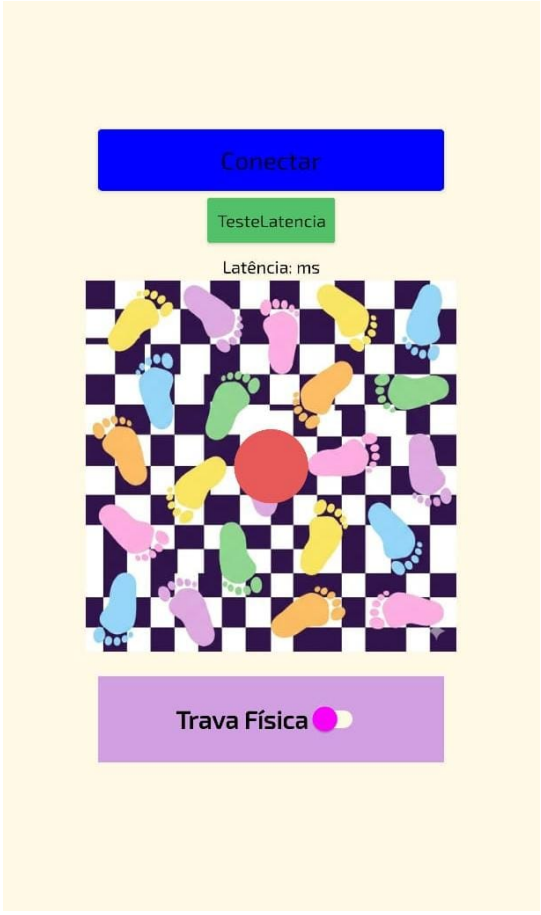

Fig. 1. Mobile application interface, highlighting the virtual joystick and the caregiver control selector switch.

environments. This structural prioritization was implemented through the master variable `travaVirtualFisico`.

Below is the finite state machine that handles the physical joystick block:

As evidenced, under the blocking condition imposed by the logic lock, the processing board simply ignores any voltage variation coming from the mechanical controller axes. Since this iteration focuses on validating the TRL 4 logic, the non-blocking safety timer (watchdog) against Bluetooth signal loss was initially set at `TEMPO_MANOBRA` $= 1000$ ms for debugging purposes. It is recognized that for future real-world trials, the active safety watchdog limit must be lowered to around 200 ms, preventing the wheelchair from advancing even if the mobile application suddenly shuts down.

E. Preliminary Bench Testing Considerations

The development of reliable embedded architectures for assistive technology requires rigorous bench testing to validate operational performance, power stability, and signal integrity. In wireless-controlled motorized wheelchair prototypes, factors such as transmission latency, mechanical braking inertia, power supply voltage drop, and command arbitration are fundamental engineering considerations.

Listing 1. Algorithm for resolution and command hierarchy.

```
if (Serial.available() > 0) {
    int valor = lerComandoBluetooth();
    if (valor == 20) travaVirtualFisico = true;
    else if (valor == 21) travaVirtualFisico = false
        ;
    else comandoBT = valor;
}

if (!travaVirtualFisico) {
    // Local permission:
    // Child's joystick reading
    int physY = analogRead(PINO_Y) - 512;
    processarJoystickFisico(physY);
} else {
    // Active caregiver control mode:
    // The physical joystick is ignored by the CPU
    if (millis() - ultimoComandoBT < TEMPO_MANOBRA)
        {
        executarMovimentoRemoto(comandoBT);
    } else {
        // Protection against signal loss
        pararMotores();
    }
}
```

This section details the methodology, raw datasets, mathematical modeling, and statistical analysis of the bench tests conducted on a Technology Readiness Level 4 (TRL 4) proof-of-concept prototype. The evaluation covers round-trip time (RTT) latency under different distances and motor states, braking distance variations, transceiver voltage stability, and response time accuracy evaluated according to the GUM (Guide to the Expression of Uncertainty in Measurement) guide [16].

F. System Architecture and Safety Limitations

The current proof of concept is strictly restricted to a bench demonstration of command arbitration via Bluetooth and power isolation. The study does not make claims of safety rating, clinical acceptance, or readiness for use by young children.

1) Link Security and Fault Handling:

- **Pairing and Authentication:** The system uses an unauthenticated HC-05 Bluetooth module operating over an RFCOMM link. Master lock commands are subject to potential delays or interference, indicating that future iterations require secure encryption and authentication protocols (e.g., BLE with secure pairing).
- **Framing and Command Integrity:** Control packets use specific framing, checksum codes, and sequence numbers to detect and mitigate serial data corruption.
- **Startup Behavior and Link Loss:** Upon startup, the firmware defaults to a fail-safe, stationary state. Disconnection events trigger immediate motor stops or reconnection protocols.
- **Emergency Stop and Physical Overrides:** The current design lacks an independent electromechanical safety relay; software-based logic manages emergency stops, which does not replace a dual-channel physical safety interlock. The watchdog timer (1 s) represents a known operational limitation and not an active safety-rated control.

G. Experimental Methodology and Bench Results

1) Latency Evaluation (Bluetooth RTT): The wireless communication delay was quantified by measuring the round-trip time (RTT) between the mobile application and the embedded microcontroller. The application recorded the send timestamp (T_{send}) when dispatching the character "P" and the receive timestamp (T_{receive}) when receiving an instant echo "E" from the Arduino. A total of 140 samples were collected across four distinct operational scenarios ($N = 35$ each).

The mathematical formulations used are:

$$\text{RTT}_i = T_{\text{receive}} - T_{\text{send}} \tag{1}$$

$$\bar{x} = \frac{1}{n}\sum_{i=1}^{n} \text{RTT}_i \tag{2}$$

$$s = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(\text{RTT}_i - \bar{x})^2} \tag{3}$$

$$J = \frac{1}{n-1}\sum_{i=1}^{n-1}|\text{RTT}_{i+1} - \text{RTT}_i| \tag{4}$$

Consolidated statistical results by scenario:

- **2 meters, at rest:** Mean $\bar{x} = 218.14$ ms, Standard Deviation $s = 36.33$ ms, Mean Jitter $J = 49.85$ ms.
- **2 meters, in motion (active PWM):** Mean $\bar{x} = 235.31$ ms, Standard Deviation $s = 53.83$ ms, Mean Jitter $J = 48.09$ ms.
- **10 meters, at rest:** Mean $\bar{x} = 222.83$ ms, Standard Deviation $s = 53.81$ ms, Mean Jitter $J = 57.06$ ms.
- **10 meters, in motion (active PWM):** Mean $\bar{x} = 216.37$ ms, Standard Deviation $s = 37.16$ ms, Mean Jitter $J = 41.91$ ms.

2) Braking Distance Test: To evaluate the mechanical inertia and stopping performance, a large marker was attached to the chassis to trace the displacement on the floor from a constant nominal speed. Measurements were performed using a 100 cm metal ruler with an accuracy of 0.1 cm.

Ten braking trials recorded the following distances (in cm): $\{2.9;\ 4.8;\ 1.5;\ 1.8;\ 4.1;\ 2.4;\ 1.3;\ 6.8;\ 1.3;\ 2.3\}$. Applied formulations:

$$\bar{d}_{\text{brake}} = \frac{1}{n}\sum_{i=1}^{n} d_i = 2.92\,\text{cm} \tag{5}$$

$$s_d = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(d_i - \bar{d}_{\text{brake}})^2} \approx 1.80\,\text{cm} \tag{6}$$

$$a = \frac{v^2}{2 \cdot \bar{d}_{\text{brake}}} \tag{7}$$

The observed variance highlights the impact of human reaction time and manual actuation delays during stopping maneuvers.

3) Bluetooth Module Power Supply Voltage Stability: The voltage stability (V_{CC}) on the VCC and GND pins of the Bluetooth transceiver was monitored using a Hikari HM-2030 digital multimeter. Before starting the motors, the recorded nominal voltage was $6.36\,\text{V}$.

During the dynamic motor actuation, ten sequential voltage readings were obtained (in V): $\{6.36;\ 6.34;\ 6.34;\ 6.35;\ 6.34;\ 6.34;\ 6.34;\ 6.33;\ 6.34;\ 6.35\}$. The mean operational voltage and the maximum relative voltage drop were calculated as:

$$\bar{V} = \frac{1}{n}\sum_{i=1}^{n} V_i \approx 6.34\,\text{V} \tag{8}$$

$$\begin{aligned}\Delta V\% &= \frac{V_{\text{nominal}} - V_{\text{minimum}}}{V_{\text{nominal}}} \times 100\% \\ &= \frac{6.36 - 6.33}{6.36} \times 100\% \approx 0.47\% \end{aligned} \tag{9}$$

The results confirm power stability, mitigating the risks of brownout and signal loss.

4) Temporal Validation and Uncertainty Analysis: System response time was evaluated by comparing internal firmware timestamps with manual timing. Following the GUM standard guidelines [16], Type A uncertainty (statistical dispersion), Type B uncertainty (digital instrument resolution), and the human reaction component due to timing were combined ($u_{\text{hum}} = 0.20\,\text{s}$):

Scenario 1: 2-meter distance ($N = 10$ trials, times in seconds): $\{0.67;\ 0.14;\ 0.72;\ 0.52;\ 0.14;\ 0.59;\ 0.26;\ 0.65;\ 0.56;\ 0.33\}$. Sum = $4.58\,\text{s}$.

$$\bar{t} = \frac{4.58}{10} = 0.458\,\text{s}, \quad s = 0.221\,\text{s} \quad (u_A \approx 0.070\,\text{s}) \tag{10}$$

$$\begin{aligned} u_C &= \sqrt{u_A^2 + u_{\text{inst}}^2 + u_{\text{hum}}^2} \\ &= \sqrt{(0.070)^2 + (0.003)^2 + (0.20)^2} \approx 0.212\,\text{s} \end{aligned} \tag{11}$$

Final Result: $t = (0.5 \pm 0.2)\,\text{s}$.

Scenario 2: 10-meter distance ($N = 10$ trials, times in seconds): $\{0.46;\ 0.20;\ 0.33;\ 0.52;\ 0.99;\ 0.46;\ 0.66;\ 0.46;\ 0.27;\ 0.79\}$. Sum = $5.14\,\text{s}$.

$$\bar{t} = \frac{5.14}{10} = 0.514\,\text{s}, \quad s = 0.241\,\text{s} \quad (u_A \approx 0.076\,\text{s}) \tag{12}$$

$$u_C = \sqrt{(0.076)^2 + (0.003)^2 + (0.20)^2} \approx 0.214\,\text{s} \tag{13}$$

Final Result: $t = (0.5 \pm 0.2)\,\text{s}$.

H. Bill of Materials (BOM) and Cost Analysis

Table II presents the component costs and the comparable total market value of the developed prototype.

I. Bench Testing Conclusions

This study documented a bench-level (TRL 4) demonstration of a low-cost Bluetooth control architecture and a power arbitration scheme for motorized wheelchairs. Quantitative data verified the transceiver power supply voltage stability ($\Delta V < 0.5\%$) and characterized the RTT latency profiles under load. The identified limitations — such as open wireless link vulnerabilities, absence of dual-channel physical safety relays, and the reliance on human reaction time — establish clear technical prerequisites for future iterations before any clinical evaluation.

TABLE II
BILL OF MATERIALS AND BENCH PROTOTYPE COST

Material / Component	**Cost (R$)**
HC-05 Bluetooth Module	34.60
Arduino Uno	39.90
LM2596 Voltage Regulator	9.80
XL4015 Module with Display	35.00
Rocker Switch	0.95
Analog Joystick Module	5.20
20m Roll of Circuit Wire	25.00
BTS7960 H-Bridge (4 units)	50.00
12V Lithium Battery	68.00
2x 12V DC Motors	98.80
MDF Board ($0.80\,\text{m}^2$)	20.15
Laser Cutting Services	45.00
2x EVA Wheels	65.00
20x Fixing Screws	2.80
Total Prototype Cost	**500.20**

IV. RESULTS AND DISCUSSION

A. Proof of Concept

To prove the material existence and the advancement of prototyping (TRL 4), Figure 2 illustrates the assembled and adapted motorized pediatric wheelchair. In addition, Figure 3 presents the embedded electronic circuit. The circuit is assembled in an experimental format, which may appear visually cluttered, but its layout was fundamental for the validation of the electrical and logical system prior to the manufacturing of a definitive printed circuit board.

B. Bluetooth Architecture Stability and Noise Mitigation

The HC-05 Bluetooth module operated well thanks to the new isolated bus topology described in the methodology. By using the LM2596 regulator module connected directly to the battery to nourish the 5V/6V logic, the voltage drops caused by the starting of the heavy motors were filtered out by the converter's capacitors. The strange noise and the sending of serial garbage to the terminal observed previously disappeared. The antenna signal operated without significant packet loss in a measured continuous radius of 5 meters in an open field, a distance compatible with the concept of close monitoring required by a child's caregiver.

C. Concurrency Resolution and Caregiver Control Effectiveness

The aspect of greatest scientific relevance validated by the trials was the hierarchical priority system. When the hypothetical child was in control and the "Physical Lock" (Trava Física) button was activated in the application, the race condition was summarily eradicated. Even with the physical joystick forced

Fig. 2. Assembled motorized pediatric wheelchair prototype (TRL 4 Proof of Concept).

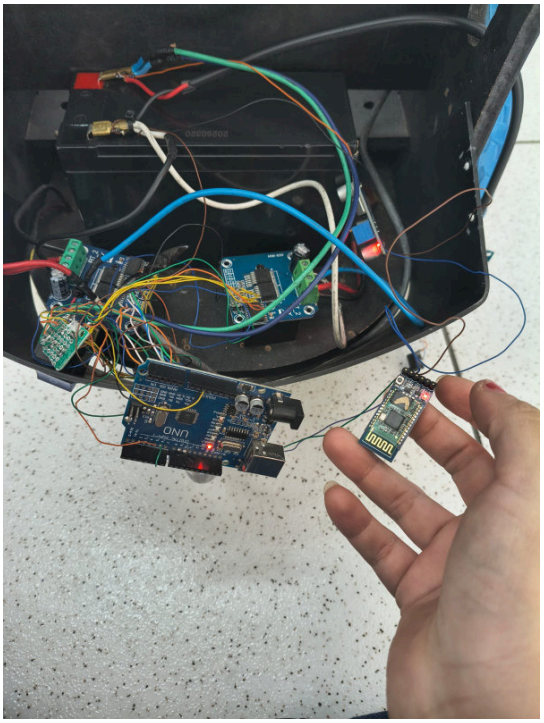

Fig. 3. Experimental assembly of the control circuit, highlighting test connections for prior logical and electrical validation (TRL 4).

to its structural axis limits, the firmware discarded the analog processing.

The experimentally measured latency (time between the button activation on the smartphone software and the cut of the PWM level of the H-bridge pins) remained consistently below the 500-millisecond window. In clinical rehabilitation practice, this rapid response time suggests that caregivers can intervene and brake the equipment before the child's lack of danger awareness results in a collision with an obstacle, psychologically enabling early motor training.

D. Cost Landscape Analysis

The architectural solution proved its financial viability. Table III exposes the structuring of the constructed electronic matrix. The material costs do not reach the 20% barrier of the actual value charged for traditional commercial pediatric equipment, whose prices usually orbit the range of 10 to 15 thousand reais [6]. The absence of closed controller boxes from multinationals makes assembly cheaper, allowing, through subsidized distributions, assistive technologies with little access by low-income families to reach social strata through the government health system.

TABLE III
ESTIMATED ANALYTICAL COST LANDSCAPE (ELECTRONIC ARCHITECTURE)

Hardware Analytical Category	**Relative Share (%)**
DC Motors (Traction Module)	∼19.8%
Lithium Battery (12V)	∼13.6%
Dual Driver Module (H-Bridge/IBT-2)	10.0%
Logic Module (Atmega, HC-05 Receiver)	∼14.9%
Comparison with Market Value	<20% of Value

E. Study Limitations (TRL 4) and Future Works

Despite confirming the hypotheses raised in the scientific gap for this Proof of Concept, the developed system has restrictions, common to the TRL 4 maturity level:

1) **Perimeter Sensory Blindness:** The caregiver-focused control system, although solving serial network conflicts, is based exclusively on the continuous alert state of the human holding the cellphone. The lack of a sensor loop inherent to the board (such as ultrasonic sensor arrays) makes automatic brakes impossible in the event that the adult does not see a hole in the ground in time to stop the wheelchair in the app.
2) **Absence of Closed Loop on the Motors:** The lack of rotary encoders connected to the Arduino interrupt pins prevents the creation of PID algorithms for route correction, requiring manual corrections in control.
3) **Autonomy and Charging Time:** Due to the use of only one battery in this bench testing phase, it will be necessary to implement a higher capacity battery bank in the future phases of the prototype to ensure an increase in the system's charging time and autonomy.

To reach TRL 5 maturity phases and subsequent longitudinal clinical trials, the scope of work requires the radio system to migrate to the BLE (Bluetooth Low Energy) standard, aiming for latency reduction and gains in the active safety spectrum against mobile application timeouts, invariably accompanied by shielding the lithium pack with an industrial protection BMS.

V. Conclusion

This study consolidated and documented the arduous integration process of a low-cost serial communication and electronic control architecture aimed specifically at the early childhood audience with mobility restrictions. By shifting the intellectual protagonism from purely mechanical parts and focusing on the premises of embedded networks engineering and structured software (resolution of noise, voltage sag, and race conditions), the project presented a functional and resilient Evolutionary Platform.

The empirical solutions adopted — separating the power buses via switching regulators to save the stability of the Bluetooth node and the hierarchical filter via master-slave code to isolate analog noise from concurrent physical commands — proved fully effective on the test bench. The latency of less than 500 ms attests that it is technologically feasible and inexpensive to transfer, imperatively and immediately, the driving of the vehicle from an immature occupant to the safe hands of an external caregiver holding a mere smartphone.

It is concluded that the systemic and widespread adoption of interfaces based on Bluetooth technology interconnected to open microcontrollers can mitigate the deepest fears and clinical resistances of physiotherapy, filling the dangerous gap left by isolated joystick control. This research transcends the technical validation of serial data communication by offering a mature logical substrate that stimulates the promotion of government distribution policies in favor of early rehabilitation in public health.

VI. Acknowledgments

The authors thank the support of the Inventive Studies in Assistive Technologies Laboratory, which enabled the development of this research. The collaboration of the Gemini (Google) artificial intelligence in the grammatical correction of this article is also acknowledged.

***Resumo*—Esta pesquisa tem como objetivo investigar os aspectos que circunscrevemos desafios de locomoção de pessoas cadeirantes em suas atividades diárias. Além disso, a pesquisa considera aspectos de acessibilidade, usabilidade, custo-benefício e impacto social dessas tecnologias. A metodologia inclui revisão bibliográfica, estudos de caso e análise de depoimentos de usuários sobre diferentes modelos de cadeiras de rodas. Os resultados esperados incluem a identificação de inovações promissoras, limitações existentes e para o desenvolvimento de cadeiras de rodas mais eficientes, seguras e acessíveis.**

***Palavras-chave*—Tecnologia assistiva, cadeira de rodas, mobilidade assistida, acessibilidade, desenho universal.**

I. Introdução

A investigação sobre a mobilidade e a acessibilidade de usuários de cadeira de rodas têm se consolidado como temas centrais nas discussões contemporâneas sobre inclusão social, planejamento urbano e desenvolvimento tecnológico. A acessibilidade deve ser compreendida de forma ampla, não se limitando à eliminação de barreiras físicas, mas abrangendo também fatores sociais, culturais, comunicacionais e econômicos que influenciam diretamente a autonomia, a participação e a qualidade de vida desses indivíduos [1]. Nesse sentido, garantir condições adequadas de acesso aos diferentes espaços da sociedade constitui um requisito essencial para a promoção da cidadania e da igualdade de oportunidades.

Apesar dos avanços legislativos e normativos observados nas últimas décadas, muitos ambientes urbanos e edificações ainda apresentam limitações significativas quanto à acessibilidade. A ausência de infraestrutura adequada, como calçadas em conformidade com normas técnicas, rampas com inclinação apropriada e sistemas de transporte público adaptados, representa um dos principais entraves à mobilidade de usuários de cadeira de rodas [3]. Essas barreiras não apenas dificultam o deslocamento, mas também contribuem para a exclusão social, restringindo o acesso a serviços essenciais como educação, saúde, trabalho e lazer.

Além das barreiras físicas, é importante destacar a presença de obstáculos de natureza social e atitudinal, que se manifestam por meio da falta de conscientização da população e da persistência de comportamentos discriminatórios. Esses fatores ampliam as dificuldades enfrentadas por pessoas com mobilidade reduzida, evidenciando que a acessibilidade deve ser tratada de forma integrada, considerando tanto o ambiente construído quanto as relações sociais estabelecidas nesse contexto [3].

Do ponto de vista legal, a acessibilidade é reconhecida como um direito fundamental assegurado por diferentes instrumentos normativos nacionais e internacionais. A Convenção sobre os Direitos das Pessoas com Deficiência estabelece que os Estados devem adotar medidas apropriadas para garantir o acesso, em igualdade de condições, ao meio físico, ao transporte, à informação e à comunicação [2]. No entanto, observa-se que a efetivação dessas diretrizes ainda enfrenta desafios relacionados à fiscalização, à adaptação de estruturas já existentes e à implementação de políticas públicas eficientes.

No campo da Engenharia Biomédica, a temática da acessibilidade se destaca principalmente pelo desenvolvimento de tecnologias assistivas voltadas à promoção da independência e da qualidade de vida das pessoas com deficiência. Nesse contexto, as cadeiras de rodas representam um dos principais recursos utilizados, sendo constantemente aprimoradas em termos de ergonomia, funcionalidade e adaptação às necessidades dos usuários [5].

Adicionalmente, a análise das percepções e experiências dos próprios usuários de cadeira de rodas desempenha um papel essencial na identificação de limitações que não são evidentes apenas sob uma perspectiva técnica. A incorporação dessas informações no processo de desenvolvimento de produtos e na avaliação de espaços acessíveis permite a criação de soluções mais eficazes e alinhadas às demandas reais da população.

Diante desse contexto, este estudo tem como objetivo investigar a mobilidade e a acessibilidade de usuários de cadeira de

rodas, com ênfase na análise dos aspectos legais que garantem a acessibilidade em espaços urbanos e edificações. Além disso, busca-se compreender as características dos modelos disponíveis no mercado e as percepções dos usuários, de modo a contribuir para o desenvolvimento de soluções mais inclusivas, eficientes e socialmente relevantes [2], [4].

II. Objetivos

A. Objetivo Geral

Investigar os aspectos que circunscrevem os desafios de locomoção de pessoas cadeirantes em suas atividades diárias.

B. Objetivos Específicos

- Identificar os principais elementos balizados pelo desenho universal que constituem a acessibilidade para pessoas com mobilidade reduzida;
- Destacar os desafios enfrentados pelos usuários das cadeiras de rodas existentes no mercado;
- Pontuar os aspectos ergonômicos e técnicos que influenciam a aquisição de modelos específicos.

III. Metodologia

A presente pesquisa possui caráter qualitativo e descritivo, tendo como objetivo analisar aspectos relacionados à acessibilidade, mobilidade e funcionalidade das cadeiras de rodas, bem como identificar as principais necessidades enfrentadas por usuários desses dispositivos no cotidiano. O estudo busca compreender os desafios vivenciados por pessoas com deficiência física em suas atividades diárias, considerando suas experiências, percepções e expectativas em relação aos diferentes modelos de cadeiras de rodas utilizados.

Inicialmente, foi realizado um levantamento bibliográfico e documental acerca das principais legislações e normas relacionadas à acessibilidade e inclusão social, com destaque para a Lei Brasileira de Inclusão da Pessoa com Deficiência (LBI) [4] e para a norma ABNT NBR 9050 [1]. Essas diretrizes foram analisadas por apresentarem princípios fundamentais voltados à promoção da acessibilidade, autonomia e igualdade de direitos para pessoas com deficiência.

Durante essa etapa, também foram estudados os princípios do Desenho Universal [5], [9], conceito voltado ao desenvolvimento de ambientes, produtos e serviços acessíveis ao maior número possível de pessoas, independentemente de idade, limitações físicas ou condições de mobilidade. O desenho universal busca garantir o uso democrático e inclusivo dos espaços e equipamentos, reduzindo barreiras e promovendo maior independência aos usuários. Dessa forma, o conceito não se restringe apenas à arquitetura, mas também se aplica ao desenvolvimento de tecnologias assistivas, contribuindo para a criação de dispositivos mais funcionais, acessíveis e adaptáveis às necessidades individuais.

Além disso, foram utilizados estudos relacionados à inclusão social e acessibilidade, como os trabalhos de [3], os quais evidenciam que fatores como ausência de rampas, calçadas inadequadas, transporte público inacessível e falta de conscientização social comprometem significativamente a mobilidade e o direito de ir e vir das pessoas com deficiência.

Vale ressaltar que foi realizada uma investigação dos principais modelos de cadeiras de rodas disponíveis atualmente no mercado. Esse levantamento foi fundamental para a compreensão e aprofundamento das limitações presentes nos modelos existentes, bem como das possíveis melhorias e adaptações que podem ser implementadas. Convém destacar que essa etapa foi de grande importância para o desenvolvimento da fase seguinte da pesquisa, que consistiu no levantamento das percepções e experiências relatadas por usuários.

A coleta de dados foi realizada por meio da análise qualitativa de depoimentos e relatos de usuários de cadeiras de rodas disponíveis na plataforma digital YouTube. A busca pelos vídeos foi realizada utilizando termos relacionados à mobilidade assistida, cadeiras de rodas, acessibilidade e experiências de usuários. Foram selecionados vídeos que apresentavam depoimentos espontâneos de usuários sobre a utilização das cadeiras de rodas em suas atividades cotidianas, totalizando 15 vídeos que atenderam aos objetivos desta pesquisa.

Os participantes relataram experiências pessoais relacionadas ao uso das cadeiras de rodas, abordando dificuldades de locomoção, conforto, transporte, acessibilidade, funcionalidade dos equipamentos e sugestões de melhorias. Esses relatos permitiram identificar problemas recorrentes enfrentados pelos usuários, bem como compreender aspectos relevantes relacionados à ergonomia, praticidade e adaptação dos dispositivos.

É importante ressaltar que os depoimentos publicados no YouTube foram transcritos e submetidos à Análise de Conteúdo proposta por Bardin (2016) [10], mediante leitura flutuante, codificação das unidades de registro, categorização temática e interpretação dos resultados.

Após a coleta das informações, os depoimentos foram organizados e analisados de forma comparativa, possibilitando a elaboração de quadros contendo as principais categorias identificadas, dificuldades relatadas e características dos diferentes modelos de cadeiras de rodas mencionados pelos usuários. Essa etapa permitiu sistematizar os dados coletados e compreender de forma mais detalhada as necessidades dos usuários.

IV. Resultados e Discussões

A análise dos depoimentos dos usuários sobre diferentes modelos de cadeiras de rodas permitiu identificar padrões recorrentes relacionados à usabilidade, conforto [7] , acessibilidade, transporte e custo dos equipamentos. Os comentários demonstram que as dificuldades enfrentadas pelos usuários vão além da função básica de locomoção, envolvendo também fatores ergonômicos [5] , sociais, econômicos e estruturais.

Entre os temas mais recorrentes, destacou-se a questão da portabilidade e transporte das cadeiras, especialmente nos modelos maiores e reclináveis. Diversos usuários relataram dificuldades para desmontar, dobrar ou acomodar as cadeiras em porta-malas de carros, além da falta de apoio de motoristas de aplicativos durante o embarque e desembarque. Esses

relatos evidenciam que a mobilidade do usuário depende não apenas da cadeira em si, mas também da compatibilidade do equipamento com os meios de transporte disponíveis no cotidiano.

Do ponto de vista ergonômico [5] e funcional, esse resultado demonstra a necessidade do desenvolvimento de cadeiras mais compactas, leves e de fácil desmontagem. Ademais, evidencia-se uma limitação na integração entre tecnologia assistiva e mobilidade urbana, já que muitos equipamentos acabam não sendo adequados à realidade do transporte individual e coletivo.

Outro aspecto frequentemente mencionado foi o conforto e a ergonomia [7]. Alguns usuários relataram desconforto causado pela ausência de acolchoamento ou pela rigidez do assento, além de dificuldades relacionadas ao ajuste dos apoios para os pés, encostos e dimensões da cadeira. Também foram observadas dúvidas sobre compatibilidade do equipamento com altura e medidas corporais dos usuários.

Essas experiências relatadas demonstram a importância da personalização ergonômica das cadeiras de rodas, principalmente para usuários que permanecem longos períodos sentados. A falta de conforto pode provocar dores, má postura, fadiga muscular e até lesões por pressão, comprometendo a qualidade de vida do usuário [5] [7]. Os depoimentos coletados foram organizados e identificados numericamente do usuário 1 ao usuário 35, apenas para fins de referência e organização na tabela. Os 15 vídeos analisados nesta pesquisa, utilizados como fonte dos depoimentos avaliados, foram reunidos em um documento eletrônico compartilhado, disponível no seguinte endereço:https://docs.google.com/document/d/10SZkrQRwS2dUMoJfJadV3yrs5mExakFNyz4yduGdv9A/edit?usp=drivesdk

Tabela I
ASPECTOS ERGONÔMICOS E DE MOBILIDADE IDENTIFICADOS

Categoria	Principais questões relatadas	Usuários
Ajustes e ergonomia	Ajuste de altura do apoio para os pés, punhos, largura da cadeira e encosto	2, 3, 17, 22
Conforto do usuário	Assento duro, ausência de acolchoamento e necessidade de almofada	4, 30
Portabilidade e transporte	Dificuldade para dobrar, desmontar e transportar no carro	5, 6, 10, 32
Acessibilidade no transporte público	Problemas com cintos, elevadores e auxílio de motoristas	7
Dimensões e compatibilidade corporal	Dúvidas sobre medidas e adequação corporal	12, 13, 25
Mobilidade e autonomia	Necessidade de uso independente da cadeira	33

Também foram identificadas reclamações relacionadas à facilidade de uso e montagem. Muitos usuários encontraram dificuldades para remover encostos, desmontar partes da cadeira ou realizar ajustes simples sem ferramentas adicionais. Em alguns casos, os mecanismos de dobragem e encaixe foram considerados complexos e pouco práticos.

Os relatos ainda revelaram problemas associados à acessibilidade urbana e ao transporte público. Um dos relatos destacou a insegurança no uso do cinto de fixação em ônibus, além da ausência de suporte adequado por parte dos motoristas e falhas em elevadores de acesso.

Outro ponto importante observado foi a forte insatisfação em relação ao alto custo das cadeiras motorizadas. Os usuários associaram os preços elevados a uma dificuldade de acesso às tecnologias assistivas, evidenciando uma percepção de desigualdade no acesso a equipamentos que promovem autonomia e qualidade de vida.

Além disso, muitos comentários apresentaram dúvidas sobre informações técnicas, como peso suportado, medidas, altura, materiais e funcionalidades específicas. Isso sugere que fabricantes e vendedores frequentemente disponibilizam informações insuficientes ou pouco claras sobre os produtos.

Também foram identificados comentários relacionados à necessidade de adaptações personalizadas, como ajustes para passagem em portas, adaptação para cama ou inclusão de almofadas adicionais.

Tabela II
ASPECTOS TÉCNICOS E FUNCIONAIS IDENTIFICADOS

Categoria	Principais questões relatadas	Usuários
Peso suportado e capacidade	Limite de peso suportado pela cadeira	18, 19
Preço e custo elevado	Reclamações sobre alto custo das cadeiras motorizadas	14, 15, 16, 20
Durabilidade e materiais	Resistência à ferrugem, impermeabilidade e tecidos	9, 27, 34
Rodas e manutenção	Pneus antifuro, rodas removíveis e travas	21, 26, 29
Funcionalidades adicionais	Uso no banho e suporte para alimentação enteral	8, 27
Informações técnicas insuficientes	Ausência de medidas e especificações completas	11, 13, 18, 25
Necessidade de adaptação personalizada	Adaptações para portas, cama e conforto	23, 30, 31
Demanda por modelos multifuncionais	Interesse em cadeiras com múltiplas funções	1
Facilidade de uso e montagem	Dificuldade para remover encostos e encaixes complicados	6, 28, 31

De forma geral, os resultados encontrados demonstram que as cadeiras de rodas precisam ser analisadas não apenas sob o aspecto funcional, mas também considerando conforto, adaptabilidade, praticidade, acessibilidade e custo-benefício. Os depoimentos reforçam a importância do desenvolvimento de tecnologias assistivas centradas no usuário, capazes de atender às necessidades reais das pessoas com deficiência e de seus cuidadores.

V. CONSIDERAÇÕES FINAIS

O desenvolvimento deste estudo permitiu identificar aspectos relevantes relacionados à mobilidade assistida e às necessidades enfrentadas por usuários de cadeiras de rodas no cotidiano. A análise dos depoimentos evidenciou que fatores como conforto, ergonomia, acessibilidade, praticidade, custo e adaptabilidade influenciam diretamente a autonomia e a qualidade de vida desses usuários.

Os resultados obtidos reforçam a importância da aplicação dos princípios do desenho universal no desenvolvimento de

tecnologias assistivas, demonstrando que soluções centradas no usuário podem contribuir para equipamentos mais inclusivos, funcionais e acessíveis.

Somado a isso, verificou-se a relevância da legislação brasileira, especialmente da Lei Brasileira de Inclusão (LBI) e da norma ABNT NBR 9050, como instrumentos essenciais para orientar projetos voltados à acessibilidade, autonomia e inclusão social de pessoas com deficiência.

Durante a pesquisa, também foram identificadas limitações relacionadas à multifuncionalidade dos equipamentos, à adaptação para diferentes perfis de usuários e às dificuldades associadas à acessibilidade urbana e ao transporte.

De maneira complementar, observa-se que o avanço das tecnologias assistivas associado à ampliação de pesquisas na área pode contribuir significativamente para a criação de soluções inovadoras voltadas às necessidades específicas dos usuários de cadeiras de rodas. Nesse contexto, torna-se fundamental incentivar estudos futuros que integrem acessibilidade, ergonomia e inovação tecnológica, visando não apenas melhorias funcionais nos equipamentos, mas também maior inclusão social, participação ativa e bem-estar das pessoas com deficiência física.

Desse modo, as informações obtidas ao longo da pesquisa serviram como base para a discussão sobre melhorias voltadas ao desenvolvimento de cadeiras de rodas mais acessíveis, confortáveis e multifuncionais, contribuindo para reflexões sobre a importância das tecnologias assistivas na promoção da autonomia, inclusão social e qualidade de vida das pessoas com deficiência física.

Além dos aspectos identificados neste estudo, observa-se que o desenvolvimento de novas cadeiras de rodas tem buscado priorizar características relacionadas à ergonomia, acessibilidade, conforto, segurança e funcionalidade, de modo a atender às necessidades dos usuários e promover maior autonomia em suas atividades diárias [5], [7], [8].

Nessa perspectiva, os resultados obtidos nesta pesquisa reforçam a importância de considerar as experiências e necessidades relatadas pelos usuários durante o processo de desenvolvimento desses equipamentos, contribuindo para a elaboração de soluções mais eficientes, acessíveis e alinhadas aos princípios do desenho universal e da inclusão social [4], [5], [10].

Por fim, espera-se que este trabalho contribua para discussões sobre acessibilidade e tecnologias assistivas, incentivando o desenvolvimento de cadeiras de rodas mais eficientes, confortáveis e inclusivas, capazes de promover maior independência, segurança e qualidade de vida para seus usuários.

Abstract*— The prevention of domestic accidents caused by gas leaks and forgotten flames requires accessible and autonomous active safety solutions. This work presents the Safe Connection System (SCS-01), a low-cost, universally applicable assistive IoT technology developed for non-invasive installation on flexible piping. The system adopts a distributed Wi-Fi architecture managed by the ESP32 microcontroller, divided into the Kitchen Sensor Module (MSC-01) and the Data Management Module (MGD). The MSC-01 performs local readings of the MQ-2 and LM35 sensors using dynamic baseline algorithms, safety timing, and mechanical flow shut-off via a stepper motor. The MGD centralizes data through a 2.4" TFT display and audible alerts using customized voice prompts, benefiting the general population, the elderly, and individuals with cognitive impairments. Practical tests demonstrated effectiveness in gas detection and thermal monitoring.

Keywords*—Biomedical engineering; accessibility; gas leak; home protection.

I. Introduction

The population aging observed in recent decades signals a profound shift in the Brazilian age structure, with a significant increase in the elderly population relative to younger generations [1]. This scenario poses urgent challenges to biomedical engineering and healthcare systems, requiring the development of solutions that ensure the autonomy, safety, and physical and mental well-being of this group. Maintaining functional independence is recognized by medicine as a determining factor for quality of life [2], directly contributing to the self-esteem and overall health of individuals with cognitive sensitivity.

In this situation, the developed equipment acts as an essential layer of preventive safety, meeting the protection needs of all users who frequently use cooking gas.

The natural decline of functions such as memory and attention, or the presence of early-stage pathologies such as Alzheimer's and Attention Deficit Hyperactivity Disorder (ADHD), significantly increases the risk of domestic accidents. Critical situations, such as leaving flames lit or liquefied petroleum gas (LPG) leaks, pose severe threats of fire and asphyxiation. This risk is frequently exacerbated by the sensory decline inherent to senescence—especially olfactory loss (presbyosmia) and hearing loss (presbycusis)—as the chronic decrease in these acuities directly compromises an elderly individual's ability to detect the smell of gas or emergency alarm sounds early on [3].

Given this problem, this work presents a safety system for the elderly using assistive technology and IoT, designed to act as preventive support in the domestic environment. The project integrates concepts of embedded systems and smart monitoring to identify risk situations in real time, establishing a link to accident prevention by offering an automated layer of protection and voice alerts that assist patients with mild cognitive deficits and everyday users seeking security for their homes, reducing reliance on full-time caregivers and maintaining their daily routines.

The SCS-01 (Safe Connection System) project, composed of two modules, the MGD (Data Management Module) and the MSC-01 (Kitchen Sensor Module), presented in Figure 1, was initially conceived for the National Biomedical Engineering Competition, Biochallenge Brasil 2025. The development was conducted by the team from LIHOM (Human-Machine Interface Laboratory) at the Federal University of Pernambuco, the institution responsible for providing the technological support and research space necessary for the device's design. Following the conclusion of the competition and its recognition with second place overall, the system demonstrated a high level of performance and effectiveness in promoting home safety and daily assistance, which motivated the continuation of academic research aimed at its constant improvement.

Fig. 1. Developed prototypes, on the left is the MGD and on the right is the MSC-01. Source: The authors, 2025.

II. Arquitetura do Sistema

The system was designed as a low-cost assistive and safety technology for both the elderly and the general public, structured into two main modules: the Kitchen Sensor Module (MSC-01) and the Data Management Module (MGD). Communication between the modules occurs in real time via a dedicated Wi-Fi network (2.4 GHz, 802.11 b/g/n), in which the MGD operates as the central server and the MSC-01 acts as the peripheral monitoring and actuation node. Each module is managed by an ESP32-C3 Super Mini microcontroller, selected for its compact dimensions, processing efficiency, and connection stability. Figure 2 shows the internal connections within the MSC-01 and MGD.

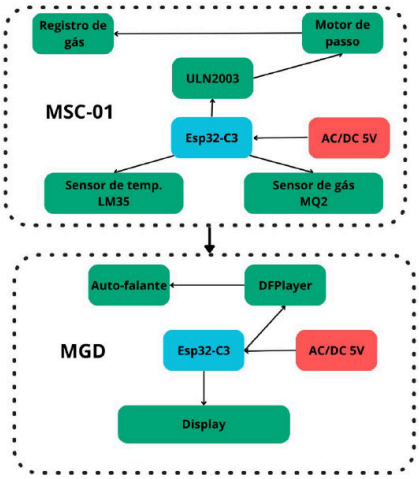

Fig.2. Block diagram of the SCS-01 interconnectivity. Source: The authors, 2025.

The Kitchen Sensor Module (MSC-01) is responsible for local environmental monitoring and active safety at the point of gas consumption. The choice of the MQ-2[4] sensor is justified by its high sensitivity to LPG and propane (in the range of 200 to 5,000 ppm), fast response time, and primarily its dual output: analog (AO), for continuous reading of gas levels, and digital (DO), which enables triggering a 0/1 signal with a threshold manually calibrated by a potentiometer on the module itself. For thermal monitoring, the LM35[5] sensor was selected due to its extremely low cost, ultra-compact dimensions, and native linear accuracy of 10 mV/°C, making it the ideal solution to measure ambient temperature variation without requiring complex external circuits. Sensory data processing occurs locally on the MSC-01, ensuring autonomy and speed in emergency decision-making. On the mechanical side, the module features a 28BYJ-48 stepper motor coupled to a ULN2003 driver, responsible for the direct angular actuation of a 5/16" copper mechanical valve to shut off the gas flow.

The Data Management Module (MGD), shown in Figure 3, acts as the core of information unification and system management. In addition to maintaining the local Wi-Fi network architecture, the MGD processes data received from the MSC-01 in real time to notify and trigger the corresponding actions. To ensure maximum accessibility for the general public and the elderly, the module manages a dual-alert multisensory interface: it visually displays system status and diagnostics on a 2.4-inch TFT display and plays customized voice audio messages through a DFPlayer Mini module connected to a 3 W speaker. This combination ensures that critical warnings remain intuitive, highly audible, and visually distinct.

Fig. 3. Prototype developed, MGD operational. Source: The authors, 2025.

III. Methodology and Sensor Calibration

The project development methodology was executed in a logical sequence, divided into hardware studies, software studies, and consolidation phases. The initial stage encompassed the analysis of the electrical characteristics of the battery, voltage regulator, and charger module. The circuits were assembled on a breadboard to validate component interconnection and perform practical torque tests on the motor-valve assembly.

A. Sensor Calibration

During the bench calibration phase, simulated scenarios were structured to establish reading routines. For the MQ-2 sensor, Qualitative Voltage Threshold Detection (Threshold-Based Detection) was adopted. For safety reasons in the test environment, lighters were initially used to simulate the leak, with subsequent readjustment for natural gas. Based on continuous readings from the ADC port in clean air ($ADC_{baseline}$) and under gas exposure (ADC_{atual}),the relative variation used by the algorithm for detection was defined:

$$\Delta ADC = ADC_{atual} - ADC_{baseline}$$

Additionally, the potentiometer on the MQ-2 module itself was adjusted to calibrate the digital output (DO) threshold, ensuring hardware redundancy by triggering a direct logic-level signal upon detecting the presence of gas.

Similarly, the calibration of the LM35 temperature sensor was based on establishing a dynamic baseline ($T_{baseline}$) captured upon each power-up of the equipment, eliminating interference from local climate variations. The algorithm performs a comparative time-averaged analysis between readings from previous seconds and the current reading, determining the thermal elevation:

$$.\Delta T = T_{atual} - T_{baseline}$$

It was experimentally established that an elevation of $\Delta T > 5°C$ indicates that the burner is lit. Confirmation of this variation initiates a 20-minute safety timer—an interval defined based on the overall average meal preparation time from Kantar Worldpanel's Consumer Watch study [6] to prevent domestic fires caused by forgetfulness. If the value of ΔT remains elevated at the end of the interval, the MGD emits a multisensory alert (audio and display) asking whether the user is still cooking. The absence of manual confirmation on the interface results in sending an emergency command via the dedicated network to the MSC-01, instructing the stepper motor to execute the immediate physical closure of the gas valve; if manual confirmation is positive, the 20-minute timer restarts.

B. Practical Testing and Validation Environment

The initial bench calibration phase was conducted at the LIHOM laboratory facilities, using a room equipped with air conditioning and exhaust ventilation. This infrastructure was essential to ensure the safety of the researchers during the handling of lighter gas, preventing risks of asphyxiation or the accumulation of flammable vapors in the room.

In the subsequent practical validation stage, the equipment was subjected to testing across multiple scenarios, including living rooms, residential kitchens, and outdoor areas. Exposure to different microclimates enabled the verification of the dynamic baseline algorithm's robustness for both sensors ($ADC_{baseline}$ e $T_{baseline}$), confirming the system's usability under background thermal fluctuations, variable humidity, and air currents characteristic of each environment.

Furthermore, the prototype returned to the controlled environment of LIHOM for the final calibration of the MQ-2 sensor. In this stage, the triggering threshold was readjusted using natural gas—the cooking fuel source effectively adopted in the project—moving beyond the preliminary testing phase with lighter gas. At this stage of development, measurements of the mechanical valve closure time (~12 s), Wi-Fi network latency, and detailed electrical consumption were not quantified by dedicated benchtop instrumentation, remaining characterized as technical metrics to be evaluated in the continuation of this work.

III. Results and Discussion

A. Sensor Validation and Performance

The development of the prototype resulted in a functional Internet of Things (IoT) system capable of continuous monitoring, issuing alerts, and automated physical intervention. To validate the effectiveness of the equipment, practical tests were conducted in controlled environments using a portable stove.

In the evaluation of the leak detection subsystem, 50 gas release simulations were conducted. In 48 of the 50 occurrences, the MQ-2 sensor demonstrated adequate sensitivity to LPG, triggering the audible alarm and activating the mechanical valve closure via stepper motor. Although the exact cause of the two residual failures has not yet been conclusively determined, hypotheses are raised for future investigation: it is hypothesized that localized, stronger air currents in the environment caused the ultra-fast dissipation of the gas flow, temporarily preventing the threshold reading ΔADC. However, it was observed that in scenarios of continuous exposure or prolonged leaks, the progressive accumulation of gas in the environment elevates the sensor reading to the triggering threshold in all situations, ensuring the system's response.

Additionally, 10 trials were conducted focusing on the identification of flames left lit due to forgetfulness. In all 10 repetitions, the LM35 sensor registered the thermal elevation characterized by the ΔT and the algorithm activated the safety protocol after 20 minutes of continuous exposure to heat. The data obtained proved that the calibration of the components and the dynamic baseline logic ensure the reliable triggering of the system's routines.

Furthermore, wireless communication between the MSC-01 and the MGD was successful across all validations, demonstrating a stable and highly secure connection for the integrated operation of the modules.

As a limitation of the current version, both devices rely on an external 12 V power supply. Thus, interruptions in the electrical power supply or installation failures temporarily disable system operation. However, it is worth highlighting the equipment's safety: if a power outage occurs while the gas valve is closed, the valve physically remains in the locked position, keeping the flow interrupted and ensuring the safety of the environment even during de-energization.

B. Assistive Interface, Connectivity, and Universal Application

The integration between the audio module (DFPlayer Mini) and the Data Management Module (MGD) established a centralized and highly intuitive communication interface, designed to serve any domestic user profile. Although the system offers assistive technology features, its application is not restricted to individuals with motor or cognitive limitations, serving as a universal residential safety solution. This demand is corroborated by research from Instituto Locomotiva (2025) [7], which indicates that 90% of Brazilians recognize a high risk of leaks or explosions when handling LPG. The ability to customize audio notifications, allowing the inclusion of recordings in familiar voices and intonation adjustment, adds value for both the general public and users with ADHD, the elderly, or individuals with memory deficits, promoting faster and more intuitive reactions in risk situations.

Simultaneously, the MGD displayed the system status clearly and objectively on the TFT display, acting redundantly with the audible alerts to reinforce the clarity of the information. Wi-Fi connectivity tests between the MSC-01, the MGD, and the central server proved the stability of real-time data exchange, ensuring reliability in command transmission and continuous monitoring.

It should be noted that, at this stage of the project, validations focused strictly on technical performance, communication stability, and the mechanical response of the actuators. Practical usability tests were not conducted with specific groups of end users (such as the elderly or individuals with cognitive deficits), so the evaluation of user experience and practical impact on these target audiences is outlined as a central proposal for future work. However, the implemented architecture demonstrates potential to ensure autonomous safety in the kitchen, mitigating the physical and psychological burden on caregivers and family members [8][9].

C. Comparative Analysis of Market, Instability, and Cost

When analyzing the gas leak safety solutions available on the market, it is noted that most commercial devices operate in a merely passive manner, limiting themselves to local audible and visual alarms. Although useful for individuals with immediate sensory and reaction capabilities, these systems fail by relying exclusively on human intervention to mitigate the hazard. In contrast, commercial systems with automatic shutoff (such as solenoid valves or block-gas devices) lack a remote and intuitive communication interface, operating without providing clear status feedback to the user and requiring invasive interventions in the residential gas and plumbing lines.

The Secure Connection System (SCS-01) stands out by integrating autonomous mechanical actuation with a dedicated Data Management Module (MGD). This centralized server combines active physical intervention (automatic shutoff) with clarity in human-machine communication through the combination of a TFT screen and voice synthesis, allowing visual and audible alerts to be positioned in any room covered by the home Wi-Fi network.

Another crucial differentiator compared to the market lies in the ease of installation. Unlike industrial solutions that require hiring specialized labor to adapt rigid gas piping, the valve integrated into the MSC-01 was designed to act directly on the flexible conduit of the residential installation (whether connected to the piped natural gas network or to an LPG cylinder). Installation occurs in a simple and non-invasive manner: the flexible gas hose is severed, and the valve coupled to the equipment's stepper motor is inserted between the two halves and secured with pressure clamps. This approach eliminates the need for masonry work or structural alterations to the property, lowering implementation costs. Figure 4 shows the connection with the equipment's valve.

From a financial perspective, the complete assembly of the two modules (MSC-01 and MGD) totaled approximately R$ 300.00 using components purchased at retail in small quantities. This value demonstrates high economic viability and market competitiveness, delivering a complete IoT solution with active shutoff, thermal/gas monitoring, and a multisensory assistive interface for a fraction of the cost of the few existing commercial alternatives. Table I displays the detailed price estimate of the devices.

IV. CONCLUSIONS

The development of the Secure Connection System (SCS-01) demonstrated promising results in controlled simulations of a low-cost residential active safety solution. Overcoming the limitations of passive commercial systems, the proposed distributed architecture (MSC-01 and MGD) stood out for its capacity for autonomous mechanical intervention, neutralizing the risk of leaks and flames left lit directly at the source. Practical validation confirmed a high efficiency rate, consolidating the equipment as a functional safety tool.

The combination of visual signaling on a TFT display and customized voice alerts acts as a crucial assistive technology resource for the elderly and individuals with ADHD or memory deficits. However, due to its easy, non-invasive installation, the system establishes itself as a universally applicable solution, capable of protecting any user profile against domestic accidents, preserving autonomy in the home, and reducing the burden on

caregivers and family members.

As stages of development and enhancement for future work, the following guidelines are established:

-Environmental Investigation and Fine Calibration: Deepen the study on the influence of airflow and wind currents on gas dissipation, adjusting the sensitivity of the algorithm to resolve the two failures observed in the tests;

-Real-World Usability Validation: Conduct field trials and user experience tests directly with the target audience (the elderly, individuals with cognitive disorders, and their caregivers) to evaluate acceptance, ergonomics, and the effectiveness of voice messages;

-Power Redundancy (Battery Backup): Incorporate an uninterruptible power supply (UPS or rechargeable battery) subsystem to supply the 12 V circuit, ensuring that monitoring and actuation routines remain active even during local power outages.

***Resumo*—A displasia espondiloepifisária tipo Kondo-Fu (SEDKF) é uma doença genética extremamente rara, caracterizada por alterações osteoarticulares que comprometem o posicionamento postural e a mobilidade, demandando tecnologias assistivas adaptadas às necessidades individuais. Este estudo teve como objetivo descrever o desenvolvimento de uma cadeira de rodas de baixo custo, adaptada para uma adolescente com SEDKF. Trata-se de um relato de caso, no qual o dispositivo foi desenvolvido a partir de avaliação fisioterapêutica, modelagem tridimensional, produção de placas de plástico reciclado obtidas de tampas plásticas, impressão 3D de componentes complementares e montagem. As dimensões da cadeira foram definidas com base nas medidas antropométricas e nas características posturais da participante, resultando em modificações estruturais voltadas ao melhor posicionamento corporal. Após o teste inicial, foram realizados ajustes para facilitar a condução do dispositivo. A cadeira apresentou peso de 4,31 kg e custo estimado de produção de R$ 226,00. Os resultados demonstram a viabilidade do desenvolvimento de uma cadeira de rodas personalizada, de baixo custo e produzida com materiais reciclados, representando uma alternativa promissora para ampliar o acesso à tecnologia assistiva para usuários com condições raras e necessidades posturais complexas.**

***Palavras-chave*—Tecnologias Assistivas; Cadeira de rodas; Doenças raras; Sustentabilidade.**

I. Introdução

A displasia espondiloepifisária tipo Kondo-Fu (SEDKF) é uma doença genética autossômica recessiva de extrema raridade, caracterizada pela presença de variantes bialélicas no gene MBTPS1, responsável por codificar a protease do sítio 1 (S1P). A deficiência dessa enzima compromete duas vias fundamentais para a formação óssea e cartilaginosa: o transporte de colágeno, levando ao acúmulo da proteína no retículo endoplasmático, resultando em apoptose dos condrócitos; e o endereçamento de enzimas digestivas (lisossomais), levando à secreção dessas proteínas para a corrente sanguínea, essas que, por sua vez, degradam a matriz óssea e cartilaginosa recém-formada [1]. Com o avanço tecnológico, somente recentemente essa condição pôde ser identificada, contando, até o momento, com apenas oito casos relatados na literatura mundial [2, 3].

Dentre as manifestações clínicas da SEDKF, destacam-se a baixa estatura com início pós-natal, cifose e/ou escoliose, deformidades torácicas como pectus carinatum e pectus excavatum, e atraso no desenvolvimento motor geral [2]. Além disso, estudos de caso evidenciaram também, alterações pélvicas importantes, como luxação de quadril com rotação externa de membro inferior e acetábulo raso [4,5]. A junção dessas características clínicas configura um conjunto de alterações posturais complexas, representando um desafio significativo para o desenvolvimento de dispositivos de tecnologia assistiva adequados para essa população.

Diante da complexidade e da gravidade dessas alterações posturais, a Organização Mundial da Saúde (OMS) estabelece diretrizes em relação ao desenvolvimento de cadeiras de rodas, visando superar a entrega de equipamentos genéricos e adotar um modelo individualizado, focado nas especificidades clínicas e ambientais de cada usuário. Para garantir que o equipamento seja realmente adequado, a OMS recomenda que se sigam quatro etapas essenciais: a avaliação, para compreender as necessidades e objetivos do usuário; a adaptação física do dispositivo, para garantir suporte postural e mobilidade ideais; o treinamento do usuário e de sua rede de apoio; e o acompanhamento a longo prazo [6]. Nesse contexto, em condições raras como a SEDKF, esse processo individualizado torna-se indispensável.

No entanto, o acesso à tecnologia assistiva adequada ainda representa um desafio significativo para grande parte da população que dela necessita, reflexo de barreiras econômicas, da oferta limitada de serviços especializados e da insuficiência de políticas públicas voltadas à provisão individualizada de TA [7]. Nesse contexto, o desenvolvimento de soluções de baixo custo emerge como uma alternativa viável e necessária. A cadeira desenvolvida no presente trabalho utiliza placas produzidas a partir de tampas de garrafas plásticas recicladas como material estrutural. Essa abordagem converge com os Objetivos de Desenvolvimento Sustentável da ONU [8], particularmente com o ODS 3 (saúde e bem-estar), o ODS 10 (redução das desigualdades) e o ODS 12 (consumo e produção responsáveis), ao propor uma solução que é, ao mesmo tempo, clínica, social e ambiental.

Diante deste contexto, o presente artigo tem como objetivo descrever o processo de adaptação de uma cadeira de rodas de baixo custo, produzida com materiais reciclados, de acordo com as especificidades posturais de uma adolescente com displasia espondiloepifisária tipo Kondo-Fu, visando proporcionar mobilidade, qualidade de vida e participação social.

II. Metodologia

Trata-se de um estudo descritivo, do tipo relato de caso, conduzido no Laboratório de Estudos Inventivos em Tecnologia Assistiva (Lab. E.I.T.A.), da Universidade Federal de Goiás (UFG), no âmbito de um projeto de desenvolvimento de cadeiras de rodas produzidas a partir de tampas de garrafas plásticas recicladas, sob aprovação do Comitê de Ética em Pesquisa da UFG (N° 7.688.714), com obtenção do Termo de Consentimento Livre Esclarecido, assinado pela responsável, bem como o Termo de Consentimento de Uso de Imagem, e o Termo de Assentimento Livre e Esclarecido (lúdico) assinado pela participante. Nesse sentido, o presente trabalho descreve o processo de adaptação desse dispositivo para as especificidades clínicas de uma adolescente com displasia espondiloepifisária do tipo Kondo-Fu. O processo de desenvolvimento foi organizado em cinco etapas: avaliação fisioterapêutica; modelagem 3D; produção de placas a partir de material reciclado; impressão de componentes 3D; montagem do dispositivo.

Durante a avaliação fisioterapêutica, foram coletados dados referentes ao perfil clínico e funcional da participante, uma adolescente do sexo feminino, com 15 anos de idade, diagnosticada com displasia espondiloepifisária tipo Kondo-Fu. Observou-se hipotonia de tronco, de membros superiores e de membros inferiores, além de baixa estatura, escoliose acentuada e luxação de quadril, com manutenção dos membros inferiores em padrão de abdução e rotação externa. Em decúbito dorsal, a participante não apresentou alinhamento da cabeça em linha média, embora fosse capaz de levar as mãos em linha média e alcançar objetos, e a flexão de membros inferiores e membros superiores apresentou resistência superável. Na posição sentada, observou-se controle de tronco e de cabeça e capacidade de alcançar objetos. Não apresentou capacidade de se manter em ortostatismo de maneira independente e deambulação, sendo dependente para locomoção, realizada por meio de um carrinho de bebê adaptado. A comunicação verbal e cognição demonstraram-se preservadas. Complementarmente, foram coletadas as seguintes medidas antropométricas na posição sentada: distância entre ombros, largura do tronco, altura do tronco, largura do quadril, comprimento da coxa e comprimento da perna.

Com base nas medidas antropométricas coletadas, iniciou-se o processo de modelagem tridimensional do dispositivo no software Fusion 360. O modelo foi inspirado na GoBro (Fig. 1), uma cadeira desenvolvida para crianças com espinha bífida, comercialmente disponível nos Estados Unidos [9]. Entretanto, sua estrutura foi consideravelmente redesenhada (Fig. 2), uma vez que o uso da cadeira de referência requer a manutenção do joelho em flexão, posicionamento inviável para a participante que mantém os membros inferiores predominantemente estendidos, em razão da luxação de quadril. A transição entre o assento e o apoio para os membros inferiores, antes marcada por um desnível acentuado, foi suavizada, o apoio abdutor foi ampliado e adotou-se um design mais curvilíneo, com bordas arredondadas. Todas essas alterações foram realizadas com o intuito de acomodar a postura natural da participante, caracterizada por quadris em abdução, rotação externa e extensão de joelho.

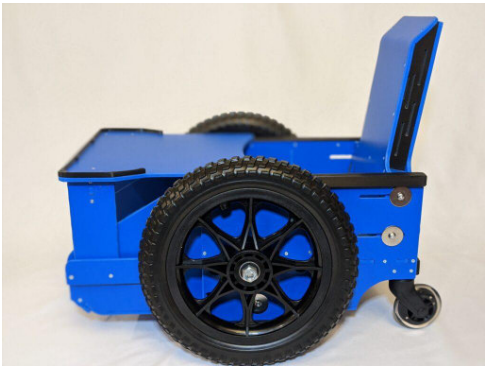

Fig. 1. Cadeira de rodas para Espinha Bífida

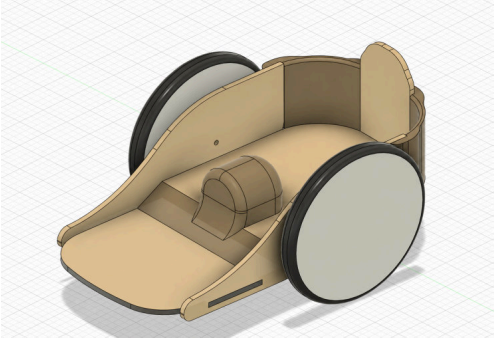

Fig. 2. Modelo 3D da cadeira de rodas desenvolvida

Após o processo de modelagem 3D, iniciou-se a produção dos componentes da cadeira de rodas. As principais estruturas foram produzidas a partir de placas de plástico confeccionadas com tampas de garrafas plásticas (Polietileno de Alta Densidade e Polipropileno). Inicialmente, as tampas passaram por um processo de separação por cores, seguida de dupla trituração em uma trituradora de 3kW em velocidade de 6.000 rpm. Após isso, o material triturado foi submetido a uma prensa térmica a 265 °C por 60 minutos, após o resfriamento durante 40 minutos, em temperatura ambiente, para a obtenção de placas plásticas que foram cortadas posteriormente por uma Fresadora CNC 3 eixos, resultando nas peças estruturais da cadeira. Complementarmente, o apoio abdutor e o encosto posterior foram produzidos por meio de impressão 3D com filamento PETG, na cor vermelha, utilizando a impressora Creality Ender-5 Max.

Com todos os componentes finalizados, foi realizada a montagem da cadeira de rodas. As peças estruturais de plástico reciclado e a impressão 3D foram unidas por meio de encaixe, parafusos e grampos quentes. Foram utilizadas rodas de EVA de bicicleta infantil, comercialmente disponíveis, e reaproveitadas de projetos anteriores do laboratório. Por fim, foram instalados rodízios giratórios tanto anteriormente quanto posteriormente, o que concluiu a montagem do dispositivo.

III. Resultados

O processo resultou em uma cadeira de rodas personalizada, de baixo custo, produzida com placas de plástico reciclado e impressão 3D (Fig. 3). As dimensões do dispositivo foram baseadas nas medidas antropométricas da participante, norteando o tamanho dos principais componentes, incluindo o encosto, o assento, o apoio para as pernas e o apoio abdutor. As medidas antropométricas utilizadas no desenvolvimento do dispositivo, obtidas durante a avaliação fisioterapêutica, são apresentadas na Tabela I.

Fig. 3. Cadeira de rodas adaptada montada.

Tabela I
Medidas Antropométricas

Medidas Antropométricas	Valores (Centímetros)
Largura dos ombros - Distâncias entre os pontos laterais mais externos dos ombros	31
Largura do tronco - Distância entre os pontos laterais do tronco ao nível da axila.	28
Largura do quadril - Distância entre os pontos laterais mais externos dos quadris.	22
Comprimento da perna - Distância da base do calçado até a fossa poplítea.	43
Comprimento da coxa - Distância da fossa poplítea até o ponto mais posterior do quadril	21,5
Altura do tronco - Distância da base do assento até o topo do ombro	26

No processo de produção das cadeiras de rodas convencionais no laboratório, utiliza-se aproximadamente 4.000 tampas plásticas. Já na produção da cadeira adaptada para SEDKF, aproximadamente 3.000 tampas plásticas foram utilizadas, cerca de 75% dessa quantidade padrão. Considerando essa proporção, estima-se que tenha levado 1h30min no processo de trituração e 2h15min na prensagem, resultando em aproximadamente 2 placas de 625x445x9 milímetros. Posteriormente, o processo de fresagem ocorreu em cerca de 25 minutos, e resultou em cinco peças estruturais.

A impressão das peças complementares em 3D, o apoio abdutor e o encosto posterior, durou 14 horas, e consumiu 780 gramas de material. Com os componentes finalizados, a montagem do dispositivo foi realizada e durou cerca de 40 minutos. Somando-se as etapas de produção das placas, impressão 3D e montagem, estima-se que o tempo total para a produção da cadeira de rodas foi cerca de 19 horas, resultando em um dispositivo com peso final de 4,31 quilogramas.

O custo dos componentes considerados no processo foi estimado em aproximadamente R$ 226,00. Foram contabilizadas as médias dos valores de mercado dos principais componentes utilizados em sua fabricação,

incluindo o filamento PETG (R$ 86,00), as rodas de EVA (R$ 120,00) e dois rodízios giratórios com trava (R$ 20,00). As placas produzidas a partir de tampas plásticas não foram contabilizadas, uma vez que a matéria-prima foi obtida via doação. Da mesma forma, os custos operacionais, como energia elétrica e equipamentos, não foram mensurados neste estudo.

Após ser finalizado, o dispositivo foi submetido a um teste, visando compreender se estava adequado para a participante e identificar possíveis ajustes (Fig. 4). Durante o teste, a equipe observou certa dificuldade na propulsão da cadeira de rodas, com cansaço e alteração no padrão respiratório. A partir dessa observação, foi instalado um rolamento (modelo ZZ809) no eixo das rodas, com o objetivo de facilitar a propulsão. Adicionalmente, foi implementado um acabamento por impressão 3D na extremidade pontiaguda do eixo da roda, visando maior segurança, e foi adicionada uma almofada ao assento para maior conforto. Após essas adaptações (Fig. 5), a cadeira de rodas foi entregue à participante. No entanto, não foi possível a realização de um novo teste formal após as modificações, de modo que os efeitos das adaptações sobre o esforço de propulsão e o conforto ainda não foram verificados, sendo prevista a avaliação desses pontos em etapas futuras do projeto.

Fig. 4. Teste da cadeira de rodas pela usuária

Fig. 5. Cadeira de rodas finalizada.

IV. Discussão

A displasia espondiloepifisária tipo Kondo-Fu é uma condição extremamente rara, com poucos casos descritos na literatura, o que representa uma lacuna de evidências sobre o desenvolvimento de tecnologias assistivas específicas para essa população. Dessa forma, o desenvolvimento de dispositivos individualizados torna-se uma estratégia importante para atender às necessidades funcionais de usuários com condições pouco frequentes e também para ampliar o conhecimento disponível sobre tecnologias assistivas aplicadas a doenças raras.

O design do dispositivo converge com princípios biomecânicos descritos na literatura, que descrevem a acomodação adequada dos membros inferiores como fundamental para o posicionamento da pelve, e essa, por sua vez, como base para o alinhamento do tronco na postura sentada [10]. Dessa forma, a ampliação do apoio abdutor e o redesenho da região entre o assento e o apoio para os membros inferiores buscaram acomodar a postura espontânea da participante, sem restringi-la a um posicionamento incompatível com suas características posturais. Além disso, o desenvolvimento foi conduzido de maneira individualizada, seguindo os princípios recomendados pelas Diretrizes para Provisão de Cadeiras de Rodas da OMS [6], que destaca a etapa de adaptação do equipamento de acordo com as necessidades do usuário. Nesse sentido, após o teste, foram adicionados rolamentos às rodas das cadeiras com o objetivo de facilitar a sua condução.

O custo estimado para a produção desse dispositivo foi de R$ 226,00. Em comparação, a cadeira utilizada como referência inicial, é comercializada por US$ 250 (R$ 1.272,50) [9], valor cerca de 82% superior ao custo estimado da solução desenvolvida. Além do baixo custo, o dispositivo incorpora princípios da economia circular ao utilizar placas produzidas a partir de material reciclado, as quais, ao final de sua vida útil, podem ser reprocessadas e reutilizadas no ciclo de produção, reduzindo a produção de resíduos e a demanda por matéria-prima.

A promoção da mobilidade, da participação social e da autonomia representa um dos principais objetivos da provisão de cadeiras de rodas [6], sendo influenciados por fatores relacionados ao ambiente, ao dispositivo e às características do usuário [11]. Nesse sentido, durante o teste, a responsável relatou informalmente a expectativa de que o dispositivo ampliasse a independência da participante para deslocamentos em sua residência, ilustrando o potencial impacto funcional esperado com o uso da cadeira. Trata-se, contudo, de uma observação preliminar, cuja validação depende de avaliação em futuras etapas do projeto.

Por se tratar de um relato do processo de desenvolvimento de um dispositivo individualizado para uma condição extremamente rara, com apenas oito casos descritos na

literatura mundial [2, 3], o trabalho teve como foco a descrição das etapas de desenvolvimento e adaptação do dispositivo, não estando entre seus objetivos a avaliação formal de aspectos como desempenho, conforto ou segurança. No entanto, uma limitação importante observada foi a ausência de um novo teste após a adição dos rolamentos e de outros ajustes complementares, impedindo verificar a efetividade dessas modificações. Como próximas etapas do projeto, será realizado o acompanhamento da utilização da cadeira, e após 3 meses uma reavaliação fisioterapêutica e aplicação do questionário *Quebec User Evaluation of Satisfaction with Assistive Technology - QUEST 2.0* (B-QUEST), para compreender o nível de satisfação da usuária e sua família em relação ao dispositivo.

V. Conclusão

O presente trabalho demonstrou a viabilidade de desenvolver uma cadeira de rodas adaptada às necessidades posturais de uma adolescente com displasia espondiloepifisária tipo Kondo-Fu, através de um processo individualizado de avaliação, modelagem, produção e ajustes finais. O dispositivo apresentou baixo custo de produção, peso reduzido e incorporação de princípios da economia circular, além de compatibilidade com as medidas antropométricas da participante e adaptações voltadas ao posicionamento corporal e facilitação da propulsão da cadeira. Contribuindo para ampliar o acesso a soluções de baixo custo para usuários com condições raras e características posturais complexas. Ressalta-se, contudo, que os resultados apresentados são preliminares, sendo necessário o acompanhamento a longo prazo da usuária para avaliar a efetividade e a satisfação em relação ao dispositivo, etapas já previstas nas próximas fases do projeto.

***Abstract*—** A amputação consiste na remoção parcial ou total de um membro, gerando um impacto profundo nas atividades diárias do indivíduo. Quando ocorre no membro inferior, como no nível transfemoral, afeta diretamente a locomoção. O objetivo deste estudo foi desenvolver, por meio de manufatura aditiva (MA), um protótipo em escala reduzida de encaixe protético transfemoral, visando estruturar e documentar um fluxo de trabalho digital para viabilizar e fundamentar investigações científicas futuras na área. Trata-se de um estudo de desenvolvimento tecnológico no qual foram realizados o escaneamento de um molde positivo em gesso, a modelagem tridimensional e a impressão 3D do dispositivo. O fluxo digital e a MA demonstraram potencial promissor como estimativa preliminar de insumos de fabricação. O coto impresso ajustou-se geometricamente ao encaixe protético em escala reduzida (60%), sendo possível realizar uma verificação preliminar da correspondência dimensional e geométrica entre o modelo digital e o protótipo impresso, demonstrando adequada reprodução da geometria planejada. dispositivo. Conclui-se que a metodologia proposta apresenta um fluxo digital bem fundamentado e potencial viabilidade técnica e econômica para o desenvolvimento de tecnologias assistivas, embora ensaios mecânicos e testes clínicos futuros sejam indispensáveis para sua validação definitiva

Palavras-chave: manufatura aditiva; impressão 3D; amputação; tecnologia assistiva; prótese transfemoral.

I. INTRODUÇÃO

A amputação consiste na remoção parcial ou total de um membro [1]. Quando ocorre em membros inferiores gera um impacto profundo nas atividades diárias do indivíduo, afetando a locomoção e, consequentemente, sua qualidade de vida e participação [2]. No caso de uma amputação transfemoral caracterizada pela retirada do membro entre as articulações do joelho e do quadril, são acarretadas diversas alterações nos padrões posturais e de marcha [3] .

De acordo com o DATASUS nos primeiros meses de 2026 (jan-abr) já foram 10.699 amputações/desarticulações de membros inferiores, resultando em uma média de 2.674 ocorrências por mês [4]. A imobilidade decorrente da amputação, pode desencadear prováveis intercorrências, como, edemas, contraturas, dores, entre outras [5].

Nesse cenário, faz-se necessária a adoção de tecnologia assistiva (TA), definida como qualquer dispositivo ou equipamento que promova autonomia e qualidade de vida ao indivíduo [5]. A deambulação precoce, posteriormente à amputação, proporciona diversos benefícios, que impactam significativamente nos resultados funcionais, pois preserva os reflexos posturais e contribui para a saúde mental do indivíduo, favorecendo a adesão à prótese, a qual é considerada uma TA [6].

Em uma revisão sistemática, cujo objetivo foi avaliar a qualidade de vida de indivíduos submetidos à amputação de membro inferior decorrente de doença arterial obstrutiva periférica, constatou-se, em 12 estudos, que a deambulação com prótese foi o fator mais significativo e de maior impacto no bem-estar dos usuários [7].

A eficácia de uma prótese depende primordialmente da qualidade da interface entre o membro residual, comumente designado “coto” e o componente artificial [8]. O encaixe, por adaptar-se anatomicamente ao coto, é o fator preponderante que determina tanto o conforto do paciente quanto a sua capacidade de controle biomecânico sobre o dispositivo [8]. Sob esse viés, o encaixe deve proporcionar uma aderência segura ao coto, promovendo maior conforto e contribuindo para a biomecânica do movimento, viabilizando o controle da prótese pelo movimento do coto [8].

No âmbito biomédico, geralmente, demandam-se produtos personalizados e específicos para cada paciente.No que tange à produção do encaixe protético, novas técnicas têm surgido, como a manufatura aditiva (MA), também conhecida como impressão 3D que além de atender essa demanda, possibilita a redução de custos, impressão de estruturas complexas e maior liberdade de design [9].

O emprego de técnicas avançadas de MA na confecção de próteses viabiliza um desenvolvimento centrado no usuário. Essa abordagem atende às suas demandas de forma personalizada, o que favorece um melhor ajuste anatômico que propicia a reabilitação funcional da marcha [10].

Sob essa perspectiva, o objetivo deste estudo foi desenvolver, por meio de manufatura aditiva, um protótipo em

escala reduzida de encaixe protético transfemoral, visando estruturar e documentar um fluxo de trabalho digital para viabilizar e fundamentar investigações científicas futuras na área. Embora diversos estudos tenham demonstrado a aplicabilidade da manufatura aditiva na fabricação de componentes protéticos, ainda são escassos os trabalhos que descrevem de forma sistemática um fluxo digital completo para o desenvolvimento de encaixes transfemorais personalizados.

II. METODOLOGIA

Trata-se de um estudo de desenvolvimento tecnológico, conduzido segundo um fluxo digital integrado, composto pelas etapas de aquisição tridimensional da geometria do coto e modelagem, manufatura aditiva e verificação preliminar da correspondência geométrica entre o modelo virtual e o protótipo físico em escala reduzida. O estudo foi desenvolvido no laboratório de Estudos Inventivos em Tecnologia Assistiva (Lab. EITA) da Universidade Federal de Goiás (UFG). O processo de desenvolvimento iniciou-se com uma visita técnica à oficina ortopédica de um Centro Especializado em Reabilitação (CER), na qual realizou-se o escaneamento de um molde em gesso de um coto transfemoral. O modelo de gesso utilizado não estava com identificação e seria encaminhado para descarte. Para a digitalização utilizou-se o scanner portátil 3D, modelo EinScan PRO 2X Plus, apresentando precisão dimensional nominal de **±0,05 mm**. Os dados gerados da malha no aplicativo *Revopoint* foram importados para o *software* Autodesk Fusion 360, onde se realizou a modelagem tridimensional. No software CAD, foram aplicadas modificações geométricas diretas sobre a malha digitalizada, conformação da borda póstero-medial para apoio isquiático e definição da espessura nominal da parede em 2,0 mm.

Posteriormente a essa etapa, aplicou-se um fator de escala 0,60 (60% do tamanho real) aos arquivos digitais do encaixe protético e do coto para adequação ao volume de impressão e realização de ensaios preliminares de ajuste geométrico. Os arquivos finais foram exportados no formato STL para o software de fatiador *Creality Print* e processados para a impressora 3D de modelagem por deposição fundida (FDM) Creality Ender-5 Max. Para a impressão do encaixe e coto utilizou-se o filamento Poli Tereftalato de Etileno Glicol (PETG) natural e o ácido poliláctico (PLA) cinza, respectivamente. Ademais, utilizou-se o ferro de solda para abertura de um círculo com diâmetro reduzido, proporcional a escala 60% simulando o local correspondente às válvulas de vácuo convencionais.

Os parâmetros de impressão e especificações operacionais do processo estão detalhados na Tabela 1.

TABELA I
Parâmetros de impressão 3D e caracterização da manufatura dos protótipos

Parâmetros	Encaixe protético	Modelo de coto
Material	PETG (natural)	PLA (cinza)
Preenchimento	100%	15%
Espessura da Camada	0,2 mm	0,2 mm
Temperatura do Bico	240 °C	210 °C
Temp. Mesa Impressão	70 °C	60 °C
Diâmetro do Bico	0,8 mm	0,8 mm
Padrão de preenchimento	Linhas/perímetros concêntricos	Giroide
Massa do modelo	25.6g	72.3g
Tempo total impressão	4h10min	2h 40min

III. RESULTADOS

Durante a visita técnica, identificou-se que o desenvolvimento do encaixe protético transfemoral, seguindo o método tradicional, demanda diversas etapas. O processo compreende a confecção do molde negativo, a obtenção do molde positivo em gesso, o aprimoramento da superfície, a moldagem do encaixe de teste para a primeira prova, na qual são verificados os pontos de pressão, seguida pela laminação e pelo acabamento.

O escaneamento foi efetuado de forma eficiente por meio da conexão do scanner ao aplicativo no smartphone. O processo demandou aproximadamente 3 minutos, visto que foi realizado diretamente no molde estático, facilitando a captura da imagem e a obtenção de uma digitalização precisa (Fig. 1).

Fig. 1- Modelo tridimensional do coto transfemoral digitalizado

Na etapa de modelagem tridimensional, realizada no software Fusion 360, a malha gerada a partir da conversão do

molde importado serviu de base para o design do encaixe de contenção isquiática. A borda póstero-medial superior recebeu um leve achatamento para atuar como o apoio do ísquio, otimizando a distribuição da descarga de peso corporal. A lateral externa, por sua vez, foi alongada a fim de proporcionar maior estabilidade ao fêmur (Fig. 2).

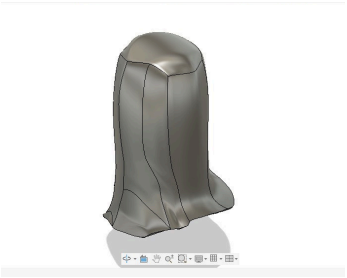

Fig. 2 - Modelagem tridimensional CAD do encaixe

A fabricação do modelo de coto por impressão tridimensional em PLA, um termoplástico biodegradável de alta rigidez, foi essencial para viabilizar os testes de acoplamento geométrico com o encaixe. Destaca-se que a confecção deste modelo se limitou a essa finalidade de validação do fluxo, contudo, caso o encaixe tivesse sido impresso em escala real, tais testes poderiam ter sido realizados diretamente no coto do próprio indivíduo (Fig. 3).

Fig. 3- Modelo do coto transfemoral impresso em 3D

Como resultado do processo de manufatura aditiva, o encaixe protético impresso com espessura de 2mm em PETG natural apresentou acabamento superficial adequado e manteve a transparência, que é uma característica do polímero (Fig. 4a e Fig. 4b). Contudo, a região de apoio isquiático recebeu um menor número de camadas de deposição devido à curvatura da borda. Em escala real, essa variação pode configurar um ponto de fragilidade estrutural, comprometendo a resistência exigida para essa área de alta descarga de peso.

Fig. 4 - Encaixe protético impresso: (a) vista anterior e (b) vista posterior.

No que tange ao acabamento pós-impressão, a confecção da abertura circular para a instalação da válvula de vácuo com ferro de solda mostrou-se um método eficiente e de fácil execução. Vale destacar que o calor aplicado promove a fusão do polímero e o surgimento de rebarbas, sendo necessário a utilização de um micro retífica para um acabamento superficial liso. Contudo, como o protótipo foi fabricado em escala reduzida de 60%, o diâmetro do furo foi reduzido proporcionalmente, o que impediu a realização de testes físicos de acoplamento com a válvula convencional de tamanho padrão (40 mm) (Fig. 5).

Fig. 5- Abertura para simulação de acoplamento da válvula pós-acabamento.

O coto ajustou-se geometricamente ao encaixe protético. A partir desses resultados, foi possível realizar a verificação dimensional e geométrica preliminar do dispositivo. Esse processo focou na avaliação volumétrica e das superfícies,

garantindo que as proporções geradas no software fossem reproduzidas fielmente no modelo físico antes da realização de testes de resistência estrutural. (Fig. 6a e Fig. 6b).

Fig.6- Acoplamento geométrico entre coto e encaixe: (a) vista anterior e (b) vista posterior

Por fim, o custo de fabricação do protótipo do encaixe em escala reduzida, considerando-se apenas os insumos de consumo direto, foi de aproximadamente R$9,00 referentes ao filamento. Ao projetar essa estimativa para o encaixe em tamanho real (escala 100%) o custo de insumos ficaria em torno de R$24,65. Ressalta-se que tais valores correspondem exclusivamente aos custos diretos de matéria-prima (filamento), excluindo outros custos como, consumo de energia elétrica, tempo de máquina, pós-processamento e mão de obra. Portanto, trata-se de estimativas parciais que não representam o custo final de produção comercial.

IV. DISCUSSÃO

No cenário da saúde pública brasileira, o Sistema Único de Saúde (SUS) desempenha um papel fundamental na reabilitação de amputados. Contudo, manter os custos desse atendimento é um desafio constante. Segundo o Sistema de Gerenciamento da Tabela de Procedimentos, Medicamentos e OPM do SUS (SIGTAP), o custo do serviço ambulatorial (SA) que engloba materiais e insumos para realizar a substituição de um encaixe protético transfemoral convencional é de R$ 1.098,00. A comparação simplificada de custos diretos não estabelece a viabilidade econômica, visto que se deve incorporar outros custos.

Ao comparar o método convencional de confecção com o fluxo digital por MA, as discrepâncias práticas são evidentes. O processo tradicional exige várias etapas manuais, como tirar o molde em gesso no paciente, fazer o modelo positivo e realizar o acabamento manual, o que gera desperdício de material e consome muito tempo. Por outro lado, a manufatura aditiva facilita esse processo. A partir do escaneamento em 3D, que não provoca incômodos ao paciente, pode-se modelar o molde diretamente por meio do software tridimensional. Assim, elimina-se a necessidade dos moldes físicos e diminui o desperdício de materiais, confirmando as afirmações sobre a redução de custos e a eficiência da manufatura aditiva [9].

Além de economizar materiais, esse novo método traz mais praticidade para o acompanhamento do paciente. Na produção convencional, os moldes de gesso são descartados após a fabricação da prótese. Com isso, se o encaixe vier a quebrar, por exemplo, todo o processo de moldagem precisará ser refeito. Já com o processo de digitalização, o arquivo digital pode ser armazenado, tornando possível novas alterações, que conforme a necessidade, poderão ser feitas sem um novo processo de escaneamento.

Salienta-se que o uso dessas novas tecnologias não substitui o trabalho dos técnicos ortopédicos e demais profissionais das oficinas de reabilitação. Esses profissionais possuem uma experiência prática e detém um conhecimento clínico biomecânico essencial para alinhamento, alívio de pressões e ajustes. Portanto, o escaneamento e a impressão 3D devem ser compreendidos como ferramentas de apoio técnico para agregar e facilitar o trabalho desses especialistas.

Contudo, este estudo apresenta limitações que devem ser consideradas. Por tratar-se de um desenvolvimento de protótipo, não foi possível realizar testes de resistência mecânica, ensaios de durabilidade do material a longo prazo ou testes clínicos com pacientes. Destaca-se que a correspondência geométrica observada em um modelo reduzido não permite prever os referidos pontos em escala real. As verificações desses pontos são fundamentais para garantir a segurança e a durabilidade do encaixe antes do uso prático.

V. CONCLUSÃO

O presente estudo estruturou e documentou um fluxo de trabalho digital integrado para o desenvolvimento de um protótipo de encaixe protético transfemoral em escala reduzida, demonstrando a viabilidade técnica da aquisição tridimensional, da modelagem CAD e da manufatura aditiva por FDM para reprodução da geometria planejada.

As análises de custo e tempo apresentadas devem ser interpretadas como estimativas preliminares de insumos e operação de bancada, visto que análises econômicas completas necessitam incorporar despesas de mão de obra, depreciação de equipamentos e pós-processamento.

A contribuição central deste trabalho consiste na disponibilização de um protocolo digital documentado que viabiliza e fundamenta investigações científicas posteriores. As conclusões deste estudo limitam-se estritamente à fabricação e verificação geométrica bem-sucedida em escala reduzida.

Portanto, embora os resultados preliminares sejam promissores, a validação definitiva desta tecnologia para o uso clínico, depende de investigações futuras dedicadas a testes mecânicos de resistência do material e durabilidade, além de avaliações de marcha com indivíduos amputados e ensaios clínicos para identificar os ajustes que precisam ser realizados e validar o produto desenvolvido.

AGRADECIMENTOS

Agradecemos o apoio institucional da Universidade Federal de Goiás (UFG), bem como o incentivo financeiro à pesquisa concedido pelo Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) e o Ministério da Ciência, Tecnologia e Inovação (MCTI).

***Resumo*—A deficiência motora afeta 14,4 milhões de brasileiros (7,3% da população), sendo que 5,2 milhões apresentam dificuldade permanente de mobilidade nos membros inferiores, segundo o Censo Demográfico 2022 do IBGE. As amputações de membro inferior representam uma condição de elevada carga clínica e social no Sistema Único de Saúde (SUS). Embora a captura de movimento sem marcadores, as arquiteturas de rede com computação de borda e os ambientes de realidade virtual (RV) para reabilitação motora tenham demonstrado viabilidade clínica individualmente, sua integração em um sistema de telessáude em tempo real permanece uma lacuna não resolvida na literatura. Este artigo apresenta uma revisão do estado da arte sobre a integração desses três campos tecnológicos aplicados ao diagnóstico remoto de marcha e à reabilitação. Conduzida nas bases Scopus e IEEE Xplore (2018–2025), a revisão resultou em um corpus de 442 documentos; 33 foram selecionados para leitura completa, dos quais 23 artigos temáticos compõem a síntese narrativa do estado da arte, complementados por 10 fontes epidemiológicas, regulatórias e fundamentais. A análise bibliométrica pelo algoritmo Louvain gerou duas comunidades no corpus analisado; a inspeção manual dos nós identificou três grupos temáticos, análise de marcha e biomecânica, computação de borda, e realidade virtual e telerreabilitação. As conexões de co-ocorrência entre os grupos de análise de marcha e de computação de borda são esparsas e de peso mínimo, o que sugere que a integração entre esses campos permanece pouco explorada. A consulta dirigida a sistemas integrados foi replicada em quatro bases, Scopus, IEEE Xplore, PubMed e Web of Science, não retornando nenhum sistema integrado em qualquer delas; a triagem em nível de conteúdo dos registros biomédicos também não identificou estudo combinando os três campos. Esses achados indicam uma direção de pesquisa promissora para o desenvolvimento de sistemas integrados de reabilitação remota no contexto do SUS.**

***Palavras-chave*—análise de marcha sem marcadores, computação de borda, realidade virtual, telerreabilitação, telessáude**

***Abstract*— Motor disability affects 14.4 million Brazilians (7.3% of the population), of whom 5.2 million have a permanent difficulty with lower limb mobility, according to the 2022 IBGE Demographic Census. Lower limb amputations represent a significant clinical and social burden within the Unified Health System (Sistema Único de Saúde, SUS). Although markerless motion capture, edge computing network architectures, and virtual reality (VR) environments for motor rehabilitation have each demonstrated clinical feasibility in isolation, their integration into a single real-time telehealth system remains an unresolved gap in the literature. This paper presents a state-of-the-art review on the integration of these three technological fields applied to remote gait diagnosis and rehabilitation. A narrative review was conducted using the Scopus and IEEE Xplore databases (2018–2025). After deduplication, the final corpus comprised 442 documents from 330 sources; 33 articles were selected for full reading, of which 23 thematic articles compose the narrative synthesis, complemented by 10 epidemiological, regulatory, and foundational sources. Bibliometric analysis using the Louvain algorithm produced two communities in the analysed corpus; manual node-level inspection identified three thematic groups, gait analysis and biomechanics, edge computing, and virtual reality and telerehabilitation. Co-occurrence links between the gait analysis and edge computing groups are sparse and of minimal weight, suggesting that their integration remains underexplored. The query targeting integrated systems was replicated across four databases, Scopus, IEEE Xplore, PubMed, and Web of Science,**

returning no integrated system in any of them; content-level screening of the biomedical records likewise identified no study combining the three fields. These findings point to a promising research direction for the development of integrated remote rehabilitation systems within the SUS context.

***Index Terms*—markerless gait analysis, edge computing, virtual reality, telerehabilitation, telehealth**

I. Introduction

Motor disability affects 14.4 million Brazilians (7.3% of the population), of whom 5.2 million have a permanent difficulty in lower limb mobility, according to the 2022 IBGE Demographic Census [1]. Motor rehabilitation of a person with lower limb amputation represents a clinical and logistical challenge of great relevance to the Unified Health System (*Sistema Único de Saúde*, SUS). Between 2018 and 2025, the public health system recorded 300,825 amputation procedures, with hospital costs exceeding 619 million Brazilian Reais [2]. The predominant causes (diabetes mellitus, peripheral vascular diseases, and trauma) are concentrated in vulnerable populations in regions far from rehabilitation reference centres [1], [2]. The phenomenon known as *ambulancioterapia* (long-distance patient transport to access specialised care) illustrates this problem: patients from inland municipalities must travel long distances to access specialised gait diagnosis, generating system costs and treatment adherence barriers [3], [4].

In this context, telehealth has emerged as a response to this challenge, enabling remote delivery of specialized healthcare services through information and communication technologies. In the field of gait analysis, three technological domains have shown significant and independent advances: markerless motion capture systems based on computer vision, edge computing architectures for real-time data processing and transmission, and virtual reality environments for remote motor assessment and rehabilitation. Each of these domains has demonstrated clinical and technical maturity in isolated studies. However, to the best of our knowledge, the integration of these three technologies into a unified real-time system compliant with the Brazilian General Data Protection Law (LGPD) and applicable to the Brazilian Unified Health System (SUS) has not been reported in the scientific literature, despite recent efforts to develop edge-based systems for healthcare [5]. The development of such a system is aligned with global priorities for universal health coverage, as rehabilitation is recognized as an essential component of integrated healthcare services, requiring coordinated efforts to scale up high-quality care and improve equitable access, in line with the United Nations Sustainable Development Goal 3 [6].

In this way, this paper proposes a bibliometric and narrative review focusing on the integration of these technological fields: markerless gait analysis, virtual reality for healthcare, and telehealth. Although the SUS already operates a national telehealth programme [7], the real-time transmission of kinematic data and LGPD compliance remain critical pre-conditions for reliable edge deployment in this context. Existing reviews address each of these fields in isolation, covering markerless motion analysis [8], [9], edge architectures for healthcare [10], and home-based rehabilitation technologies [11]. The objective of this work is to characterise, through bibliometric mapping and narrative synthesis, the degree of integration among these three fields in the literature, identifying whether systems combining them into a single telehealth pipeline have been reported.

II. Background

A. Lower Limb Amputation and Clinical Gait Analysis

Lower limb amputation is a highly prevalent condition in Brazil, concentrated in populations with reduced access to specialised care [1]. Between 2008 and 2015, the SUS recorded 361,585 amputation procedures [3], complementing the more recent hospital-cost figures reported in Section I [2].

Amputation causes significant biomechanical alterations in gait, including step length asymmetry, excessive heel elevation, foot circumduction, and compensatory postural deviations [12]. Quantitative gait assessment enables measurement of kinematic and spatiotemporal parameters such as velocity, cadence, step length and width, and joint angles, providing objective support for clinical diagnosis [8]. Reference commercial systems, based on reflective markers and infrared cameras, offer high accuracy but are costly, operationally complex, and incompatible with primary care and telehealth environments [8].

B. Markerless Motion Capture and Human Pose Estimation

OpenPose, introduced by Cao et al. [13], was the first open-source system capable of detecting multiple joint keypoints in real time from RGB images, using deep convolutional neural networks and part affinity fields. The Three-dimensional reconstruction of the virtual skeleton from multiple calibrated cameras through multiview geometry allowed the estimation of kinematic parameters without patient contact [14]. More recent approaches expand on this foundation: MediaPipe Pose employs a lightweight neural architecture achieving real-time inference at over 30 fps on mobile hardware, while RTMPose proposes optimised architectures for improved accuracy under partial occlusion [15]. The BODY_25 model of OpenPose defines 25 joint keypoints in three-dimensional coordinates, a configuration adopted in intelligent-space markerless capture setups reported in the literature [16].

C. Telerehabilitation and the SUS Context

Telerehabilitation is defined as the remote delivery of rehabilitation services through information and communication technologies. In the Brazilian context, telehealth emerges as a response to the phenomenon of *ambulancioterapia* [7]. One example is the Espírito Santo Physical Rehabilitation Centre (*Centro de Reabilitação Física do Espírito Santo*, CREFES), located in the metropolitan area, which receives patients from municipalities outside the metropolitan area. This geographic concentration creates transportation and access barriers for patients living outside the metropolitan area, issues that could often be avoided through remote care via a telehealth system.

However, even with a national telehealth programme in operation [7], the real-time transmission of kinematic data, LGPD compliance, and integration with existing clinical platforms remain open requirements for edge deployment [10].

III. Methodology

This work adopts a narrative state-of-the-art review approach, guided by the following research question: *which real-time data transmission architectures enable the integration of markerless gait analysis systems with virtual reality diagnostic environments in the context of telehealth?*

The search was conducted between April and May 2026 in the IEEE Xplore and Scopus databases, covering publications from 2018 to 2025, restricted to articles, conference papers, and reviews in Computer Science and Biomedical Engineering. Although other important databases exist, these two were chosen due to the technological nature of the research. Search fields were title, abstract, and author keywords; no language restriction was applied. Seminal foundational works published before 2018 were additionally included when they provided essential technical or conceptual grounding for one of the thematic blocks; this inclusion is stated explicitly to distinguish the systematic corpus retrieval from the narrative synthesis, and applies to a small number of highly cited references such as [17] and [13]. Search strings were organised into four thematic blocks: Block A (markerless gait analysis), Block B (network architectures for real-time biomedical data transmission), Block C (virtual reality applied to motor rehabilitation), and Block D (integrated telehealth systems, i.e., systems combining markerless capture, edge transmission, and VR into a single real-time pipeline). The Block D string, applied to Scopus, was: `TITLE-ABS-KEY ( ( "markerless motion capture" OR "gait analysis" ) AND ( "virtual reality" ) AND ( "telehealth" OR "telemedicine" ) AND ( "real-time" OR "network architecture" OR "data transmission" ) )`. Its fourth clause was intentionally broadened to include the general terms *network architecture* and *data transmission*, so as not to exclude integrated systems described under different technical vocabulary.

Block D yielded no results in the Scopus and IEEE Xplore databases during corpus construction. To check for the potential omission of important articles from biomedical databases not considered in this review, the four thematic queries were also replicated in PubMed and the Web of Science Core Collection in September 2026, using syntax adapted from the original IEEE Xplore strings without adding or removing terms. For the Block D combination, PubMed returned no results, and Web of Science returned a single record. An individual analysis confirmed that the latter was a contact-based wearable posture-capture sensor, related in scope but not a system integrating all three areas. Therefore, the Block D combination did not yield any integrated systems across the four independent databases. As an additional independent check, a content screening of the records retrieved from PubMed and Web of Science was conducted, searching titles and abstracts for the simultaneous presence of terms indicating markerless capture, virtual reality, and edge or real-time transmission; no record met all three conditions in either database. The PubMed and Web of Science searches were used as an external sensitivity check and were not incorporated into the 442-document bibliometric corpus, which was constructed from the four thematic search blocks applied to Scopus and IEEE Xplore.

Exported records in BibTeX format were imported into the Bibliometrix package (v. 4.x) via Biblioshiny (RStudio). Duplicate records across the two databases were removed by matching on DOI and, where the DOI field was absent, on normalised title. The final corpus comprised 442 documents from 330 distinct sources, with 2,043 unique authors and an annual growth rate of 11.94%, computed as the compound annual growth rate of scientific production over the analysed period. The average document age was 4.1 years, indicating a corpus concentrated in the last four to five years.

IV. Results and Literature Synthesis

The 442 documents were used for quantitative bibliometric mapping but were not all read in full. Article selection for the narrative synthesis followed a two-stage process: (1) the Biblioshiny 'Most Cited Documents' function was applied independently to each of the four thematic blocks; (2) articles published after 2022 were additionally screened to ensure coverage of recent advances. Selection through a most-cited criterion is known to favour older and more established works, which may under-represent recent integrated systems; the second-stage screening was introduced specifically to mitigate this bias. This process yielded 33 articles selected for full reading. Subsequently, articles meeting either of two predefined exclusion criteria were excluded: (i) insufficient technical detail on real-time transmission protocols, or (ii) absence of alignment with the scope of gait analysis applied to telehealth. This retained 23 thematic articles for the narrative synthesis. Screening was conducted by a single reviewer, a limitation discussed in Section V. A small number of foundational references directly relevant to this theme's technical basis (e.g., [13], [16]) were included by the authors' domain expertise, independently of the corpus retrieval process. Of the 23 thematic articles retained for the narrative synthesis, 15 representative studies are summarised in Table I; the remaining thematic articles are discussed in the text but are not included in the table because of space limitations. Fig. 1 summarises the full selection process.

In this study, a keyword co-occurrence analysis was also conducted. To this end, the Louvain algorithm was employed with association strength normalisation, applied to the All Keywords field ($n = 50$, minimum frequency $= 3$). It should be noted that the corpus was assembled from four independent thematic search blocks; co-occurrence patterns therefore reflect both genuine cross-field integration and the composition inherent in block-structured searches. The few connections between the gait analysis and edge computing groups were

Table I
COMPARATIVE SUMMARY OF REVIEWED ARTICLES

Ref.	Technology / Focus	Key Contribution	Gap / Limitation
Block A: Markerless Gait Analysis			
[8]	Review of vision-based motion analysis	Systematic review of markerless systems for sport biomechanics (515 citations)	No telehealth or real-time integration
[18]	OpenPose + mobile camera for gait	Knee angle error 13–18%; outperformed Kinect under clothing occlusion	No 3-D reconstruction; no amputee validation
[19]	OpenPose vs. MediaPipe vs. MMPose	MediaPipe: highest correlation (0.944), inference speed (30.19 fps)	No 3-D; no clinical population; no telehealth
[9]	Review of markerless gait biomechanics	Promising for sagittal plane; limitations under occlusion/prostheses	No transmission or VR integration
[20]	Markerless systems for clinical gait	Suitable for step length, velocity, hip/knee angles when validated	No telehealth context; no amputees
[21]	MAEVE: embedded 3-D pose (Jetson Xavier AGX)	Knee deviation $<5°$; correlation 0.91–0.99 vs. Vicon; edge execution	No VR diagnostic environment; no amputee validation
Block B: Network Architectures & Edge Computing			
[22]	Fog-IoT architecture for patient monitoring	Three-layer fog architecture reduces latency vs. cloud-only (448 citations)	Scalar physiological signals only; no kinematics
[23]	Edge computing for healthcare	Systematised edge/fog concepts and healthcare applications	No gait data or VR integration
[24]	Survey: fog/edge telemedicine monitoring	MQTT and WebSocket identified as dominant real-time protocols	No kinematic data transmission; no VR
[10]	Edge computing in IoMT	Data protection compliance as precondition for edge deployment	No gait or VR component
Block C: Virtual Reality & Motor Rehabilitation			
[17]	VR for motor rehabilitation (review)	4 consolidated findings on motor learning in VR (1,003 citations)	Pre-edge era; no real-time kinematic transmission
[25]	VR telerehabilitation for balance/gait (RCT)	Clinical equivalence between VR-remote and in-person interventions, post-stroke participants	No markerless capture; no amputee population
[26]	VR telerehabilitation for Parkinson's (RCT)	Significant improvement in balance/QoL ($p < 0.05$)	No lower limb amputee population
[27]	Telerehabilitation after TKA (RCT)	Non-inferiority of telerehabilitation vs. in-person care	No VR; no gait kinematics; no amputees
Block D: Integrated Systems (closest approximation)			
[16]	VR diagnostic room + intelligent space	Novel system integrating VR + markerless gait; validated by 12 physiotherapists	Asynchronous (static JSON); no real-time transmission; TRL 4

***Note:** This table consolidates 15 representative studies, selected as the most relevant works within each thematic block (Blocks A–D) and complemented by recency screening, as described in Section III. The narrative synthesis integrates 23 thematic articles cited throughout the text. References [1]–[7], [12], and [14] are epidemiological, regulatory, and foundational sources supporting the problem statement, the regulatory framework, and the technical basis of the system. Reference [4] provides the empirical basis for the concept of *ambulancioterapia*. Technology Readiness Level attributions are estimates by the authors, derived from the descriptions available in each publication, and were not validated against an independent rubric.

consistent with the search results obtained using the Block D string, which encompassed the four thematic groups. In the analysed corpus, the Louvain algorithm identified two network communities. A subsequent descriptive inspection of the nodes grouped the keywords into three interpretive thematic domains: (i) gait analysis and biomechanics; (ii) network architectures and edge computing; and (iii) virtual reality and telerehabilitation. Nodes conceptually affiliated with network architecture literature (*edge computing*, *internet of things*, *telemedicine*, *medical computing*) were assigned to a distinct thematic group for visualization purposes, consistent with established bibliometric practice when algorithmic community detection yields fewer clusters than the number of thematic domains identified in the literature. Demographic indexing terms describing study populations were distributed within these groups rather than forming a separate group. Co-occurrence links between the gait analysis group and the edge computing group are limited to two low-weight connections (weight $= 1$ each), namely between *gait analysis* and *edge computing* and between *gait analysis* and *internet of things*. Fig. 2 illustrates the resulting network.

A. Markerless Gait Analysis

Conventional clinical gait analysis relies on infrared cameras and reflective markers attached to the patient's body. Although these systems offer high accuracy, they are costly, require specialised calibration, and are incompatible with telehealth environments [8]. This limitation motivated the development of markerless systems based on human pose estimation through computer vision, which is particularly relevant to the present scenario, in which gait is captured at

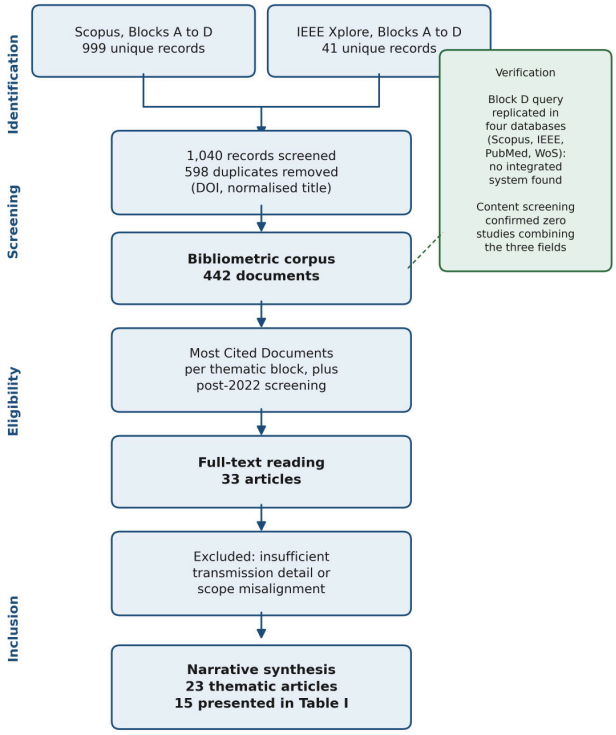

Figure 1. Flow of records from database retrieval to the final narrative synthesis. The Block D query, targeting integrated systems, yielded no eligible integrated system across the four databases consulted; Web of Science returned one adjacent record, which was excluded after content inspection.

a distance by a multi-camera intelligent space rather than by body-worn markers.

Viswakumar et al. [18] demonstrated the feasibility of OpenPose for gait analysis using a mobile phone camera, calculating knee flexion/extension angles with a mean error of 13–18%, outperforming Microsoft Kinect in clothing occlusion scenarios. Tony Hii et al. [19] conducted a direct comparison of OpenPose, MediaPipe Pose, and MMPose for lower limb kinematics during gait, with MediaPipe Pose achieving the highest overall correlation (0.944) and inference speed (30.19 fps).

Wade et al. [9] concluded that RGB camera-based systems show promising results for spatiotemporal and sagittal plane kinematic parameters, but accuracy remains inferior to marker-based systems under severe occlusion or in patients with prostheses. Needham et al. [20] confirmed that markerless systems are suitable for clinical gait analysis when validated against a reference system, particularly for step length, velocity, and hip and knee angle variables.

The most relevant advance for telehealth was proposed by Martini et al. [21], who developed the MAEVE system on a Jetson Xavier AGX embedded device. In healthy participants walking on a treadmill, recorded in the coronal plane, the system showed deviation below 5° in knee flexion angle and correlation of 0.91–0.99 relative to a marker-based reference system, with local, edge-based processing that can reduce the transmission of raw video data.

Recent work has begun to address the amputee population directly. Diffusion-based models have been applied to zero-shot pose estimation for lower-limb prosthetic users [28], and video-based motion analysis has been assessed in individuals with lower limb amputation [29]. The gap identified in this block is therefore not the absence of markerless methods applied to amputees, but the absence of such methods integrated into a validated real-time telehealth deployment.

B. Network Architectures for Real-Time Transmission

Cloud-only architectures introduce latencies of hundreds of milliseconds, often rendering them incompatible with real-time diagnosis [22]. Verma and Sood [22] proposed a three-layer fog architecture for remote patient monitoring, demonstrating significant latency reduction compared to cloud-only solutions. Abirami and Chitra [23] systematised edge computing concepts for healthcare applications. He et al. [24] identified MQTT and WebSocket as the dominant protocols in time-sensitive health applications, owing to their low overhead and real-time bidirectional transmission capability. Fog-assisted architectures have further demonstrated energy-efficient, low-latency local processing for continuous remote health monitoring, with on-gateway data handling reducing reliance on cloud round-trips [30]. Furthermore, Yaraziz et al. [10] highlighted data protection compliance as a foundational precondition for edge deployment in public health. The gap identified in this thematic block is the absence of architectures specifically validated for the real-time transmission of markerless joint kinematic data to immersive diagnostic environments.

C. Virtual Reality Applied to Motor Rehabilitation

Holden [17], in a review predating the edge computing era, established four consolidated findings: motor learning is possible in VR; movements learned in VR transfer to equivalent real-world motor tasks; VR outperforms conventional practice in comparative studies; and no cybersickness was reported in motor-impaired populations using the low-immersion systems available at the time, a finding that does not extend directly to current head-mounted displays. Lloréns et al. [25], in a randomised controlled trial with post-stroke participants, reported clinical equivalence between VR-based remote and in-person interventions for balance recovery. Gandolfi et al. [26] demonstrated significant improvement in Parkinson's disease patients through VR telerehabilitation. Prvu Bettger et al. [27] identified non-inferiority of telerehabilitation versus in-person care for functional outcomes after total knee arthroplasty. Recent developments indicate that spatiotemporal and muscle activation patterns adapt across walking modalities and VR pace constraints [31], while high-fidelity immersive designs influence patient engagement and motor learning [32]. Beyond amputee-specific systems, Toh et al. [11], in a scoping review of home-based wearable technologies for stroke rehabilitation, found that research has concentrated overwhelmingly on the

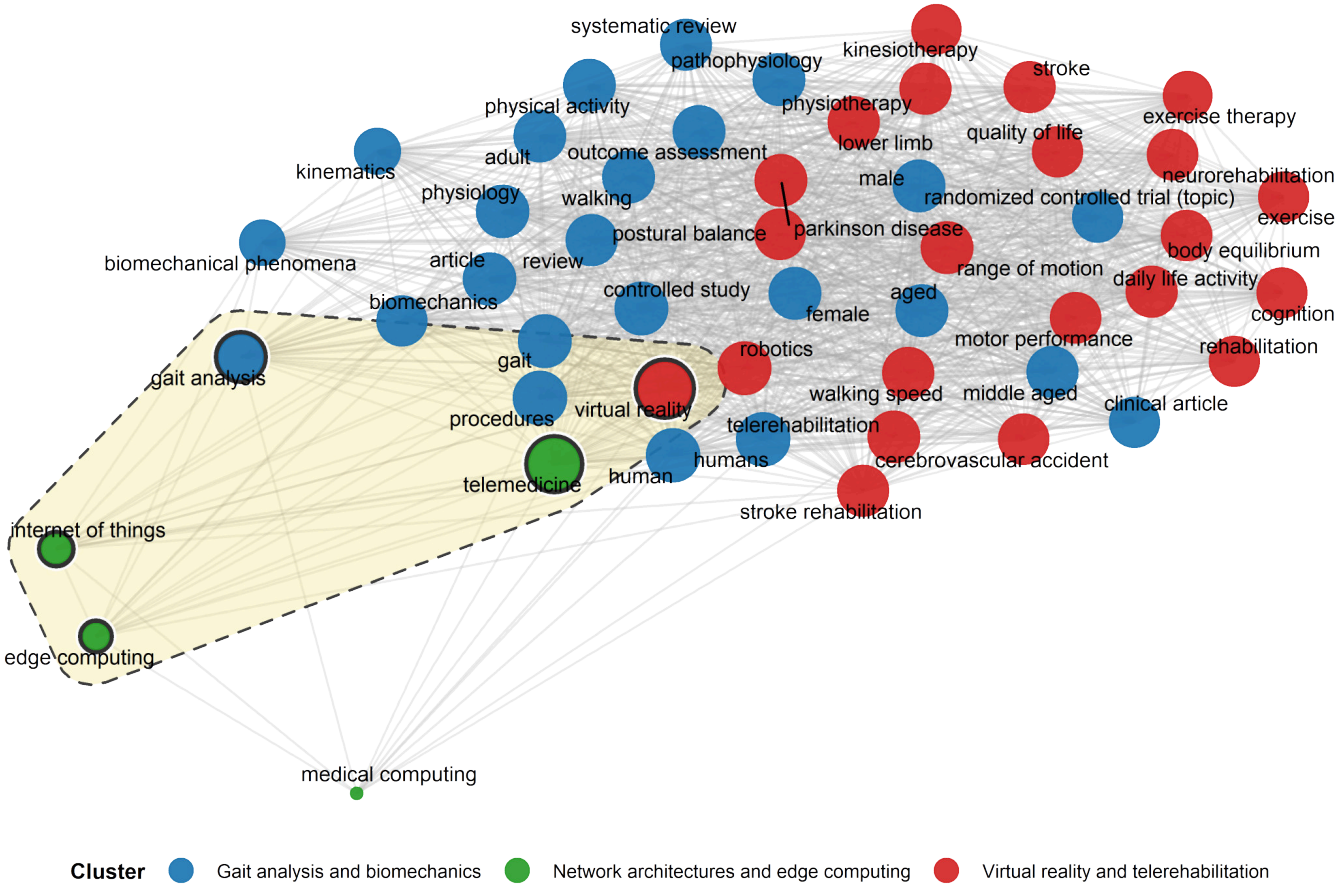

Figure 2. Keyword co-occurrence network of the bibliometric corpus ($n = 442$ documents, Scopus and IEEE Xplore, 2018–2025). Louvain algorithm, association strength normalisation, All Keywords field ($n = 50$ nodes, minimum frequency $= 3$). The Louvain algorithm produced two communities in the analysed corpus; manual node-level inspection identified three thematic groups, rendered here in distinct colours: gait analysis and biomechanics (blue; e.g., *gait analysis*, *biomechanics*, *kinematics*), network architectures and edge computing (green; e.g., *edge computing*, *internet of things*, *telemedicine*), and virtual reality and telerehabilitation (red; e.g., *virtual reality*, *telerehabilitation*, *stroke rehabilitation*). Demographic indexing terms (e.g., *human*, *male*, *female*, *adult*, *aged*) are distributed within the blue group. The dashed polygon highlights the region of the network where the terms most directly related to the integration problem investigated by this review are concentrated. Co-occurrence links between the blue and green groups within this corpus are sparse and of minimal weight.

upper limb, with only very limited evidence addressing the lower limb. This asymmetry reinforces the gap in remote lower limb rehabilitation that the present work targets. Unlike most of the reviewed telerehabilitation solutions, which aim to give patients autonomy to carry out their own rehabilitation at home, the system addressed in this work is intended for use by the health professional, supporting remote gait diagnosis rather than patient-administered therapy. Within this landscape, Silva et al. [16] advanced a VR-based diagnostic environment designed specifically for lower limb amputees, integrating an intelligent space for markerless gait capture, which constitutes the direct precursor to the present work.

D. Integrated Systems: Technological Gap

Silva et al. [16] propose a VR-based system for gait diagnosis in individuals with lower limb amputation, combining an intelligent space with a virtual environment. This framework achieved high performance in gait classification. However, the integration of all components into a real-time, low-latency, and LGPD-compliant architecture for remote clinical settings remains an unresolved challenge. A recent narrative review of gait analysis systems in clinical rehabilitation for individuals with lower limb amputation [33] likewise reports that integration into routine clinical workflows remains incipient. The bibliometric mapping of the surveyed corpus corroborates this direction: co-occurrence links between the gait analysis and edge computing groups are sparse and of minimal weight (Fig. 2), indicating that the integration of these two fields remains largely unexplored rather than entirely absent.

V. Discussion

The three investigated fields present sufficient maturity to individually support components of the proposed system. Markerless systems report correlations above 0.90 against marker-based references for sagittal plane parameters, across heterogeneous populations and protocols [9], [19]–[21]; edge

architectures with MQTT and WebSocket are consolidated for real-time transmission [22], [24]; and VR environments show clinical equivalence to in-person care in the populations studied [17], [25], [26].

From a technological maturity perspective, reviewed systems are predominantly between TRL 4 and TRL 5. Advancing to TRL 6 requires three conditions: demonstration in a clinically relevant environment with people with lower limb amputation, a standardised assessment protocol, and LGPD-compliant data transmission over a public network. The literature does not record systems that have reached this level for remote VR-based gait diagnosis in people with amputation.

Network instability in remote regions served by the SUS represents an additional constraint on any real-time architecture. Sacco et al. [34] report packet-loss recovery in latency-sensitive networked applications, a class of technique whose applicability to kinematic data streams was not evaluated in the surveyed literature and would require dedicated investigation.

Several limitations should be considered when interpreting these findings. This work is a bibliometric-informed narrative review and does not follow the full protocol of a systematic review: screening was conducted by a single reviewer, no formal quality or risk-of-bias assessment was applied, and no grey literature or clinical trial registry searches were performed. The quantitative corpus was built from Scopus and IEEE Xplore. To assess the effect of this restriction, the four thematic queries were replicated in PubMed and Web of Science in September 2026. Of the records carrying a registered DOI, 60.5% of the PubMed set and 44.4% of the Web of Science set were already present in the corpus, indicating substantial coverage of the thematic intersection by the two databases used for corpus construction. Content-level screening of the additional records identified no study combining markerless capture, virtual reality, and real-time transmission, and the Block D query returned no integrated system in any of the four databases. Attributions of Technology Readiness Level are estimates made by the authors from the reviewed publications, and were not validated against an independent rubric. A full systematic review, with dual independent screening and formal quality assessment, is planned as a subsequent phase of this research, with an expanded research team.

VI. Conclusion

This study aimed to conduct a bibliometric analysis and a narrative literature review to identify articles related to gait analysis and virtual reality within the context of telehealth-based rehabilitation. To this end, four distinct searches were performed: the first focused on markerless or wearable-sensor-free gait analysis; the second on communication architectures for synchronous biomedical data transmission; the third on virtual reality for rehabilitation; and the fourth integrated these three areas.

The review demonstrated that these fields have achieved independent, well-established development, with evidence of clinical feasibility for each component in isolation. Bibliometric analysis of 442 documents indicated that co-occurrence connections between the gait analysis and edge computing groups are scarce and carry minimal weight (Fig. 2); this finding, combined with the absence of integrated systems identified in Block D across four databases, suggests that integrating these fields into a synchronous telehealth system remains unexplored and constitutes an open research problem.

Future work could include conducting a full systematic review, involving independent double screening and formal quality assessment, with an expanded research team. Future work should investigate interoperability with health-information standards such as HL7 FHIR and, where medical-imaging integration is required, DICOM, as well as the scalability of the proposed solutions within the healthcare sector. Expanded research on cybersecurity should also be conducted to better understand these solutions for the healthcare field. The potential for designing a system that offers remote rehabilitation within the Brazilian telehealth context, enabling patients in remote areas to access specialised home-based care without the need for travel, must also be analysed.

Acknowledgments

***Abstract*— Mental workload is a relevant but inconsistently measured factor in motor imagery-based brain-computer interfaces (MI-BCIs), particularly in applications aimed at neuromotor rehabilitation. This rapid systematic review aimed to synthesize evidence on the relationship between mental workload or mental fatigue and BCI performance, identify the metrics used, and examine methodological limitations. Searches were conducted in IEEE Xplore, PubMed/MEDLINE, Web of Science, and Scopus for studies published between 2016 and 2026, with complementary searching in Google Scholar. Eligible studies included human participants, involved motor imagery-based BCI or rehabilitation-related applications, assessed mental workload or fatigue, and reported performance-related outcomes. Methodological quality was appraised using the MMAT. Fourteen studies were included. Overall, higher mental workload or fatigue tended to be associated with poorer BCI performance, reduced EEG class separability, altered cortical engagement, or decreased motor imagery stability. However, effects varied across users, sessions, and experimental conditions, and some studies reported preserved accuracy despite increased workload or fatigue, indicating that accuracy alone may not capture these changes. Subjective and neurophysiological measures provided complementary information. Only two studies (14.3%) included post-stroke participants, limiting clinical generalizability. Small samples, heterogeneous measurement approaches, and methodological limitations further reduced the strength of the evidence. Future studies should include larger clinical samples and standardized multimodal protocols integrating workload, fatigue, neurophysiological markers, and objective BCI performance outcomes.**

Keywords*— *brain-computer interface; motor imagery; mental workload; electroencephalography; neuromotor rehabilitation.

I. INTRODUCTION

A brain-computer interface (BCI) establishes a direct communication pathway between brain activity and external devices, enabling the translation of neural signals into operational commands without relying on peripheral neuromuscular pathways [1]. Among non-invasive modalities, electroencephalography (EEG) based systems and motor imagery (MI) have received increasing attention in neuroengineering and rehabilitation, especially in applications targeting patients with stroke, spinal cord injury, and other disabling neurological conditions [1,2]. In post-stroke rehabilitation, systematic review and meta-analysis evidence indicates that BCI training combined with conventional therapy may promote upper-limb motor recovery and brain function recovery. However, more standardized protocols, assessment of MI ability, and control of neuropsychological factors such as attention and concentration are still needed [2]. The neurophysiological principle of MI-based BCIs involves the modulation of sensorimotor rhythms or sensorimotor alpha rhythms, approximately between 8–13 Hz, and beta rhythms, between 13–30 Hz, expressed through event-related desynchronization and synchronization patterns (ERD/ERS), observed during movement execution or imagination [1,3].

Mental workload reflects the relationship between the cognitive demands imposed by a task and the individual's available resources to perform it, and can be estimated using performance measures, subjective self-reports, and psychophysiological or neurophysiological markers [4,5]. In the context of MI-based BCIs, this workload is modulated by task complexity, sustained attention, presence of distractors, session duration, fatigue, motivation, and the user's emotional state [1,4,6]. Recent evidence indicates that age, cognitive function, attention, mental rotation ability, and mental state explain a relevant portion of the variability in EEG-based BCI system performance; MI paradigms appear to be more sensitive to cognitive and developmental differences than visual paradigms [1]. Mental fatigue, in turn, should be understood as a psychophysiological state that can reduce user responsiveness, alter cortical power patterns, attenuate ERD responses, and compromise EEG signal separability and classification accuracy, especially during prolonged MI tasks [1,3,7].

It is important to distinguish between related but distinct constructs that are often conflated in the BCI literature.

Mental workload refers to the relationship between task demands and the individual's available cognitive resources [8]. Mental fatigue is a psychobiological state caused by prolonged cognitive activity, characterized by subjective tiredness and reduced performance [9]. Mental effort represents the active allocation of resources to meet task demands [10], while attention involves the selective focus on relevant stimuli [11]. This review encompasses studies using any of these terms, as they are often interconnected in BCI research, however, we explicitly acknowledge their conceptual distinctions in our analysis.

As illustrated in Figure 1, electrodes positioned on the scalp capture EEG signals generated during MI, which undergo preprocessing, feature extraction, and classification stages, producing neurofeedback or commands for external devices. In parallel, mental workload can be estimated through electrophysiological markers, behavioral metrics, or subjective instruments. In recent studies with wearable EEG and fNIRS devices, aspects such as comfort, adaptability to head shape, electrode positioning, signal quality, portability, interoperability, usability, and user acceptability have been recognized as central requirements for expanding BCI applications from laboratory settings to clinical and real-life contexts [4].

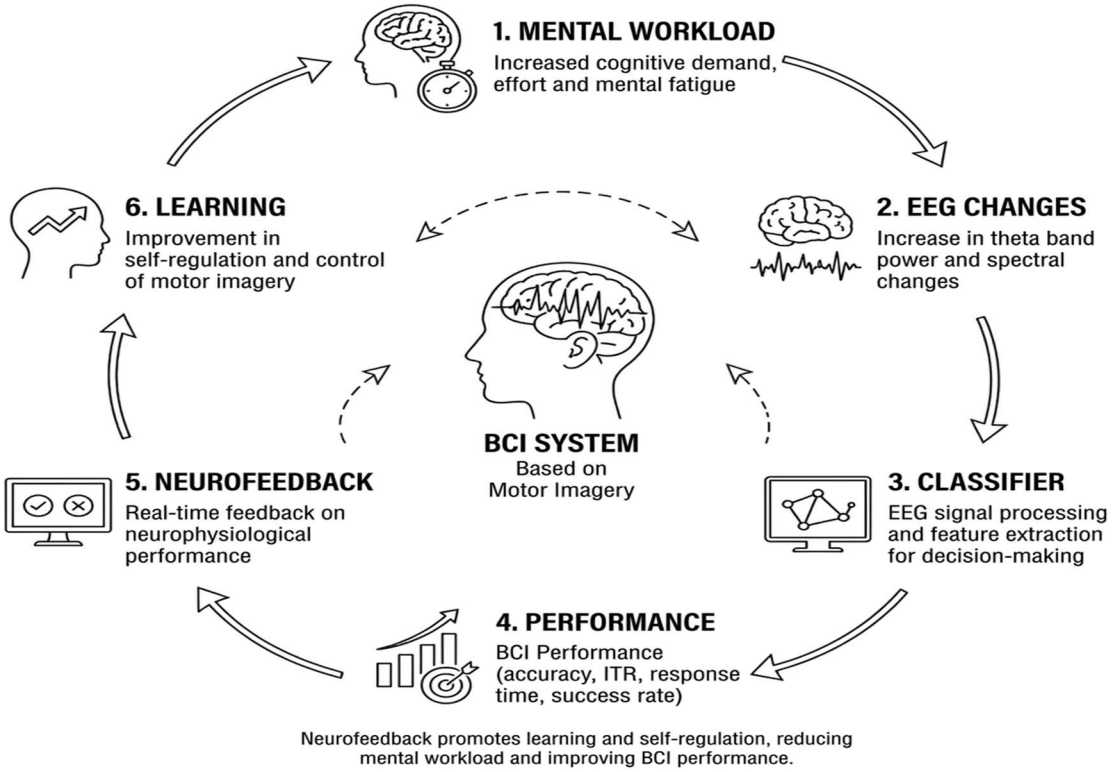

Fig. 1. Flowchart of the EEG signal acquisition process and user neurofeedback.

Given this scenario, this review was guided by the following question: among users of motor imagery-based brain-computer interfaces, does exposure to high mental workload, compared with lower cognitive-demand conditions, compromise interface performance?

The objective of this rapid systematic review was to analyze evidence from experimental studies that investigated the relationship between mental workload and performance in motor imagery-based brain-computer interfaces, describing the metrics used to assess mental workload and interface performance, evaluating the risk of bias of the included studies, and identifying individual, neurophysiological, and operational factors that modulate this relationship, especially in applications aimed at neuromotor rehabilitation.

II. METHOD

This rapid systematic review followed a predefined a priori protocol that was prospectively registered with the Open Science Framework (OSF) (https://osf.io/ahuym). The review process took place between March and June 2026, divided into two phases: (i) electronic database searches, performed from March to April 2026 (last search conducted on April 30, 2026); and (ii) screening of records, data extraction, and evidence synthesis, carried out from April to June 2026. The searches were performed in IEEE Xplore, PubMed/MEDLINE, Web of Science, and Scopus, covering the period from January 2016 to April 2026.

This 10-year window was selected to capture the contemporary evidence base that followed the consolidation of standardized workload metrics and deep learning approaches in MI-BCI research. This period includes studies on neurorehabilitation applications of BCIs [12], EEG-controlled exoskeletons [13,14], and the increasing application of deep learning methods for EEG decoding [15,16]. Review articles published during this period also summarized classification approaches and performance metrics for MI-EEG [17]. This timeframe allows for the inclusion of recent developments while maintaining a scope that is feasible for a rapid, systematic review.

Google Scholar was also employed as a complementary source of grey literature to identify potentially relevant studies not retrieved from the indexed databases. Studies published in either English or Portuguese were included. Figure 2 presents the study selection flow diagram, adapted from the PRISMA 2020 statement [18].

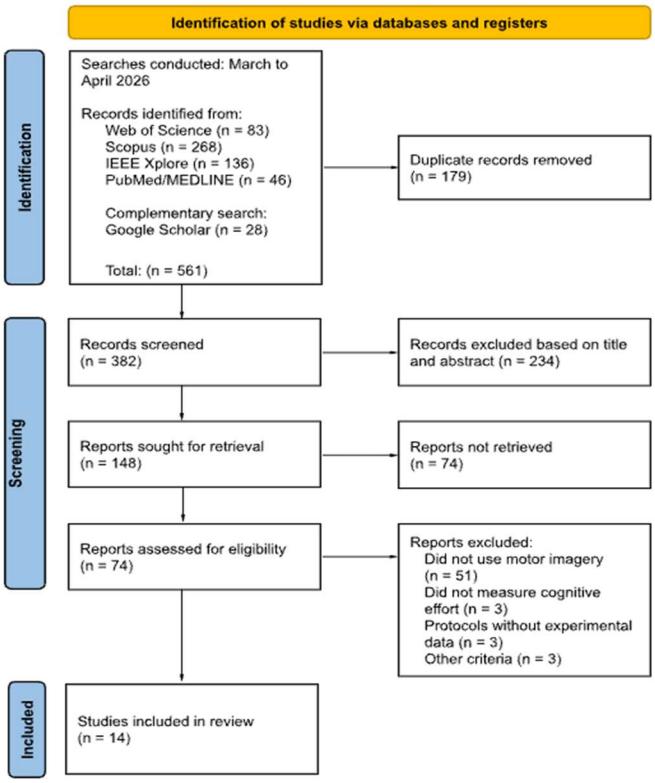

Fig. 2. PRISMA flow diagram of the study selection process.

The research question was structured according to the PICOT acronym, as outlined below:

- P (Population): users of motor imagery-based brain-computer interfaces;
- I/E (Intervention/Exposure): exposure to high mental workload, mental fatigue, or high cognitive demand;
- C (Comparison): low mental workload, control conditions, or lower cognitive demand;
- O (Outcome): BCI performance assessed by metrics such as accuracy, information transfer rate (ITR), ERD/ERS patterns, response time, and success rate;
- T (Time): studies published between 2016–2026.

The methodological quality and risk of bias of the included studies were appraised using the Mixed Methods Appraisal Tool (MMAT), version 2018 [19]. The MMAT was selected because it is specifically designed to assess the quality of studies with heterogeneous methodological designs, including qualitative, quantitative, and mixed-methods research. This characteristic was essential for this review, given the diversity of experimental protocols, populations, and outcome measures observed in the MI-BCI literature.

A. Search Strategy

The definition of search terms was guided by the three central axes of the review: brain-computer interfaces, mental workload, and interface performance. For the first axis, the terms “BCI” and “brain-computer interface” were used; for the second, "cognitive load," "mental effort,” and “mental workload”; and for the third, “performance.” In Google Scholar, “motor imagery” and “rehabilitation” were added to refine the search for studies with greater adherence to clinical applications based on motor imagery. The search strategies employed Boolean operators AND and OR, quotation marks for exact phrases, and parentheses for logical grouping, with adaptations tailored to the syntax and available search fields of each database.

In PubMed/MEDLINE, the following strategy was used: (BCI OR “brain-computer interface”) AND (“cognitive load” OR “mental effort”) AND performance. In IEEE Xplore, the following was employed: (BCI OR “brain-computer interface”) AND (“cognitive load” OR “mental effort” OR “mental workload”) AND performance. In Scopus, the search was conducted in the title, abstract, and keyword fields, using: TITLE-ABS-KEY((BCI OR “brain-computer interface”) AND (“cognitive load” OR “mental effort” OR “mental workload”) AND performance). In Web of Science, the search was conducted in the topic field, with the following strategy: TS=((BCI OR “brain-computer interface”) AND (“cognitive load” OR “mental effort” OR “mental workload”) AND performance).

As a complementary search, Google Scholar was consulted using the combination: BCI “motor imagery” “mental workload” “cognitive load” “rehabilitation” performance. The most relevant results retrieved by the platform were considered, according to the pre-defined eligibility criteria.

B. Screening Process

For reference management and study screening, Rayyan, in its web version developed by the Qatar Computing Research Institute (QCRI), was used [20]. The tool was employed to organize records retrieved from databases, identify duplicates, and support the selection process of eligible studies. Title/abstract screening, data extraction, and risk-of-bias assessment were carried out independently by two reviewers. Disagreements were resolved by consensus. The full list of excluded full-text articles with reasons for exclusion is provided in Supplementary Material S1 (Annex A).

C. Eligibility Criteria

Primary studies of experimental, observational, or pilot design, conducted with human participants, that investigated motor imagery-based brain-computer interfaces, measured mental workload, cognitive effort, or mental fatigue, and reported interface performance metrics such as accuracy, response time, error rate, success rate, or ITR were included. Studies developed in the context of neuromotor rehabilitation, clinical application, or experimental simulation with potential relevance to rehabilitation were also considered.

D. Data Extraction and Synthesis

Data were extracted directly from the published texts, tables, and figures as reported by the original authors. No missing summary statistics were imputed, and no data conversions or transformations were performed. Because a meta-analysis was not feasible due to substantial heterogeneity in study designs, populations, workload metrics, and performance outcomes, no pooled effect measures were calculated. Instead, effect directions and estimates were extracted and reported narratively as presented in the primary studies.

III. Results and Discussion

The search and selection process yielded 14 eligible studies. The main reasons for excluding full-text reports were: (i) absence of a motor imagery paradigm; (ii) lack of mental workload or fatigue assessment; and (iii) non-experimental designs. A complete list of excluded studies is available from the corresponding author upon request.

When analyzing the included articles presented in Table 1, 10 of 14 selected studies (71.4%) reported an inverse relationship between increased mental workload and user performance on the interface. This association was evidenced by reduced classification accuracy, decreased separability between EEG signal classes, alterations in ERD/ERS patterns, and impaired cortical engagement during motor imagery tasks [21–30].

Additionally, 2 studies (14.3%) identified a context-dependent relationship, suggesting that the impact of mental workload may vary depending on the experimental paradigm, task type, user profile, exposure time, or feedback strategy [31,32]. Another 2 studies (14.3%) did not observe a statistically significant association between mental workload and interface performance [33,34].

A conceptual challenge identified in the included studies is the inconsistent use of terminology and measurement approaches for mental workload, fatigue, and related constructs. Studies [21,22,26,28,30,32,34] used the NASA-TLX as a subjective measure of mental workload, while [24,25,33] focused specifically on mental fatigue using subjective scales (BFI, fatigue scale) and EEG spectral markers. Some studies [23,29,31] addressed cognitive state, attention, and mental load more broadly, using both subjective ratings and neurophysiological metrics.

Sim *et al*. [23] explicitly examined attention and somnolence, whereas Yang et al. [31] used fNIRS to assess cognitive load objectively. Wang *et al*. [29] focused on mental load in the context of post-stroke patients, using MRCP and ERD as markers of neural engagement. This terminological heterogeneity reflects broader discussions in the literature and complicates direct comparisons between studies. Future research should adopt clearer operational definitions and consider using multiple complementary measures, subjective, electrophysiological, and autonomic, to capture the distinct dimensions of cognitive demand, fatigue, and attentional state in BCI users.

Regarding measurement approaches, the studies employed a wide range of parameters to assess mental workload and performance, subjective scales (NASA-TLX, BFI, VAS, SAM, SUS, TAM, QUEST 2.0), spectral EEG markers (theta/alpha ratio, DAR, DABR, DTABR, spectral power in delta/theta/alpha/beta bands), physiological signals (HRV, GSR, pupil dilation, blink rate), neuroimaging (fNIRS), and behavioral metrics (classification accuracy, ITR, response time, command success rate, MRCP amplitude, ERD patterns). This diversity underscores the need for standardized, multimodal protocols in future MI-BCI research to improve comparability and replicability.

The studies included in this review exhibit substantial heterogeneity not only in terminology and measurement approaches, as detailed above, but also in experimental protocols, classification algorithms, participant characteristics, and application contexts. These factors likely modulate the relationship between mental workload and BCI performance and are discussed below across seven thematic topics:

A. User Proficiency and Vulnerability to Mental Workload

Regarding the relationship between user proficiency and vulnerability to mental workload, Emami and Chau [21] demonstrated that subjective mental workload, measured by the NASA Task Load Index (NASA-TLX), significantly predicted performance decline among participants with accuracy below 75%. This effect was not observed among participants with better performance, suggesting that less proficient users, or those in the initial adaptation phase to the interface, may be more vulnerable to high cognitive demand.

Complementarily, Ozkan and Kahya [22] found that participants classified as being in a high-risk cognitive state performed significantly worse, with agreement ranging from 87.1% to 100% across alternative classification methods. This finding indicates that the cognitive profile may represent a relevant and potentially predictive dimension of user behavior on the interface.

Sim *et al*. [23], in turn, demonstrated that incorporating the cognitive attention state as an auxiliary signal in a multi-task EEGNet-TCN decoder elevated classification accuracy to 75.9%, surpassing the model without cognitive state supervision by 4.5 percentage points. This result reinforces the idea that information about the user's attention and cognitive state can add predictive value to BCI performance, even when obtained through simplified monitoring strategies.

B. Impact of Mental Fatigue and Observed Exceptions

Mental fatigue emerged as a recurring factor in performance degradation in motor imagery-based brain-computer interfaces, although the neural mechanisms involved and the most sensitive metrics varied across studies. Talukdar *et al*. [24] demonstrated that prolonged MI sequences produce substantial mental fatigue, significantly reducing separability between EEG signal classes and directly compromising the quality of the classifier's input signal.

Li *et al*. [25] observed a more refined temporal pattern: the MI recognition rate increased in the first three blocks, in a dynamic suggestive of learning or initial adaptation to the task, but declined in the fourth block, when mental fatigue became more evident. This decline was accompanied by increased theta power in frontal, central, parietal, and occipital regions, as well as weakened phase synchronization between these areas, suggesting progressive deterioration of the functional integration necessary for interface control.

However, not all studies confirmed a direct association between mental fatigue and performance decline. Roc *et al*. [33] did not find a significant correlation between performance and subjective measures of mental workload across three sessions, although they recorded a consistent increase in mental demand and fatigue within each session. This divergence may reflect limitations of the self-report scales used, interindividual variability, or the particularities of the initial adaptation process for inexperienced users of the system.

Similarly, Yang *et al*. [31] observed that the virtual reality environment increased mental workload and fatigue without significantly reducing accuracy. However, MI stability decreased, suggesting that the impact of elevated mental workload is not always captured by accuracy alone. Thus, complementary metrics such as EEG pattern stability, inter-class separability, ERD/ERS, functional connectivity, and subjective fatigue measures may be necessary for a more sensitive assessment of the effects of mental fatigue on interface performance.

C. *Influence of Neurofeedback and Interface Design*

Arpaia *et al*. [28] demonstrated that real-time neurofeedback increased accuracy from 62% to 69% while maintaining high perceived usability in both groups. This finding suggests that continuous feedback may favor learning of conscious interface control without necessarily increasing the perceived cognitive cost in proportion.

He *et al*. [27], in the only randomized clinical trial included in the sample, evaluated 48 post-stroke patients, distributed between an intervention group with BCI (n=25) and a control group (n=23). The authors observed significantly greater improvement in upper-limb motor function in the group that underwent BCI with multimodal neurofeedback in virtual reality, accompanied by evidence of neuroplasticity assessed using EEG and fNIRS. These results position neurofeedback not only as a user feedback resource but as an active therapeutic component in the neuromotor rehabilitation process.

In a convergent direction, Li *et al*. [26] reported that an asynchronous MI-BCI system, developed based on cognitive ergonomics principles, reduced subjective workload, as measured by the NASA-TLX, by 32% compared to synchronous paradigms. This reduction was accompanied by 27% fewer commands and 34% less time to complete tasks, thereby directly linking the decrease in mental workload to operational performance gains.

Lyu *et al*. [30] reinforced this perspective by observing, during a rapid, iterative prototyping process for a BCI system aimed at lower-limb rehabilitation, that simpler MI tasks reduced perceived mental workload and yielded more reliable brain signals. Furthermore, performance and satisfaction are correlated, indicating that usability is a dimension that can amplify or reduce overall interface performance.

In turn, Lu *et al*. [32], adopting a user experience-centered approach, reported an average online accuracy of 85% and a latency of 0.12 seconds in an MI-BCI system with virtual reality. These results were associated with moderate levels of mental workload and a strong sense of agency reported by participants. This finding suggests that moderate mental workload, far from representing only a risk factor, may constitute a favorable condition for effective engagement with the interface, provided it is balanced by adequate feedback, intuitive design, and good usability.

In post-stroke patients (n=6), Wang *et al*. [29] observed that the cognitively more demanding condition produced later and attenuated movement-related cortical potentials. These results indicate that reducing cognitive demand during the task may favor more consistent neurophysiological responses and, potentially, amplify the therapeutic effect of BCI in populations with neurological impairment.

D. *Methodological Variability in Mental Workload Measurement*

It is observed that there is still no methodological standardization for assessing mental workload in studies with MI-based BCIs, as the works included in this review employed different measurement approaches. Some studies used the NASA-TLX exclusively [26,28,30,32], while others relied on electrophysiological markers, especially spectral ratios between the theta and alpha bands [23–25,27]. There are still studies that combine subjective measures, such as the NASA-TLX, with physiological indicators, including heart rate variability (HRV) [23], pupillometry, and galvanic skin response (GSR) [22].

Emami and Chau [21], in turn, combined the NASA-TLX with the theta/alpha spectral ratio and found that the theta-alpha ratio with parietal-parietal topography showed 22.5% higher sensitivity than the conventional fronto-parietal ratio in capturing changes in mental workload during tasks with visual distractors. Badesa *et al*. [34] also reinforce the relevance of complementary physiological measures by demonstrating that, among the modalities evaluated, HRV was the only measure with a statistically significant difference between participants with good and poor performance.

Taken together, these findings indicate that a single isolated metric should not be used to evaluate mental workload in BCI. The combination of subjective instruments, electrophysiological markers, and autonomic indicators can offer a more sensitive and multidimensional characterization of the cognitive demand imposed on the user.

E. *Methodological Quality and Risk of Bias of Included Studies*

The methodological quality of the 14 included studies was assessed using the Mixed Methods Appraisal Tool (MMAT), version 2018 [19]. The results are summarized in Table 1. Only the study by He *et al*. [27] showed a low risk of bias, meeting all five quality criteria for randomized clinical trials.

Seven studies were classified as moderate risk [21–23,26,28,31,33], mainly due to methodological weaknesses such as absence of randomization, lack of sample size calculation, insufficient control of potential confounders, and limitations in the description of experimental procedures. Another six studies were classified as high risk of bias [24,25,29,30,32,33] for presenting descriptive or pilot designs, small samples (generally $n \leq 11$), the absence of a control group, and convenience sampling.

Specific relevant limitations were also identified, such as gender bias in Yang *et al*. [31], whose sample included only male participants, and the 45% sample loss in Talukdar *et al*. [24], without sensitivity analysis to assess the impact of these losses on the results. Thus, the predominance of studies with a moderate to high risk of bias requires caution in interpreting findings and highlights the need for future investigations with more consistent designs, larger sample sizes, comparator groups, randomization strategies, and better control of confounders. Additionally, as this is a rapid systematic review focusing on qualitative evidence synthesis, formal assessments of publication bias and certainty of the body of evidence were not performed.

A total of 14 studies were included, which evaluated fatigue, mental workload, performance, accuracy, neurophysiological activity, and usability of BCI systems. The majority of studies were conducted with healthy participants, while two included post-stroke individuals.

Overall, the results indicated an association between higher fatigue/mental workload and reduced BCI performance, although some studies observed preserved accuracy despite increased cognitive demand. In post-stroke studies, changes in neurophysiological markers were associated with cortical engagement and motor function.
.

F. Synthesis of Results

TABLE I. SUMMARY OF INCLUDED STUDIES

Author(s) / Year	Population (n)	Variability Type	Main Outcomes	Observed Relationship	Risk of Bias (MMAT)
[21] Emami & Chau (2020)	Healthy: *n*=16	Inter-user	Fatigue, EEG, accuracy	↑ theta/alpha → ↓ accuracy (R^2=0.32)	Moderate
[22] Ozkan & Kahya (2018)	Healthy: *n*=70	Inter-user	Cognitive load, performance	High cognitive state → higher risk of low performance (87.1–100%)	Moderate
[23] Sim *et al.* (2026)	Healthy: *n*=54	Inter-user / individual state	Attention, somnolence, accuracy	↑ attention → ↑ accuracy (*r*=0.25); somnolence = worse performance	Moderate
[24] Talukdar *et al.* (2019)	Healthy: *n*=11	Intra-user	Fatigue, EEG, accuracy	↑ delta/theta/alpha → ↓ class separability and accuracy	High
[25] Li *et al.* (2024)	Healthy: *n*=10	Intra-user	Fatigue, EEG, MI recognition	↑ fatigue/theta → ↓ MI recognition rate	High
[26] Li *et al.* (2026)	Healthy: *n*=16	Not specified	Mental workload, accuracy	↓ NASA-TLX (32%) → 95.36% online accuracy	Moderate
[27] He *et al.* (2025)	Post-stroke: BCI (*n*=25) Control (*n*=23)	Intergroup + longitudinal	EEG, FMA-UE, EMG	FMA-UE: 4.0 points in BCI group vs. 2.0 in control; ↓ DAR/DABR	Low
[28] Arpaia *et al.* (2023)	Healthy: Neurofeedback (*n*=13) Control (*n*=14)	Intergroup	Effort, MI, usability	Accuracy: 69% vs. 62% (neurofeedback *vs*. control)	Moderate
[29] Wang *et al.* (2025)	Post-stroke: *n*=6	Intra-user	MRCP, ERD, mental load	↑ MRCP/ERD → ↑ cortical engagement	High
[30] Lyu *et al.* (2023)	Healthy: *n*=10	Not specified	Mental workload, satisfaction	↑ NASA-TLX → ↓ user satisfaction	High
[31] Yang *et al.* (2023)	Healthy: *n*=9	Intra-user / between conditions	Mental load, fNIRS, MI	Accuracy preserved (51.32%); ↓ MI stability	Moderate
[32] Lu *et al.* (2025)	Healthy: *n*=6	Limited evidence for inter/intra	Workload, usability, performance	Accuracy ≈85%; latency ≈0.12s	High
[33] Roc *et al.* (2026)	Healthy: *n*=24	Intra-user	Fatigue, demand, accuracy	↑ fatigue/demand, but no significant correlation with accuracy	Moderate
[34] Badesa *et al.* (2020)	Healthy: *n*=11	Inter-user	HRV, workload, BCI success	↓ HRV and ↑ NASA-TLX → worse performance	High

Abbreviations: BCI: brain-computer interface; EEG: electroencephalography; MI: motor imagery; FMA-UE: Fugl-Meyer Assessment – Upper Extremity; EMG: electromyography; MRCP: movement-related cortical potentials; ERD: event-related desynchronization; fNIRS: functional near-infrared spectroscopy; HRV: heart rate variability; NASA-TLX: NASA Task Load Index; DAR: delta/alpha ratio; DABR: delta/alpha/beta ratio; MMAT: Mixed Methods Appraisal Tool.

G. Implications for Rehabilitation and Directions for Future Research

Considering these limitations, future randomized clinical trials should explore adaptive motor imagery training protocols that use continuous monitoring of mental workload to adjust the intensity, complexity, and progression of tasks across sessions in neurological patients. This approach would allow investigation into whether maintaining mental workload at tolerable or moderate levels favors better functional outcomes compared to fixed protocols, and would also contribute to defining more consistent parameters for the frequency, duration, intensity, and progression of training.

IV. Conclusion

The evidence synthesized in this rapid systematic review suggests that elevated mental workload and mental fatigue are generally associated with poorer performance in motor imagery-based BCIs. However, the magnitude and expression of these effects vary across users, sessions, and experimental conditions. Subjective measures and neurophysiological markers provided complementary information, and some studies showed that accuracy alone may not capture changes in MI stability, EEG separability, cortical engagement, or fatigue. Evidence in post-stroke populations remains limited and does not yet support firm clinical conclusions, although preliminary findings suggest that neurophysiological monitoring may help characterize cortical engagement and motor response during BCI-based rehabilitation. Methodological heterogeneity, small sample sizes, and the predominance of studies with methodological limitations restrict the strength and generalizability of the evidence. Future studies should include larger clinical samples and standardized multimodal protocols integrating mental workload, fatigue, neurophysiological markers, and objective BCI performance outcomes.

Acknowledgments

This rapid systematic review was conducted as part of the Health Technology Assessment (HTA) course in the Postgraduate Program in Biomedical Engineering (PPGEB) at the Federal Technological University of Paraná (UTFPR). The authors would like to thank the UTFPR for providing all resources for the development of the project, and the Araucária Foundation (FA) & Superintendence of Science, Technology and Higher Education (SETI) for the conference scholarship for H. C. C.

Conflict of Interest

The authors declare no conflict of interest.

Data Availability

All data extracted from the included studies are presented in Table I. Supplementary Material S1, containing the full list of excluded studies with reasons (Annex A) is permanently available online at https://osf.io/munf5. Data collection forms and other materials used in the review are available upon reasonable request from the corresponding author.

***Abstract*—This work presents an instrumental Proof of Concept (PoC) for a modular Brain-Computer Interface (BCI) framework aimed at robotic rehabilitation. The system adopts an asynchronous, decoupled platform to support post-stroke therapies at the Center of Physical Rehabilitation of Espirito Santo (CREFES). Using the Emotiv EPOC X headset [14], the platform consolidates two independent control architectures: (1) a Hybrid mode that fuses facial electromyography (EMG) inferences as a safety trigger and inertial kinematic data (IMU) for proportional speed modulation; and (2) a Binary Visual Mode based on Steady-State Visually Evoked Potentials (SSVEP) at 15 Hz. Processing is performed in Python under the Model-View-Controller (MVC) pattern, transmitting commands via Wi-Fi to an ESP32-based module controlling a rehabilitation minibike. A pilot study with three healthy volunteers ($N = 3$) evaluated preliminary performance and workload. The Hybrid mode achieved a mean accuracy of 84.92% (SD = 14.35%) and an Information Transfer Rate (ITR) of 9.91 bits/min (SD = 8.99), while the SSVEP mode achieved 77.23% (SD = 5.96%) and 1.77 bits/min (SD = 0.81). NASA-TLX assessments suggested a trend towards lower mental workload for the Hybrid mode. The implementation of Exponential Moving Average (EMA) and temporal refractory filters effectively mitigated biosignal bouncing effects, establishing a methodological foundation for future clinical trials.**

***Index Terms*—BCI Framework, Robotic Rehabilitation, SSVEP, Emotiv EPOC X, ESP32, Cognitive Load.**

I. Introduction

Stroke is one of the leading public health challenges and the primary cause of permanent motor disability in adults. In Brazil, stroke accounts for approximately 11 deaths per hour [1]. Robot-assisted motor rehabilitation has proven effective for promoting neuroplasticity and accelerating functional recovery [2]. However, integrating Brain–Computer Interfaces (BCIs) into real hospital environments, such as the Center of Physical Rehabilitation of Espirito Santo (CREFES), presents significant operational barriers.

This work was developed in the Robotics and Assistive Technology Laboratory (LRTA) at the Universidade Federal do Espírito Santo (UFES).

Traditional paradigms, particularly pure Motor Imagery (MI), impose severe cognitive workloads, leading to mental fatigue and the phenomenon of *BCI illiteracy* [3], [5]. Cognitive fatigue induced by repetitive sessions alters the patient's neurophysiological response, rapidly saturating attention and reducing therapeutic efficacy over the medium term [4].

To address these limitations, this paper proposes a Decoupled Bimodal BCI Architecture. Unlike conventional approaches that rigidly link processing software to a single physical actuator, this work focuses on a formal separation of layers via standardized network commands and mathematical temporal filters to improve operational stability. Using the Emotiv EPOC X wireless headset, the control load is divided into two selectable processing architectures (Hybrid and Visual) to explore the reduction in cognitive demand associated with continuous voluntary control.

II. State of the Art

The design of BCI architectures for clinical environments requires a rigorous balance between setup complexity, acquisition modality, and patient fatigue. Medical-grade systems (e.g., g.tec) offer excellent spatial resolution but necessitate skin abrasion and conductive gel, extending setup times beyond 25 minutes and limiting practicality in high-turnover public healthcare settings [6]. Consumer-grade alternatives such as the Emotiv EPOC X enable an agile setup of approximately 3 minutes using felt matrices immersed in saline solution [7], [13]. Prior work with the Emotiv EPOC has exploited its inertial sensors and facial expression streams for wheelchair control [10], while other studies have used OpenBCI for lower-limb robot actuation [8]. However, these systems typically couple processing tightly to a single actuator, lacking the decoupled architecture proposed here. Table I positions this work against contemporary BCI systems.

Table I
COMPARATIVE ANALYSIS OF BCI SYSTEMS FOR REHABILITATION

System / Author	Device / Channels	Setup	Paradigm	Load / Portability	Critical Limitations
López-Larraz *et al.* (2018) [6]	EEG gel (32–64 channels)	$>$ 25 min	Pure Motor Imagery	Critical (Extreme fatigue); Null portability	Skin abrasion and gel impede daily use. Mental fatigue limits therapeutic sessions.
Al-Quraishi *et al.* (2022) [8]	OpenBCI dry (8 channels)	15 min	Multiclass SSVEP	High (Photic fatigue); Low portability	Visual fatigue and frequent calibration. Lower signal quality than gel systems.
Elnady *et al.* (2015) [10]	Emotiv EPOC (14 channels + IMU)	3 min	Head movement (IMU)	Low; High portability	Exclusive dependence on inertial signals; cortical EEG potential unused.
g.tec (g.Nautilus PRO) [11]	Active EEG (8–64 channels)	15–25 min	MI / SSVEP / P300	Variable (High); Medium portability	Prohibitive cost for public health systems. Proprietary software and dedicated infrastructure required.
Pfurtscheller *et al.* (2010) [9]	Laboratory EEG ($>$ 16 channels)	$>$ 20 min	Hybrid BCI (Concept)	Reduced (Theoretical); Null portability	Purely conceptual; no validation on low-cost hardware or clinical protocol.
Proposed Framework	**Emotiv EPOC X + ESP32 (14 EEG + IMU)**	**3 min**	**Hybrid (EMG+IMU) / SSVEP**	**Reduced (by design); High portability**	**Preliminary validation with healthy users (N=3); clinical trials pending.**

III. Methodology and Platform Design

A. Cybernetic and Mechatronic Infrastructure

The global architecture relies on a Wi-Fi hotspot communication structure with logically isolated responsibilities. The software was developed under an asynchronous paradigm in Python 3.11, structured under the Model-View-Controller (MVC) pattern. Instead of relying solely on blocking native threads that disrupt biosignal temporal windows, the `asyncio` framework maintains a single thread of high-speed concurrent coroutines interacting with the Cortex API v3 via WebSockets. Parallel output communication to the ESP32 utilizes a dedicated queue (`queue.Queue()`) managed in a daemon thread.

The decoupling is achieved through a custom local mechatronic module incorporating an ESP32-WROOM-32 microcontroller and a galvanic isolation stage with power relays. The Python software transmits standardized plain text strings (e.g., TURN_ON, `"+"`, `"−"`) via a Wi-Fi hotspot on port 3333, acting directly on the original physical buttons of a DC motor minibike.

B. Architecture 1: Hybrid Mode (EMG + IMU)

This logical flow divides the discrete myoelectric channel and the proportional kinematic channel (Fig. 1). The discretized safety control is executed via the `fac` stream of the Emotiv API, which represents a proprietary facial-expression inference rather than directly measured raw EMG. An intentional jaw clench acts as an alternating toggle switch. During empirical bench testing, the optimal algorithmic sensitivity for this gesture was found to be between 18% and 30%. Below 18%, the system registered false positives caused by involuntary facial movements (e.g., swallowing, phonation). An adaptive threshold of 22% was established to provide the best balance between sensitivity and robustness.

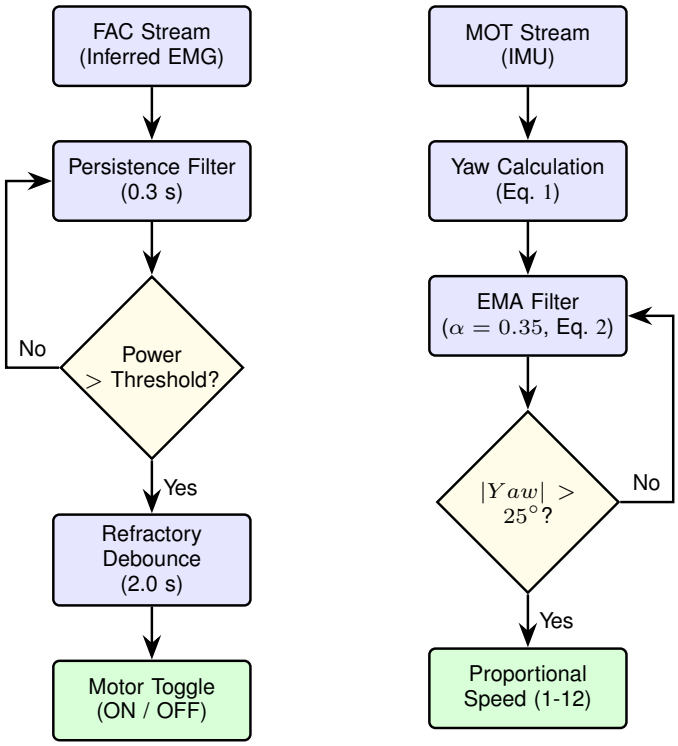

Fig. 1. Operational flowchart of the Hybrid architecture: division of the discrete myoelectric channel and the proportional kinematic channel.

Proportional kinematic control processes the quaternions (Q_0 to Q_3) from the `mot` stream at 32 Hz to derive the neck's yaw angle:

$$Yaw = \text{atan2}\left(2(Q_0Q_3 + Q_1Q_2), 1 - 2(Q_2^2 + Q_3^2)\right) \quad (1)$$

To suppress micro-tremors and spastic spasms, the relative angle passes through an Exponential Moving Average (EMA)

filter:

$$Y_{filtered}[n] = (1 - \alpha) \cdot Y_{filtered}[n-1] + \alpha \cdot Y_{raw}[n] \quad (2)$$

with a smoothing factor of $\alpha = 0.35$. A $\pm 25^\circ$ dead zone was programmed to generate proportional speed commands only when intentional rotations occur.

C. Architecture 2: Visual Mode (Binary SSVEP)

A visual channel was implemented based on the Power Spectral Density in the occipital channels (O_1, O_2). A stimulus frequency of 15 Hz was selected to maximize the cortical Signal-to-Noise Ratio (SNR) in the Low-Beta band. Visual safety regarding lower photoconvulsive risk and fatigue ultimately depends on individual luminance, contrast, and visual-field exposure susceptibility [12].

To eradicate the entrainment effect, a Finite State Machine (FSM) isolates visual rest from the actuation phase. (Fig. 2).

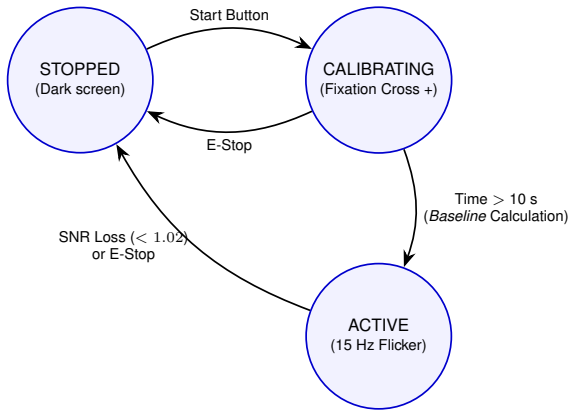

Fig. 2. Finite State Machine (FSM) implemented to ensure a blind spectral calibration, isolating visual rest from the actuation phase.

In the calibration phase (10 s), the GUI displays a dark fixation cross to mathematically register the median cortical white noise as the *Baseline*. During the 15 Hz stimulation, the current SNR is attenuated by an EMA filter ($\alpha = 0.05$). If the SNR exceeds the fixed threshold of 1.20, the minibike advances. A 1.5 s conformation window was programmed, including a release factor of 0.85 (hysteresis zone), to prevent abrupt shutdowns from transient signal drops caused by reflexive blinking. All system parameters are consolidated in Table II.

IV. Technical Validation and Laboratory Results

As handling neurological patients requires extensive ethical evaluation, this research was consolidated as an Instrumentation Proof of Concept (PoC). Validation was conducted through functional laboratory trials with three healthy volunteers ($N = 3$) (Fig. 3).

A. Pilot Study Protocol

Each participant performed a structured protocol consisting of 5 complete on/off cycles (10 targeted activations) in each modality. A 2-minute familiarization period was provided before each session. Performance data (command timestamps, motor state, yaw angle, EMG power, SNR) were logged synchronously using a custom Python datalogger. Classification accuracy was calculated as the ratio of intended activations to total recorded activations (including false positives). The Information Transfer Rate (ITR) was computed using the standard formula with binary selection ($N = 2$), fixed average selection times defined by protocol design ($T = 3.0$ s for the Hybrid mode and $T = 8.0$ s for the SSVEP mode, based on the nominal debounce and confirmation windows of each architecture), and the measured accuracy. Subjective workload was assessed using the NASA Task Load Index (NASA-TLX). Given the reduced sample size ($N = 3$), inferential statistical comparisons (e.g., hypothesis testing) between modalities were not performed; the reported means and standard deviations should be interpreted as preliminary descriptive trends rather than statistically validated differences.

Table II
CONFIGURATION PARAMETERS FOR BCI ARCHITECTURES

Parameter	Description	Value
α_{yaw}	EMA constant for yaw angle	0.35
α_{snr}	EMA constant for SNR tracking	0.05
Dead Zone	Angle dead zone (micro-movements)	$\pm 25^\circ$
Threshold EMG	Inferred jaw clench threshold	0.22 (22%)
Debounce EMG	Refractory time to prevent bouncing	2.0 s
SSVEP Calib.	Blind calibration for *Baseline*	10 s
SSVEP Thresh.	Motor activation threshold via SNR	1.20
Release Factor	Hysteresis factor for deactivation	0.85
SSVEP Conf.	Visual confirmation window	1.5 s

B. System Performance and Information Transfer Rate

Fig. 4 summarizes the classification accuracy and ITR for both control modes across the three subjects. Table III consolidates the individual and average values.

Table III
PERFORMANCE METRICS FROM PILOT STUDY (N=3)

Metric	S1	S2	S3	Mean $\pm$ SD
Hybrid Mode (EMG+IMU)				
Accuracy (%)	100.00	71.43	83.33	84.92 $\pm$ 14.35
False positives	0	4	2	2.00 $\pm$ 2.00
ITR (bits/min)	20.00	2.74	7.00	9.91 $\pm$ 8.99
SSVEP Mode (15 Hz)				
Accuracy (%)	76.92	71.43	83.33	77.23 $\pm$ 5.96
False positives	3	4	2	3.00 $\pm$ 1.00
ITR (bits/min)	1.65	1.03	2.62	1.77 $\pm$ 0.81

The Hybrid mode achieved a mean classification accuracy of 84.92% (SD = 14.35%), with individual accuracies of 100.00%, 71.43%, and 83.33% for Subjects 1, 2, and 3, respectively. In contrast, the SSVEP paradigm presented a mean accuracy of 77.23% (SD = 5.96%), with per-subject values of 76.92%, 71.43%, and 83.33%. The mean ITR was substantially higher in the Hybrid mode (9.91 bits/min, SD = 8.99) compared to the SSVEP mode (1.77 bits/min, SD = 0.81), reflecting the faster nominal actuation window of

Fig. 3. Instrumental functional testing of the PoC in the laboratory. The user asynchronously operates the framework using the sensor headset and the unified GUI.

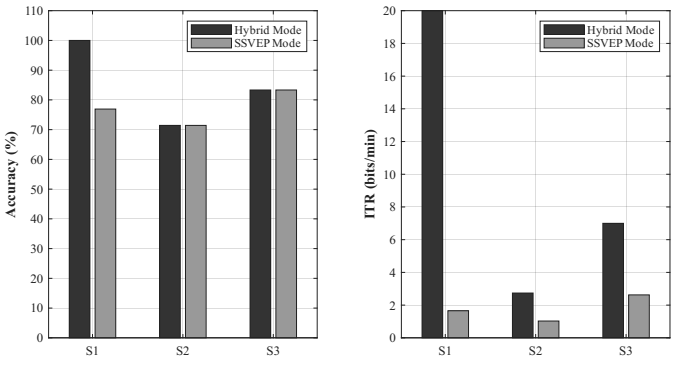

Fig. 4. Comparative performance across three healthy subjects. The Hybrid mode demonstrated superior accuracy and ITR due to the rapid execution of facial gestures compared to sustained visual fixation.

facial gestures ($T = 3.0$ s) relative to sustained visual fixation ($T = 8.0$ s).

False positive activations were observed in both modes. In the Hybrid mode, Subjects 2 and 3 registered 4 and 2 false positives, respectively, while Subject 1 achieved perfect performance. In the SSVEP mode, all subjects exhibited at least 2 false positives, with Subject 2 reaching 4. These false activations occurred predominantly during the initial trials and were attributed to insufficient familiarization with the control paradigm. After verbal clarification and the 2-minute practice period, all subjects were able to operate the system reliably.

C. Cognitive Workload Assessment (NASA-TLX)

Fig. 5 presents the average NASA-TLX scores for the six workload dimensions.

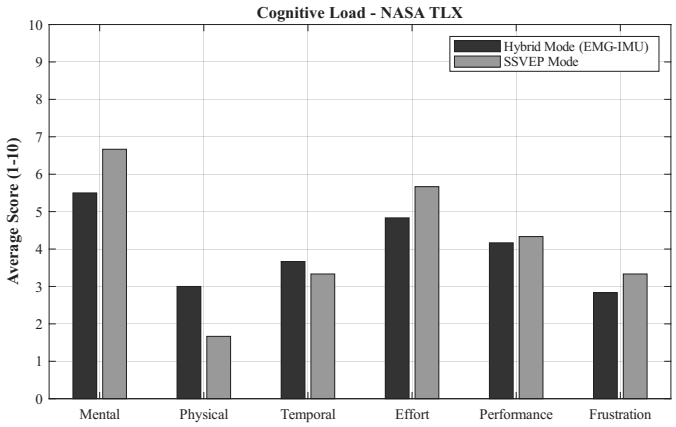

Fig. 5. Cognitive workload comparison (NASA-TLX). The Hybrid architecture shows a trend towards lower mental demand and overall effort.

Results reveal distinct workload profiles for the two control paradigms. The Hybrid mode imposed slightly higher physical demand (mean = 3.00, SD = 1.79) compared to the SSVEP mode (mean = 1.67, SD = 0.58), consistent with the explicit muscular engagement required for jaw clenches and head movements. Conversely, mental demand was higher in the SSVEP mode (mean = 6.67, SD = 1.15) than in the Hybrid mode (mean = 5.50, SD = 2.17), reflecting the sustained attentional focus required by the flickering stimulus. Overall perceived effort followed a similar trend, with means of 4.83 (SD = 1.47) and 5.67 (SD = 1.53) for the Hybrid and SSVEP modes, respectively. Frustration was also slightly higher for SSVEP (mean = 3.33, SD = 2.52) compared to Hybrid (mean = 2.83, SD = 1.94), likely related to the initial false activations and learning curve. Given the small sample size, these workload differences are reported descriptively and should be regarded as preliminary trends rather than statistically confirmed effects; they nonetheless support the rationale for a bimodal architecture that allows selection based on individual patient capabilities.

D. Dynamic Behavior and Signal Filtering

Initial bench tests revealed a high involuntary activation rate due to biosignal bouncing at the threshold boundaries. Detailed

temporal dynamics for both architectures were captured via a native Python datalogger.

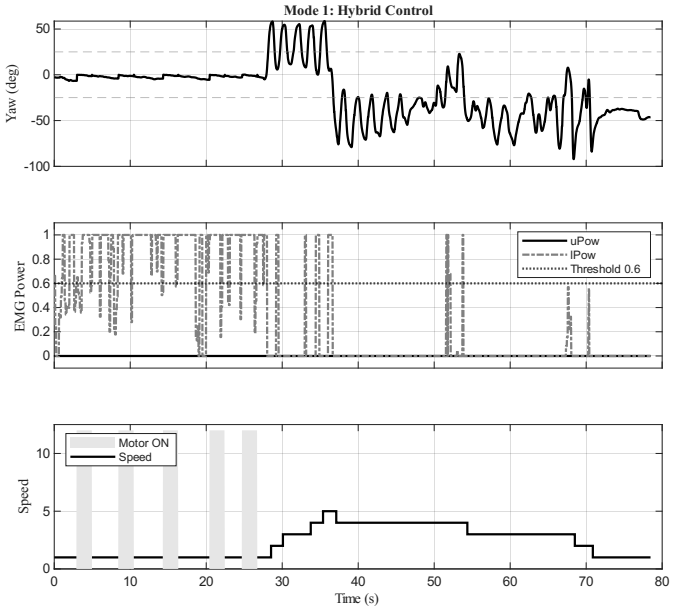

Fig. 6. Dynamic records of the Hybrid Mode. Kinematic Yaw modulates speed, while the discrete facial inference acts as a toggle. The $\pm 25^{\circ}$ dead zone effectively ignores micro-movements.

For the Hybrid mode (Fig. 6), the implementation of the 2.0 s refractory time filter completely stabilized the ESP32 relay response. Natural myoelectric oscillations (uPow/lPow) around the 0.22 threshold were effectively ignored post-activation, suppressing erratic cyclic switchings.

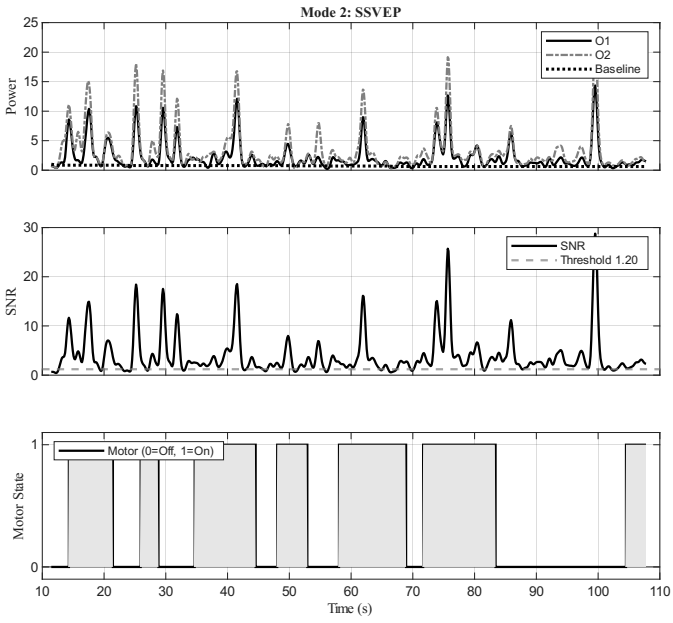

Fig. 7. Dynamic records of the SSVEP Mode. Stable mechatronic pulse generation provided by the sustained crossing of the 1.20 SNR threshold following the 10 s baseline calibration.

For the SSVEP mode (Fig. 7), spectral monitoring validated the stability of the FSM. During the first 10 seconds (blind calibration), the baseline remained immune to background noise. Upon 15 Hz stimulation, the SNR demonstrated monotonic growth, crossing the 1.20 threshold reliably. The 1.5 s conformation window successfully eliminated false commutations caused by reflexive blinks. Furthermore, a Wi-Fi timeout mechanism was implemented on the ESP32 to trigger an automatic motor shutdown within 500 ms upon TCP disconnection, providing a basic fail-safe behavior.

V. Discussion and Limitations

While the modular architecture efficiently decouples cortical processing from actuation, several limitations must be acknowledged. Experimental trials were conducted in a controlled environment with healthy subjects ($N = 3$), which does not account for the neurophysiological variability of post-stroke patients (e.g., hypertonia, spasticity, or cognitive impairments). The EMG threshold (22%) and head yaw dead zone ($\pm 25^{\circ}$) may require recalibration for the target clinical population.

The high standard deviation observed in Hybrid mode accuracy (SD = 14.35%) and ITR (SD = 8.99 bits/min) indicates substantial inter-subject variability, underscoring the need for individualized calibration protocols. During the sessions, Subject 2 was informally observed to require repeated head-rotation attempts before the system registered a deceleration command; this anecdotal observation was not captured with a dedicated metric and is reported here only as a qualitative note suggesting that the dead zone or EMA parameters may need adjustment for users with different movement patterns.

The relative contribution of each individual stabilization mechanism (refractory debounce, EMA smoothing, and SSVEP hysteresis) to overall system performance was not isolated through formal ablation testing; each filter was evaluated only as part of the complete pipeline. Quantifying these individual contributions remains an open direction for future work.

Technologically, the use of the Emotiv EPOC X imposes restrictions due to the unavailability of raw EEG signals through its standard API, limiting the implementation of advanced deep learning algorithms for raw feature extraction. The `fac` stream, while correlated with facial muscle activity, is a proprietary inference that may introduce algorithmic dependencies not transparent to the end user. Furthermore, while the reuse of TCP commands successfully drives a laboratory minibike, immediate compatibility cannot be guaranteed for complex physical therapy machines such as exoskeletons or treadmills without rigorous adaptation of electrical interfaces, specific functional safety protocols, and strict compliance with medical device regulatory requirements (e.g., IEC 60601).

Although a Wi-Fi timeout mechanism was implemented, its behavior under intermittent connectivity or electromagnetic interference has not been formally tested. Future work should include controlled fault-injection tests to evaluate system robustness. Similarly, the SSVEP mode's safety depends on

stimulus parameters (luminance, contrast, flashing rate) and individual susceptibility to photosensitivity; the fixed 15 Hz frequency and 1.20 SNR threshold should be validated in a clinical setting.

VI. Conclusion

This paper presented a functional Proof of Concept for a modular BCI framework designed to control a rehabilitation minibike. The central contribution lies in the decoupled bimodal architecture, standardized network commands, and mathematical filters (EMA and refractory debounce) that successfully improved operational stability by mitigating the biosignal bouncing effect. A pilot study with three healthy volunteers ($N = 3$) demonstrated that the Hybrid mode achieved higher mean accuracy (84.92%) and ITR (9.91 bits/min) compared to the SSVEP mode (77.23% and 1.77 bits/min, respectively). NASA-TLX assessments suggested a trend towards lower mental workload for the Hybrid mode, at the cost of slightly higher physical demand. These results, while preliminary and based on a small, non-clinical sample, support the rationale for offering both control modalities to accommodate diverse patient capabilities.

Key *lessons learned* highlight the critical necessity of physical fail-safes and refractory filters to transform erratic biosignals into reliable robotic commands. Significant *research gaps* remain open for future development, including the need for controlled clinical trials with post-stroke patients at CREFES, formal System Usability Scale (SUS) assessments, systematic comparison of control modes with larger cohorts and inferential statistical analysis, ablation studies isolating the contribution of each stabilization filter, robustness testing under fault conditions, and the potential integration of machine learning for automatic personalization of dynamic control parameters.

***Abstract*—Stroke frequently impairs upper-limb motor function and reduces the functional independence of affected individuals. This paper presents a proposal for the development of a motor imagery (MI)-based Brain–Computer Interface (BCI) to control a Functional Electrical Stimulation (FES). This device will be used as a support tool for physiotherapists during post-stroke motor rehabilitation sessions. The proposed BCI includes a Graphical User Interface (GUI) for patient registration, session configuration, motor-task presentation, electroencephalography (EEG)-signal acquisition and processing, MI detection, safe FES activation, and automatic recording of technical metrics. The initial evaluation was limited to functional validation of the computational workflow in a controlled environment over four weeks, without aiming to demonstrate clinical therapeutic efficacy. The application is expected to help standardize sessions, support physiotherapist decision-making, and provide an experimental basis for future studies in neurofunctional rehabilitation.**

***Index Terms*—Stroke, brain–computer interface, electroencephalography, functional electrical stimulation, motor imagery, motor rehabilitation.**

I. Introduction

Stroke remains one of the leading causes of disability worldwide, with direct effects on autonomy, social participation, and quality of life [1], [2]. One of its most limiting sequelae is upper-limb motor impairment, often manifested as hemiparesis, loss of strength, reduced motor selectivity, tone alterations, and difficulty performing activities of daily living (ADLs) [3], [4]. Recovery of hand, wrist, and finger movement is particularly challenging because it depends on sensorimotor reorganization and repetitive practice of functional tasks.

In the State of Espírito Santo (Brazil), the Physical Rehabilitation Center of Espírito Santo (CREFES), located in Vila Velha-ES, is a reference service for physical rehabilitation. It provides multiprofessional care, including physiotherapy, occupational therapy, physiatry, neurology, and clinical support areas [5]. Therefore, technologies designed for professional use may help structure rehabilitation sessions, record performance, and support future clinical assessments.

Functional Electrical Stimulation (FES) uses controlled electrical pulses to activate peripheral muscles and produce functional movements. In the upper limbs of post-stroke patients, Functional Electrical Stimulation may target wrist and finger extensors or flexors, assisting movements such as hand opening, hand closing, and grasping [6], [7]. Clinical guidelines recognize Functional Electrical Stimulation as an adjunct resource for motor recovery, especially when combined with task-oriented training [4]. However, when applied alone, Functional Electrical Stimulation is not necessarily synchronized with the patient's voluntary motor intention or motor imagery (MI). This limitation motivates the integration of Functional Electrical Stimulation with a Brain–Computer Interface (BCI).

Brain–Computer Interface systems transform central nervous system signals into commands for external devices [8].

In noninvasive Brain–Computer Interface systems, electroencephalography (EEG) is widely used because of its safety, portability, and high temporal resolution [9]. During MI, sensorimotor rhythms in the mu and beta bands may show event-related desynchronization (ERD) and synchronization (ERS) [10], [11]. These modulations provide physiological information that can be used to infer motor intention and activate an assistive device.

The integration of Brain–Computer Interface and Functional Electrical Stimulation is particularly relevant because it creates a closed feedback loop between cortical intention, peripheral motor assistance, and sensory feedback. In this paradigm, the user attempts or imagines a movement, the EEG signal is processed, a motor-intention criterion is evaluated, and Functional Electrical Stimulation is activated only when the decision condition is satisfied. Clinical studies and reviews indicate that Brain–Computer Interface systems associated with Functional Electrical Stimulation or assistive devices have potential for post-stroke upper-limb rehabilitation [12]–[18]. Nevertheless, the literature highlights persistent challenges related to standardization, usability, safety, EEG signal variability, and transfer to real clinical environments [19]–[21].

Beyond the therapeutic component, robust MI decoding remains a central technical challenge. Methods such as Common Spatial Pattern (CSP), Filter Bank Common Spatial Pattern (FBCSP), Support Vector Machine (SVM), Linear Discriminant Analysis (LDA), Riemannian Geometry (RG), and autoencoder-based techniques have been applied to improve MI task classification [9], [23]–[26]. These approaches differ in complexity, interpretability, calibration requirements, and amount of data needed for reliable training. Classical pipelines such as CSP or FBCSP combined with LDA or SVM are relatively interpretable and have been widely used in MI-Brain–Computer Interface studies. Riemannian Geometry (RG) methods exploit the covariance structure of multichannel EEG, whereas autoencoder-based approaches may improve feature learning but usually require larger datasets and stronger validation.

In the present work, the initial motor-intention detection strategy is not based on a full machine-learning classifier. Instead, it adapts a threshold-based MI detection algorithm previously proposed for upper-limb MI-Brain–Computer Interface control [38]. This algorithm uses C3/C4 sensorimotor rhythms, relative mu (8-13Hz) and high-beta (20-38Hz) band power, a stabilized lateralization index, baseline-derived thresholds, hysteresis, and finite-state-machine logic. In this study, the algorithm is adapted to authorize Functional Electrical Stimulation activation during functional validation, prioritizing interpretability, safety, and workflow verification before implementing more complex classifier-based approaches.

Recent studies reinforce the relevance of MI-Brain–Computer Interface approaches for post-stroke rehabilitation, but they also show important methodological differences. Some protocols combine MI with neurofeedback, Functional Electrical Stimulation, robotic gloves, or assistive devices to provide contingent sensory and motor feedback, whereas others focus mainly on EEG decoding and clinical outcome assessment [27]–[31]. These differences are relevant because the therapeutic effect of Brain–Computer Interface-based rehabilitation depends not only on the detection method, but also on the temporal coupling between motor intention, feedback, and assisted movement.

For upper-limb MI, most protocols focus on sensorimotor rhythms in the mu and beta bands because these frequency components are directly associated with ERD/ERS during movement imagination [32]. Other EEG frequency ranges may provide complementary information, but they are less specific to sensorimotor modulation and may be more affected by attention, visual processing, or artifacts. Therefore, mu and beta activity remain a practical and physiologically grounded choice for detecting hand opening and hand closing MI.

Another relevant distinction concerns the type of motor imagery task. Kinesthetic MI requires the participant to imagine the sensation of performing the movement, while visual or action-observation strategies emphasize external observation or visual representation of the task. Kinesthetic MI is especially relevant for rehabilitation because it is more closely related to sensorimotor activation, whereas visual strategies may facilitate task understanding, attention, and protocol adherence [33]–[35].

Thus, the present proposal contributes to the advancement of Brain–Computer Interface-, Functional Electrical Stimulation-, and assistive-device-based technologies for neurorehabilitation by focusing on a practical and configurable system oriented toward physiotherapist-supervised upper-limb motor rehabilitation sessions. The initial validation emphasizes functional integration, motor-intention detection, safe Functional Electrical Stimulation activation, and session recording rather than clinical therapeutic efficacy.

II. Methodology

The methodological approach is conducted as technological development with preliminary functional validation. The initial stage does not aim to demonstrate clinical efficacy, but rather to verify the computational workflow required for a MI-based BCI-FES application intended for supervised use by physiotherapists. For this preliminary validation, a pilot test with ten healthy subjects aged between 20 and 30 years is performed to verify protocol execution, signal acquisition, computational processing, FES activation, and recording of the information generated by the system. Participants are informed about the nature of the test and sign an informed consent form.

A. Experimental Setup

The experimental setup integrates EEG acquisition, protocol execution, stimulation command generation, and session supervision. EEG is acquired using an OpenBCI system with a Daisy expansion module, allowing 16-channel acquisition. The EEG stream is received through the OpenViBE Acquisition Server and processed in OpenViBE Designer, which is used to execute the experimental scenario, synchronize protocol events, and manage online signal processing. The

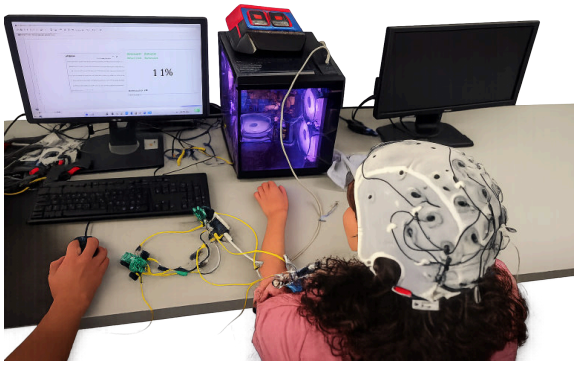

Fig. 1. Representative setup used during the preliminary pilot test. The system includes the OpenBCI EEG cap, the acquisition and interface computer, OpenViBE monitoring, the ESP32 command bridge, the FightArt FES device, and FES electrodes positioned on the forearm for hand-opening and hand-closing stimulation.

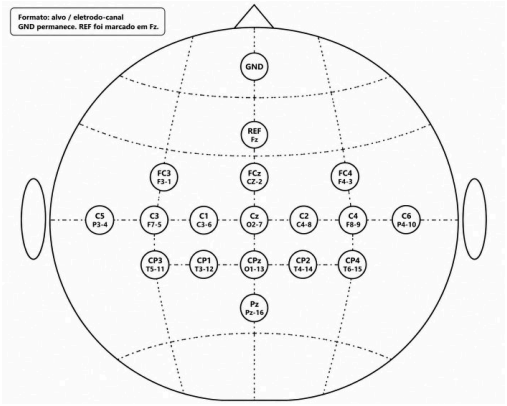

Fig. 2. EEG electrode montage used in the MI-based BCI-FES protocol. The configuration uses 16 active channels focused on fronto-central, central, centro-parietal, and parietal regions. The reference electrode was marked at Fz, and the ground electrode was maintained according to the OpenBCI cap configuration.

stimulation pathway includes an ESP32 microcontroller used as a digital command bridge and a FightArt FES device used for stimulation. The preliminary functional tests are performed by the development team to verify protocol execution, EEG acquisition, signal processing, FES command generation, safety behavior, and data logging. In addition, the interface design receives clinical-usability input from the physiotherapist co-author regarding configurable stimulation channels, activation duration, current intensity, safety controls, and session monitoring.

The system is operated through a clinical GUI developed for physiotherapist supervision. This interface allows participant registration, session configuration, FES authorization, safety monitoring, protocol execution, and event logging. The ESP32 receives serial commands from the interface and translates them into pulse trains associated with the hand-opening and hand-closing commands of the FES device. Therefore, OpenViBE remains responsible for EEG acquisition and online processing, while the external interface acts as the clinical control and safety layer.

The physical FES command bridge uses the ESP32 as an interface to the control inputs of two FightArt FES units. The first command pair is assigned to GPIO25 and GPIO26, and the second command pair is assigned to GPIO32 and GPIO33. These outputs are used to emulate brief button activations according to the firmware commands, while the stimulation output stage remains managed by the FES equipment. During non-motor phases or safety blocks, the firmware releases the GPIO pins to avoid sustained activation.

A preliminary pilot setup is used to verify the complete acquisition-control-stimulation workflow. During this test, the participant remains seated in front of the acquisition computer while wearing the OpenBCI EEG cap, as shown in Fig 1. FES electrodes are positioned on the forearm according to the stimulation targets, and the ESP32 is connected between the software interface and the FES device. The clinical interface and OpenViBE monitoring window are used simultaneously to observe the protocol state, EEG activity, threshold behavior, serial communication, and stimulation authorization.

B. EEG Montage and FES Preparation

The EEG montage is defined to prioritize cortical regions involved in upper-limb MI, especially the bilateral sensorimotor cortex. Sixteen active channels are positioned according to the 10–20 system, as shown in Fig. 2. This configuration covers fronto-central, central, centro-parietal, and parietal regions, with emphasis on C3, Cz, and C4 due to their relevance for hand MI. The acquisition follows a common-reference configuration, with the reference electrode at Fz and the ground electrode maintained according to the OpenBCI cap configuration.

FES electrodes are positioned over the main forearm muscle groups responsible for hand opening and hand closing. For hand closing, electrodes are placed over the anterior forearm region, prioritizing the wrist and finger flexor muscle mass. For hand opening, electrodes are placed over the posterior forearm region, prioritizing the wrist and finger extensor muscle mass. This placement follows the principle that stimulation electrodes should be positioned over the target muscle belly or motor point region to elicit the desired functional movement [36], [37].

Before starting the BCI-FES protocol, an individual FES validation procedure is performed with each participant under physiotherapist supervision. The stimulation intensity is initially set to the minimum available level and gradually increased to identify the lowest intensity capable of producing visible functional hand opening or closing without pain. If the participant reports pain, excessive discomfort, or an inadequate motor response, the electrode position is adjusted and the intensity is reduced. Thus, the selected stimulation level is individualized for each participant and movement condition before online activation is allowed.

During the experimental protocol, FES activation is restricted to valid motor events, namely hand opening and hand

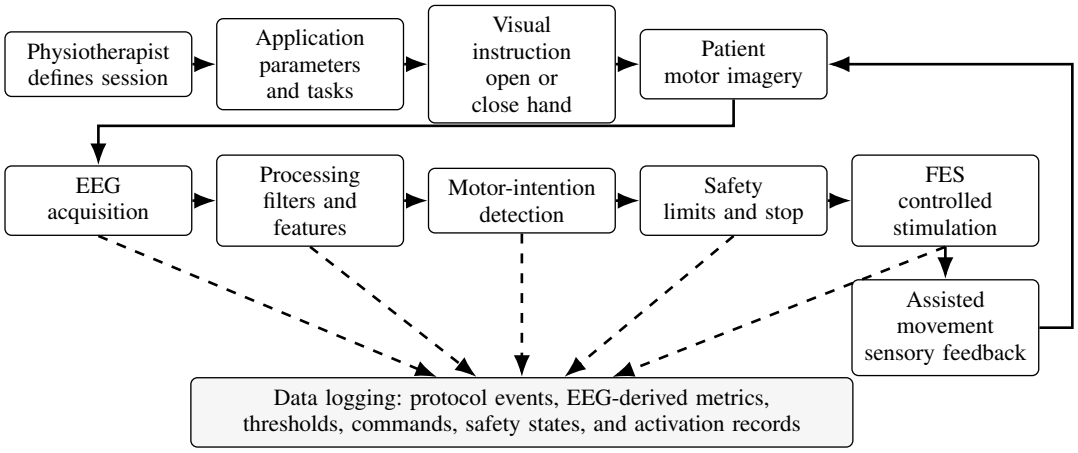

Fig. 3. Functional architecture of the MI-based BCI-FES application for upper-limb motor rehabilitation support. Solid arrows indicate the control loop, and dashed arrows indicate session data logging.

closing. During baseline, rest, idle, start-of-block, and end-of-session events, all stimulation outputs remain disabled. Therefore, the FES device is not controlled directly by the EEG marker alone; stimulation depends on the current protocol event, the baseline-derived threshold, the physiotherapist's authorization, the safety state, and the previously calibrated intensity level.

C. Solution Architecture

The BCI development is organized into five modules: clinical interface, BCI processing, FES control, operational safety, and data storage. Fig. 3 presents the proposed workflow. The physiotherapist configures the session in the GUI, the patient receives a visual instruction, EEG is acquired during MI, the signal is processed, motor intention is detected, safety rules are checked, and FES is activated only when the activation criterion is met. The assisted movement provides sensorimotor feedback, while the application records session events and metrics.

Additionally, key security measures were implemented, such as the requirement for professional authorization, individual calibration for each user, and an emergency stop button to immediately halt the interface.

D. Session Workflow

The session begins with patient registration or selection in the case they are already registered. Next, the physiotherapist defines the motor task, such as hand opening or closing, and configures acquisition and stimulation parameters. The GUI presents visual instructions to the patient and records time windows associated with MI. The EEG signal is filtered, segmented, and processed for feature extraction. If the EEG-derived control variable exceeds the decision threshold, the interface sends a command to the FES module. All events are recorded for later analysis.

E. Experimental Protocol Design

The experimental protocol is designed to standardize the preliminary functional validation of the MI-based BCI-FES system and to synchronize visual instructions, EEG acquisition, decision logic, FES command generation, and data logging. As shown in Fig. 4, the protocol starts with a 10 s welcome and instruction period, followed by a 120 s baseline period with all output pins off. This baseline is used to calculate the reference threshold for later activation decisions. A 3 s start-of-block event then indicates the beginning of the experimental task sequence.

The main task cycle is repeated four times and follows the sequence: rest, close hand, rest, idle, rest, open hand, and rest. Each rest event lasts 3 s and is used to turn off all outputs and reset the system state. The close-hand and open-hand events last 10 s each; during these periods, only the pins associated with the current task can be activated, and activation is allowed only when the current signal exceeds the baseline-derived threshold. The idle event lasts 20 s and does not allow pin activation.

With four repetitions, the repeated task block lasts 208 s. Considering the welcome and instruction period, the baseline, and the start-of-block event, the complete protocol has a total duration of 341 s.

Pin activation follows a strict priority rule. First, the current protocol event has to allow stimulation. Second, the processed signal has to exceed the threshold calculated during the baseline. Third, the system applies the intensity and speed values configured by the physiotherapist. Finally, the corresponding pins are activated according to the current task. Therefore, during welcome, baseline, start-of-block, rest, idle, and end-of-session events, all pins remain off regardless of the signal value. During close-hand and open-hand events, activation is restricted to the pins associated with the current task.

F. EEG Processing and Motor-Intention Detection

The motor-intention detection algorithm is adapted from a previous upper-limb MI-BCI protocol based on C3/C4 sensorimotor rhythms [38]. In the present system, EEG signals are processed in sliding windows with overlap. For each window,

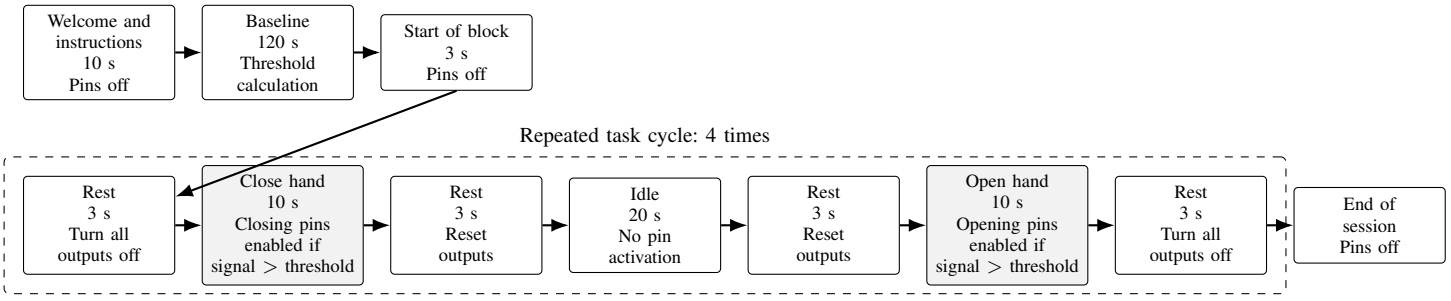

Fig. 4. Temporal flow of the experimental protocol used for preliminary functional validation of the MI-based BCI-FES system. The protocol includes fixed initial events, a baseline period for threshold calculation, and a repeated task cycle composed of rest, hand closing, idle, and hand opening events.

the algorithm estimates the relative power of the mu band (8–12 Hz) and the high-beta band (18–24 Hz), normalized by the broader sensorimotor band from 8 to 30 Hz.

The processing focuses on sensorimotor activity around C3 and C4 because these regions are associated with upper-limb motor imagery. The relative mu and high-beta components are combined into C3- and C4-centered sensorimotor indices. Then, a lateralization index is computed from the difference between the right and left sensorimotor indices, normalized by their sum. This index provides a bounded control variable related to motor-intention modulation.

To improve online stability, the control variable is stabilized using a running median and exponential smoothing. During the baseline period, the system learns an individualized decision threshold from the percentile distribution of the baseline control variable. The activation threshold is bounded by minimum and maximum safety limits to avoid excessively sensitive or insensitive behavior.

FES activation is not triggered by a single threshold crossing. The system applies hysteresis and finite-state-machine logic. The ON threshold must be exceeded for a predefined number of consecutive windows before stimulation is authorized. The OFF threshold, minimum ON/OFF dwell times, sticky-hold behavior, and inactivity failsafe reduce unstable switching and prevent accidental or sustained activation.

Therefore, stimulation is generated only when four conditions are satisfied: the current protocol phase allows motor activation, the EEG-derived control variable exceeds the decision criterion, the physiotherapist authorization is active, and no safety lockout is present. This strategy is used as a preliminary threshold-based MI detection approach for functional validation of the BCI-FES workflow. Future versions should compare this interpretable strategy with classifier-based approaches such as CSP/FBCSP, LDA, SVM, and Riemannian Geometry.

G. Experimental Data Organization and Statistical Analysis

The experimental files are organized by participant, with one session per participant. The offline EEG database contains the protocol cycle, task phase, hand condition, EEG-derived features, threshold values, threshold-crossing flags, and temporal information. Participant identifiers are inferred from the session folders, hand conditions from the hand labels, and trial fields are used only to identify protocol cycles. Therefore, cycles and internal processing windows are not treated as independent statistical samples.

For the open-versus-closed comparison, each EEG feature is first summarized by participant and condition, using the mean as the default summary statistic. The analysis is paired, with the effective sample size defined as the number of participants with valid data in both conditions. The Wilcoxon signed-rank test is used as the principal nonparametric test, complemented by a paired permutation test and an additional paired t-test. Effect sizes include Cohen's dz for the paired t-test and rank-biserial correlation for the Wilcoxon test. When multiple EEG features are analyzed, Benjamini–Hochberg false discovery rate (FDR) correction is applied to the Wilcoxon p values.

The neurofeedback threshold is calculated individually from the baseline period. During baseline, the absolute MI score is stabilized with a short median window, and the participant threshold is defined as the 90th percentile of the baseline metric, clipped to the range from 5 to 30 units. Threshold-based metrics are then summarized at the participant level before the paired comparison between hand opening and hand closing.

III. Results

A. Functional Interface Validation

The first result of the preliminary validation was the implementation of an integrated GUI for configuring, executing, and monitoring MI-based BCI-FES sessions. The GUI integrated participant registration, session configuration, protocol timing, OpenViBE control, FES authorization and safety settings, serial communication, execution controls, live monitoring, and event logging. Clinical-usability input from the physiotherapist co-author indicated that the developed interface may support supervised BCI-FES rehabilitation by allowing individualized configuration of active stimulation channels, activation duration, and current intensity according to the therapeutic goals and clinical characteristics of each participant. From a clinical perspective, the main advantage of the system is that FES activation is not delivered as a passive stimulation routine, but is conditioned on EEG-derived evidence of motor intention, physiotherapist authorization, and safety rules. This organization may promote a closer association between voluntary

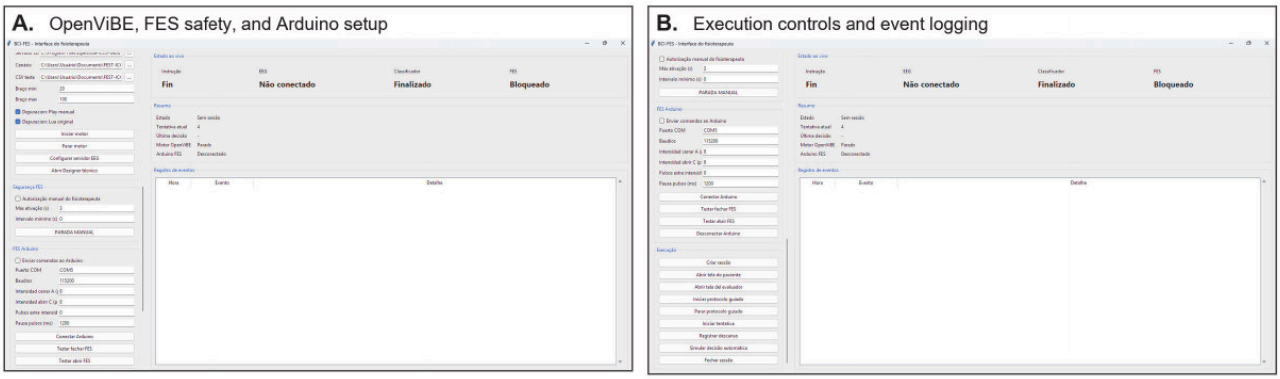

Fig. 5. Technical control areas of the physiotherapist interface.

cortical activation, peripheral muscle stimulation, and sensorimotor feedback, which is relevant for activity-dependent neuroplasticity. The physiotherapist also highlighted that the interface may support clinical decision-making because it enables personalized and reproducible protocols without hardware modifications and integrates EEG acquisition, motor-intention processing, FES control, safety supervision, and session recording in a single platform. This input is interpreted as a qualitative assessment of clinical usability and workflow organization.

Fig. 5 details the technical controls used during session execution. Panel A groups OpenViBE configuration, FES safety parameters, and Arduino serial communication. Panel B shows manual safety controls, FES testing commands, execution buttons, live state, and the event log. These controls support traceability and supervised operation of the MI-based BCI-FES workflow.

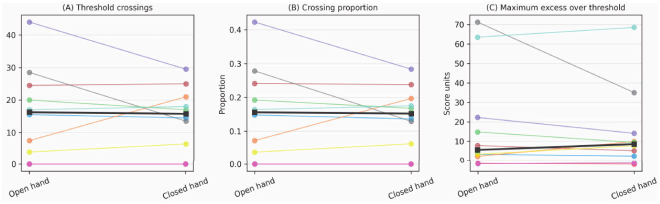

Fig. 6. Paired threshold-based metrics summarized at the participant level.

B. Exploratory Statistical Analysis

The statistical analysis used the experimental CSV files from ten anonymized participants, labeled Subject 1 through Subject 10. The inspected EEG databases contained 4,742,750 rows in total. Open- and closed-hand task labels accounted for 1,038,875 rows. After reducing repeated samples to unique processing windows, 8,311 windows were retained for feature extraction, but the final paired comparisons were performed at the participant level. Thus, the effective statistical sample size was $n = 10$ participants with valid data in both conditions.

Table I summarizes the paired open-versus-closed comparison for the channels with the greatest exploratory interest using the real electrode mapping. No channel survived Benjamini–Hochberg FDR correction. The smallest uncorrected Wilcoxon values appeared in C4 and CP3 ($p = 0.049$), but their corrected values were $p_{\mathrm{FDR}} = 0.371$. Permutation tests showed low exploratory values for C4, CP3, CPz, and Pz, but these findings remain exploratory because the study was limited to ten participants. The remaining channels did not show statistically supported differences after FDR correction.

Derived non-channel EEG metrics from the CSV included `eeg_value`, `li_median`, `li_signed`, `li_strength`, and `rmi`; these were internal EEG-derived values, not electrode locations. None of these derived features remained significant after FDR correction. For the main controller metric, `eeg_value`, the open-hand mean was 8.91 and the closed-hand mean was 8.15, with a Wilcoxon value of $p = 0.193$ and an FDR-corrected value of $p_{\mathrm{FDR}} = 0.404$.

TABLE I
SELECTED PAIRED OPEN-VERSUS-CLOSED EEG CHANNEL COMPARISONS

Channel	Electrode	Open	Closed	Δ	Wilc.	FDR	Perm.
Ch. 9	C4	-0.015	0.050	-0.065	**0.049**	0.371	0.027
Ch. 11	CP3	-0.009	0.051	-0.060	**0.049**	0.371	0.047
Ch. 13	CPz	-0.013	0.045	-0.058	0.064	0.371	0.047
Ch. 16	Pz	-0.014	0.046	-0.060	0.064	0.371	0.043

All comparisons used $n = 10$ participants. Values were computed after summarizing each participant by condition; cycles and internal windows were not treated as independent samples. Δ indicates the open-hand minus closed-hand mean difference. Wilc., FDR, and Perm. report the Wilcoxon, FDR-corrected, and permutation p values, respectively. Bold values indicate the lowest uncorrected exploratory Wilcoxon p values; no comparison survived FDR correction.

Table II reports the baseline-derived threshold for each participant. The thresholds ranged from 5.00 to 30.00 units. Subjects 5 and 8 reached the lower clamp, whereas Subject 1 reached the upper clamp. These thresholds should be interpreted as technical calibration values for the neurofeedback controller, not as clinical outcome measures.

TABLE II
BASELINE THRESHOLD LEARNED FOR EACH PARTICIPANT

Subject	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10
Threshold	**30.00**	10.42	5.07	14.65	**5.00**	7.19	6.40	**5.00**	28.70	19.47

Threshold values are expressed in EEG-derived control-score units. Bold values indicate thresholds clipped by the predefined lower or upper safety limits.

Table III summarizes the threshold-based paired comparison between hand opening and hand closing. The median number of threshold crossings was similar between open hand and closed hand (16.25 versus 15.75 windows), with a median open-minus-closed difference of 0.00. The crossing proportion was also similar between conditions (0.156 versus 0.152), and the Wilcoxon signed-rank test did not show a statistically supported paired difference before or after FDR correction.

The first-crossing latency was available for eight valid paired participants and was numerically longer for open hand than for closed hand, but this difference also did not survive correction.

TABLE III
EXPLORATORY PAIRED COMPARISON OF THRESHOLD-BASED METRICS

Metric	n	Open median [IQR]	Closed median [IQR]	Δ	p	FDR
Threshold crossings	10	16.25 [18.50]	15.75 [12.00]	0.00	1.00	1.00
Crossing proportion	10	0.16 [0.182]	0.15 [0.11]	0.00	0.48	0.78
Any crossing	10	1.00 [0.00]	1.00 [0.00]	0.00	1.00	1.00
Maximum value	10	18.47 [20.05]	20.80 [17.97]	0.64	0.56	0.78
Maximum excess over threshold	10	5.54 [17.93]	8.53 [10.02]	0.64	0.56	0.78
Windows over threshold	10	16.25 [18.50]	15.75 [12.00]	0.00	0.53	0.78
First-crossing latency (s)	8	1.73 [0.76]	1.30 [1.26]	0.58	**0.15**	0.78

Values are summarized at the participant level. Δ indicates the open-hand minus closed-hand median difference. Tests were Exact sign for threshold crossings, Exact McNemar for any crossing, and Wilcoxon for the remaining metrics. FDR correction was applied across the principal open-versus-closed tests. The bold value indicates the lowest uncorrected exploratory p value; no metric survived FDR correction.

Fig. 6 visualizes the paired threshold-based metrics, with connected lines emphasizing the within-subject comparison. Overall, the workflow registered EEG-derived features, baseline thresholds, protocol events, and paired open-versus-closed comparisons, but no principal comparison showed a statistically robust difference in this preliminary dataset.

IV. DISCUSSION

The primary objective of this study was to verify the functional viability of an integrated MI-based BCI-FES workflow operating in a supervised environment: combining EEG acquisition, visual task presentation, OpenViBE signal processing, threshold-based event detection, ESP32 communication, controlled FES authorization, and session logging into a dedicated interface for healthcare professionals. Reliable system integration across this acquisition–processing–stimulation chain is an essential prerequisite prior to clinical testing [19]–[21]. Crucially, the findings of this study validate the functional operation and safety of this integrated pipeline, but they do not demonstrate successful EEG decoding or class discrimination of motor imagery (MI).

The statistical analysis revealed no robust differences between hand-opening and hand-closing conditions. No EEG channel or derived metric survived False Discovery Rate (FDR) correction; thus, uncorrected trends observed in C4, CP3, CPz, and Pz must be regarded strictly as exploratory observations. Utilizing participant-level analysis avoided pseudoreplication and provided a conservative interpretation of this feasibility dataset. High inter-subject variability is well-documented in EEG-based MI paradigms [9]–[11], and these findings align with broader BCI-FES literature for post-stroke upper-limb rehabilitation, where protocols, populations, and detection outcomes remain highly heterogeneous [12]–[18].

A primary limitation of the current algorithm is the threshold-based activation strategy itself. Adapted from the sensorimotor rhythm processing pipeline described by Rodríguez-Ugarte et al. [38]—utilizing C3/C4 relative mu and high-beta power, lateralization indices, baseline-derived thresholds, hysteresis, and finite-state logic—this strategy was intentionally simplified to authorize FES activation rather than robotic actuation. However, because hand-opening and hand-closing tasks yielded nearly identical neurophysiological responses, this strategy cannot and must not be interpreted as a functional MI classifier. Instead, it serves solely as a baseline-referenced, safety-contingent gating mechanism to ensure stimulation is authorized only during intended task windows. Future developments must replace this preliminary logic with dedicated machine learning approaches—such as Common Spatial Patterns (CSP/FBCSP) combined with Linear Discriminant Analysis (LDA) or Support Vector Machines (SVM), or Riemannian geometry frameworks—built upon larger datasets with multi-session calibration.

Furthermore, severe sample limitations constrain the scope of these results. With data collected from only ten healthy participants across a single session and a small number of repetitions, no claims can be made regarding system generalizability or clinical efficacy in post-stroke populations. This stage was strictly aimed at technical and functional debugging. Before engaging individuals post-stroke, future research must incorporate multi-session protocols, expanded trial counts, systematic stimulation tolerance assessments, adaptive calibration, and direct comparisons between simple threshold gating and supervised classification. Controlled functional testing in healthy cohorts remains an obligatory stepping stone before clinical evaluation.

V. CONCLUSIONS

This work presented the preliminary engineering development and functional proof-of-concept for an MI-based BCI-FES system tailored for upper-limb neurorehabilitation. The framework successfully demonstrated that EEG acquisition, task presentation, signal processing, therapist GUI control, wireless communication, and logging can run as a synchronized system under supervised conditions.

Importantly, participants with lower baseline activation thresholds did not exhibit superior control. A low baseline threshold often reflects low background power rather than strong, stable task-related modulation. Consequently, future iterations must integrate adaptive thresholding with relative baseline shifts, signal-to-noise ratio metrics, trial consistency checks, and true machine-learning classification.

In summary, the proposed prototype provides a viable, safe platform for controlled pilot experimentation, validating workflow functionality rather than MI classification accuracy. The

next development phase will focus on expanding trial counts, implementing robust artifact rejection, evaluating latency, testing clinical usability, and validating true MI detection in post-stroke participants. Additionally, integrating a synchronized robotic glove alongside FES will allow simultaneous cortical activation, peripheral electrical stimulation, and passive mechanical assistance within a unified multimodal rehabilitation framework.

***Abstract*— Interactive three-dimensional visualization can provide a complementary approach to orthopedic training by enabling the exploration of anatomical configurations and joint movements in an interactive environment. This work presents a preliminary multi-platform 3D application developed as a visualization tool for orthopedic training, focusing on the interactive manipulation of seated hip postures and simplified visual representations of hip dislocation. The main technical contribution is the combination of a two-dimensional Blendspace for continuous interpolation between predefined postures with a multi-skeleton rendering technique that allows the lower limbs to be transformed independently without deforming the torso. Five reference poses were created in Blender and subsequently integrated into Unreal Engine 5. The Blendspace was used to generate continuous variations between these poses through two input parameters. For the dislocation representation, three instances of the same skeleton were rendered simultaneously using opaque and transparent textures, allowing the torso and each lower limb to be manipulated as visually independent components. A physiotherapist, who is a co-author, reviewed the selected model and the implemented poses qualitatively for anatomical consistency. No quantitative biomechanical validation, motion-capture comparison, clinical imaging comparison, or formal end-user usability study was performed at this stage. The resulting prototype demonstrates the technical feasibility of combining continuous posture interpolation with independent lower-limb transformation in a multi-platform environment and establishes a foundation for the use of interactive 3D visualization in orthopedic training. The dislocation component should be interpreted as a simplified visual representation rather than a biomechanical simulation. Further studies are required to quantify anatomical fidelity, evaluate computational performance, assess usability and educational effectiveness, and determine the contribution of the proposed tool to orthopedic training.**

Keywords—biomedical simulation, unreal engine 5, hip dislocation, blendspace, multi-platform UI, orthopedic training

I. INTRODUCTION

Hip posture and spinopelvic mobility play an important role in hip stability, as changes in pelvic tilt during daily activities can influence the risk of impingement and dislocation after total hip arthroplasty [1]. In this context, Unreal Engine, a real-time 3D development platform, can be used to simulate hip postures and mobility, providing an interactive environment for visualizing movements associated with hip stability.

Such a platform may facilitate medical simulation by integrating biomechanical data with real-time rendering and kinematics. This potentially supports orthopedic training, gait analysis, and musculoskeletal modeling through rigging, motion calibration, and physics-based animation [2]. In orthopedics, it enables the creation of immersive, high-fidelity surgical simulators for complex procedures such as femoral stem implantation and hip screw fixation [3,4]. Its real-time rendering also generates realistic anatomical imagery to assist surgical planning and enable a diverse approach to clinical cases for training [3]. In musculoskeletal modeling, it visualizes and simulates human movement, including hip and leg motion, using 3D pose models with independent coordinate systems for each body part. This enables precise analysis of joint displacements and angular changes [2].

Researchers use this technology for real-time posture display with calibrated motion, ensuring anatomical consistency [2], and also integrate biomechanical alignment data from OpenSim (an open-source biomechanical modeling platform) to enforce physiological constraints [5]. Among the main methods used are inverse kinematics (a technique that calculates joint angles and movement paths from desired end-effector positions) [6], motion calibration to keep interconnected joints within physiological limits [2], Blueprint and C++ programming for pose modeling and external hardware synchronization [2], and animation layering that applies variations to 3D models without causing unnatural leg deformations [6]. Additionally, its architecture allows the

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

adjustment of smooth curves for key joints such as the hips, resulting unconstrained skeletal animations that can be made suitable for both medical analysis and joint movement emulation [5].

These capabilities are clinically relevant because hip and leg positioning are fundamental to joint stability [7], and understanding the specific positions that cause dislocation is essential for diagnosis [8]. Also, adherence to positioning precautions is the basis for successful prevention and rehabilitation [9]. These clinical contexts motivate the development of interactive visualization tools for exploring hip and lower-limb positioning. However, the technical feasibility of reproducing such positions in a virtual environment should be distinguished from clinical validation or educational effectiveness. In this work, the focus is therefore on the computational representation and interactive manipulation of hip posture, rather than on demonstrating diagnostic accuracy, surgical planning capability, rehabilitation effectiveness, or clinical decision-making support.

A. *Objectives*

General Objective: To develop a multi-platform application that allows users to customize the posture of a 3D skeleton, with a focus on the hip positioning and dislocation.

Specific Objectives: (1) integrate a rigged 3D skeleton model and a set of reference poses into a real-time 3D environment; (2) provide interactive control of posture variation through input controls and sliders; (3) implement a visual representation of independent lower-limb displacement without deforming the torso; (4) deploy the prototype in desktop and mobile environments; and (5) design an interface based on established usability principles as a preliminary step toward future end-user evaluation.

B. *Justification*

This work is justified by the need for a multi-platform tool that allows user-controlled customization of the positioning of the hip and leg in a 3D skeleton model. Although Unreal Engine is already used for orthopedic simulations [4,5] and motion analysis [2,5,6], there remains a need for an accessible, real-time interface for manipulating joint positioning, particularly hip alignment, while preserving anatomical realism and fluid performance across computers and mobile devices. The proposed application seeks to address the technical challenge of interactively manipulating hip posture while preserving the visual integrity of the remaining skeletal mesh. Its contribution is centered on the combination of continuous posture interpolation, independent lower-limb transformation, and a multi-platform interface. At this stage, the work is intended as a technical prototype and does not claim biomechanical fidelity or validated clinical applicability.

II. Methodology

The simulator development process is structured into five stages, which can be visually seen in the flowchart illustrated in Fig. 1. The development order is: (1) selection of a publicly available 3D skeleton model with a distortion-free rig; (2) creation of references poses; (3) qualitative anatomical review of the model, poses and and movement limits; (4) implementation of the interactive application (programming and posture) within a game engine; and (5) development of an adaptive User Interface (UI). Stage 1 used 3D model-sharing platforms such as Sketchfab and CGTrader, whereas Stage 2 was performed using the 3D editing software Blender.

Stages 1–3 were conduct with the assistance of a physiotherapist (an author of the present work) for validation before going into stages 4 and 5, in which the game engine Unreal Engine 5 (UE5), a freely available real-time 3D development platform, was chosen as the main tool for developing the application itself. It should be noted that the term “skeletal” refers to the structure that allows a 3D mesh to be animated and customized, while “skeleton” refers to the appearance of the 3D mesh itself. No quantitative angular measurements, motion-capture comparison, biomechanical model comparison, or formal inter-rater agreement procedure was performed during this stage.

A. *Development Tools*

Blender is a free and open-source 3D modeling, texturing, and animation software that enables developers to create and edit any vertex mesh of virtually any object, customize textures through multiple approaches, and produce videos and animations [10]. During the development of this project, Blender played a critical role in the creation of the assets employed, particularly the customized skeletal poses.

UE5 is a comprehensive suite of creation tools designed for game development, architectural and automotive visualization, linear content production for film and television, live event production and broadcasting, training and simulation, and other real-time applications [11]. Such platform was developed to provide realistic graphical capabilities while simultaneously ensuring low computational cost and high optimization efficiency. It offers two programming approaches: one based on the written programming language C++, and another unique visual scripting system known as Blueprints [12]. In the present project, Blueprints were selected, as they provide a comprehensive node-based interface system for creating gameplay elements and implementing programming logic directly within the Unreal Engine editor.

B. *3D Model Search*

More specifically, the search for the 3D model to be utilized followed a set of predefined requirements: the model had to be free of charge, editable, visually representative of a human skeleton, and equipped with a functional rig suitable for skeletal animation. Anatomical plausibility was subsequently reviewed by the physiotherapist co-author. The search resulted in the selection of the 3D model made by CreativeMachine, entitled “Skeleton Rig”, available on the digital 3D model-sharing platform Sketchfab, as it fulfilled all established model requirements. Fig. 2 illustrates the “Skeleton Rig”, a free 3D model by CreativeMachine [13].

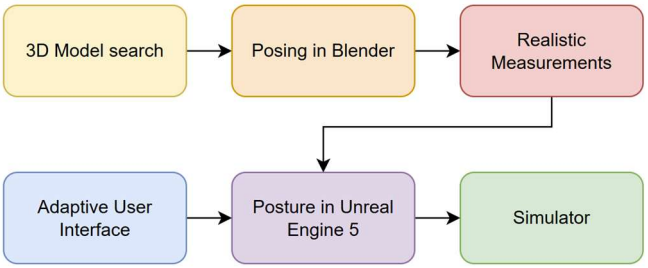

Fig. 1. Methodology flowchart (details in the text).

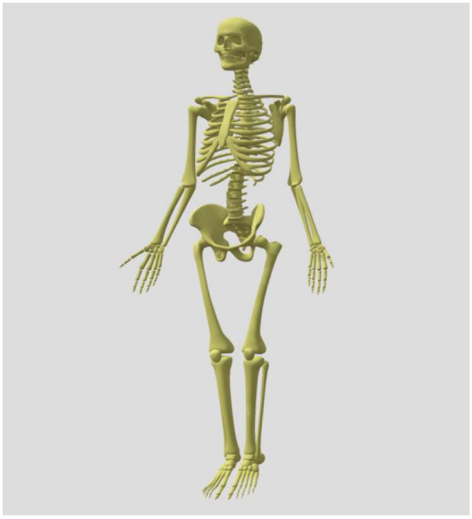

Fig. 2. Skeleton rig" by CreativeMachine, 2020.

The selected 3D mesh was qualitatively reviewed by the physiotherapist co-author before its integration into the application. The review considered the overall skeletal organization, number and relative arrangement of bones, general body proportions, and the behavior of the rig during the implemented movements. Next, the same reviewer inspected the five reference poses and the available posture transitions to identify movements that were visually inconsistent with the intended anatomical configuration.

This review was qualitative and was not based on a formal validation checklist, quantitative angular measurements, inter-rater agreement, motion-capture data, or comparison with clinical imaging. Therefore, the review should be understood as an expert anatomical inspection rather than as a quantitative validation of anatomical fidelity.

C. *Posing in Blender*

For this specific project, the most important feature of Blender is its animation structure tool known as bones [14]. Bones interact with an object's point mesh through an influence field, and each bone possesses three-dimensional transformation properties, including positioning, rotation, and scaling within the 3D environment. These properties are editable, allowing the properly rigged skeleton to be manipulated through the use of bones. This enables the creation of anatomically plausible and customizable poses. Rigging is a general term used for adding controls to objects, typically for the purpose of animation and, in this case, the posing of the skeleton [14]. The seated position was chosen for the focus on the hip, with five different poses being created: Default, turned right, turned left, curved back and curved forward. Once the poses were created, they were exported into UE5.

D. *Anatomical Review of Poses and Movement Limits*

The reference poses and movement limits were defined to provide visually plausible variations of the seated hip position. A physiotherapist co-author reviewed each reference pose, the resulting interpolated movements, and the intended customization limits from an anatomical perspective. The review was qualitative and was used to identify gross inconsistencies in the direction and appearance of the simulated movements. At this stage, the system does not associate the Blendspace coordinates with experimentally measured joint angles. Consequently, the numerical values of the X and Y parameters represent animation-space control values rather than degrees of anatomical motion.

E. *Posture in UE5*

Importing the assets produced in Blender into the UE5 editor constitutes a particularly delicate stage of the process, as it requires the proper definition of which 3D meshes are associated with specific bone structures, which, in turn, must be correctly linked to their corresponding animations. Such approach provides a robust set of tools supporting a wide range of media creation and development possibilities, among which one of the most crucial for the present project is the Blendspace feature. Blendspace is an environment in which multiple animations can be blended based on the values of several input parameters, provided that they share the same bone structure and 3D mesh, thereby enabling smooth transitions between animations. Through UE5's Blendspace, it is possible to define points within an XY plane, each corresponding to a specific animation. The Blendspace blends animations dynamically according to command-based inputs [15].

The main systems to be programmed in the platform are: (1) Hip posture customization through Blendspace and (2) Hip dislocation through object transformation editing. The Blendspace imported allow every intended system and functionalities to be developed in tandem and to run alongside each other in the finished product.

F. *Adaptive User Interface*

The User Interface (UI) of this application is designed to be adaptable to different types of content, provide a high level of accessibility, and maintain functionality across multiple platforms. Based on the work of Molich and Nielsen [16], which describes heuristic approaches for evaluating the quality of user interfaces, the present project adhered to these principles as part of its quality control strategy.

When studying the heuristics, a few characteristics were defined as essential for the design ideals of the UI: (1) Large buttons, lettering and text boxes for good readability; (2) Preserving the same layout logic consistently across different menus to allow for low effort and easy understanding of the application's systems.

III. RESULTS

The results section of this article is divided into three facets, all that can be achieved by implementing the methodologies described. These three facets are: (1) Hip posture customization; (2) Hip dislocation; and (3) UI ease of use and adaptability. It should be noted that, as it is currently the case for this simulation, it does not incorporate forces, joint constraints, capsule, ligaments, soft tissues, or the physical dynamics of dislocation, focusing on simulating a visual representation of angle and position changes of the hip.

A. *Hip Posture Customization*

The customization aspect of the posture was achieved once the 3D meshes and animation poses were imported into the game engine. Fig. 3 illustrates the Blendspace developed for the project, highlighting colored points representing different animations positioned within an XY coordinate system ranging from -100 to 100. The yellow point represents the "default" pose and is positioned at coordinates XY (0, 0); the green point corresponds to the "curved forward" pose at XY (0, 100); the blue point represents the "turned right" pose at

XY (100,0); the purple point indicates the “curved back” pose at XY (0, -100); and the red point represents the “turned left” pose at XY(-100, 0). These graph positions enable a resting state at the coordinate point XY (0, 0), while any increase or decrease in the values of the X and/or Y variables generates a gradual transition toward the remaining poses. Fig. 4 illustrates the resulting pose when the X value increases while the Y value decreases, producing a fully customized hip position in which the posture becomes simultaneously slightly rotated to the right and flexed backward. This configuration enables the simulation of numerous hip-bas postural conditions; however, an additional method of posture modification was implemented to further expand the range of simulation possibilities: the development of a hip dislocation simulation between the pelvis and lower limbs. position changes of the hip.

B. Hip Dislocation

The development of a dislocation pose or animation required the implementation of a new logic to enable the simultaneous blending of Blendspace poses with the specific displacement of body segments. For this purpose, the textures applied to the skeleton model in this project were specifically created: a white texture for standard visualization and a fully transparent texture to conceal unnecessary anatomical segments.

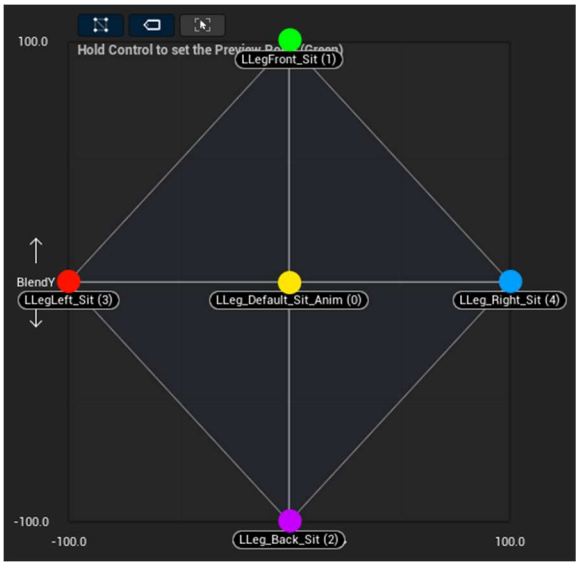

Fig. 3. Assembled Blendspace in UE5.

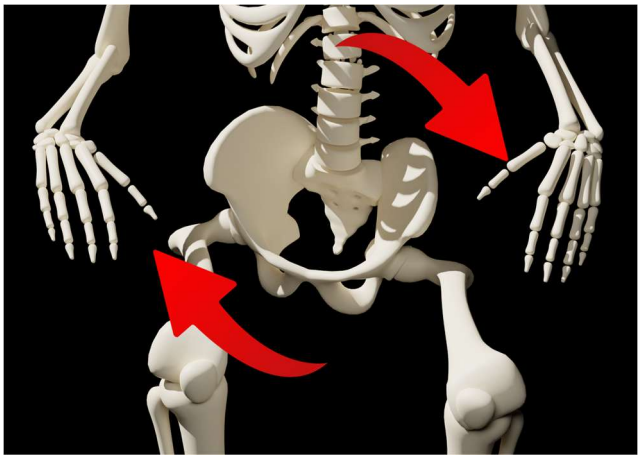

Fig. 4. Customized pose generated through the simultaneous application of positive X values and negative Y values.

By employing three duplicated instances of the 3D skeleton model, each with its respective bone structures and animations linked to the Blendspace, it becomes possible to create the visual effect of a single skeleton when, in fact, three separate models are being rendered simultaneously. Through the strategic application of opaque and transparent textures, specific skeletal regions can be selectively hidden such that: (1) one model visually excludes both lower limbs; (2) another displays only the left leg; and (3) a third displays only the right leg. Fig. 5 presents a representation of the three skeletons occupying the same spatial position, with the colors red, green, and blue indicating the distinct skeletal instances, thereby demonstrating that the resulting visual effect corresponds to the appearance of a single unified skeleton.

The fact that each lower limb is treated as an independent object from the torso enables the application of positional and rotational transformations without affecting or deforming other regions of the skeleton. Consequently, it becomes possible to modify the position and rotation of one or both lower limbs independently in order to generate a simplified visual representation of hip dislocation. Fig. 6 illustrates the resulting visual representation obtained with this method. The independent treatment of the lower limbs allows positional and rotational transformations to be applied while preserving the posture generated by the Blendspace. This demonstrates the technical operation of the proposed rendering strategy; it does not constitute a biomechanical or clinical validation of hip dislocation.

C. User Interface Ease of Use and Adaptability

The interface was implemented as a conceptual multi-platform layout organized into functional regions for camera control, application settings, simulation selection, parameter adjustment, and feedback. The design follows selected principles derived from the human-computer dialogue guidelines described by Molich and Nielsen [16], including consistency, feedback, and visibility of relevant controls. At the present stage, these principles were used as design guidelines rather than as the result of a formal usability evaluation. No end-user testing, usability questionnaire, cognitive-load assessment, task-performance measurement, or acceptance study was conducted.

With the heuristics proposed by Molich and Nielsen in mind, Fig. 7 presents a representative conceptual design of the planned interface for this application, while Fig. 8 divides the interface into sectors to facilitate the identification of the elements composing the user interface.

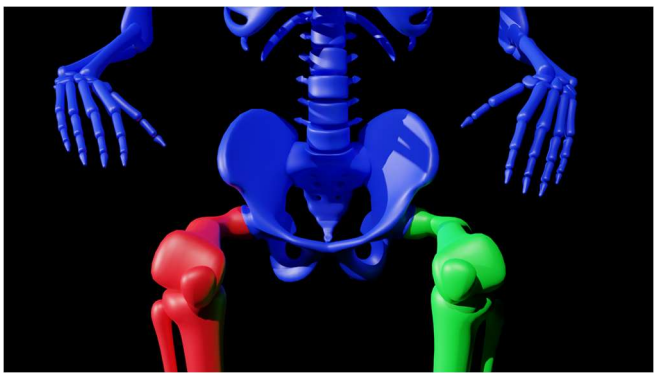

Fig. 5. Three color-coded skeletons combined to visually appear as a single skeleton structure.

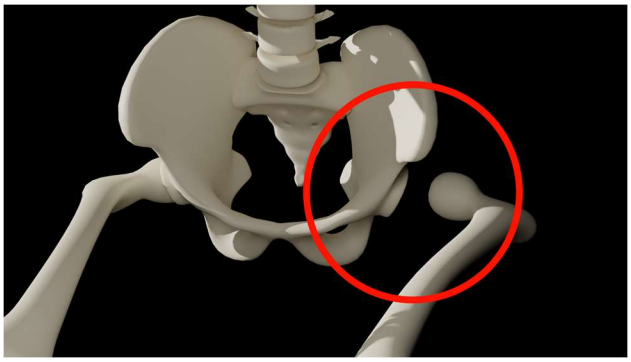

Fig. 6. Simulated hip dislocation highlighted by a red circle.

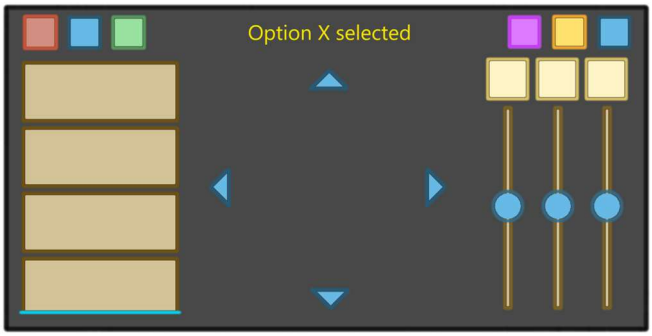

Fig. 7. Planned User Interface.

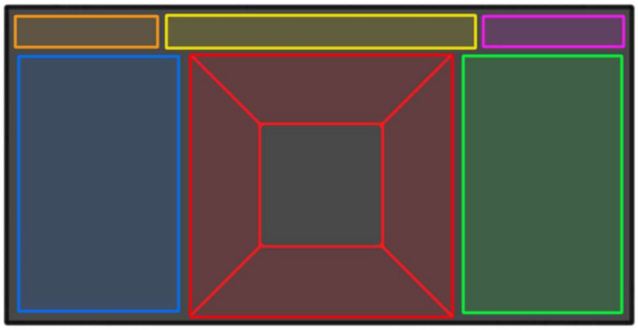

Fig. 8. Segmented User Interface in colored areas.

The red area corresponds to the active region assigned to the directional controls. It is responsible for manipulating the user's viewpoint, enabling both skeleton rotation and camera displacement across the screen plane. The switching mechanism between rotational and translational camera control is performed through a button located in the orange area.

The orange area is also intended to contain additional option buttons, such as camera mode selection, interface element visibility control, and access to the app's functionalities.

The purple area is designated to contain buttons related to general application settings, alternative operational modes, and notifications. The yellow area serves as a feedback display region, where textual information is presented to the user, including performed actions, general notifications, and the names of accessed menus.

Initially, the blue and green areas are not intended to be visible to the user. The blue area may be accessed through a button located in the orange area and contains buttons associated with simulation options, such as posture customization or dislocation simulation.

The green area becomes visible whenever a simulation option is selected in the blue area. It provides controls for modifying simulation parameters and dynamically adapting its interface according to the option selected within the blue area. An example of the controls it would provide is modifying the value through sliders or simply inputting exact values. All measurements are meant to reflect converted realistic values for the user once the calibration is finished. The menu logic was designed to be intuitive, featuring continuous feedback, accessible design principles, and expandability for future functionalities. Furthermore, the interface architecture was conceived with the intention of ensuring compatibility across multiple platforms, including desktop computers and mobile devices, when necessary.

User testing and feedback is required for validation and potentially enhancing the designs.

IV. Discussion

The interface was implemented as a conceptual multi-platform layout organized into functional regions for camera control, application settings, simulation selection, parameter adjustment, and feedback. The design follows selected principles derived from the human-computer dialogue guidelines described by Molich and Nielsen [16], including consistency, feedback, and visibility of relevant controls. At the present stage, these principles were used as design guidelines rather than as the result of a formal usability evaluation. No end-user testing, usability questionnaire, cognitive-load assessment, task-performance measurement, or acceptance study was conducted. The following discussion outlines the potential clinical application, the educational implications, limitations, and future direction.

A. Postural Customization and Biomechanical Relevance

The Blendspace system developed in this project enables continuous control over the interpolated posture via a two-dimensional coordinate system (X, Y) spanning -100 to 100. This approach allows for gradual transitions between five distinct poses: default (0,0), curved forward (0,100), turned right (100,0), curved back (0,-100), and turned left (-100,0). The resulting capacity to generate continuous variations between these poses, as demonstrated in Fig. 4, enables the simulation of numerous hip-based postural conditions with continuous control over the interpolated posture within the defined animation space.

The ability to customize hip postures is clinically significant, as hip and leg positioning are fundamental to joint stability [2]. Understanding the specific positions that cause dislocation is essential for diagnosis [9], while adhering to positioning precautions is the cornerstone of prevention and successful rehabilitation [8]. The Blendspace system enables users to explore the full spectrum of hip positioning, including the classic provocative positions associated with dislocation risk.

From a biomechanical perspective, the capacity to simulate simultaneous rotations and flexions (e.g., positive X values combined with negative Y values) is particularly valuable. This approach emulates real-world clinical scenarios, in which hip dislocations typically occur during complex, multiplanar movements rather than isolated motions. For instance, posterior hip dislocations—which

account for the majority of hip dislocations—typically occur when an axial load applies to a flexed, adducted, and internally rotated hip [9]. The two-dimensional Blendspace allows combinations of the predefined animation directions to be explored continuously. For example, simultaneous changes in the X and Y parameters produce postures that combine more than one animation direction. Such combinations are useful for exploring the visual behavior of the model in multiplanar configurations. However, because the parameters are not calibrated to measured anatomical angles and no biomechanical constraints are currently implemented, these configurations should not be interpreted as quantitatively reproducing physiological or pathological hip motion.

B. Hip Dislocation Simulation: Technical Innovation and Potential Clinical Applications

The development of the dislocation simulation feature was made by employing three duplicate instances of the 3D skeleton model and strategically applying opaque and transparent textures. This system creates the visual impression of a single, unified skeleton while enabling independent manipulation of each lower limb. This approach offers several advantages over traditional skeletal animation methods. First, treating each lower limb as an independent object from the torso enables positional and rotational transformations without affecting or deforming other regions of the skeleton. This strategy addresses the specific mesh-deformation problem encountered during the development of the present prototype. Second, the method preserves the posture generated through the Blendspace system while simultaneously applying dislocation-specific transformations (Fig. 5), enabling realistic simulation of hip dislocation across multiple postural contexts.

The project anticipates potential clinical relevance from those features. Hip dislocation is a medical emergency requiring urgent reduction, and diagnostic accuracy depends on recognizing characteristic limb positions [9]. Posterior dislocation typically presents with the leg shortened, flexed, adducted, and internally rotated, whereas anterior dislocation is generally associated with extension, abduction and external rotation [7]. By enabling users to simulate and visualize these characteristic presentations, the system may to serve as training tool for medical students, residents, and emergency medicine practitioners. Furthermore, the ability to simulate dislocations within a controlled virtual environment may provide a safe setting for exploring hip positioning relevant to surgical planning.

Approximately two-thirds of dislocation episodes are treatable with non-surgical management, including closed reduction, education, and muscle strengthening [9]. Virtual simulation could allow practitioners to practice reduction techniques involving hips, joints and leg bones without risk to patients, potentially improving clinical outcomes.

C. User Interface Design and Potential Educational Utility

The interface design described in this study adheres to established usability heuristics, including the principles proposed by Molich and Nielsen [16], such as consistency, feedback, and progressive disclosure. The modular architecture may promote intuitive navigation and reduce cognitive load with clearly delineated functional areas (viewpoint control, menu access, feedback display, and simulation parameter controls).

The design decision to initially hide advanced simulation options (blue and green areas) until accessed through primary navigation is consistent with progressive disclosure principles, preventing information overload while maintaining full functionality for advanced users. The inclusion of continuous feedback mechanisms (yellow area) and dynamic interface adaptation (green area) aims to further enhance usability.

The modular design enables the addition of new simulation options and alternative operational modes, and supports compatibility across multiple platforms (desktop and mobile). This forward-compatible approach is essential given the rapid evolution of both simulation technologies and clinical applications.

As a whole, these features of the user interface are particularly important in educational contexts where users may have varying levels of technical expertise. However, future tests with final users are still necessary to verify such potential resources.

D. Relationship to Existing Simulation Approaches

Previous studies have explored real-time 3D environments for the visualization and analysis of human movement. Liu et al. [2], for example, developed a visual gait analysis system based on Unreal Engine, while Pescaru et al. [6] investigated human movement simulation using full-body inverse kinematics in Unreal Engine. In the context of orthopedic training, Racy et al. [3] developed and validated a virtual reality simulator for femoral intramedullary nailing, combining a 3D virtual environment with haptic interaction and image intensifier functionality. More broadly, a systematic review by Sun et al. [17] identified 40 studies investigating virtual and augmented reality applications in hip-related surgery, including preoperative simulation, surgical training, intraoperative applications, and postoperative rehabilitation [17]. These studies demonstrate the growing use of interactive and immersive technologies in musculoskeletal and orthopedic contexts, but they address objectives and levels of validation that differ from those of the present work.

In contrast, the present prototype focuses on a more specific technical problem: combining continuous posture interpolation through a two-dimensional Blendspace with independent transformation of the lower limbs using multiple instances of the same skeletal model. Unlike validated surgical simulators, the proposed system does not currently provide haptic feedback, biomechanical constraints, quantitative anatomical calibration, or validated educational tasks. Its contribution should therefore be understood as a rendering and interaction strategy that establishes a technical basis for future investigation of interactive 3D visualization in orthopedic training.

E. Integration with UE5 Capabilities

The platform visualizes and simulates human movement using 3D pose models with independent coordinate systems for each body part, enabling precise analysis of joint displacements and angular changes [3]. The present project extends these capabilities by developing a specialized approach to hip dislocation simulation to address specific clinical needs.

Researchers have used Unreal Engine for real-time posture display with calibrated motion, ensuring anatomical

consistency [3]. The Blendspace-based customization approach in this project similarly ensures calibrated motion transitions, providing anatomical consistency across the range of simulated postures. Additionally, previous work has integrated biomechanical alignment data from OpenSim to enforce physiological constraints [6]. Future iterations of this project could incorporate additional constraints to enhance biomechanical realism further and validate the simulation against established biomechanical models.

The methods employed in this project—including inverse kinematics, motion calibration, and animation layering—align with established field practices. The use of Blueprint and C++ programming for pose modeling and animation control builds upon established UE5 architectures [3,7].

F. Limitations and Future Directions

While the results presented are promising, the work has some limitations. First, the current implementation focuses on visual simulation rather than biomechanical simulation. The system visualizes postures and dislocations without simulating the underlying forces, torques, and constraints that govern actual joint mechanics. Future developments may integrate OpenSim-based biomechanical models to enforce physiological constraints during simulation.

Second, validation of the simulation against real, customized clinical data has not yet been performed, although we have considered dislocation values consistent with those described in the literature. Comparison with motion capture data from patients with hip dislocations or post-surgical complications would help establish the system's accuracy and further clinical utility.

Third, the system currently relies on a simplified skeleton model. Integration with more detailed anatomical models, including surrounding muscles, tendons, and ligaments, could enhance the simulation's fidelity and expand its educational utility.

Fourth, regarding its educational purpose, the platform still lacks testing with final users, including medical educators, students, and professionals.

Future directions for this include possibilities for: (1) Integration of haptic feedback to simulate the sensation of joint reduction procedures; (2) Implementation of real-time biomechanical analysis, including joint contact forces and stress distributions; (3) Development of patient-specific simulations based on individual anatomical data; integration of virtual reality (VR) capabilities for immersive surgical training; (4) Validation studies comparing simulation results with clinical outcomes, and user tests.

V. Conclusion

This study presented the development of a preliminary multi-platform 3D prototype for interactive manipulation of hip posture and simplified visual representation of hip dislocation. The main technical contribution is the combination of a two-dimensional Blendspace for continuous posture interpolation with a multi-skeleton rendering strategy that enables independent transformation of the lower limbs while preserving the visual configuration of the torso.

The implemented prototype demonstrates the technical feasibility of this approach within Unreal Engine 5 and provides a basis for exploring interactive skeletal configurations in desktop and mobile environments.

The main lessons learned from the development process concern the usefulness of separating the visual representation of body segments when direct manipulation of a single rigged mesh produces undesirable deformations, as well as the need to distinguish animation-space parameters from quantitatively validated anatomical measurements.

Future work should focus on quantitative anatomical validation, biomechanical constraints, objective computational performance evaluation, formal usability studies, educational validation with representative users, and comparison with existing orthopedic and musculoskeletal simulation approaches. Further extensions may include patient-specific models, virtual reality, haptic feedback, and artificial intelligence for controlled generation of clinical scenarios. Thus, the present work should be regarded as an initial technical feasibility study that establishes an interactive foundation for subsequent biomechanical, usability, and educational investigations.

***Abstract*— This article investigates the main barriers and difficulties in the use of lower limb prostheses, from the perspective of users and health professionals. Through a qualitative-quantitative approach, data were collected from 20 prosthesis users and 20 health professionals. The results reveal that, although 100% of professionals recognize the positive impact of the prosthesis on quality of life, 60% of users report partial adaptation, 80% experience physical discomfort, and 65% experience social discomfort. The comparative analysis highlights divergences between clinical perception and the user's subjective experience, pointing to the need for innovation in prosthetic component design and user-centered rehabilitation protocols, and providing guidance for rehabilitation engineering.**

I. INTRODUCTION

Disability is defined, under Brazilian Law No. 13.146/2015 (Lei Brasileira de Inclusão), as a long-term physical, mental, intellectual, or sensory impairment that, in interaction with environmental barriers, may hinder an individual's full and effective participation in society on an equal basis with others, being a definition aligned with the social model of disability [1]. Complementarily, Decree No. 3.298/1999, as regulated by Decree No. 5.296/2004, classifies disability into distinct categories, including physical, hearing, and intellectual/mental disability, among others. Amputation is categorized as a physical disability, defined as the total or partial loss of a limb or segment resulting in long-term functional impairment, as specified in Article 4, item I, of Decree No. 3.298/1999 [2]. Globally, the World Health Organization estimates that over one billion people live with some form of disability, of whom approximately 200 million experience severe functional limitations [3].

In Brazil, lower limb amputations account for roughly 85% of cases, with an incidence of 13.9 per 100,000 inhabitants/year. Leading causes include diabetes-related peripheral vascular disease (90.7% of major amputations), trauma (5.6–33%), infections (~13%), and neoplasms (0.8–1.9%), with congenital malformations playing a minor role. By procedure type, external causes/trauma (33.1%), infections (17.9%), circulatory disease (16.1%), and diabetes (13.6%) predominate, most often affecting men over 60 at higher amputation levels (transfemoral or transtibial). [4]. Thus, amputation ends up being, for the individual, a multifaceted trauma that considerably alters the individual's existence, perception, and experience, generating physical repercussions, such as phantom pain, motor limitations, and functional dependence [5]; psychological repercussions, including grief, depression, anxiety, low self-esteem, and social isolation [6]; and psychosocial repercussions, with impacts on body identity, interpersonal relationships, and return to work, often high due to the action of stigma and lack of support [7].

Thus, stigma emerges as a social disqualification arising from stereotypes that label the amputee as inferior, fostering embarrassment, shame, and aversion to one's own body, which interferes with self-care, rehabilitation, and daily interactions, as reported in studies that identify the perception of discrimination as a catalyst for isolation [8]. This marginalization synergizes with clinical and sociodemographic harms, promoting therapeutic non-adherence and perpetuating a vicious cycle of exclusion, in which physical prejudice promotes distress and social withdrawal [9].

As Chamlian and Varanda [10] show, abandonment of prostheses by individuals with lower limb amputations is a prevalent phenomenon, often exceeding 50% after discharge from rehabilitation. This high dropout rate stems from multifactorial barriers, notably the excessive weight of the prosthesis (47.5% of cases), fear of falling (20%), difficulty putting on and removing the device (16.25%), reamputations (6.25%), fatigue (2.5%), phantom pain (1.25%), and comorbidities (5%), which were the main factors compromising autonomy and leading patients to prefer wheelchair mobility.

Abandonment originates both from a stigmatizing web combined with emotional burdens that generate very negative effects on the person who underwent amputation, such as anxiety and depression, as well as from technical and functional problems associated with prosthesis use. For this reason, this alteration of body image ends up breaking affective bonds and generates marital ruptures or parental estrangement, especially when combined with fears of dependence and perceived incapacity [11]. Understanding this stigmatizing web is key to grasping both patients' experiences and health professionals' perspectives, since medical perception shapes the rehabilitation process. This raises the study's guiding question: what are the main problems in using a lower-limb prosthesis, according to patients and health professionals?

II. METHODOLOGY

A. Research characterization

The present research is characterized by a qualitative-quantitative approach, as it integrates qualitative and quantitative procedures to achieve a broader understanding of the phenomenon under investigation. Such an approach allows not only the measurement of objective data but also the in-depth interpretation of participants' experiences and perceptions, and is widely recommended in studies in the health field and applied social sciences [11][12]. In this sense, the combination of methods enables greater analytical robustness by articulating different perspectives on the use and rehabilitation of lower limb prostheses.

The methodological procedure followed sequential stages: a literature review to ground the theoretical framework and define data collection instruments [15]; data collection using the described instruments; and data processing, involving organization, categorization, and analysis. In the case of qualitative data, content analysis procedures were adopted, as proposed by Bardin [16], allowing the identification of relevant thematic categories. Bardin's Content Analysis comprises three phases: pre-analysis (floating reading and definition of objectives), material exploration (data coding and categorization), and treatment of results (inference and interpretation). In this study, the material was read, categorized by tabulation in a spreadsheet, and subjected to frequency counting of occurrences within each category. The codification of the data generated through Bardin's content analysis method was conducted by a single researcher, thereby ensuring consistency and uniformity throughout the data coding process,Thematic categories were constructed inductively: each open-ended response was first segmented into meaning units, which were then grouped by semantic similarity. Codes with overlapping meaning were merged, and checked against two criteria recommended by Bardin: mutual exclusivity and exhaustiveness until a stable set of categories per group was reached.

Quantitative data were analyzed using descriptive statistics, enabling the systematization of professionals' responses. Finally, the results were interpreted in light of the theoretical framework, culminating in the elaboration of the research conclusions. In summary, the methodological procedure is outlined in the following steps in Fig. 1:

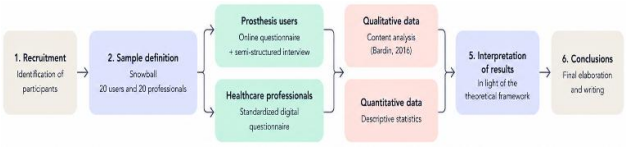

Fig. 1. Methodological flowchart for data collection and processing

Regarding the sampling strategy, the snowball method was adopted, characterized by the successive referral of participants from initial contacts. This type of sampling is particularly useful in research with specific or hard-to-reach populations, allowing the progressive construction of the sample from the participants' own social and professional networks [13]. This strategy proved suitable for the research context, especially for identifying prosthesis users and professionals with experience in rehabilitation. Participant recruitment was conducted primarily through referrals from healthcare professionals responsible for the direct care and follow-up of individuals with lower-limb amputations. These professionals identified potential participants who met the study's inclusion criteria and, upon obtaining their consent to be contacted, invited them to take part voluntarily.

Data collection was carried out using two complementary techniques. For the user group, an online questionnaire and a semi-structured interview were used (17 questions), allowing exploration of subjective aspects, perceptions, and individual experiences [14]. The interviews were made available in online video call format and were answered only by participants who were prosthesis users.

For the health professionals group, a standardized digital questionnaire was used (15 questions), favoring standardization of responses and access to geographically dispersed participants [15]. It is important to note that the two instruments were designed independently, with different question wordings and, in several cases, different underlying constructs; professionals were not reporting on the same patients who answered the user questionnaire, and the two samples do not form user–professional dyads. This methodological feature is revisited in Section III.D, where its implications for the comparative analysis are made explicit.

The study was approved by the Research Ethics Committee (CEP) of the Hospital Universitário Alcides Carneiro, Universidade Federal de Campina Grande (HUAC-UFCG), under Opinion No. 7.050.410 and CAAE 81041924.6.0000.5182, in accordance with Resolution CNS 466/12.

The sample consisted of two distinct groups: lower limb prosthesis users and health professionals. In both groups, the participation of 20 individuals was estimated, being a number considered adequate for exploratory studies with a mixed approach, in which a balance is sought between qualitative depth and quantitative representativeness [11]. The sample (n=20 per group) was defined by theoretical saturation: data collection ended when the open-ended responses stopped generating new codes, with the cumulative-code curve stabilizing around the 20th participant, a criterion aligned with methodological recommendations for transparency and adequate sample size. [23].

To map the main perceptual points of both groups, a total of 17 questions were administered to prosthesis users[1] and 15 to healthcare professionals[2]. Table I presents only the key questions selected to capture the physical, emotional, social, and contextual impacts addressed in the study, outlined in Table I below:

TABLE I. KEY QUESTIONS ASKED TO BOTH GROUPS

Users key questions	Health professionals key questions
1. Do you feel any discomfort when using your prosthesis?	1. In your view, does prosthesis use improve the patient's quality of life? Why?

[1] amputees questionnaire: https://forms.gle/k2RP9bHrttuyxMCU7

[2] professionals questionnaire: https://forms.gle/6BJFxC2Za42vnXGq8

2. Is there anything about the appearance of your prosthesis that bothers you? Why?	2. Do you perceive any negative relationship between the user and the prosthesis's appearance?
3. Do you feel comfortable exposing your prosthesis in public?	3. Have any patients mentioned social discomfort when using their prosthesis? If so, in what situation?
4. Is there any situation that prevents you from using the prosthesis for long periods?	4. In your experience, what is the greatest challenge in adapting to the prosthesis?
5. Have you ever felt frustrated while using the prosthesis?	5. Which aspects are most positively impacted by prosthesis use?

The inclusion criteria for the user group were: being a person with a lower limb amputation at any level, using a prosthesis, being between 18 and 80 years old, having no visual limitations that would prevent reading the instruments or cognitive impairments that would hinder understanding of the questions, in addition to agreeing to the terms established in the Informed Consent Form (ICF). For the professionals group, the inclusion criteria involved: being a health professional with experience in the treatment and rehabilitation of amputees, having knowledge about prosthesis use, and accepting the terms of the ICF. The implementation of this methodological framework facilitated an in-depth analysis of the phenomenon under investigation by integrating both quantitative and qualitative data, along with multiple perspectives from users and healthcare professionals regarding the rehabilitation process and the utilization of lower limb prostheses.

B. Limitations and future research

This study presents the following limitations: a small non-probabilistic snowball sample (n = 20 amputees + 20 professionals), a lack of control for variables such as amputation level and time since amputation. Also, this research shows a lack of quantitative results and variation in the answers, both synchronous and asynchronous. Additionally, since coding was performed by a single researcher, inter-rater reliability could not be assessed.

Future research should employ larger and more representative samples, combine self-report with psychometric measures (e.g., EEG, eye tracking), compare some specific cover design configurations, and include paired user-professional analyses of the same cases.

III. RESULTS & DISCUSSION

To understand the experience of using a lower-limb prosthesis in all its complexity, it is necessary, above all, to recognize the plurality of perspectives that shape the perceptions of both amputees and health professionals. For that purpose, this study collected data from 20 users for each of these profiles (where it will be represented by the letter 'n', that is, the number of participants/respondents).

A. Content Analysis

Based on the responses provided by the professionals, a content analysis was carried out based on the method proposed by Bardin [16], allowing the identification of five central thematic categories, presented in Table II below:

TABLE II. CONTENT ANALYSIS (HEALTH PROFESSIONALS)

Category	***Definition***	***Relative frequency***
1. Functionality and independence	Recovery of functional capacity and autonomy in activities of daily living and work	20/20 (100%)
2. Technical barriers to adaptation	Difficulties related to socket fit, donning, and prosthetic suspension	11/20 (55%)
3. Psychosocial dimension and self-esteem	Emotional impact, self-image, and grieving the loss of the limb	13/20 (65%)
4. Discomfort and social stigma	Reports of embarrassment, stares, and accessibility barriers in public spaces	9/20 (45%)
5. Abandonment and continuation of use	Factors favoring the continuation or discontinuation of prosthetic use	8/20 (40%)

On the other side, the content analysis [16] was also carried out on the users' responses, which revealed five central categories, described in Table III below:

TABLE III. CONTENT ANALYSIS (PROSTHESIS USERS)

Category	***Definition***	***Relative frequency***
1. Return to routine and functionality	Recovery of daily, work-related, physical, and leisure activities	20/20 (100%)
2. Physical discomfort and bodily limitations	Pain, heat, friction, and restricted movement are associated with the prosthetic socket	16/20 (80%)
3. Specific functional limitations	Movements or activities that remain inaccessible even after adaptation	13/20 (65%)
4. Appearance and cosmetic covering	Aesthetic perception of the device and desire for covering or customization	8/20 (40%)
5. Social discomfort and stigma	Stares, comments, jokes, and embarrassing situations in public spaces	10/20 (50%)

The following section will present in detail all the information and categories identified in the Content Analysis, exposing and discussing the main points of the data collection for both groups.

B. Perceptions of Health Professionals

Regarding the 20 professionals' area of practice, the composition was: Physical Therapy (in its various specialties: neurofunctional, motor, respiratory, occupational, rehabilitation) n=16 (80%); Psychology n=3 (15%); Physical Medicine and Rehabilitation/Physiatry, n=1 (5%).

Within this sample, in most cases, there is adequate integration of a multidisciplinary team in the rehabilitation process: 35% (n=7) of respondents stated that a multidisciplinary relationship always exists, 50% (n=10) stated that it frequently exists, and rarely (n=1, 5%). Adding together the categories Always and Frequently, 85% of professionals report satisfactory multidisciplinary integration in their practice contexts. However, 5% report rare integration, which shows that some patients do not undergo full rehabilitation, given the universal recognition of the importance of integrated care in rehabilitation.

Thus, the question of whether prosthesis use improves the patient's quality of life obtained positive unanimity: all 20 respondents (100%) said yes, with different qualifications, which is consistent with the literature, which documents significant gains in mobility, independence, and psychological well-being after prosthetic fitting [17].

The justifications converged around: return to mobility and functional independence (n=18, 90%); improved self-esteem (n=15, 75%); social and occupational reintegration (n=9, 45%); reduced caregiver burden (n=2, 10%); and general psychological well-being (n=4, 20%). It is observed, therefore, that mobility and functional independence are

perceived as the main gains in the rehabilitation relationship with prosthesis use. Two professionals added that improved quality of life depends on the conditions of prosthesis use. One physical therapist pointed out that, in some cases, functionally independent patients using crutches may perform better without the prosthesis. A psychologist, in turn, stressed that the benefits depend on proper fitting of the device and effective training, showing that the results are directly related to the quality of the rehabilitation process.

However, when asked about the challenges, the main reports from professionals were associated with problems related to socket fit and suspension (n=4, 20%), difficulty putting on and managing the prosthesis by the patient (n=5, 25%), acceptance of the prosthesis itself and the new body image (n=3, 15%), adjustment of patient expectations regarding use (n=3, 15%), and comfort and pain (n=3, 15%).

The difficulty in putting on and managing the prosthesis shows that its use requires motor coordination, strength, and technique, representing a challenge for some users. In addition, problems with fit and suspension directly compromise the user experience, since the socket constitutes the main interface between the limb and the prosthesis.

In addition, acceptance of the prosthesis itself and of the new body image, as well as the adjustment of expectations, are challenges that belong to the psychological and psychosocial domain, confirming the need for specialized support in this area. Indeed, Hogan and MacLachlan [9] point out that factors such as emotional adaptation, self-image, coping with amputation, and expectations regarding prosthesis use have a direct influence on satisfaction, device adherence, and the overall rehabilitation process.

As for prosthesis abandonment, it is a real phenomenon, frequent enough to be systemically relevant. Ten participants (50%) stated that most patients continue using the device; seven (35%) stated that it depends on multiple factors; and three (15%) stated that abandonment is frequent. Adding together the dependent and abandonment responses, 50% of professionals recognize that long-term use is not guaranteed for all patients. Professionals pointed out that the maintenance of prosthesis use depends on the level of amputation, comfort of fit, family support, access to maintenance, and individual patient characteristics, showing that adherence is influenced by the interaction of biomechanical, psychosocial, and contextual factors.

Thus, these data directly corroborate the study developed by Missio and Queiroz [18], which shows that consistent use of assistive technologies is directly related not only to the characteristics of the device but also to the conditions of access, follow-up, comfort, and user adaptation. Taken together, the results reinforce that the maintenance of prosthesis use depends on the interaction between biomechanical, psychosocial, and contextual factors, making abandonment a multifactorial consequence rather than one exclusively related to the device.Regarding the perception of users with a negative relationship with the appearance of the prosthesis, professionals reported: No (n=10, 50%), Yes (n=5, 25%), Initially/rarely (n=4, 20%), and no definite answer (n=1, 5%). Among those who perceive a negative relationship, the following stand out: greater aesthetic dissatisfaction among the elderly (who most often use foam cosmetic covering); dissatisfaction during the phase without cosmetic finishing of the prosthesis; and discomfort in transfemoral prostheses with a rigid knee that forces gait with a straight leg.

Biddiss and Chau [19] show that the appearance of the prosthesis is one of the factors that influence its acceptance and continued use, since aesthetic aspects directly affect the user's perception of their body image and their willingness to use the device in social settings. In addition, Connelly, Jairath, and Bhatt [21] show that user-centered approaches, which incorporate aesthetic preferences, comfort, and personal identity during prosthesis development, favor greater satisfaction, acceptance, and adherence to the device. Together, these studies reinforce that aesthetics transcends the visual dimension, influencing self-esteem, social interaction, and the continued use of assistive technology.

Professionals' perception of users' confidence when using the prosthesis reveals a procedural and nuanced view. Twelve respondents (60%) stated that most patients feel confident; five (25%) stated that this depends on factors such as the level of amputation and length of use; and three (15%) stated that, initially, patients are not confident, but that confidence is acquired progressively. Confidence, therefore, is conceived by professionals as a process, not as an immediate post-fitting state.

The results indicate that confidence in prosthesis use is influenced by the complexity of the amputation and the quality of the rehabilitation process. More proximal amputations require greater biomechanical adaptation, while adequate training favors the development of confidence. This perception is reinforced by the fact that most professionals reported that their patients use the prosthesis partially or fully exposed, suggesting good acceptance of the device in social contexts. Indeed, this corroborates the study by Biddiss and Chau [20], which identifies confidence, functionality, and support during rehabilitation as determining factors for adherence and continued use of the prosthesis.

On the other hand, despite the high level of confidence, eleven of the twenty professionals (55%) reported having received mentions of social discomfort from their patients, while nine (45%) stated they had not received this type of report. The main context of social discomfort described by professionals is excessive staring in public places (six respondents, 30%), followed by difficulties in bathrooms and inaccessible public spaces (three respondents, 15%), problems with public transportation and obstruction of entitled spaces (two respondents, 10%), and leisure situations (two respondents, 10%).

This shows that, even though users wear their prostheses exposed because they feel empowered and confident using the technology, stigma remains present in the gaze of external observers, which has a direct impact on users' perception. Thus, as Vaes, Stappers, and Standaert [22] discuss, the stigma associated with assistive products directly influences the user experience, reinforcing the need for multidisciplinary work that addresses, in addition to functional recovery, the psychosocial aspects that are frequently neglected. In addition, a report from an occupational physical therapist deserves special attention: she described the situation of a patient who sweated heavily in the work environment and encountered physical barriers in the workplace bathrooms to adequately clean the prosthesis. This report illustrates the intersection between architectural accessibility, working conditions, and

daily management of the prosthetic device, which are external factors that directly impact the use experience.

The factors identified by professionals as most influential in prosthesis acceptance converge around the return to locomotion and previous routine (eight respondents, 40%) and the gain in functionality and independence (seven respondents, 35%). An adequate multiprofessional rehabilitation process is mentioned by four respondents (20%), which is significant, as it indicates that some professionals recognize that the quality of the rehabilitation process is, in itself, a determining factor in acceptance, regardless of the characteristics of the prosthetic component.

As for rejection factors, pain and physical discomfort lead (six respondents, 30%), followed by difficulty putting on the device (five respondents, 25%) and unmet high expectations (n=4, 20%). Shame and social stigma (n=3, 15%), the weight of the prosthesis (two respondents, 10%), lack of a support network and depression (n=2, 10%), appearance (n=2, 10%), and inadequate or limiting components (n=2, 10%) complete the list. This diversity of factors confirms the multidimensional nature of the adaptation process and the need for equally multidimensional interventions.

The analysis of the professionals' data reveals a clinical perspective that is, at the same time, committed to patients' well-being and partially limited in its ability to capture the totality of the experience lived by these patients. The unanimity regarding the positive impact of the prosthesis on quality of life is clinically coherent and reflects the device's real value.

The professionals' emphasis on functional factors (such as mobility, independence, difficulty putting on the device, fitting problems) is understandable and has a solid clinical basis. However, it may produce an evaluation bias that underestimates equally important dimensions of the prosthetic experience: aesthetics, sexuality, stigma, and the everyday experience of social discomfort. These are domains that require competencies beyond traditional physical therapy training and that demand the active presence of psychologists, social workers, and other professionals in the rehabilitation process, which, incidentally, in most cases already has a multidisciplinary presence in the care and rehabilitation of these people, but which does not address specific points that make up the totality of the amputee's experience.

The issue of prosthesis abandonment, recognized by 50% of professionals as a possibility and by 15% as a frequent occurrence, is probably the most critical indicator of how well the current prosthetic rehabilitation system meets the real needs of users. If a significant portion of patients abandon the device after fitting, something in the process is failing, whether in component selection, training, post-discharge follow-up, or the management of expectations and social integration after rehabilitation.

C. Amputees perceptions

To understand the experience of using a lower limb prosthesis in all its complexity, it is necessary to recognize the plurality of human trajectories that make up this universe. The sample consists of 20 lower limb prosthesis users, of both sexes. Length of use varies significantly among participants: from 3 months to 32 years. The average length of use is concentrated between two and six years (n=10; 50%), forming a group mostly in an intermediate or advanced stage of adaptation. Some research indicates that this stage is marked by continuous adjustments between the user, the prosthetic component, and the social context, which makes qualitative listening especially relevant for understanding the real needs of this population [12],[14].

When asked what they most enjoy doing while using the prosthesis, users mentioned activities that mainly reflect a return to daily mobility and social life. The most frequent responses were: walking (n=10, 50%), carrying out daily activities such as work, household tasks, and driving (n=6, 30%), exercising such as weight training, going to the gym, and running (n=3, 15%), going out with family, friends, and pets (n=5, 25%), and leisure activities such as the beach, concerts, and dancing (n=3, 15%). Thus, these data indicate that the return to independent locomotion is the main benefit perceived by users. For most, the prosthesis is directly associated with the act of walking – which is directly related to the recovery of autonomy and social participation.

On the other hand, regarding discomfort, of the 20 participating users, (n=16, 80%) reported feeling some kind of physical discomfort when using the prosthesis, while only n=4 (20%) stated they felt no discomfort. The types of discomfort mentioned varied and include: pain in the residual limb/socket area, reported by (n=9, 45%); discomfort in the groin area, by 3 participants (15%); excessive heat and sweating, by 4 participants (20%); lower back pain, by 2 participants (10%); and itching or skin irritation on the residual limb (10%).The situations reported as most uncomfortable were long periods of use (8 respondents, 40%), extensive walks of more than 500 meters or 1 km (4 respondents, 20%), hot weather or use combined with heat-retaining clothing (3 respondents, 15%), and body weight variation that alters the fit (1 respondent, 5%).

The inability to run is by far the most recurrent functional limitation, present in 40% of responses. This reveals that the prosthetic components available, especially those provided by SUS (the Brazilian Unified Health System), do not keep pace, structurally and functionally, with the desire to engage in more intense physical activities, generating frustration and a sense of limitation that goes beyond basic daily use. In addition, there are reports of being unable to use the prosthesis for long periods, where n=13 (65%) reported some factor that prevents use, while 7 (35%) stated they had no such limitation. The main factors cited were: pain in the residual limb or socket (6 respondents, 30%), heat and sweating (n=4, 20%), injuries/wounds on the residual limb (n=2, 10%), lower back pain (n=1, 5%), a thinned residual limb with a loose socket fit (n=1, 5%), and elbow pain making donning difficult (n=1, 5%).

According to [18], [19], factors such as physical discomfort, functional inadequacy, and psychosocial aspects are among the most frequent causes of assistive technology abandonment.Regarding movement, the most frequently cited difficulties were: crouching/bending down (n=7; 35%), running (n=5; 25%), climbing stairs or steps (n=5; 25%), walking quickly (n=4; 20%), crossing the legs or flexing the knee beyond 90° (n=3; 15%), and walking without looking at the ground (n=2; 10%). Only 20% reported having no specific movement difficulties. These biomechanical restrictions, such as crouching, running, and climbing stairs, reflect the technical limitations of commonly used components, directly

affecting quality of life and participation in daily activities [9],[17],[21].

When asked about their level of adaptation to the prosthesis, respondents were distributed as follows: "Yes, completely" (n=8, 40%), indicating full adaptation; "Yes, but I still feel some difficulties" (n=12, 60%), indicating partial adaptation with persistent functional restrictions. No respondent stated they were not adapted, which may reflect either the ongoing rehabilitation process or a possible reluctance to acknowledge non-adaptation.

However, even though some are well adapted to the prosthesis, one of the participants interviewed said that, despite good functional adaptation, recurrent physical discomfort is reported, especially in the groin and ischial regions, requiring temporary workarounds, as described below: “When use is prolonged, the friction can even cause micro-cracks and wounds on the skin, you know? So I have to use sanitary pads as padding and wrap the residual limb with a bandage to compensate for the volume loss, because my residual limb has gotten smaller,” showing that, despite being adapted, they still feel some difficulties in use.

Indeed, the finding that 60% of users still perceive difficulties is clinically relevant. Even among those with decades of use, such as the respondent with 32 years of experience and the one with 25 years, specific limitations are mentioned – which suggests that full adaptation is a relative state, mediated by each individual’s functional expectations and by the technical capabilities of the prosthetic component used.

Regarding the appearance of the prosthesis, 11 participants (55%) stated that something about its appearance bothers them, while 9 (45%) stated they had no aesthetic discomfort. The aesthetic elements cited as sources of discomfort were: the visible tube/pylon (n=5, 25%), the foam cosmetic covering (n=2, 10%), the prosthetic foot, which evokes the amputated limb (n=1, 5%), and a simple/unsophisticated appearance compared to more modern models (n=1, 5%). Two participants (10%) indicated a desire to cover the tube with carbon fiber covers or more aesthetically elaborate materials. Two participants expressed a desire to cover the tube with a carbon fiber cover or more elaborate materials. The literature suggests that the aesthetics of the device directly influences the user’s willingness to expose it publicly and their relationship with their own body image [6],[22].

In contrast, one participant describes the prosthesis as an object of visual appreciation and personal identity, associating it with his affinity for mechanisms: "I think it’s beautiful [...] from seeing the knee movement happening [...]" and, for this reason, chooses to use it uncovered most of the time, exposing the mechanism. This exposure is described as a trigger for positive social interaction, especially with children, attributing observers’ curiosity to the visual asymmetry between the anatomical limb and the metal structure, which he compares to a cyborg. Visual customization emerges as a recurring theme for the interviewee. The participant reported having had the socket of a previous prosthesis painted with a modern design of the Brazilian flag; as the user puts it: “It’s like a tattoo [...] it becomes whatever you like.” He expresses interest in expanding this customization in the future, layering personal images along the prosthesis tube, in the manner of compositions used in tattoos with multiple figures. Indeed, there is a study [23] that observes the stigma and the symbolic dimension of assistive technology equipment, such as the cane, and found that when developing covers for the product, it was possible to observe that the prototypes presented to users helped create a less stigmatizing environment, by combining fashion and product design, showing that

At the same time, the participant identifies two concrete aesthetic problems that, in his assessment, compromise the device’s social acceptance and could be solved at low engineering cost. The first concerns the fixation screws between the socket and the knee, usually made of brass, which oxidize and produce an appearance he describes as “old iron” or “scrap metal”; in addition, the participant raises a second problem regarding the use of long trousers, because: due to the lack of filling at calf and ankle height, the trouser fabric hangs loosely over the thin tube of the structure, creating an effect he vividly compares to a snake: “It ends up looking like a snake [...] that ugly thing.” For this specific use, he expresses a desire for a partial, two-piece cover, as shown in the following statement: “I didn’t want those that look like a leg from start to finish [...] I just wanted that lower cover.”

Overall, to determine how users typically use the product, users were asked how they usually use the prosthesis. The responses were: fully exposed (n=10, 50%), fully covered (n=5, 25%), and partially exposed (n=3, 15%). Two participants chose not to clearly specify their mode of use. Fully exposed use, present in half of the respondents, indicates a posture of acceptance or inevitability regarding the prosthesis’s exposure. On the other hand, the other participants, who indicated they tend not to expose it fully or expose it only partially, demonstrate a stigmatized relationship with the product, since, when asked about their comfort exposing the prosthesis in public, 12 participants (60%) stated they felt comfortable with exposure, while 8 (40%) said they did not feel comfortable. To mitigate this social discomfort, they adopt concealment strategies such as wearing long trousers (n=4, 20%), a long dress (n=1, 5%), and cosmetic covering (n=1, 5%).

Thus, seeking to understand where this uncomfortable relationship arises, participants were asked about social discomfort. Of the 20 participants, 13 (65%) reported at least one situation of social discomfort associated with prosthesis use, while 7 (35%) stated they had not experienced such situations. The reports include: curious or embarrassed stares from strangers (n=9, 45%), jokes or derogatory comments from acquaintances and strangers (n=5, 25%), embarrassment in institutional settings such as banks and priority queues (n=2, 10%), and accessibility difficulties in public transportation and public spaces (n=2, 10%).

Two reports illustrate the severity of social stigma: one participant (16 years of prosthesis use) was made by bank security guards to remove the cosmetic covering for inspection, while another (32 years of use) faced difficulties in priority queues due to not being visually recognized as disabled while wearing trousers. These cases show that stigma extends beyond the social gaze into institutional practices. When asked about frustrations, 55% (n=11) reported at least one specific frustration. The most frequently cited were: falls (n=3; 15%), inability to run or play sports (n=3; 15%), movement limitations that reduce independence (n=2; 10%), components breaking in public (n=1; 5%), and discomfort from not feeling at ease without the prosthesis (n=1; 5%). These data reveal both frustrations related to use and the product itself, as well as impacts on body image, affected by

the amputation procedure and the prosthetic experience [6],[7],[8].

The data reveal a complex and multidimensional picture of the prosthetic experience. Most participants (60%) are in a process of partial adaptation, living with physical and social limitations that affect quality of life and self-esteem. Physical discomfort is frequent in this sample (80%), suggesting that the components used by these particular participants may not fully meet their individual needs.[18], [20].

The social dimension of the experience is equally significant: 65% reported social discomfort and 65% stated they felt less confident in at least one public situation, showing that prosthetic adaptation involves a complex process of identity renegotiation and coping with stigma [9], [22]. Four central reflections emerge from these analyses: The technical limitation (1) generates discomfort that feeds the reduced-use/adaptation cycle (2); aesthetics (3) modulates the psychosocial impact of that cycle; and all of this unfolds within a social/institutional context that remains inadequate (4), compounding both insecurity and exclusion.

D. Comparison of perceptions between amputees and professionals

Comparing both groups in the Content Analysis, both converged on functionality/independence as the central value of prosthesis use (100% users / 100% professionals). Here, both categories ("Return to routine and functionality" and "Functionality and independence") are conceptually equivalent, both capturing the recovery of activities of daily living, work, and mobility, which supports a direct comparison [5], [9], [21]. For the remaining categories, equivalence is only partial, and comparisons are presented with that caveat made explicit for each pair: Physical/technical barriers were reported by 80% of users (captures pain, heat, friction associated with the socket) and 55% of professionals. Although related, the categories differ conceptually; therefore, the comparison indicates thematic convergence around barriers to comfortable use rather than direct numerical equivalence. Figure 2 below shows and compares both reports:

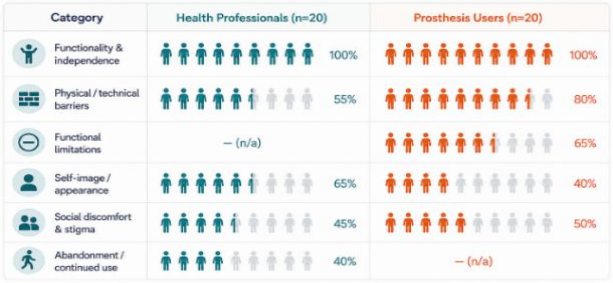

Fig. 2. Integrated content analysis of health professionals' and prosthesis users´ responses in the Content Analysis [7]. Each icon represents 10% of respondents in each group who mentioned the theme (n=20).

However, while 100% of professionals state that the prosthesis improves quality of life, only 40% of users reported being fully adapted. The remaining 60% still report difficulties, and 80% report physical discomfort. This divergence suggests that the clinical perception of therapeutic success may be disconnected from the user's subjective experience. Professionals, in general, assess outcomes based on observable functional metrics, while users perceive adaptation as a process that also encompasses the psychosocial dimension and the absence of pain.

For this reason, pain and physical discomfort appear as a central barrier from both the users' and the professionals' perspectives. Among users, 80% report discomfort; among professionals, 30% identify pain as the main factor in prosthesis rejection and 20% as the greatest challenge in adaptation. This convergence indicates that prosthetic component design is a critical point requiring improvement. Inadequate fit is not merely a biomechanical issue: it compromises the user's use, confidence and integration.

Social discomfort appears consistently in both groups: 65% of users reported situations of social discomfort, and 55% of professionals received similar reports from their patients. This convergence shows that the stigma associated with the prosthesis is a reality recognized by both sides [22]. The gaze of others is the main trigger of discomfort in both users' and professionals' reports, though asymmetrically detailed. Users cite specific situations (banks, jokes from acquaintances, priority queues), while professionals generalize it as "excessive staring," suggesting only partial access to patients' social experience. [6], [7]. Confidence in using the prosthesis publicly is a gradual, mutually recognized process. Professionals report 60% of users as confident, developing over time with use and training. Users similarly report 60% comfort exposing the prosthesis, yet 65% cite situations of lower confidence, suggesting confidence is contextual rather than absolute. Specific situations (stairs, ramps, crowds, institutional settings) remain sources of insecurity even for experienced users.

Looking at design aspects, both the user and professional data point to prosthetic product design as a central variable. Users mention the visible tube/pylon (25%), the foam covering (10%), and the prosthetic foot (5%) as sources of aesthetic discomfort. Professionals mention the donning system, fit, and weight as rejection factors. These findings converge to indicate that prosthetic design, in its functional, ergonomic, and aesthetic dimensions, is a fertile field for innovation that directly impacts users' quality of life.

The comparative analysis reveals five key implications: (1) physical discomfort (80% of users) and donning difficulties (25% of professionals) point to the need for more adaptable, intuitive prosthetic sockets [18], [20]; (2) high rates of social discomfort and aesthetic limitations (55-65%) indicate that prosthetic aesthetics is a clinically relevant factor, not merely cosmetic [22], [23]; (3) a gap between some users' exercise-related expectations and the components available to them was reported within this sample, whether this reflects a broader pattern in SUS-provided components nationally cannot be established from this study and would require research with a representative sample [19], [20]; (4) reported abandonment (15%) aligns with frustration, falls, and partial adaptation rates, suggesting abandonment results from cumulative, unmanaged physical, functional, and social difficulties [10], [19]; and (5) the absence of spontaneous mentions of sexuality, despite its clinical relevance to body image and intimacy, suggests it remains a taboo topic in interviews [6], [7].

IV. RECOMMENDATIONS FOR BIOMEDICAL ENGINEERING

Content Analysis [16] identified patterns that translate into concrete recommendations for lower-limb prosthesis development (Table IV) for Biomedical Engineering researchers and professionals:

TABLE IV. RECOMMENDATIONS FOR BIOMEDICAL ENGINEERING PROFESSIONALS

design requirement	empirical basis (frequency/source)	target outcome
1. Thermal management in socket/liner design	Heat/sweating cited as discomfort by 20% of the users.	Reduce heat retention; improve ventilation.
2. Socket pressure distribution at residual limb interface	Pain in residual limb cited by 45% of the users and 30% of the professionals, leading rejection factor.	Paticient-specific, adaptative socket contouring.
3. Aesthetic personalization / modular cosmetic covering	Visible tube discomfort, foam-covering dissatisfaction.	Modular, customizable partial/full cosmetic covers.
4. Participatory, multidisciplinary design process	Gap between professional (100% report QoL) improvement and user perceptions.	User feedback loops embedded in component development and rehabilitation protocol.
5. Expanded functional/ mobility range	Crouching/bending running, stairs, cited by users as movement limitations	Components enabling wider range of motion beyond current baseline.

V. CONCLUSION

The joint analysis of user and professional data allows for an exploratory look at the multidimensional experience of lower-limb prosthesis use. While the device appears to hold significant therapeutic value for restoring mobility and independence, the accounts analyzed suggest that this potential may be compromised by physical (socket discomfort, pain, heat), functional (component limitations), aesthetic, and social (stigma, stares, inaccessibility) barriers.

The convergence between users and professionals around mobility as a central value, physical discomfort as a recurring barrier, and social discomfort as a dimension present across accounts points to the relevance of addressing these dimensions in an integrated way in future design interventions and rehabilitation protocols. Conversely, the divergence observed regarding the degree of adaptation, may indicate the need for assessment tools more sensitive to users' subjective, lived experience, complementing the functional parameters traditionally observed.

These findings may contribute to Biomedical Engineering by broadening understanding of demands related to lower-limb prosthesis development and use. Results suggest technological development could benefit from going beyond mechanical improvements to also consider comfort, ergonomics, aesthetics, usability, and user experience. These initial findings may also support future research on improving rehabilitation, defining criteria for new prosthetic components, and applying user-centered design, approaches that could later be examined for their relationship with adherence to use, quality of life, and social participation of people with amputations.

Abstract*—Parkinson's disease (PD) is a progressive neurodegenerative condition clinically delineated by primary motor deficits, such as rigidity, bradykinesia, and tremor. Clinical management aimed at mitigating these symptoms predominantly relies on pharmacological interventions—chiefly dopamine replacement therapy—alongside surgical procedures, including deep brain stimulation or targeted tissue ablation. Nevertheless, a significant patient cohort is excluded from surgical eligibility, while others experience debilitating medication-induced side effects. Consequently, recent research has focused on non-invasive peripheral electrical stimulation as a complementary therapeutic modality, with particular emphasis on tremor suppression. This pilot study aimed to evaluate the feasibility of a protocol combining noninvasive peripheral electrical stimulation and blinded video-based assessment of motor performance in PD. Eleven participants were randomized to receive either peripheral transcutaneous electrical nerve stimulation (TAPS) or transcutaneous somatosensory sine wave electrical stimulation (t-SSES) stimulation. Six participants received pulse current stimulation and five received sinusoidal current stimulation. Seven selected motor tasks were assessed before and after stimulation; the tasks are included in the Movement Disorder Society-Unified Parkinson's Disease Rating Scale part III (MDS-UPDRS Part III). The assessment was realized by video-recorded. The videos were independently scored in a blinded manner by a neurologist specializing in movement disorders. The videos were randomized before evaluation to ensure blinded scoring. The protocol was successfully implemented, with a satisfactory number of participants, good tolerability of the intervention, blinding of the evaluators, and no significant technical or safety issues. The exploratory video assessment, conducted in a blinded manner, indicated a trend toward a reduction in scores for most patients, and there was only one case of an increase in scores. The findings support the feasibility of conducting a blinded study to investigate the effects of t-SSES and TAPS on motor symptoms in patients with Parkinson's disease using the proposed experimental protocol.

***Keywords*—Parkinson's disease, noninvasive peripheral electrical stimulation, MDS-UPDRS Part III, blinded video assessment.**

I. Introduction

Parkinson's disease (PD) is the most common form of parkinsonism and is a progressive neurodegenerative disorder characterized by the loss of dopaminergic neurons in the substantia nigra. PD has a prevalence of approximately 1% to 2% in populations exceeding 65 years of age [1]. Clinically, PD is characterized by classical motor symptoms, including rigidity, resting tremor, bradykinesia, postural instability, and gait disturbances [2; 3; 4]. Pharmacological interventions constitute the primary therapeutic modality for PD, with levodopa-carbidopa—a metabolic dopamine precursor paired with a decarboxylase inhibitor—serving as the gold-standard, first-line therapy [5]. A major limitation of long-term pharmacological management is the progressive loss of efficacy over time, which frequently necessitates dosage

escalation [6]. Ultimately, while these agents alleviate symptomatic burden, they lack disease-modifying capabilities to halt neurodegeneration and may induce intolerable adverse effects in a subset of patients [6]. Surgical intervention serves as a viable therapeutic alternative for a select cohort of patients with Parkinson's disease (PD). Current neurosurgical modalities encompass cellular ablation of aberrant, hyperactive neuronal populations and Deep Brain Stimulation (DBS) [7; 8, 9; 10]. Furthermore, widespread clinical translation of these surgical approaches is constrained by their high financial burden and invasive nature.

These limitations have motivated the investigation of non-invasive therapeutic approaches. Among the available non-invasive complementary modalities—designed to supplement rather than replace optimal pharmacotherapy—are rhythmic interventions, which can be administered via visual, auditory, or vibrotactile channels; the latter specifically engages the somatosensory system.

II. Somatosensory Stimuli

Somatosensory modulation can be delivered via either electrical or mechanical modalities. Mechanical stimulation has been extensively investigated in patients with Parkinson's disease (PD) utilizing wearable biomedical devices [11]. Currently, commercially available systems employing this therapeutic approach include the CUE1 (Charco Neurotech Ltd.) and the VILIM ball (Vilimed) [12; 13].

A. Peripheral Electrical Stimulation

The primary modalities of peripheral electrical intervention encompass Functional Electrical Stimulation (FES), Sensory Electrical Stimulation (SES)—operationalized at intensities below the motor threshold—and Transcutaneous Electrical Nerve Stimulation (TENS). TENS preferentially activates Aβ sensory fibers to modulate nociceptive processing via the gate control theory [14]. Afferent signals propagated along Aβ fibers ascend through the dorsal column–medial lemniscus pathway to the thalamus [15], where they may influence thalamocortical networks involved in tremor generation [16, 17].

Extensive literature has investigated the therapeutic efficacy of these electrical stimulation modalities on parkinsonian tremors. Notably, the commercially available Cala Trio device employs by delivering alternating transcutaneous electrical nerve stimulation (TAPS-Transcutaneous Afferent Patterned Stimulation) to the sensory branches of the radial and median nerves, effectively achieving significant tremor suppression [18].

The TAPS technique was based on electrophysiological recordings [19,20] obtained using DBS electrodes, which demonstrated that peripheral nerve stimulation evokes somatosensory potentials within the VIM nucleus and other tremor-related brain regions.

In clinical practice, TAPS consists of delivering transcutaneous electrical stimulation to the median and radial nerves of the dominant upper limb for a 40-minute session. Commercial devices operate under standardized parameters based on charge-balanced, biphasic pulse trains, featuring a phase duration of 300 µs, an interphase interval of 50 µs, and a repetition frequency of 150 Hz. The core mechanism of this method relies on alternating the stimulus delivery between the median and radial nerves, controlled by an alternating stimulation frequency individually calibrated to each patient's tremor frequency [19].

Pulsatile electrical stimulation is widely used to activate large-diameter myelinated Aβ afferent fibers, thereby eliciting tactile sensations [21, 22]. However, increasing the stimulation intensity may also recruit smaller-diameter Aδ and C fibers [23, 24]. Therefore, it is reasonable to hypothesize that more selective stimulation of the somatosensory pathways could have a beneficial effect on motor symptoms.

Transcutaneous somatosensory sine wave electrical stimulation (t-SSES) is a modality of noninvasive peripheral stimulation that has been scarcely investigated as an intervention for PD. Unlike rectangular pulse stimulation, t-SSES allows preferential activation of different sensory fiber populations by varying the stimulation frequency. This frequency-dependent selectivity has been attributed to differences in the electrophysiological properties of sensory nerve fibers, including their membrane dynamics and ion channel activation characteristics [23, 25]. Previous studies have reported that different activation patterns of somatosensory nerve fibers depending on the frequency of the sinusoidal stimulus: lower frequencies, such as 1 Hz and 5 Hz, preferentially stimulate C-type fibers; a frequency of 250 Hz stimulates Aδ-type fibers; and finally, high frequencies, such as 2 kHz and 3 kHz, preferentially activate Aβ-type fibers [26; 27; 28; 24].

Given the limited evidence regarding t-SSES in Parkinson's disease and the absence of standardized blinded assessment protocols, this pilot study was designed to evaluate the feasibility of a protocol combining t-SSES with blinded video-based assessment of motor performance.

In this study, a novel paradigm with t-SSES of 3 kHz was implemented, based on the TAPS stimulation framework, for motor symptoms.

III. Materials and Methods

The experimental protocol was approved by the Institutional Ethics Committee (CAAE registration no. 58744222.2.1001.5257).

This pilot study enrolled 11 participants diagnosed with Parkinson's disease (PD) and exhibiting clinical tremor.

Participants were eligible if they were 40–75 years old, had a diagnosis of idiopathic Parkinson's disease established by a movement disorders specialist according to the United Kingdom Parkinson's Disease Society Brain Bank criteria, had a Hoehn and Yahr (H&Y) [2] stage between 1 and 4, and provided written informed consent (or consent provided by a legal representative when applicable).

Exclusion criteria included Parkinson's disease dementia; musculoskeletal or orthopedic disorders affecting upper-limb motor performance; implanted cardiac pacemakers or deep brain stimulation (DBS) systems; neurological disorders other than Parkinson's disease; the use of medications known to significantly impair attention or motor performance and failure to perceive the electrical stimulation.

Participants were randomly assigned to one of the two intervention groups using simple randomization. Allocation was performed by drawing one of two identical folded slips of paper labeled "TAPS" or "t-SSES" from an opaque container which was thoroughly shaken before each draw so that the allocation could not be predicted.

After each draw, both slips were returned to the container before the next participant was enrolled, ensuring that each participant had an equal probability of being assigned to either intervention. Eleven participants were randomized TAPS group, n = 6; t-SSES group, n = 5). As this was a pilot feasibility study, no formal sample size calculation was performed. The sample size was determined based on participant availability and the feasibility of conducting the experimental protocol within the study period.

During the experimental sessions, participants were seated in an ergonomic chair with their forearms resting on an adjacent table to minimize muscle fatigue. Experiments were conducted in a dedicated laboratory environment at the Clementino Fraga Filho University Hospital (UFRJ), maintained under controlled thermal conditions (24 ± 1°C). Motor performance was assessed before and after the stimulation protocol using Part III of the Movement Disorder Society-Unified Parkinson's Disease Rating Scale (MDS-UPDRS III) [29]. Specifically, seven upper-limb motor tasks were evaluated: 3.4 - finger tapping, 3.5 - hand movements, 3.6 - pronation-supination movements, 3.15 - postural tremor of the hands, 3.16 - kinetic tremor of the hands, 3.17 - rest tremor amplitude and 3.18 - constancy of rest tremor [30]. The recorded video data were subsequently evaluated by a blinded neurologist specializing in movement disorders.

All assessments were performed while participants were in the ON medication state to ensure clinical stability and to minimize variability in motor performance during testing. Although dopaminergic medication may reduce baseline tremor severity and consequently decrease the opportunity to detect additional treatment effects, this approach reflects routine clinical practice and improves the consistency of repeated motor assessments.

A. Video recording

Video recording was performed using two high-resolution mobile cameras operating at 1080p resolution and a frame rate of 30 frames per second (fps). The devices were mounted on independent tripods; the first camera was aligned perpendicular to the participant's sagittal plane, while the second camera provided a frontal view. Crucially, the tripods were mechanically isolated from both the examination table and the chair. This structural decoupling minimized the influence of physiological tremors or subject movements on camera stability, reducing the likelihood of motion artifacts in the recorded videos.

The stimulation electrodes remained in the same position during both the pre- and post-stimulation motor assessments. Because the electrodes were visible in all recordings, their presence did not disclose whether a video had been acquired before or after stimulation, thereby helping preserve evaluator blinding.

B. Tremor Frequency Quantification

To quantify postural tremor frequency before and after the neuromodulation protocol, kinematic data were acquired using a triaxial accelerometer positioned on the dorsum of the stimulated hand. During data collection, participants maintained their upper limb extended horizontally for 20 s, allowing the sensor to record tremor amplitude and frequency dynamics. The dominant tremor frequency was estimated using power spectral density (PSD) analysis implemented in LabVIEW.

The peak tremor frequency derived from this baseline assessment was subsequently integrated into the patient-specific stimulation protocol parameters [18; 30].

C. Stimulation Electrodes

Peripheral electrical stimulation was delivered via two pairs of self-adhesive gel electrodes (1 cm diameter) targeting the radial and median nerves. The radial electrodes were positioned on the lateral-dorsal aspect of the wrist, adjacent to the anatomical snuffbox, while the median electrodes were placed on the palmar surface [18]. The center-to-center distance between the cathode and anode of each electrode pair was maintained at 2 cm. Compared with the original protocol [18], the inter-electrode distance was adjusted to accommodate the smaller electrode dimensions used in the present study. This modification likely increased the local current density while maintaining the stimulation over the same anatomical target, which should be considered when comparing the present findings with those obtained using the original protocol. To maintain comparable electrode geometry across participants, the edge-to-edge distance between the electrodes was adjusted according to the participant's wrist circumference, classified as: small (13.5–15.4 cm circumference; 2.5 cm separation), medium (15.5–17.4 cm circumference; 3 cm separation), or large (17.5–19.5 cm circumference; 3.5 cm separation). The interelectrode distance values (cathode and anode) were readjusted due to the reduction in electrode surface area compared to the protocol established by reference [18]. Stimulation was applied unilaterally to the upper limb presenting the higher tremor severity; in cases of symmetrical tremor presentation, the dominant hand was selected [18]. The duration of the stimulation was 40 minutes.

The stimulation was generated by Mestin equipment, a stimulator developed at *Universidad Politécnica Salesiana* (UPS) in Ecuador in collaboration with Coppe/UFRJ. The stimulator is equipped with two independent channels, each of which is capable of generating arbitrary waveforms, including sinusoidal, square, or custom waveforms. The stimulation parameters are configured and transmitted to the stimulator via an Ethernet connection, employing a LabVIEW interface [31].

D. Stimulation Parameters

Participants were randomly allocated to two experimental groups to receive distinct peripheral electrical stimulation paradigms: conventional TAPS or an adapted TAPS protocol using a 3 kHz sinusoidal waveform instead of biphasic rectangular pulses. The conventional TAPS paradigm consisted of charge-balanced, biphasic square pulses with a phase duration of 300 µs and an interphase interval of 50 µs [18], delivered at a pulse repetition rate of 150/s (150 Hz).

Prior to establishing the stimulation intensity, the baseline current sensory threshold (ST) was characterized for each participant. Stimulation intensity was customized for each participant by escalating the current in 0.25 mA increments until the ST was reached in the hand or digit dermatomes. The target intensity was defined as the maximum tolerable paresthesia intensity below the motor threshold and did not induce discomfort, ensuring the complete absence of muscle contractions. For both cohorts, stimulation was alternated between the median and radial nerves at a switching frequency locked to the patient's specific tremor frequency.

E. The randomization of videos.

The videos were randomized using a computer-generated random number sequence. Each number corresponds to a specific video. All videos were anonymized and presented in randomized order to an experienced neurologist specializing in movement disorders. The evaluator was blinded to the stimulation condition and assessment time point (pre- or post-stimulation). Each video was independently scored according to the MDS-UPDRS Part III criteria.

F. Statistical analysis

Given the exploratory nature of this pilot study, the limited sample size resulted in insufficient statistical power to detect small-to-moderate effects. Accordingly, the results are presented primarily through descriptive statistics, with inferential tests performed for exploratory purposes and interpreted with appropriate caution.

Each item of the MDS-UPDRS Part III is scored on an ordinal scale ranging from 0 to 4, allowing changes in performance for each task to be classified as improved (decrease in score), unchanged, or deteriorated (increase in score). In addition, because only seven MDS-UPDRS Part III tasks were evaluated, patients were also classified according to a composite score obtained by summing the scores of these seven items rather than the complete Part III score.

A partial MDS-UPDRS Part III score was calculated by summing the scores of the selected motor items (3.4, 3.5, 3.6, 3.15, 3.16, 3.17, and 3.18) evaluated exclusively on the most affected upper extremity. Frequencies were reported for each group, both at the item level and for the composite score.

Results are presented as the median and interquartile range, together with the numbers of patients who improved, remained unchanged, or deteriorated for each individual task and for the composite score.

Within-group comparisons of pre- and post-stimulation values were performed using the Wilcoxon signed-rank test. Between-group comparisons of change scores (Δ = post-stimulation − pre-stimulation) were performed using the Mann-Whitney U test.

Statistical analyses were performed in R (version R 4.5.1) using the wilcox.test() function, which excludes zero-difference pairs from the signed-rank test.

IV. Results

A. Feasibility outcomes

Recruitment - Patients were recruited at the HUCFF outpatient clinic and neurology department while awaiting consultation with a physician. The principal investigator then proceeded to approach the patients and their companions in order to deliver the explanation of the experiment. The most salient points of this explanation encompassed the nature, safety and comfort of the stimulation; the duration of the stimulation itself and the total duration of the experimental session; and the purpose of the experiment. Patients who consented to participate in the study were escorted to the designated experiment room following their clinical consultation.

Sixteen patients were invited to participate in the study; however, five were excluded. Two met at least one of the predefined exclusion criteria, whereas three were excluded because the stimulation intensity could not be adjusted to the target level relative to the sensory threshold required by the protocol. Eleven participants were included and randomized (Group TAPS, n = 6; Group t-SSES, n = 5). All participants were on stable dopaminergic medication regimens. The TAPS group exhibited a mean age of 64.8 ± 6.5 years and a mean H&Y stage of 2.0 ± 0.6. The t-SSES group presented a mean age of 67.8 ± 5.9 years and a mean H&Y stage of 2.1 ± 0.7.

Protocol adherence - All remaining participants completed the stimulation session and the pre- and post-intervention motor assessments without any deviations from the protocol. Consequently, no requests were made to disrupt the experimental session. It was also found that there were no complaints regarding the accommodation, the room temperature, or the duration of the session.

Safety and tolerability - Prior to the commencement of each experimental session, the electrostimulator was tested using an oscilloscope to verify the waveform and voltage. In the event of an offset being detected in the delivered current, the stimulator was meticulously calibrated and retested to ensure its optimal functionality. The mean stimulation intensities applied to the median and radial nerves in the TAPS group were 1.5 x ST (2,752.6 µA) and 1.5 x ST (2,669.7 µA), respectively. For the t-SSES group, the corresponding average intensities for the median and radial nerves were 1.2 x ST (4,195.4 µA) and 1.3 x ST (4,329.7 µA), respectively. The predominant sensory experiences reported by patients included tingling, vibration, sting, and needling, yet these were generally characterized as mild or tolerable. No reports were received of discomfort.

Blinding - The blinded video assessment was successfully completed, as the evaluating physician was unaware of the type of stimulation administered to the participant, and whether the assessment video corresponded to the pre- or post-stimulation period. The neurologist did not participate in the experimental sessions. The videos did not contain the participants' names or the date on which the experiment was conducted.

Technical feasibility - The stimulation system operated in accordance with the intended protocol throughout the study. The video recordings were suitable for blinded assessment.

B. MSD-UPDRS Part III Results

Table 1 summarizes the number of patients who showed improvement, worsening, or no change in scores for each task in Part III of the MDS-UPDRS. A trend toward improvement was observed in most of the tasks assessed in both groups, particularly in the Hand Movements task in both groups and in the TAPS group for the Finger Tapping task. In the t-SSES group, no patient showed improvement in the "Postural Hand Tremor" task, while in the TAPS group, no improvement was observed in the "Resting Tremor Amplitude" task. In both groups, all tasks included patients whose scores remained unchanged. A worsening in scores was observed for the "Hand Pronation-Supination Movements" and "Resting Tremor Amplitude" tasks in both groups.

In addition, patients in the TAPS group showed a worsening in scores for the "Hand Postural Tremor" and "Hand Kinetic Tremor" tasks.

Table 1. Number of participants showing improvement, no change, or deterioration in MDS-UPDRS Part III scores for each analyzed motor task. TAPS: transcutaneous afferent patterned stimulation; T-SSES: transcutaneous somatosensory sine wave electrical stimulation

Tasks	Groups	Improvement	No Change	Deterioration
FINGER TAPPING	*TAPS*	3/6	3/6	0
	t-SSES	1/5	4/5	0
HAND MOVEMENTS	*TAPS*	4/6	2/6	0
	t-SSES	3/5	2/5	0
PRONATION-SUPINATION MOVEMENTS OF HANDS	*TAPS*	1/6	4/6	1/6
	t-SSES	1/5	3/5	1/5
POSTURAL TREMOR OF THE HANDS	*TAPS*	1/6	4/6	1/6
	t-SSES	0	5/5	0
KINETIC TREMOR OF THE HANDS	*TAPS*	1/6	3/6	2/6
	t-SSES	2/5	3/5	0
REST TREMOR AMPLITUDE	*TAPS*	0	4/6	2/6
	t-SSES	1/5	3/5	1/5
CONSTANCY OF REST TREMOR	*TAPS*	1/6	4/6	1/6
	t-SSES	1/5	4/5	0

Based on the change in the partial MDS-UPDRS Part III score (Δ = post − pre), improvement was observed in four of six patients (67%) in the TAPS group and in four of five patients (80%) in the t-SSES group. The remaining participants showed no change, and only one patient exhibited a worsening of the partial score following stimulation (Table 2).

Table 2. Individual pre- and post-stimulation partial scores (MDS-UPDRS Part III) and the corresponding change scores (Δ = post − pre). TAPS: transcutaneous afferent patterned stimulation; T-SSES: transcutaneous somatosensory sine wave electrical stimulation

Patient	Group	Pre	Post	Δ (Post − Pre)
P1	*TAPS*	4	2	-2
P2		15	15	0
P3		4	2	-2
P4		9	3	-6
P5		1	0	-1
P6		3	9	6
P7	*t-SSES*	10	1	-9
P8		3	2	-1
P9		21	19	-2
P10		4	4	0
P11		5	4	-1

Within-group comparisons of the partial MDS-UPDRS Part III scores using the Wilcoxon signed-rank test revealed no statistically significant differences between the pre- and post-stimulation assessments in either group (TAPS: V = 10.5, p = 0.4962; t-SSES: V = 10, p =0.09751), as shown in Table 3.

Table 3. Results of the Wilcoxon signed-rank test comparing pre- and post-stimulation partial MDS-UPDRS Part III scores within the TAPS and t-SSES groups.

Grupo	n	Pre (median [Q1–Q3])	Post (median [Q1–Q3])	Δ (Post − Pre) (median [Q1–Q3])	p (Wilcoxon)
TAPS	6	4 [3 - 8]	3 [2 -8]	-2 [-2-0]	0.4962
t-SSES	5	5 [4 - 10]	4 [2 - 4]	-1 [-2 - (-1)]	0.0975

Comparison of the changes in the partial MDS-UPDRS Part III scores (Δ = post − pre) between the TAPS and t-SSES groups using the Mann–Whitney U test also showed no statistically significant difference (W = 13.5, p = 0.8521), as shown in Table 4.

Table 4. Between-group comparison of changes (Δ = post − pre) in partial MDS-UPDRS Part III scores using the Mann–Whitney U test.

Variable	TAPS (n = 6)	t-SSES (n = 5)	p (Mann-Whitney)
Δ MDS-UPDRS Part III Partial Score	-2 [-2-0]	-1 [-2 - (-1)]	0.8521 (W =13.5)

Discussion

Patient recruitment for PD, as well as study adherence, stimulus tolerance, and safety, were satisfactory. Blinding of

the evaluating physician was also satisfactory; however, only one evaluator participated in this pilot study. To minimize bias due to individual subjectivity, future studies will include three evaluators who are blinded to the MDS-UPDRS Part III scoring.

The results of the MDS-UPDRS Part III scores showed a descriptive reduction in post-stimulation scores after 40 minutes for both forms of stimulation, which is consistent with previous larger-scale studies [30, 32]; however, due to the small sample size, the statistical tests—the Wilcoxon signed-rank test and the Mann-Whitney test— did not indicate significant differences either between the pre- and post-stimulation periods or among the experimental groups, respectively.

Another limitation of this pilot study was the baseline imbalance in disease severity between the experimental groups. The t-SSES group presented higher and more variable pre-stimulation MDS-UPDRS Part III scores than the TAPS group, consistent with a greater degree of motor impairment. In such a small sample, this baseline heterogeneity may have disproportionately influenced the between-group comparisons and reduced the ability to detect differences attributable to the stimulation protocols.

The ON medication state of patients was another limitation of the study; anti-Parkinson's medication could have attenuated the severity of motor symptoms, so any small existing difference may have been imperceptible to the evaluator.

There was no sham (placebo) stimulation condition. Without a sham stimulation condition, the descriptive improvements observed in the present study cannot be attributed specifically to the stimulation, as placebo effects, spontaneous variability, or evaluator-related factors cannot be excluded. Future controlled studies should include a sham condition.

The groups differ not only in waveform—the average intensity also differs (1.5×ST / ~ 2.7 mA in TAPS vs. ~1.3×ST / ~4.3 mA in t-SSES). These values were determined based on each patient's tolerance of the sensations caused by the stimulation. However, this should be considered when interpreting future comparisons. Another issue that may be raised concerns the frequency-selective recruitment of fibers, since higher intensities recruit a greater variety of fiber types [24].

Conclusion

A preliminary, blinded, video-based assessment of the motor tasks in Part III of the MDS-UPDRS revealed descriptive improvements in the scores for those tasks in some participants following peripheral electrical stimulation. However, no statistically significant differences were observed, and the findings should be interpreted with caution given the exploratory nature of this pilot study.

The study nevertheless demonstrated the feasibility of implementing the proposed stimulation protocol together with blinded video-based motor assessment in individuals with Parkinson's disease. Patient recruitment, protocol adherence, stimulation tolerability, and evaluator blinding were successfully achieved, supporting the practicality of this methodological approach.

Because of the small sample size and the absence of a sham control, no conclusions regarding the clinical efficacy of either stimulation protocol can be drawn. These preliminary findings support the conduct of adequately powered, randomized controlled studies to determine the therapeutic effects of non-invasive peripheral electrical stimulation in Parkinson's disease.

Consequently, the authors conducted a double-blind crossover trial in which participants, evaluators, and data analysts were fully blinded. To this end, 50 patients diagnosed with PD will be enrolled in the study. Subjects will be randomly assigned to receive either the t-SSES intervention or a placebo, with the intervention and placebo administered on different days. The sample size of N = 50 was determined using a Monte Carlo simulation of the paired Wilcoxon test, assuming a significance level of 0.05 and a power of >80%. Two movement disorder specialists will independently evaluate patient performance using Part III of MDS-UPDRS before and after the intervention. Inter-rater reliability will be assessed using the Intraclass Correlation Coefficient (ICC) and the Weighted Kappa Coefficient. Furthermore, to provide an objective measure of tremor, accelerometry signals will be recorded alongside the clinical evaluations.

Acknowledgment

The authors express their gratitude to CAPES (PROEX), FINEP (grant 01.24.0122.00), CNPq, and FAPERJ (grants E-26/204.393/2024 and SEI-260003/020273/2025) for their financial support. Additionally, the authors would like to express their gratitude to SisAssistiva-MCTI for its collaboration.

***Abstract*—This study aims to define and implement a gamification proposal for a virtual reality FES-assisted cycling system (*v-FES-Cycling*) using the Octalysis framework and an expert judge evaluation methodology, conceptually structuring an exergame for a preliminary rehabilitation platform for people with spinal cord injury (SCI). The evaluation methodology of the expert judge was used to select techniques based on the eight motivational drivers of the Octalysis framework. The mechanics were implemented in the Unreal Engine 5 (UE) game engine, integrating FES hardware, sensors, and a Virtual Reality (VR) environment. The judges prioritized the drives Unpredictability and Curiosity (4.21), Development and Accomplishment (3.92), Empowerment, Creativity, and Feedback (3.54) and Scarcity and Impatience (3.38). Techniques such as coin collection, scoring, obstacle avoidance, lap counting, visual and audio feedback, and the selection of avatars and scenarios were implemented, resulting in a functional serious game (exergame). The study demonstrated the preliminary technical feasibility of the exergame's technological development. Controlled clinical trials to evaluate usability and efficacy with real patients with SCI will be conducted in future phases.**

***Index Terms*—Rehabilitation, FES-Cycling, Octalysis framework, Judge-based assessment methodology.**

I. Introduction

This study is part of an ongoing research project that integrates Virtual Reality (VR), Functional Electrical Stimulation (FES), and an instrumented tricycle for the rehabilitation of individuals with Spinal Cord Injury (SCI). The study is based on the *v-FES-Cycling* system, originally proposed in [1], [2] e [3], which developed the data communication interface between the stimulation hardware and the immersive environment of a VR game. This phase of the research aims to add structured layers of gamification to the previously developed exergame. Thus, the focus of this article is the definition of the motivational design and the preliminary implementation of software in the Unreal Engine (UE) game engine for gamification strategies intended for FES-assisted cycling (FES-Cycling), preliminarily assessing the initial ludic relevance with experts.

SCI is a debilitating neurological condition that results in partial or total disruption of motor and somatosensory functions below the level of the lesion [4], [5], directly impacting the mobility, functional independence, and quality of life of affected individuals [5], [6]. In this context, motor rehabilitation, when performed continuously and intensively, plays a fundamental role in promoting neuroplasticity, restoring motor functions, and preventing secondary complications [7], [8].

Among the available therapeutic approaches, FES stands out as an effective strategy, based on the application of electrical pulses to induce contractions in paralyzed muscles. This technique helps prevent muscle atrophy, maintain range of motion, and enable the performance of functional movements, even in the absence of voluntary control [7], [9]. One of the most well-established applications of FES is FES-Cycling, which involves the use of a cycle ergometer or tricycle combined

Financial support from the Distrito Federal Research Support Foundation (FAPDF), through Public Call No. 10/2023 - FAPDF Learning Program (project No. 00193-00002152/2023-95).

with electrical stimulation to promote cyclic movement of the lower limbs, thereby facilitating the coordinated activation of muscle groups during pedaling cycles [10].

Given this scenario, emerging technologies such as VR and serious games have been explored as promising strategies to increase patient motivation and engagement during rehabilitation [11], [12], [13]. The use of immersive virtual environments allows for the creation of dynamic, multisensory experiences, providing real-time feedback, enhancing the sense of presence, and transforming therapeutic exercises into more engaging and playful activities. In this context, *exergames*, which combine physical exercise with game elements, have shown potential for increasing intrinsic motivation and encouraging the continued practice of therapeutic activities [14], [15]. Based on this aforementioned approach, in [1] the *v-FES-Cycling* system was proposed, which integrates an FES-powered tricycle into a VR environment [1], [3], [10]. Despite its established clinical benefits, FES-Cycling still faces challenges related to low user engagement, often associated with the repetitive, monotonous, and physically demanding nature of the exercises, which can compromise motivation and long-term treatment adherence [11], [12].

At the same time, gamification has become established as an effective approach to promoting engagement in non-game contexts, including healthcare field [16], [17]. This approach consists of applying game elements and mechanics, such as scoring, rewards, challenges, and progression, with the aim of motivating and influencing behavior and increasing user adherence [18]. Evidence indicates that gamified interventions can improve self-efficacy and reduce negative emotions associated with prolonged treatments [18], [19]. However, the effectiveness of these strategies depends directly on a structured design capable of considering the psychological and motivational needs of the target audience [18], [20]. In this context, the Octalysis framework, developed by Yu-kai Chou, stands out for offering a systematic approach based on eight core motivational drives, known as core drives (CD) [16], [21]. Unlike simplified approaches centered only on points and rewards, the Octalysis framework allows for the analysis and development of gamified experiences in a more systematic way, considering different aspects of human motivation [21], [22].

Other studies have involved initiatives such as the *iCycle* platform, which integrates FES-Cycling with commercial games, but without detailing a formal gamification framework [8]. *PedaleoVR*, on the other hand, uses *exergames* in cycling, but without integration with FES [14]. Despite studies using the Octalysis framework in different contexts, the combination of FES, VR, and structured gamification remains underexplored in the rehabilitation literature [18]. There are also methodological gaps in the preliminary evaluation of these systems that integrate games by expert reviewers prior to conducting clinical trials [23].

Given this context, this article aims to define gamification techniques and present the initial results of implementing these techniques in Unreal Engine software for the *v-FES-Cycling* system, using the Octalysis framework to propose preliminary game mechanics aligned with the target audience's perceived motivational profile as evaluated by expert judges, as well as evaluation by expert judges as a method for defining these gamification techniques. It is thus expected to contribute to the development of a more adaptable and functional preliminary solution in the context of rehabilitation for people with SCI, serving as a basis for future clinical trials and usability evaluations with patients.

II. Methods

The methodology adopted for this study follows a structured process for applying the expert judge evaluation methodology and the Octalysis gamification framework to the *v-FES-Cycling* rehabilitation system, aiming to overcome the repetitive and demotivating nature of conventional rehabilitation for people with SCI. It is important to note that this study focuses on defining gamification techniques and developing these game mechanics within the UE software for the *v-FES-Cycling* system. Thus, the phases described here did not involve the direct participation of patients, since this initial stage was intended for the development and technical assessment of system feasibility, as well as for the preliminary definition of gamification techniques using the expert judge evaluation methodology, as described in [16].

The process is illustrated in Fig. 1, which presents the stages from the characterization of the current system to the development and analysis of gamification results using the Octalysis framework.

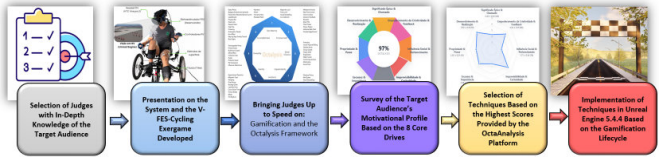

Fig. 1. Methodological flowchart of the steps carried out in this study.

The methodology is based on expert evaluation, leveraging the expertise of professionals specializing in health, rehabilitation, and the developed *v-FES-Cycling* system to assess and define the gamification strategies best suited to the perceived motor and psychological profile of the target audience [16].This approach allows the system's design to be preliminarily evaluated and technically verified prior to clinical trials and ensures that the game is grounded in clinical and pedagogical knowledge, so that these initial definitions make the proposed mechanics safer and more effective before future clinical trials are conducted.

A. Current v-FES-Cycling System

The *v-FES-Cycling* system is a rehabilitation platform that integrates an adapted, FES-assisted tricycle with an immersive VR environment. The hardware consists of an 8-channel functional electrical stimulator, based on the STM32 microcontroller, which activates the patient's lower limbs in a synchronized manner [7]. The instrumentation includes an

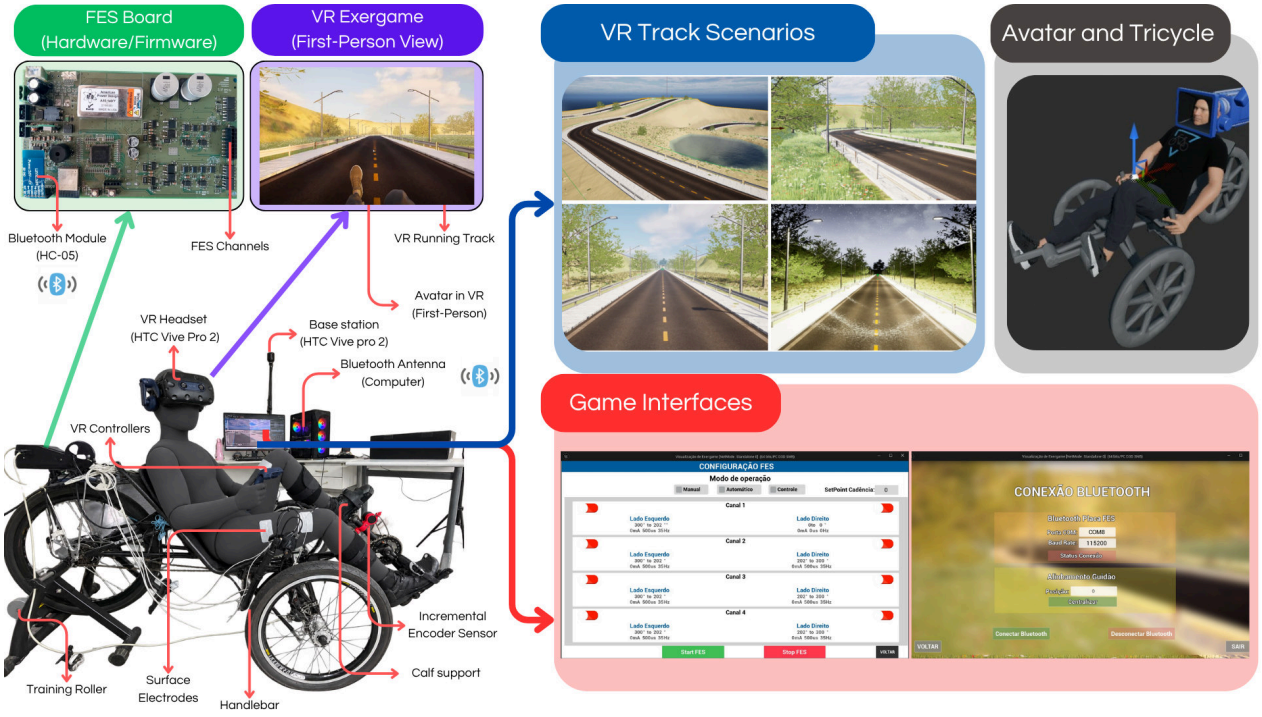

Fig. 2. Diagram highlighting the overall architecture of the *v-FES-Cycling* system focusing on the developed game, the *HTC Vive Pro 2*, the connection of the surface electrodes to the lower limbs, the avatar on the tricycle, and the visual interface rendered in UE, showing the communication mesh between the hardware and the game's VR environment.

incremental encoder sensor that monitors the pedaling angle and cadence, sending the data via Bluetooth (HC-05 module) to the software developed in Unreal Engine 5.4.3 (UE) [1]. The overall architecture, shown in Fig. 2, highlights the focus on the game experience, in which the user with SCI wears an HTC Vive Pro 2 headset while pedaling on the adapted FES-driven tricycle, allowing the patient to view an avatar that replicates their actual movements in a virtual scenario.

The VR environment developed in [1] was implemented with the game category known as *exergame* (a game category aimed at encouraging physical exercise) in mind, as shown in Fig. 2, and corresponds to the initial version of the system, still without the implementation and application of the gamification techniques proposed based on the Octalysis framework.

These environments were built using UE's native terrain-modeling tools, in addition to 3D modeling software such as Blender, used to model the tricycle. Assets available on the UE Marketplace's FAB platform were also used. Thus, this initial version is characterized as a VR racetrack simulator, in which five distinct racing scenarios were developed in UE, each with different environmental designs and routes to be traveled.

The system also features a virtual tricycle linked to a VR avatar, capable of simulating the user's displacement and pedaling motion along the routes proposed in each scenario. The tricycle's physics and movement dynamics exhibit realistic behavior, similar to that of a real vehicle, thanks to the physics simulation resources provided by UE and the use of the Chaos Vehicle plugin. In addition, the game provides interfaces for configuring the electrical stimulation parameters of each FES channel, as well as functionalities for configuring and pairing the Bluetooth device, both essential for starting the game.

B. Gamification through the Octalysis Framework

The strategy for aligning the game mechanics with the motivational profile of the target audience uses the Octalysis framework, which analyzes human motivation through eight central drives called Core Drives (CD). CD1 - Epic Meaning and Calling: Frames the exercise as part of a higher narrative mission. CD2 - Development and Accomplishment: Focuses on measurable progress, such as visualizing progress through status bars and achieving therapeutic milestones on the racetrack. CD3 - Empowerment of Creativity and Feedback: Stimulates the user's sense of control through immediate responses from the virtual environment to pedaling cadence and freedom of visual exploration. CD4 - Ownership and Possession: Creates attachment through the collection of virtual items such as coins, stars, and rays, which reinforce the user's connection to their progress, as well as through the ability to choose and customize the avatar, for example. CD5 - Social Influence and Relatedness: Compares metrics and fosters a sense of belonging to the rehabilitation group. CD6 - Scarcity and Impatience: Uses the temporary exclusivity of content to maintain interest, such as the progressive unlocking of new track stages after meeting rehabilitation-related goals in the game. CD7 - Unpredictability and Curiosity: Introduces surprise elements to encourage continued practice, such as the random appearance of collectible items and variations in

the track scenario. CD8 - Loss and Avoidance: Encourages regularity to avoid stagnating in the ranking or losing accumulated bonuses. It must be applied moderately, aiming to avoid setbacks, since, in the context of SCI rehabilitation, the loss of content is avoided so as not to generate excessive frustration, focusing instead on preserving achievements [21].

In this work, each selected gamification technique aims to stimulate one or more of these drives to increase adherence to repetitive treatment, turning a repetitive pedaling exercise into a mission with purpose. To analyze and visualize the motivational profile obtained through the expert-rating methodology, the *OctaAnalysis* tool (https://octaanalysis.cedis.tec.br/) is used, which generates a radar chart, allowing for a balance between "White Hat" (positive motivation) and "Black Hat" (motivation based on urgency/loss) motivations. In the context of rehabilitation for people with SCI, the use of mechanics that involve loss of content or progress is avoided in order to minimize feelings of frustration by focusing on preserving the achievements made by the patient. In addition, the framework defines the gamification lifecycle, consisting of the Discovery, Onboarding, Day-to-Day, and Endgame phases [16].

C. Judges' Evaluation Methodology

The specific techniques for implementing the game mechanics were obtained through the judge-based elicitation strategy proposed by [16]. For this stage, an interdisciplinary group of six specialists was formed, with knowledge and experience in the target audience, FES-Cycling rehabilitation, and the development of the *v-FES-Cycling* system. The committee consisted of a physical educator, a physical therapist, three electrical engineers, and a software engineer. The committee's role was to define requirements and perform technical evaluation and design verification of the implemented game mechanics based on the gamification techniques defined by the Octalysis framework, with the aim of supporting the initial development of the *v-FES-Cycling* system's *exergame*. The workflow included the following stages:

- **Leveling:** Theoretical training for judges on the Octalysis framework and how the *v-FES-Cycling* system works.
- **Discussion:** Periodic meetings to analyze the constraints and suitability of the techniques in the framework's catalog, identifying those that best adapt to the motor limitations and profile of patients with SCI.
- **Independent Evaluation for Scoring:** Assigning scores on a Likert scale (1-Very Poor, 2-Poor, 3-Fair, 4-Good, and 5-Excellent) to rate the potential of gamification techniques in relation to the perceived effectiveness of their application in the context of rehabilitation. This methodology is particularly important when direct contact with the target audience is limited in the early stages of the design process, as it draws on the expertise of specialist judges to avoid implementing techniques that could cause frustration or *cybersickness* (a sensation of nausea caused by VR use).
- **Consensus Analysis:** Next, the means and standard deviations of the suitability scores assigned to the techniques are calculated, followed by a meeting for the qualitative consolidation of the results, taking into account the gamification life cycle. The scoring, as well as the analysis and visualization of the data, is performed using the *OctaAnalysis* tool, which is used to evaluate and support the selection of the highest-ranked gamification techniques according to the Octalysis framework.

D. Development of the Selected Techniques

The definition of gamification techniques for the *v-FES-Cycling* system was based on prioritizing the motivational drives considered most relevant to the target audience. Techniques associated with the highest-scoring CDs were selected, according to the analysis performed by the *OctaAnalysis* tool. The selection considered criteria such as motivational potential and suitability to the users' profile. Based on the selected techniques, the gamification life cycle was structured, comprising the stages of discovery, onboarding, day-to-day use, and endgame [21].

Based on the definition of the stages and gamification techniques, the system's functional and non-functional requirements were defined, guiding the application's development. Assets and 3D elements from the UE Marketplace were used, including collectible coins, energy stars, arches, start and finish lines, particle effects, and widget-based interfaces. These elements were programmed according to the implemented gamification techniques and distributed along the virtual track, providing immediate performance feedback through dynamic updates in the graphical interface. *Blueprints* and Widgets programming systems were used to implement scoring events, along with the *Niagara* system for creating visual effects associated with item collection. The *Control Rig* system was used to synchronize the avatar's leg movement with the encoder data, as described in [1]. Spatial sounds were integrated to signal item collection and the completion of objectives, which helps reinforce the sense of accomplishment and stimulate the user's curiosity.

Safety measures aimed at mitigating risks through the system's hardware, firmware, and software components were also considered during the development of the *v-FES-Cycling* system, as described below:

1) **Electrical Stimulation (FES):** The electrical stimulation parameters are limited by the hardware and firmware of the FES board, as well as by the configuration interface implemented in the *exergame*. The system's maximum operating ranges are restricted to a current amplitude of up to 100 mA, a pulse width of up to 1000 μs, and a frequency of up to 100 Hz; these can be configured to lower values according to each patient's clinical needs.
2) **Emergency button:** The adapted tricycle features an emergency button accessible to both the patient and the healthcare professional, connected directly to the FES board's power line. This mechanism allows the system's operation to be immediately interrupted whenever necessary.

3) **Effects of VR-induced *cybersickness*:** To facilitate the user's gradual adaptation to the headset and the immersive environment and to reduce the visual discomfort associated with VR use, the *exergame* was designed to maintain a stable refresh rate of 90 frames per second (FPS) on the HTC Vive Pro 2 headset, minimizing delays in the rendering of the virtual environment. In addition, the initial race track scenarios were designed with predominantly straight paths and few game mechanics interactions, avoiding sudden changes in the virtual camera's position and excessive visual stimuli.
4) **Gamification Mechanics:** In the gamification design based on the Octalysis framework, the dynamics associated with the Core Drives of Scarcity (CD6) and Loss and Avoidance (CD8) were calibrated for passive engagement in this preliminary implementation. Thus, no punitive penalties are applied, nor is there any loss of progress accumulated during rehabilitation if the user fails to complete the proposed challenges. This strategy aims to eliminate feelings of coercion or excessive frustration, prioritizing positive motivational reinforcement (White Hat).

III. Results and Discussion

This section presents and discusses the results obtained in the process of selecting and implementing the gamification techniques applied to the *v-FES-Cycling* system. First, the scores assigned to the eight CDs of the Octalysis framework through the expert judges' evaluation process are analyzed. Next, the selected gamified techniques are discussed, along with their organization throughout the gamification life cycle and their practical implementation in the virtual environment developed in UE.

Fig. 3 shows the radar chart depicting the average scores assigned to the eight Octalysis framework CDs by the six expert judges in the fields of health, engineering, and neurorehabilitation using FES-based technologies. This type of graphical representation allows for a comparative visualization of which motivational dimensions were considered most relevant to the target audience, thereby aiding in this preliminary stage of *exergame* development.

According to the results, the highest values were observed for the CDs Unpredictability & Curiosity, Development & Accomplishment, Empowerment of Creativity & Feedback, and Scarcity & Impatience, showing that factors related to curiosity, exploration, progression, autonomy, and gradual rewards tend to exert greater motivational influence in the context of gamified rehabilitation. In contrast, dimensions such as Social Influence & Relatedness, Loss & Avoidance, and Epic Meaning & Calling showed lower averages, indicating lower perceived relevance to the profile of the game's target audience by the expert judges. In particular, the lowest score (1.77 ± 0.16) in Social Influence & Relatedness suggests that, in the experts' view, the initial focus of rehabilitation should be individual and centered on personal progress and the discovery

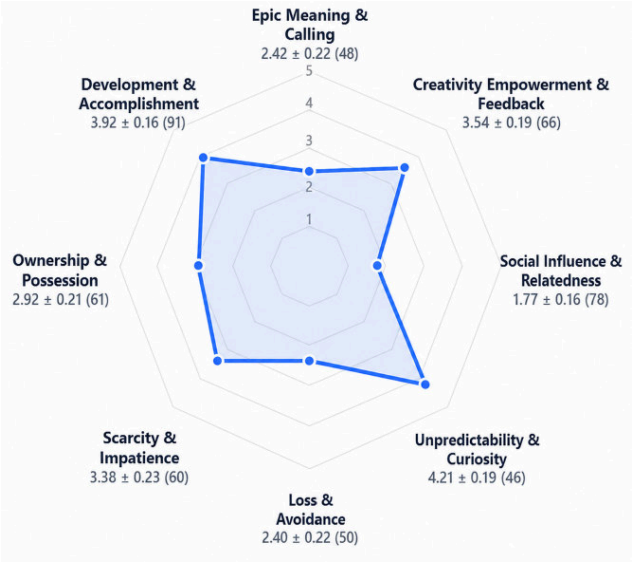

Fig. 3. Radar chart corresponding to the scoring results of the eight Core Drives of the Octalysis Framework after the judges' evaluation process.

of new stimuli, rather than on competitive or social dynamics, which are more likely to generate comparison and frustration.

As shown in Table I, the four drives with the highest scores were Unpredictability & Curiosity (4.21), Development & Accomplishment (3.92), Empowerment of Creativity & Feedback (3.54), and Scarcity & Impatience (3.38). Thus, the combination of judges' evaluation and the application of the Octalysis framework enabled a selection of motivational strategies based on expert perception of the needs of the target audience.

TABLE I
Means and Standard Deviations of the Four Octalysis Core Drives Selected for Having the Highest Scores

Core Drive	Mean and SD
Unpredictability & Curiosity	4.21 ± 0.19
Development & Accomplishment	3.92 ± 0.16
Empowerment of Creativity & Feedback	3.54 ± 0.19
Scarcity & Impatience	3.38 ± 0.23

Based on these results, specific gamification techniques linked to each CD were selected, following the criterion of prioritizing those that received the highest scores from the judges for each dominant CD, in line with the guideline of using professional expertise to identify the most effective basic motivations. In the context of Unpredictability & Curiosity, the techniques of mini-missions, progressive rewards, and visual narrative stood out, used to arouse continuous interest and anticipation in the user. For Development & Accomplishment, progress bars, mission lists, badges, and points were prioritized, promoting a sense of advancement and achievement. In the Empowerment of Creativity & Feedback CD, techniques such as immediate feedback and milestone unlocking were selected, encouraging continuous interaction and recognition of actions taken. In Scarcity & Impatience, the reward-pacing

technique stood out, applied to distribute rewards over time and encourage continued use of the system.

Based on the prioritized techniques, the gamification life cycle was structured, composed of the discovery, onboarding, day-to-day, and endgame stages [21]. The techniques were distributed to allow for a progressive and adaptable experience, essential for maintaining long-term engagement.

In the discovery phase, the techniques of mini-missions, visual narrative, progress bar, and points were defined, aiming to introduce the user to the system in an intuitive and attractive way. In the onboarding phase, mission lists, badges, immediate feedback, and milestone unlocking were used, favoring initial adaptation to the game mechanics. In the continuous-use (day-to-day) stage, the techniques of progressive rewards, milestone unlocking, and reward pacing were defined, seeking to maintain engagement over time. Finally, in the endgame phase, progressive rewards, badges, points, and milestone unlocking stood out, reinforcing the sense of completion and final reward.

Fig. 4 shows a *gameplay* scene in which the user rides the tricycle toward coins distributed throughout the virtual environment. When collected, the coins are converted into particle visual effects accompanied by sound feedback, providing immediate feedback to the patient and positively reinforcing their interaction with the game. In addition, a start and finish line was used to mark the beginning and end of the route, as well as obstacles such as barriers and cones, used to vary route difficulty and introduce mini-missions related to rehabilitation exercises. Heads-Up Display (HUD) interface elements are also shown, presenting real-time information such as the number of laps completed and the number of coins collected.

Fig. 5 shows some of the system's configuration interfaces, allowing the healthcare professional to customize the experience according to the patient's needs. Among the available functionalities are the configuration of Bluetooth communication, adjustment of the FES electrical stimulation parameters, setting the player's name, and selecting among three avatars with distinct designs, positioned on the tricycle in VR.

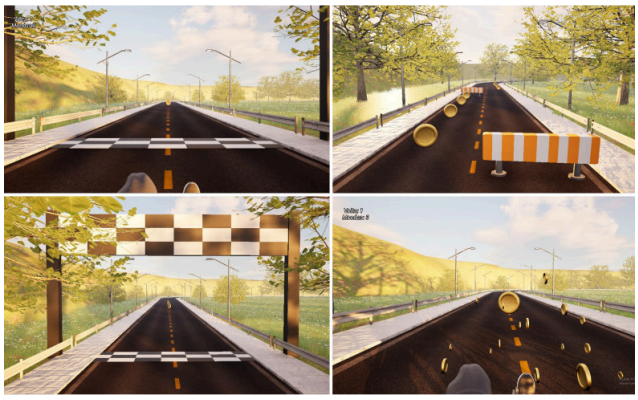

Fig. 4. Gameplay scene with coin collection, obstacles, and immediate feedback to the user.

In addition, the system offers the option to choose among five scenarios with distinct visual characteristics and routes. Scenario 1 consists of a straight track surrounded by trees, set during the day. Scenario 2 features a straight track through a forest at night. Scenario 3 is made up of a closed-circuit track with curves, surrounded by mountains, trees, and a flowering field. Scenario 4 is a track with varied curves, including both closed and open sections. Finally, Scenario 5 consists of a track with curves and varying uphill and downhill sections, set in a coastal landscape with an ocean view.

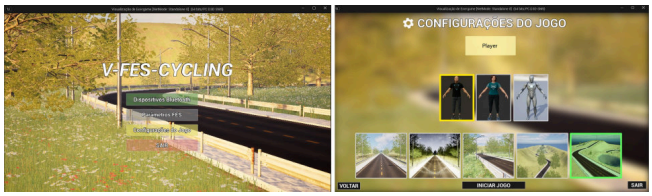

Fig. 5. Game configuration interfaces and scenario selection.

Finally, Table II presents, in greater detail, the relationship between the prioritized Core Drives and the innovative gamification mechanics in this initial version of the *exergame*.

TABLE II
RELATIONSHIP BETWEEN CORE DRIVES AND IMPLEMENTED MECHANICS.

Core Drive (Octalysis)	**Gamification Mechanics (UE5)**
Unpredictability & Curiosity (CD7)	Coins, obstacles, and varying scenarios appear in various positions scenarios.
Development & Execution (CD2)	Points earned by collecting coins and the count of laps completed.
Creativity Empowerment & Feedback (CD3)	Immediate visual/auditory feedback on pedaling and the ability to choose on avatar.
Scarcity & Impatience (CD6)	Temporary blocking of the most complex routes based on the healthcare profissional's assessment of the patient's performance by a healthcare profissional.

Overall, the results demonstrate that the development of gamification techniques, guided by expert evaluation and structured based on the Octalysis framework, made it possible to build a preliminary solution consistent with the perceived needs and limitations of the target audience, as evaluated by the experts. The application of the judges' methodology proved particularly relevant in this process, as it allowed the selection of game mechanics compatible with the therapeutic context without prematurely exposing users to risks during the early stages of development. As noted by [16], resources such as immediate feedback can act as positive biofeedback, contributing to motor reinforcement and processes associated with neuroplasticity. Furthermore, the distribution of techniques throughout the gamification lifecycle has facilitated the development of an *exergame* designed to provide a progressive and motivating experience during this initial implementation phase, with the potential to increase user engagement and encourage continued use of the system in future versions.The following link presents a complementary video with further details on the results of the gamification techniques implemented in the *v-FES-Cycling* system: https://drive.google.com/drive/folders/1Ks1rxSy-oby1Bs3D20dnj4vIJ2CmcOG3?usp=sharing.

IV. Conclusions

This study achieved its overall objective by defining and initiating the development of gamification mechanics in Unreal Engine software for the *v-FES-Cycling* system. The application of the Octalysis framework, combined with an internal evaluation methodology conducted by expert judges, made it possible to propose and prioritize initial gamification mechanics for the FES-assisted cycling rehabilitation *exergame* that are better aligned with the target audience's perceived motivational profile as judged by the experts. This approach contributed to the development of an initial version of the system, with the potential to transform repetitive exercises into a more adaptive, engaging, and playful rehabilitation platform. Furthermore, its practical implementation in Unreal Engine demonstrated that theoretical concepts of gamification can be consistently translated into interactive features designed for motor rehabilitation. As limitations, it should be noted that direct contact with the target audience, composed of patients with SCI, was still limited during the initial phases of system design and implementation; therefore, no clinical trials were conducted on patients at this early stage. Consequently, the participation of expert judges became necessary; although this represents a limitation of this initial stage and is subject to the subjectivity of the evaluations conducted, it contributed to the preliminary development of the *exergame* by guiding the selection of the gamification techniques employed, minimizing risks related to *cybersickness*, frustration, and the execution of potentially inappropriate or unsafe movements during the proposed activities, as well as enabling the preliminary technical verification of the integration between the *exergame* and the hardware, firmware, and software components of the *v-FES-Cycling* system. Looking ahead, it is essential to validate the system and the implemented gamification techniques through clinical trials with patients with SCI. These future studies will allow for the objective measurement of the solution's impact on motivation, treatment adherence, and long-term motor recovery. Nevertheless, the results obtained so far are promising and indicate that the *v-FES-Cycling* system has the potential to establish itself as a tool to support rehabilitation through FES-Cycling.

***Abstract*—Independent mobility is essential for child development. Access to appropriate pediatric wheelchairs remains limited, particularly in resource-constrained settings. This pilot study characterized the manufacturing workflow, production efficiency, and costs of an open-source pediatric wheelchair fabricated by fused filament fabrication (FFF). The wheelchair was produced from the Toddler Mobility Trainer design using PETG and TPU filaments. Printing time, material consumption, failures, reprinting events, and direct and operational costs were prospectively recorded. After assembly, the prototype underwent visual and manual inspection and preliminary unloaded verification in a controlled indoor environment. The wheelchair was completed after 27 print runs, requiring 453 h of printing and 11,031 g of filament. Failures consumed 1,543 g of filament corresponding to a material loss rate of 14%. TPU presented a higher proportional material loss than PETG (24.6% versus 11.3%). Reprints accounted for an additional 144 h, representing 31.8% of the total printing time. The direct material and hardware cost was US$ 231.97, and manufacturing failures increased this cost by approximately 17.1%. The wheelchair was successfully assembled, with satisfactory integration of printed and commercial components and a visually coherent final configuration. During preliminary unloaded verification, it could be manually propelled and maneuvered on a flat indoor surface without visible deformation or component failure. Operational costs were mainly influenced by prolonged printing time and reprinting events. These findings support workflow optimization and indicate the potential of open-source additive manufacturing for developing mobility solutions for young children. Standardized mechanical testing, durability assessment, and clinical evaluation are required before pediatric use.**

Keywords—digital manufacturing; fused filament fabrication; pediatric wheelchair; assistive technology.

I. INTRODUCTION

Independent mobility is essential for children's physical, cognitive, and social development. Appropriate pediatric wheelchairs enable participation in education, daily activities, and community life while promoting autonomy and environmental exploration. Conversely, delayed or inadequate provision of mobility devices may negatively affect child development and contribute to long-term social inequalities [1]-[2]. Despite their recognized benefits, access to wheelchairs remains limited worldwide, particularly in low- and middle-income countries. According to the World Health Organization (WHO), approximately 80 million people worldwide require a wheelchair, but only a limited proportion have access to a device that adequately meets their needs [3]. Pediatric wheelchair provision is particularly challenging because children's anthropometric characteristics, postural support requirements, and functional needs change continuously as they grow, frequently requiring device adjustment, adaptation, or replacement [4].

Digital manufacturing has emerged as a promising approach to the developing of personalized assistive technologies by integrating computer-aided design, digital fabrication, and additive manufacturing. Among the available technologies, fused filament fabrication (FFF) offers relatively accessible equipment, broad material availability, and the ability to produce geometrically complex and customized components. When combined with open-source design initiatives, digital designs can be shared, locally adapted, and manufactured in distributed production environments, potentially expanding access to personalized mobility solutions and reducing dependence on centralized manufacturing systems [5]-[7].

Previous studies have demonstrated the application and feasibility of additive manufacturing in healthcare and assistive technology, including orthoses, prostheses, seating

Brazilian Innovation Agency (FINEP) and São Paulo Research Foundation (FAPESP).

systems, and wheelchair accessories [5], [8]-[13]. However, investigations addressing the fabrication of complete additively manufactured pediatric wheelchairs remain scarce. Furthermore, published studies frequently emphasize prototype development, design characteristics, or mechanical performance, while practical manufacturing indicators such as printing time, material consumption, failed prints, reprinting events, material losses, and production costs, remain insufficiently documented. These indicators are essential for evaluating not only whether a device can be manufactured, but also the resources required for its production and the extent to which the workflow may be optimized, replicated, and implemented in rehabilitation laboratories or local manufacturing centers.

Open-source wheelchair designs may reduce barriers to replication and adaptation; however, their practical implementation may be affected by prolonged printing times, material-specific manufacturing difficulties, incompatibility with locally available components, and costs associated with unsuccessful prints and reprocessing. Moreover, estimates provided by design developers may not fully reflect the conditions encountered during local production, including differences in equipment, materials, infrastructure, and commercially available hardware. Systematic documentation of these factors is therefore necessary to identify manufacturing bottlenecks, quantify their effects on production efficiency and costs, and support optimization before mechanical validation and future clinical evaluation. Therefore, this study aimed to characterize the digital manufacturing workflow, evaluate production efficiency, and analyze the direct and operational costs of an open-source pediatric wheelchair fabricated using fused filament fabrication. By systematically documenting manufacturing time, material consumption, failures, reprinting events, and associated costs, this study sought to establish baseline data for workflow optimization and future mechanical and clinical validation.

II. Materials And Methods

A. Study Design

This descriptive pilot study assessed the manufacturing feasibility and production costs of a single open-source pediatric wheelchair prototype fabricated using the FFF process. The analysis focused on characterizing the digital manufacturing workflow, quantifying production efficiency, and estimating direct and operational manufacturing costs. The device was manufactured using the open-source digital files of the Toddler Mobility Trainer (TMT), developed by MakeGood Inc. in collaboration with TOM Global and LINK PBC [14]. The original structural geometry was preserved throughout the manufacturing process. However, adaptations related to printing configuration and compatibility with commercially available components were documented when required.

The study focused on the technical feasibility of the manufacturing process and the documentation of baseline production indicators. The study was not intended to assess process reproducibility across multiple devices or different manufacturing settings. The primary outcomes were the total number of print runs, total printing time, filament consumption by material type, failed prints, material losses, reprinted components, reprinting time, causes of manufacturing failures, and direct and operational production costs.

After fabrication and assembly, the prototype underwent visual and manual inspection and preliminary non-clinical functional verification under controlled indoor conditions. The verification assessed component fitting, free wheel rotation, basic maneuverability during manual pushing, visible deformation, and the occurrence of mechanical failure in the unloaded prototype. The study did not evaluate clinical effectiveness, user safety, therapeutic outcomes, long-term durability, or performance in children with mobility impairments.

B. Wheelchair Manufacturing

The wheelchair components were fabricated by FFF using the original stereolithography (STL) files provided by the project developers [14]. Printing was performed using a Bambu Lab H2D 3D printer (Bambu Lab, Shenzhen, China), with FFF tecnology, and single-nozzle printable build volume of 300 x 320 x 325 mm. The print bed surface used was the genuine Bambu Lab Textured PEI Plate. The print bed was prepared by applying a thin layer of PVP-based glue, following the printer's usage recommendations. We used the printer's standard calibration. The filament diameter was 1.75 mm. Structural components were manufactured using glycol-modified polyethylene terephthalate (PETG) filament (Voolt 3D, Brazil), whereas flexible components were produced using thermoplastic polyurethane with a Shore A hardness of 95A (TPU 95A, Slim 3D, Brazil), according to the material specifications recommended by the original project.

The printing parameters specified by the project developers were adopted as the initial manufacturing configuration, and any adjustments required during production were documented. The printing speed for the TPU components was set to 40 mm/s, following our laboratory's protocol. The main parameters used for each material are presented in Table I. The overall digital manufacturing and evaluation workflow adopted is summarized in Fig. 1.

TABLE I. FFF Parameters

Parameters	Material	
	PETG	**TPU 95A**
Bed temperature	70°	35°
Nozzle diameter (mm)	0.4	0.4
Layer height (mm)	0.2	0.2
Nozzle temperature (°C)	255	240
Infill density (%) [a]	15–20	2–15
Infill pattern	Gyroid	Gyroid
Support configuration	Tree	Tree
Outer wall speed (mm/s)	200	40

[a] The infill density varied according to the geometry and functional requirements of each component

The workflow included open-source file acquisition, file preparation and slicing, FFF printing, support removal and post-processing, inspection, final assembly, production data recording, cost analysis, and preliminary non-clinical verification. During manufacturing, the following production indicators were prospectively recorded: total number of print runs, total printing time, PETG and TPU filament consumption, number of reprinted components, material

discarded because of failed prints or rejected components; additional printing time associated with reprinting; and causes of manufacturing events requiring reprinting. A print run was defined as one complete printer operation initiated from a prepared build plate, and could include one or multiple components. A reprinted component was defined as any part manufactured again because the initial part was incomplete, defective, dimensionally incompatible, or unsuitable for assembly. After printing, support structures were removed from all components.

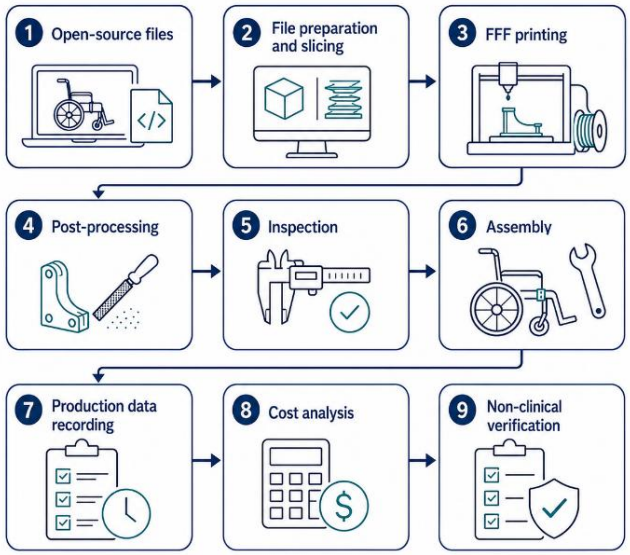

Fig. 1. Methodological workflow for the digital manufacturing, production-data recording, cost analysis, and preliminary non-clinical verification of the open-source pediatric wheelchair.

Each part underwent visual and manual inspection to identify cracks, warping, delamination, under-extrusion, incomplete layers, dimensional incompatibility, or other defects that could compromise assembly. Components were considered suitable for assembly when no visible defect affected their geometry, fitting, or apparent structural continuity. Commercial components not produced by FFF, including wheels, bearings, screws, nuts, washers, and other fasteners, were incorporated during final assembly according to the project instructions and the availability of components in the Brazilian market.

C. Economic and Technical Evaluation

The economic evaluation included direct material and hardware costs and estimated operational manufacturing costs. Direct costs were calculated from PETG and TPU consumption and from the acquisition cost of commercially available hardware required for assembly. Operational costs included equipment depreciation, electricity consumption, preventive maintenance, and labor. The cost components and manufacturing scenarios considered in the economic evaluation are summarized in Fig. 2.

All costs were based on the acquisition prices, electricity tariff, and laboratory costing assumptions applicable in April 2026. The estimated operational manufacturing cost was calculated using the laboratory hourly production rate of USD 5.20 per hour, which included equipment depreciation, electricity consumption, preventive maintenance, and labor. For each manufacturing scenario, the estimated operational cost was obtained by multiplying the hourly production rate by the corresponding printing time. The individual cost components used to derive the hourly rate are presented in Table II. Events requiring reprinting included interrupted or unsuccessful prints and components that required replacement because of power outages, filament extrusion problems, warping, incomplete printing, structural defects, or incompatibility with locally available commercial components. To quantitatively assess manufacturing efficiency, two production indicators were calculated from the prospectively recorded manufacturing data: the material loss rate and the proportion of printing time associated with reprinting.

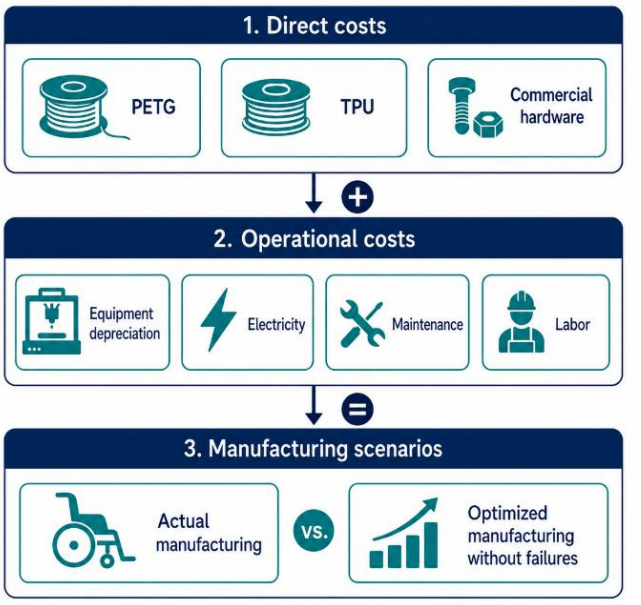

Fig. 2. Cost components and manufacturing scenarios considered in the economic evaluation.

TABLE II. HOURLY RATE COMPOSITION

Individual Cost Components	Estimated Hourly Rate (USD) [b]
Equipment depreciation	0.23/h
Electricity consumption	0.22/h
Preventive maintenance	1.00/h
Labor	3.75/h

b. Costs were calculated in Brazilian reais and converted to dollars using an approximate exchange rate of BRL 1.00 = USD 0.20 on July 26, 2026.

The material loss rate was calculated as:

$$\text{Material loss rate (\%)} = \text{M loss} / \text{M total} \times 100 \quad (1)$$

where "M loss" is the mass of filament discarded because of unsuccessful prints or rejected components that subsequently required reprinting, and "M total" is the total filament consumption across all print runs.

The proportion of printing time associated with reprinting was calculated as:

$$\text{Reprinting time proportion (\%)} = \text{T rep} / \text{T total} \times 100 \quad (2)$$

where "T rep" is the additional printing time required to replace both rejected components and the replacement components, and "T total" is the total printing time.

Two manufacturing scenarios were subsequently compared:

1. Actual manufacturing, including all recorded material consumption, unsuccessful prints, and reprinting events; and
2. A counterfactual scenario excluding the recorded material losses and 69 h of additional printing time directly attributable to manufacturing failures that resulted in discarded components.

III. Results And Discussion

The open-source pediatric wheelchair prototype was successfully fabricated using FFF and assembled from additively manufactured components and commercially available hardware. The main component groups, classified according to manufacturing material and source, are shown in Fig. 3.

Fig. 3. The main component groups used in the assembled wheelchair: (a) TPU flexible components; (b) PETG structural components, and (c) commercially available hardware.

A. Manufacturing Output and Production Efficiency

A total of 27 print runs were required resulting in 453 h of printing and a total filament consumption of 11,031 g, comprising 8,829 g of PETG and 2,202 g of TPU. Manufacturing failure events resulted in 1,543 g of discarded filament, corresponding to an overall material loss rate of 14%. Reprinting required an additional 144 h, representing 31.8% of the total printing time. Of this period, 69 h corresponded to unsuccessful prints or rejected components, whereas 75 h corresponded to replacement components that were incorporated into the final wheelchair. The material loss rate was proportionally higher for TPU than for PETG, at 24.6% and 11.3%, respectively, suggesting greater process instability during the fabrication of flexible components under the conditions adopted in this study. Furthermore, the increase in printing time was due to the reduced printing speed for the TPU parts. A printing speed of 40 mm/s was used; compared to the speed in the original file (200 mm/s), the parts were printed at 20% of that speed.

The original project developers estimated a total filament consumption of approximately 11,000 g and a printing time of 250 h. Although the observed filament consumption was similar to this estimate, the actual manufacturing time was 81.2% higher. This difference indicates that locally encountered production conditions, including printer configuration, material behavior, environmental conditions, component arrangement on the build plate, and unexpected manufacturing events, can substantially affect production efficiency.

B. Economic Evaluation

The direct cost of filament consumed during manufacturing was USD 213.71, while commercially available hardware required for assembly represented an additional USD 18.26. Therefore, the total direct material and hardware cost was USD 231.97, including material losses. In an optimized scenario excluding unsuccessful prints and discarded components, the estimated direct cost would have been USD 198.16. Thus, manufacturing failures increased the direct material and hardware cost by approximately 17.1% relative to the optimized scenario. The estimated operational cost associated with the actual manufacturing process was USD 2,355.12. In the counterfactual scenario excluding the printing time associated with manufacturing failures (69 h), the estimated operational cost would have been USD 1,995.19. Accordingly, failure events generated approximately USD 359.94 in additional operational costs. Comparable operational cost data were not reported by the original project developers. The complete cost analysis is presented in Table III.

TABLE III. Direct and Estimated Operational Costs for Manufacture of One Open-Source Pediatric Wheelchair

Cost category	Actual manufacturing (USD) [c]	Counterfactual scenario excluding failures (USD) [c]
PETG Filament	135.49	120.11
TPU Filament	78.22	59.79
Commercial hardware	18.26	18.26
Total: Direct material and hardware cost	**231.97**	**198.16**
PETG-related operational cost	1,512.98	1,331.63
TPU-related operational cost	842.14	663.56
Total: Estimated operational manufacturing cost	**2,355.12**	**1,995.19**

c. Costs were calculated in Brazilian reais and converted to dollars using an approximate exchange rate of BRL 1.00 = USD 0.20 on July 26, 2026.

The economic analysis showed that filament and commercial hardware represented only a small proportion of the estimated overall manufacturing expenditure. Although the direct material and hardware cost was approximately USD

231.97, the estimated operational cost was high. Thus, prolonged machine utilization and reprinting events, rather than raw material consumption alone, were the principal factors influencing the estimated manufacturing cost. This finding is particularly relevant for additive manufacturing workflows because economic feasibility is frequently discussed primarily in terms of filament price. However, equipment depreciation, electricity consumption, preventive maintenance, labor, and extended printing time may have a substantially greater effect on total production expenditure. Therefore, reducing printing time and preventing manufacturing failures may provide greater economic benefits than reducing filament consumption alone.

The material-specific findings also highlighted differences in manufacturing efficiency between PETG and TPU. Although TPU represented a smaller proportion of the total filament consumed, it presented a considerably higher material loss rate. Flexible filaments present material-specific processing challenges that may include extrusion and feeding instability and dimensional variability [15]. Therefore, optimization of printing parameters and production conditions may reduce manufacturing failures and improve process efficiency [15], [16]. In the Brazilian commercial market, the acquisition cost of pediatric manual wheelchairs varies according to the model, materials, adjustability, and postural support features. A market survey conducted in July 2026 identified retail prices ranging from approximately USD 558.00 to USD 813.40 (BRL 2,790.00 to 4,067.00) for standard pediatric manual wheelchair models, without customizations. These wheelchairs have standard dimensions and do not adjust as the child grows, requiring replacement over time.

C. Manufacturing Failures and Process Adaptations

Overall, 28 components required reprinting, resulting in 1,543 g of material loss and 144 h of additional printing time. Representative manufacturing defects and process-related inadequacies are in Fig. 4. The use of PETG and TPU enabled the fabrication of components with distinct functional requirements. PETG was used for structural components, whereas TPU 95A was used for tires, seating-related components, straps, and supports. This combination illustrates an important advantage of additive manufacturing in assistive technology: different polymeric materials can be selected within the same device according to the required flexibility and structural function. However, the higher loss rate observed for TPU indicates that the use of multiple materials also introduces material-specific manufacturing challenges. Visual inspection indicated that additional support structures were required around the seat-belt slots to improve print quality. Localized under-extrusion was also observed on the external surfaces of some TPU straps, suggesting minor extrusion instability. These defects did not prevent assembly; however, their mechanical significance was not assessed.

The recorded manufacturing events included a power outage, TPU nozzle clogging, incompatibility between the original digital files and locally available wheel components, warping of an adapted PETG component, and filament depletion during a long print run. The manufacturing losses resulted from a combination of external interruptions, material-specific processing difficulties, production planning, and compatibility with locally sourced hardware. Table IV shows the manufacturing indicators and their comparison with the estimates reported by the original project developers. The recorded manufacturing events included a power outage, TPU nozzle clogging, incompatibility between the original digital files and locally available wheel components, warping of an adapted PETG component, and filament depletion during a long print run. These events, together with their associated material losses and corrective actions, are presented in Table V. They indicate that manufacturing losses resulted from a combination of external interruptions, material-specific processing difficulties, production planning, and compatibility with locally sourced hardware.

Following the TPU-related events, the number of components arranged on each build plate was reduced to limit the amount of material and printing time at risk during a single run. Components that were incompatible with locally available wheels were adapted and reprinted, while all defective or incomplete parts were replaced. These actions allowed completion of the wheelchair without altering its overall structural concept. The documentation of unsuccessful prints, material losses, and reprinting events provided a more realistic assessment of manufacturing performance than reporting only the completed prototype. Such information is particularly relevant for rehabilitation laboratories and distributed manufacturing centers intending to reproduce open-source assistive technologies. Moreover, prospective recording of these indicators enabled the identification of process-specific bottlenecks and established baseline values for subsequent optimization studies.

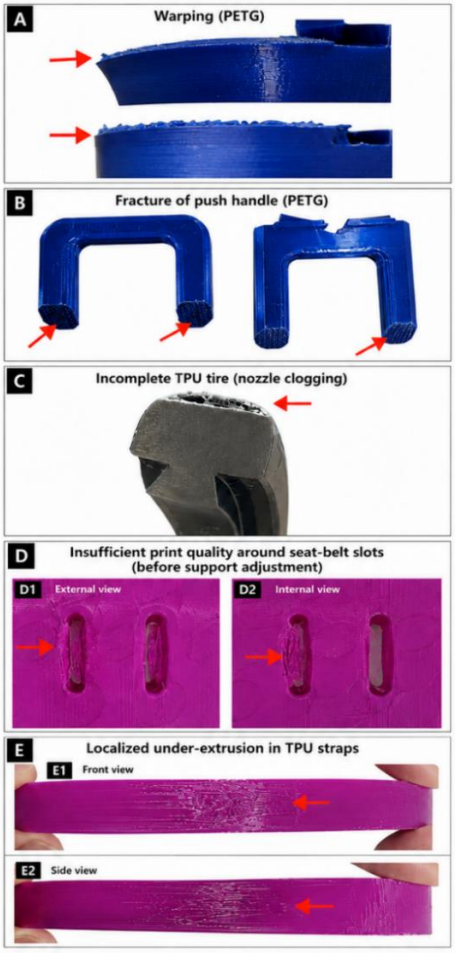

Fig. 4. Manufacturing defects and process-related inadequacies observed in FFF-produced components. (A) warped PETG component; (B) fractured PETG push handle; (C) incomplete TPU tire caused by nozzle clogging; (D) insufficient print quality around the seat-belt slots before support adjustment; and (E) localized under-extrusion in TPU straps.

TABLE IV. OBSERVED MANUFACTURING INDICATORS AND ESTIMATES REPORTED BY THE ORIGINAL PROJECT DEVELOPERS

Manufacturing Indicator	Observed Value	Original Project Estimated [14]
Print runs	27	22
Printing time (h)	453	250
PETG consumption (g)	8,829	9,000
TPU consumption (g)	2,202	2,000
Total filament consumption (g)	**11,031**	**11,000**
PETG material loss (g)	1,001	Not reported
TPU material loss (g)	542	Not reported
Reprinted components	28	Not reported
Reprinting time (h)	144	Not reported

TABLE V. RECORDED MANUFACTURING EVENTS, MATERIAL LOSSES, AND CORRECTIVE ACTIONS

Manufacturing Event	Material	Component affected	Material loss (g)	Corrective action
Power outage (external/ infrastructure)	TPU	16 tire components	181	Number of components per build plate was reduced
Nozzle clogging (material-process-related)	TPU	8 tire components	361	Number of components per build plate was reduced
Wheel incompatibility (local adaptation)	PETG	2 rear-caster components	452	Components were adapted and reprinted
Warping of adapted component (material-process-related)	PETG	1 rear caster components	226	Component was reprinted
Filament depletion (production planning)	PETG	1 push handle components	323	Component was reprinted
Total	-	**28**	**1,543**	-

D. Prototype Dimensions and Preliminary Verification

Most printed components were considered suitable for assembly after visual and manual inspection. Nevertheless, the need to reprint 28 components and the substantial additional printing time demonstrate that successful assembly alone should not be interpreted as evidence of an optimized or fully reproducible manufacturing process (Fig. 5). In assistive technology, manufacturing feasibility encompasses not only fabrication of the final device but also consistency, post-processing, assembly, local component compatibility, documentation of failures, and the possibility of implementing design adjustments. The final dimensions of the assembled wheelchair were generally similar to those reported by the original developers [14]. The original design has an approximate mass of 9 kg, width of 51 cm, height of 61 cm, and length of 66 cm. The prototype manufactured in the present study has a mass of 10.7 kg, a width of 49 cm, a height of 60.5 cm, and a length of 67 cm (Fig. 5). The observed dimensional differences may be associated with differences in measurement procedures, FFF processing, design adaptation, and the incorporation of locally sourced commercial components. However, the 1.7 kg difference in total mass should not be described as a manufacturing tolerance and requires consideration of the specific hardware and materials incorporated during assembly.

Following assembly, the unloaded wheelchair was visually and manually inspected and pushed over a flat surface in a controlled indoor environment. Wheel rotation, basic maneuverability, component fitting, visible deformation, and the occurrence of component failure were assessed. No visible structural instability, abnormal deformation, or component failure was observed during this preliminary non-clinical verification. However, no standardized load, fatigue, stability, impact, or durability tests were performed. Therefore, these observations do not demonstrate compliance with wheelchair safety standards or suitability for pediatric use. They should be interpreted only as a preliminary confirmation that the unloaded prototype could be assembled and manually moved under controlled conditions.

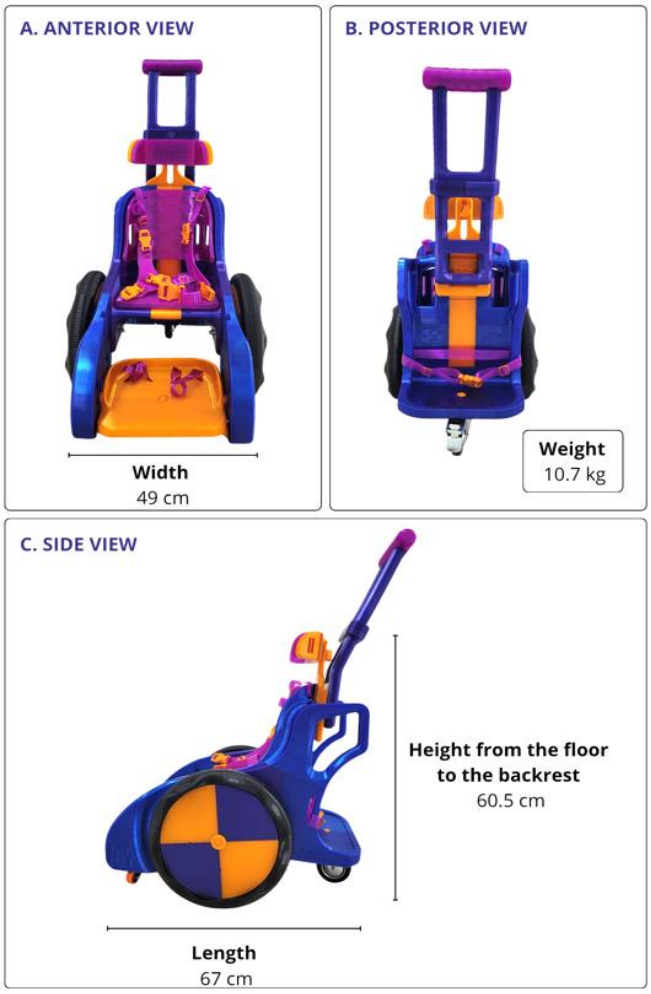

Fig. 5. Assembled open-source pediatric wheelchair (total mass and overall dimensions).

Previous feasibility studies involving additively manufactured assistive devices have similarly reported that iterative adjustment to printing parameters, material selection, and manufacturing conditions are common during prototype development [8], [17]-[18]. The present findings add quantitative information on the material, temporal, and economic consequences of these iterations during fabrication of a complete pediatric mobility device. Beyond the

quantitative manufacturing indicators, qualitative observations obtained during fabrication, assembly, and preliminary non-clinical verification provided additional insights into the strengths and current limitations of the proposed wheelchair. The WHO emphasizes that appropriate wheelchair provision requires more than product availability; it must include assessment, fitting, training, and follow-up [19].

E. Design Characteristics and Potential Future Adaptations

According to the original MakeGood Inc. design, the wheelchair is intended for children aged 1–8 years and weighing up to 20 kg [14]. Its modular frame permits adjustment of seat width through replacement of specific structural components, while the footrest can be positioned at three height levels. These characteristics indicate potential adaptability to growth; however, this adaptability was not experimentally assessed in the present study.

A limitation identified during assembly was the lack of seat-depth adjustment. Increasing seat width without a corresponding adjustment in seat depth may compromise positioning as the child grows. Appropriate seating configuration is important for postural control and functional and may also influence activity and participation in children with motor impairments [20]-[23]. Future design iterations should therefore investigate mechanisms that enable coordinated adjustment of seat width and depth while preserving structural integrity.

The open-source digital model also permits future modification or incorporation of structural and postural-support components. Potential developments include individualized seating and backrest systems, lateral trunk supports, and pelvic-positioning devices. Adaptive seating systems can improve postural control and functional performance in children with cerebral palsy [21]-[23]. Nevertheless, these components were not designed or evaluated in the present study and should be regarded as future development possibilities rather than demonstrated advantages of the current prototype. The wheelchair has a relatively low seat position, which may facilitate floor-level interaction and age-appropriate play. Independent wheelchair mobility may contribute to greater participation and engagement in family, educational, and community environments [2], [19]. However, the potential effects of seat height and wheelchair configuration on participation were not evaluated in this manufacturing study.

F. Practical Implications and Study Limitations

Feasibility studies represent an important stage in technology development because they support process refinement, guide subsequent validation, and reduce the risk of inefficient resource allocation [24]. The findings are consistent with previous evidence indicating that additive manufacturing can support the development of customized assistive technologies, particularly when local production and iterative design are required [5]-[6], [25]-[26]. In the present study, manufacturing feasibility was demonstrated by completion and assembly of a single prototype; however, the prolonged printing time, number of reprinted components, material losses, and estimated operational costs indicate that the current workflow requires substantial optimization before broader implementation. The systematic recording of production indicators established baseline values for future investigations and demonstrated that filament cost alone does not adequately represent the economic requirements of FFF-based assistive-technology production. The main observed manufacturing and design features, together with the current limitations identified during fabrication and assembly, are summarized in Table VI.

TABLE VI. MANUFACTURING ADVANTAGES AND CURRENT LIMITATIONS

Observed manufacturing and design features	Current limitations
The prototype was successfully fabricated and assembled.	Only one prototype was manufactured.
The direct material and hardware cost was relatively low compared with the estimated operational cost.	The manufacturing process required prolonged printing time and generated high estimated operational costs.
The open-source digital files permitted local production and design adaptation.	Compatibility with locally available hardware required modification of some components.
Modular construction allowed individual components to be replaced.	Seat depth was not adjustable, limiting adaptation to growth.
PETG and TPU enabled the fabrication of components with different functional requirements.	TPU presented a higher material loss rate and greater process instability under the conditions evaluated.
Individual components could be reprinted without replacing the entire device.	Mechanical performance and long-term durability were not evaluated.
The unloaded prototype could be manually moved under controlled indoor conditions without visible component failure.	Clinical safety, effectiveness, usability, and user satisfaction were not evaluated.
The digital design permits future incorporation of customized components.	Production requires additive-manufacturing expertise and appropriate infrastructure.

The principal limitations of this pilot study were the fabrication of a single prototype, the absence of standardized mechanical testing, the lack of long-term durability assessment, and the absence of clinical evaluation with the target population. The economic findings are also specific to the equipment, labor assumptions, electricity tariffs, maintenance model, and laboratory costing structure adopted in this study and should not be generalized directly to other production settings. In addition, the contrafactual scenario was a retrospective estimate based on the exclusion of recorded failure-related material consumption and printing time. It did not represent a second wheelchair experimentally manufactured under optimized conditions. Further work will include the manufacture of an additional prototype under revised production conditions to assess process reproducibility and compare manufacturing efficiency. These findings provide a foundation for subsequent studies focused on reducing printing time, optimizing TPU processing, improving compatibility with locally sourced components, validating mechanical performance according to applicable standards, and conducting ethically approved clinical evaluations of safety, usability, user satisfaction, and functional performance.

IV. CONCLUSION

This pilot study demonstrated the technical feasibility of fabricating and assembling an open-source pediatric wheelchair using FFF. The wheelchair was successfully assembled, with satisfactory integration of printed and commercial components and a visually coherent final

configuration. However, the findings also showed that manufacturing feasibility should not be assessed solely by successful prototype completion. Printing failures, material-specific processing difficulties, prolonged production time, and compatibility with locally available hardware substantially influenced workflow efficiency and estimated costs. The systematic documentation of these factors provides a basis for improving the manufacturing process before broader implementation. Further work should focus on process optimization, production of additional prototypes, and standardized mechanical validation. Only after these steps should the wheelchair proceed to ethically approved clinical evaluation of safety, usability, durability, and functional performance in children with mobility impairments.

ReabNet: A Web-Based Markerless Serious-Games Platform for Motor–Cognitive Rehabilitation in Parkinson's Disease

Edilaine Aparecida da Silva, Danilo Santos Rocha, Eduardo Lázaro Martins Naves
Biomedical Engineering Laboratory, Universidade Federal de Uberlândia (UFU), Uberlândia, MG, Brazil
edilaine.silva@ufu.br

***Abstract*—Camera-based serious games can support motor–cognitive rehabilitation without wearable sensors or handheld controllers. We describe ReabNet, a browser-based platform that uses a standard webcam and client-side MediaPipe BlazePose estimation to control RehaBEAT! for upper-limb reaching and Rock'in Roller for weight shifting and postural control. Game and task difficulty was progressed through a predefined, physiotherapist-supervised schedule that modified stimulus speed, required distance, base of support, and postural complexity across the 8-week protocol. During a single exploratory 902-frame live-gameplay session on a representative laptop, the pose pipeline showed an approximate median throughput of 18.9 frames/s and a median per-frame processing time of 44 ms. ReabNet was deployed in the experimental arm of an 8-week non-randomised controlled pilot involving 22 adults with mild-to-moderate Parkinson's disease; 12 participants used ReabNet and completed 16 sessions. Post-intervention usability was good (System Usability Scale 77.5 ± 9.5), exploratory first-to-last-session changes were observed in game scores, and one mild transient episode of vertigo occurred without discontinuation. These results support supervised operational feasibility but not biomechanical accuracy, because pose-derived kinematic measures were not independently validated against an optical reference system. We therefore frame the remaining validation needs—optical-reference accuracy, multi-device benchmarking, tracking-quality metrics, and component ablation—as an explicit research-gap agenda. Comparative clinical outcomes are reported separately.**

***Index Terms*—serious games, markerless pose estimation, Parkinson's disease, neurorehabilitation, browser-based rehabilitation, usability**

I. Introduction

Serious games combine structured physical exercise with gamified, goal-directed tasks and real-time feedback, and they are increasingly used in Parkinson's disease (PD) to train balance, mobility, and executive function under the dual-task demands that mirror everyday activity [1]–[3]. Two practical barriers limit their adoption. First, many systems rely on wearable sensors, instrumented mats, or handheld controllers that older adults with PD operate with difficulty because of tremor and bradykinesia. Second, research-grade exergames are often local installations tied to a specific device, which complicates deployment across a clinic and, increasingly, into the home.

Markerless motion capture, in which a standard camera and a computer-vision model estimate body pose without any attached sensor, removes the first barrier [4], [5]. Delivering the games through a web browser addresses the second: the same application can run on a clinic workstation, a tablet, or a phone, with central storage of session data for the clinician. We describe ReabNet, a platform that takes this combined approach, and report its design, its deployment considerations, and the operating assumptions that support browser-based pose tracking for coarse therapeutic game control. Clinical effects are reported separately [7]. The present contribution is engineering-focused: browser architecture, protocol-based difficulty progression, exploratory runtime measurement, clinician-facing telemetry, and platform-specific feasibility and usability.

A. Related Work

Serious games and exergames are established approaches to motor–cognitive training in PD, often using depth cameras or commercial consoles [1], [9], [10]. Browser delivery and markerless camera control are not individually novel: NeuroPose combined a webcam, browser-side PoseNet, and home-oriented geriatric rehabilitation [15], while Rehabilite Game+ integrated camera-based hand-pose games into a web platform configurable by clinicians [16]. A recent PD study also combined MediaPipe Pose with a customised exergame suite and related a derived digital-performance index to clinical measures [17]. ReabNet's contribution is therefore the evaluated integration of client-side whole-body pose control, upper- and lower-limb games, a predefined physiotherapist-supervised progression schedule, and account-linked longitudinal telemetry in a 16-session PD pilot. In contrast to systems proposing quantitative motion or digital clinical indices, ReabNet uses pose landmarks for coarse game control and does not claim biomechanical validity or a validated digital biomarker. Section V-A positions ReabNet against these systems on the dimensions that matter for browser-based, markerless deployment.

B. Scope and Relation to Companion Work

This paper reports ReabNet architecture, browser-side runtime, game-control logic, data handling, telemetry, deployment conditions, and preliminary operational evaluation. Its engineering contribution is the integration and supervised clinical deployment of these components rather than a new pose-estimation algorithm. Comparative clinical outcomes are

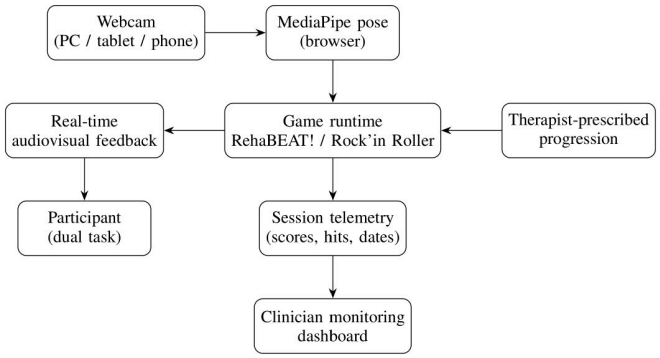

Fig. 1. ReabNet architecture. A standard webcam on a PC, tablet, or phone feeds a browser-side MediaPipe pose estimate that drives the game runtime; real-time audiovisual feedback closes the loop with the participant. Difficulty is progressed according to a predefined, physiotherapist-supervised protocol, and per-session telemetry is stored for review in the clinician monitoring dashboard.

reported in a companion study [7]; only platform-specific feasibility, usability, safety, and in-game metrics are included here.

II. System Architecture

A. Overview

ReabNet is a web application served to an ordinary browser (Fig. 1). It has two coupled sides. A clinician-facing module manages patient records, session scheduling, an exercise and game library, clinical assessments, and a monitoring dashboard. A participant-facing runtime executes the selected game, captures movement from the webcam, drives the game from the estimated pose, and sends per-session telemetry to the platform. The interface was accessible on compatible desktops, tablets, and smartphones without a separate installation; formal runtime measurement in this study was restricted to one Windows laptop running Chrome.

B. Implementation and Deployment

ReabNet is implemented as a single-page web application. Pose estimation runs entirely in the browser: the MediaPipe Pose (BlazePose) solution is loaded as a WebAssembly (SIMD) build from a content-delivery network and executed on the live webcam stream, and the estimated landmarks drive game logic that is rendered with WebGL. No client-side installation, browser plugin, or dedicated graphics card is required, so the same URL runs on a clinic workstation, a tablet, or a smartphone. Session configuration, telemetry, and clinician assessments are persisted on a server managed by the platform and retrieved through the clinician dashboard. Because inference is performed on the client, the network carries only lightweight telemetry rather than a video stream, which keeps the platform usable on ordinary connections; the trade-off is that responsiveness depends on the client device, as quantified in Section III-A.

C. Markerless Pose Estimation

Movement is captured from a standard RGB webcam and converted to a whole-body pose estimate in real time by MediaPipe Pose (BlazePose) [5], [6], which returns 33 landmarks. The model runs client-side in the browser through a WebAssembly (SIMD) build, with no markers or wearables; `modelComplexity` is 1 and minimum detection confidence is 0.5. Landmarks are mapped to discrete game actions, such as hand contact with a target or knee elevation for obstacle clearance, and the games are rendered in WebGL. In the clinical deployment, the webcam was approximately 2 m from the participant, centred on the body midline and at eye level; games were shown on a 20-inch monitor. Body detection was checked before each session, and a physiotherapist supervised all tasks, particularly tandem, unstable-surface, and single-leg conditions. The model is used as a fixed, pre-trained component; because its accuracy for the present cohort was not independently verified, Section III states the operating assumptions explicitly and Section VI sets out the validation still required.

D. Game-Control Logic and Participant Positioning

RehaBEAT! uses the estimated on-screen position of either hand as the control input (Fig. 2). A coloured block is registered as hit when the hand position overlaps it; no minimum dwell time is required. Bombs are negative game elements that must be avoided. In Rock'in Roller, knee elevation controls target contact and obstacle clearance. In the target-reaching task, the participant raises the knee until its estimated position overlaps the on-screen target. In the obstacle task, knee elevation triggers the jump action required to clear the obstacle.

No automated anthropometric calibration was used. Before each session, the physiotherapist positioned the participant and camera at the predefined distance and alignment, confirmed whole-body detection, and manually selected game level, stimulus speed, distance, and postural condition. Participants viewed the estimated body representation in real time. If tracking was temporarily lost, the game continued without automatic pause; the supervising physiotherapist repositioned the participant when necessary. This behaviour limits unsupervised use and motivates confidence-based warnings and automatic pause-and-resume logic, discussed in Section VI.

E. Configurable Session Parameters

Each game exposes clinician-configurable parameters that are set from a preferences panel before a session begins. For RehaBEAT!, these include the active hand (left, right, or both), the stimulus speed (slow, medium, or fast), the presence or absence of bomb obstacles, and the target size and spacing, which together set the spatial precision and temporal pressure of the reaching task. Rock'in Roller exposes analogous speed and obstacle-density settings. Combined with the postural condition selected by the physiotherapist, these parameters let a single game span a broad range of motor and cognitive demand without any change to the code, and every selected value is stored with the session record so that the configuration under

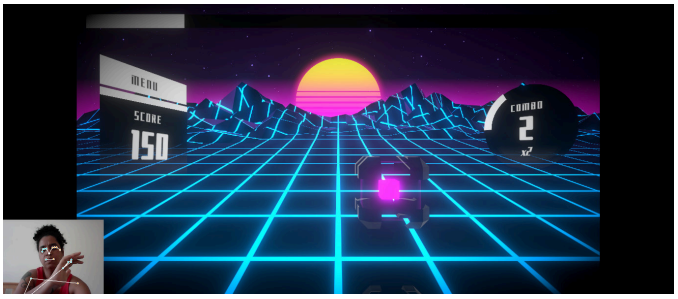

Fig. 2. RehaBEAT! gameplay. The participant reaches to contact rhythmic targets while avoiding bombs; the running score and combo multiplier are displayed. The lower-left inset is the live webcam view with the client-side MediaPipe pose skeleton overlaid, which drives game control.

Fig. 3. Clinician monitoring dashboard. For each patient the module aggregates standardised assessment scales (e.g., Berg Balance Scale, shown) and per-session game metrics, supporting longitudinal review of training and clinical progress.

which each score was obtained is auditable. This parameter logging is a prerequisite for the performance-driven automatic adaptation proposed in Section VI.

F. Therapeutic Games

The library is organised by therapeutic target. RehaBEAT! trains bilateral upper-limb reaching, elevation, abduction, and bimanual coordination. Participants reach to contact rhythmic coloured blocks while avoiding bombs. Consecutive block hits increase the combo multiplier and score. Missing a block or being hit by a bomb resets the combo to zero, and bomb contact also incurs a score penalty. Successive levels increase stimulus speed and density.

Rock'in Roller trains lower-limb and trunk control through weight transfer, mediolateral and anteroposterior displacement, partial squats, and progression toward single-leg stance. Challenge mode uses timed target reaching, whereas Infinite mode requires obstacle clearance through knee elevation. Both games combine motor execution with visual selection, sequencing, and time pressure and therefore produce discrete game-performance events rather than laboratory-grade continuous kinematic outcomes.

G. Protocol-Based Difficulty Progression

Difficulty was progressed according to a predefined, physiotherapist-supervised schedule. Every two weeks, the protocol increased motor and cognitive demands by changing the base of support (parallel stance, tandem stance, unstable surface, and single-leg stance), stimulus speed, and/or required distance. Software-level changes in game speed and task demand were coordinated with clinically prescribed changes in stance and balance conditions. This approach preserved clinician control over task selection, postural safety, and progression, at the cost of manual configuration—a dependence that Section VI addresses through performance-driven adaptation.

H. Telemetry and Clinician Monitoring

Each session stores participant-linked telemetry for longitudinal clinician review (Fig. 3). For RehaBEAT!, the dashboard reports session date, completion percentage, selected hand condition, coloured-block count, stimulus speed, bomb condition, score, maximum combo, overall hit rate, side-specific hit rates, and bomb-avoidance rate. Rock'in Roller likewise records score and obstacle-related performance across sessions. The game demands differ: RehaBEAT! requires upper-limb contact with coloured blocks while avoiding bombs, whereas Rock'in Roller requires knee elevation to trigger obstacle-clearing jumps. The first- and last-session scores and RehaBEAT! bomb-contact events used in the clinical analysis were exploratory outcomes; no game-derived variable is interpreted as a validated biomechanical or clinical measure.

I. Data Handling, Access, and Privacy

The operational platform identified participants by full name. Session telemetry and pose-landmark coordinates were stored on a server managed by the ReabNet startup. Camera-derived recordings were also retained with participant consent; however, the available technical documentation did not establish whether the retained material comprised complete video, still images, or selected frames, or whether upload occurred independently of client-side pose inference. Clinicians authenticated using unique logins and could access all patients registered under their own account, but not patient lists assigned to other clinician accounts. Startup engineers could access stored data for technical purposes. Encryption in transit, access logging, backup procedures, retention and deletion schedules, and formal security testing were not verified in this study; consequently, no formal cybersecurity or regulatory-compliance claim is made. The regulatory and scalability implications of these gaps are discussed in Section V-C.

III. Operational Responsiveness and Tracking Assumptions

ReabNet relies on the pre-trained MediaPipe BlazePose model [5], [6], whose performance against reference motion-capture systems has been characterised in prior work [11], [12]. An independent optical-reference validation was not performed in the present cohort.

The games were designed around coarse whole-body actions—reaching to sizeable targets, shifting body weight, and elevating the knee—rather than fine joint-angle estimation. Body detection was checked before each session and a physiotherapist supervised participants. The present evaluation

TABLE I
EXPLORATORY SINGLE-SESSION CLIENT-SIDE RUNTIME MEASUREMENT (902 FRAMES). THIS IS A DESCRIPTIVE MEASUREMENT ON ONE CONFIGURATION, NOT A MULTI-DEVICE BENCHMARK (SEE SECTION VI).

Device	Browser	Camera	FPS	Time (ms)
i5-8265U, UHD 620	Chrome	640×480	18.9	44 [34–48]

therefore addresses operational responsiveness and functional game control under supervision, not biomechanical accuracy. Optical-reference validation remains necessary before pose-derived kinematic measures can be proposed as digital biomarkers; Section VI specifies the metrics and protocol this validation should adopt.

A. Client-Side Runtime

An exploratory runtime measurement was conducted during a single live-gameplay session using a Windows 11 64-bit laptop equipped with an Intel Core i5-8265U processor (4 physical cores and 8 logical processors), 12 GB of DDR4 RAM, integrated Intel UHD Graphics 620, Google Chrome, and a 640×480 webcam. A total of 902 consecutive frames were analysed. The median inter-frame interval was 53 ms, corresponding to an approximate throughput of 18.9 frames/s. Median per-frame processing time was 44 ms, with an observed range of 34–48 ms (Table I). Because the measurements were obtained from a single session on one hardware configuration, they are interpreted as descriptive runtime measurements rather than a generalisable performance benchmark. Replication across sessions, users, browsers, and devices—and across camera resolutions and lighting conditions—is required to characterise variability, frame loss, jitter, and thermal stability; this multi-factor benchmarking is formalised as a research gap in Section VI.

B. Operational Evaluation Methods

Platform-specific operational outcomes comprised protocol completion, post-intervention usability, adverse events, and exploratory first-to-last-session game metrics. Protocol completion was defined as completion of all 16 supervised sessions; missed appointments were rescheduled. All 12 ReabNet participants provided complete platform-specific data, and no imputation was required.

After the 16th session, usability was assessed using the Portuguese-language System Usability Scale (SUS). The questionnaire was administered by an evaluator, and the therapist provided clarification of item wording when requested. Standard SUS scoring was used, including reverse scoring of the negatively worded items, to obtain a total score from 0 to 100. Potential adverse events were actively assessed and recorded at every session. For exploratory in-game analyses, each participant's first and last completed sessions were compared for RehaBEAT! score, RehaBEAT! bomb-contact events, and Rock'in Roller score. Analyses were performed in Python. Because of the small sample and the ordinal or non-normally distributed game metrics, paired first-to-last-session comparisons used Wilcoxon signed-rank tests. Results are reported as median [interquartile range]. The analyses were exploratory; no adjustment for multiple comparisons was applied, and p values should not be interpreted as confirmatory evidence of clinical efficacy.

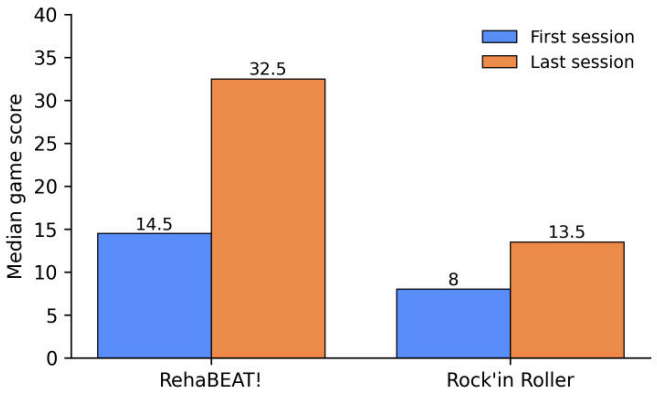

Fig. 4. Median RehaBEAT! and Rock'in Roller scores at the first versus the last completed session in the ReabNet arm ($n = 12$; values from Table II). Exploratory; changes may reflect familiarisation and protocol-driven difficulty changes.

TABLE II
EXPLORATORY IN-GAME PERFORMANCE IN THE REABNET ARM ($n = 12$). VALUES ARE MEDIAN [IQR]; p FROM WILCOXON SIGNED-RANK TESTS. RESULTS ARE EXPLORATORY AND MAY REFLECT TASK FAMILIARISATION AND CHANGING DIFFICULTY.

Metric	First [IQR]	Last [IQR]	p
RehaBEAT! score	14.5 [12.0–16.0]	32.5 [29.0–34.0]	< 0.001
RehaBEAT! bombs	1.0 [1.0–2.0]	0.0 [0.0–0.25]	0.002
Rock'in Roller score	8.0 [5.0–10.5]	13.5 [10.0–15.0]	0.0005

IV. CLINICAL FEASIBILITY

ReabNet was deployed in the experimental arm of an 8-week non-randomised active-comparator pilot involving 22 adults with mild-to-moderate PD (Hoehn & Yahr 1–3): 12 received ReabNet and 10 received dose-matched conventional physiotherapy [7]. The ReabNet arm completed 16 supervised sessions over 8 weeks; occasional absences were rescheduled and made up. All 12 ReabNet users completed the protocol. Post-intervention usability was good (System Usability Scale 77.5 ± 9.5; median 77.5; range 62.5–95) [13], [14]. One mild transient episode of vertigo occurred during ReabNet use, with complete recovery and no discontinuation. Exploratory first-to-last-session in-game performance is summarised in Table II and Fig. 4. Comparative clinical outcomes are reported separately [7].

V. DISCUSSION

ReabNet demonstrates that therapeutic games controlled by client-side markerless pose estimation can be delivered through an ordinary browser and operated on commodity

hardware under supervised clinical conditions. The exploratory runtime measurement, complete protocol among the 12 ReabNet users, good SUS score, and longitudinal telemetry support operational feasibility and learnability. They do not demonstrate tracking accuracy or clinical efficacy; comparative effects are addressed separately [7]. Observed first-to-last-session changes in scores and bomb-contact counts may reflect engagement, but are confounded by familiarisation, protocol-driven level changes, and scoring rules and should not be interpreted as direct motor-recovery measures.

A. Comparison with Related Camera- and Sensor-Based Systems

Table III positions ReabNet against representative camera-based and wearable rehabilitation approaches. Relative to NeuroPose [15] and Rehabilite Game+ [16], ReabNet adds whole-body (upper- and lower-limb) control and an account-linked longitudinal telemetry dashboard evaluated in a 16-session PD cohort; relative to the digital-index approach of Ferraris et al. [17], ReabNet deliberately restricts pose use to coarse game control and makes no digital-biomarker claim. Against wearable- and depth-camera systems, the browser-based markerless design removes attached hardware and per-device installation but shifts the burden to per-deployment runtime characterisation and to the tracking validation that wearables obtain by construction. A controlled, head-to-head comparison of tracking robustness and clinical utility against these alternatives was not performed and is identified as a research gap in Section VI.

B. Limitations of 2D Markerless Pose in Clinical Use

ReabNet's control signal is a single-camera 2D pose estimate. Two limitations follow directly. First, monocular pose lacks metric depth and true joint angles, so movements dominated by out-of-plane components (anteroposterior weight shift, trunk rotation) are captured only approximately; this is acceptable for coarse game control but precludes kinematic interpretation. Second, estimation quality degrades under self-occlusion, atypical body proportions, loose clothing, and non-frontal camera placement, and PD-specific factors—resting tremor, reduced amplitude, festination, and stooped posture—can further perturb landmark stability in ways that a healthy-adult-trained model may not represent well. The coarse, large-target game design tolerates these errors, but their magnitude in a PD cohort is unquantified. We therefore avoid any claim that ReabNet measures movement quality, and we treat pose only as a game-control input.

C. Scalability, Security, Regulatory Compliance, and Unsupervised Use

Client-side inference scales favourably: because only compact telemetry crosses the network, server cost grows with session metadata rather than video bandwidth, and the same URL serves heterogeneous devices. However, three deployment barriers remain. (i) *Security and privacy:* the study did not verify transport/at-rest encryption, access logging, backup, or defined retention and deletion, and engineers could access identifiable stored data; least-privilege role-based access and auditable data governance are prerequisites for real-world use. (ii) *Regulatory compliance:* a supervised research prototype is distinct from a regulated medical device—a production version handling health data would need to align with the applicable data-protection law (e.g., Brazilian LGPD) and, if therapeutic claims were made, with software-as-a-medical-device requirements; no such claim is made here. (iii) *Unsupervised/home use:* the absence of automatic pause on tracking loss and the reliance on a supervising physiotherapist for positioning and level selection currently preclude safe unsupervised deployment. A performance-driven automatic difficulty adaptation—for example, adjusting stimulus speed and target spacing from the trailing hit rate and bomb-contact rate already logged per session—would reduce manual configuration and is a natural step toward home use, provided it is paired with confidence-based tracking warnings and safety limits.

VI. LESSONS LEARNED AND RESEARCH GAPS

A. Lessons Learned

Three engineering lessons emerged from developing and deploying ReabNet. First, *client-side inference is an accessibility enabler but a characterisation liability*: exchanging only telemetry keeps the platform usable on ordinary connections, yet it makes responsiveness device-dependent and therefore demands per-deployment runtime characterisation rather than a single benchmark. Second, *coarse game control tolerates imperfect pose, but only under supervision*: large targets and body-scale actions absorb landmark noise, while the lack of automatic pause on tracking loss showed that robustness features, not just accuracy, gate unsupervised use. Third, *auditable configuration is as important as the games themselves*: logging every clinician-selected parameter with each score was what made exploratory in-game changes interpretable, and it is the foundation on which automatic, performance-driven adaptation can later be built.

B. Research Gaps and Future Work

The reviewer-identified needs are consolidated below as a structured agenda; none were addressed in the present study and each is stated as future work rather than a current result.

(G1) Optical-reference tracking validation. Quantify the accuracy and reliability of BlazePose landmarks in a PD cohort against a marker-based optical reference (e.g., Vicon), reporting per-landmark positional error, temporal stability (jitter), detection-loss rate, and robustness to occlusion, body type, tremor, and PD-typical postures.

(G2) Multi-configuration performance benchmarking. Characterise runtime across devices (laptop, tablet, phone), browsers, camera resolutions, and lighting conditions, over multiple sessions, reporting frame loss, jitter, and thermal stability rather than a single-session median.

(G3) Component ablation. Isolate the contribution of the progression protocol, audiovisual feedback, configurable parameters, and interaction strategy to engagement and in-game performance, so that design choices are evidence-based rather than assumed.

(G4) Controlled comparison. Benchmark ReabNet head-to-head against alternative computer-vision and wearable rehabilitation solutions on tracking robustness, usability, and clinical utility.

(G5) Objective tracking-quality telemetry. Add detection-loss rate, landmark temporal stability, and confidence-based warnings with automatic pause-and-resume to the runtime, both to support unsupervised use and to expose tracking quality as a monitored signal.

(G6) Automatic difficulty adaptation. Replace manual level selection with performance-driven adaptation derived from the logged hit-rate and bomb-contact telemetry, reducing dependence on the supervising physiotherapist.

(G7) Governance and regulatory readiness. Implement and audit least-privilege access, encryption in transit and at rest, access logging, and defined retention/deletion, and align data handling with applicable health-data regulation.

(G8) Clinical validation at scale. Pursue multicentre and longitudinal evaluation, home-deployment testing without continuous supervision, biomechanical validation in real rehabilitation settings, and integration with AI models for therapeutic personalisation.

VII. Conclusion

ReabNet is a browser-based serious-games platform combining client-side markerless pose estimation, therapist-prescribed task progression, and clinician-facing telemetry. In a single exploratory 902-frame session on the tested laptop, it showed an approximate median throughput of 18.9 frames/s and a median per-frame processing time of 44 ms; all 12 ReabNet users completed the supervised 16-session protocol, usability was good, and exploratory first-to-last-session changes were observed in game scores; these comparisons were confounded by familiarisation and protocol-driven changes in difficulty. These findings establish preliminary operational feasibility, not biomechanical validation. Optical-reference testing, event-recognition validation, multi-device characterisation, component ablation, and home-deployment evaluation—consolidated here as an explicit research-gap agenda—remain necessary before broader implementation.

***Abstract*— Essential tremor is a neurological disorder that typically causes tremors in the upper limbs. These tremors are usually in the 2 Hz to 10 Hz range. This work presents a preliminary metrological bench validation of a low-cost wearable device, based on an ESP32-C3 microcontroller and an accelerometer integrated into a passive weighted bracelet. The development of such assistive technologies requires characterization of their embedded sensing capabilities under controlled conditions. The system was evaluated using a damped harmonic oscillator bench test and a laboratory rotary motion sensor used as a reference instrument. The measurements from the accelerometer and the laboratory rotary sensor were compared in the frequency domain using the Fast Fourier Transform (FFT) across several tests with different springs and bracelet weight configurations. Results showed that the embedded sensor was able to detect the mass-dependent reduction in the natural frequency of the oscillating system across different experimental configurations. The embedded system measured a frequency drop from 2.97 Hz to 1.66 Hz in a configuration when a 137-gram mass was added to the bracelet. The results demonstrated good agreement with the reference sensor for the tested frequencies between approximately 1 and 3 Hz, while frequencies below 1 Hz showed substantial errors. These findings support the preliminary technical feasibility of the sensing module under controlled bench conditions, but validation across the full 2–10 Hz tremor range and in human subjects remains necessary.**

Keywords*— *Sensor validation, Inertial sensors, Damped harmonic oscillator, Fast Fourier Transform, Essential tremor

I. Introduction

Essential Tremor (ET) is a chronic neurological movement disorder characterized by rhythmic and involuntary oscillations of the upper limbs, with frequencies predominantly ranging between 2 Hz and 10 Hz [1], [2]. Essential tremor affects fine motor control, impairing patients' autonomy in basic daily activities such as eating, writing, and personal care [3], [4], [5]. Wearable technologies, such as those based on inertial measurement units (IMUs), have been used to assess and monitor these tremors outside the clinical environment [6], [7], [8].

The determination of the dominant tremor frequency is typically performed using frequency-domain signal processing techniques, such as the Fast Fourier Transform (FFT). The current challenge in biomedical instrumentation is how to adopt low-cost embedded platforms capable of continuous data acquisition while providing frequency measurements with acceptable agreement with laboratory reference instruments.

In parallel with the digital monitoring performed by embedded systems, the use of passive assistive technologies—such as bracelets with incorporated weights—exploits the physical principles of inertia and damping, aiming to reduce involuntary oscillatory movement [9], [10]. The mechanical dynamics of this attenuation resemble those of a damped harmonic oscillator (mass-spring system). According to the fundamental laws of dynamic systems modeling, increasing the mass of an oscillatory system directly decreases its natural frequency of oscillation.

Therefore, the main objective of this study is to perform a preliminary metrological characterization of a low-cost embedded inertial sensing module integrated into a modular weighted bracelet, designed via additive manufacturing for continuous tremor monitoring. The system was evaluated in a standardized bench test simulating a damped harmonic oscillator, in which raw acceleration data were simultaneously compared with measurements from a laboratory rotary motion sensor serving as a reference sensor.

To evaluate the system's frequency measurement behavior under controlled conditions, kinematic data from both devices across multiple trials were analyzed using the Fast Fourier Transform. Thus, this work aims to demonstrate the low-cost device's ability to characterize both the frequency reduction associated with the addition of mass and the oscillatory frequencies relevant to ET under the tested bench conditions.

II. Methods

To evaluate the frequency measurement performance of the proposed low-cost embedded system, a controlled bench test based on a damped harmonic oscillator was designed. The

experimental approach emphasizes the technical feasibility of using accessible hardware for frequency monitoring and compares its performance against a laboratory reference sensor through frequency-domain analysis.

A. Bench Test Setup and Data Acquisition

To perform the experiment, we used a 3D-printed bracelet with a weight container suspended by a spring mechanism to simulate the oscillatory behavior of a human arm. The embedded sensing module **(Fig. 1)** has an ESP32-C3 microcontroller and an MPU-6050 Inertial Measurement Unit (IMU). The electronic architecture is detailed in the block diagram **(Fig. 2)** and also includes power management and data communication between the components. The IMU captured the raw 3-axis acceleration data using a sampling rate of 100 Hz during the experiments.

To initiate each bench trial, we manually displaced the mass-spring-bracelet system vertically from its equilibrium position by approximately 5.0 cm and released it from rest, generating a consistent damped harmonic oscillation. For each physical configuration, the IMU continuously captured raw triaxial acceleration data at a sampling rate of 100 Hz for a continuous duration of 15 seconds, ensuring the complete decay of the oscillatory motion was captured. Although the embedded system continuously acquired data throughout the 15-s bench trials, the present study focused on frequency-domain agreement with the reference sensor. Therefore, latency, long-term continuous operation, power consumption, and communication stability were not quantitatively assessed in these experiments.

We used a PASCO rotary motion sensor (model PS-2120) as the laboratory reference for our validation, coupling it mechanically to the mass-spring system **(Fig. 3)**. This reference sensor recorded the system's angular position simultaneously with the embedded module. The sampling rate of the reference sensor was also set to 100 Hz through the DataStudio software. To align the datasets from these independent hardware acquisitions, we implemented a temporal synchronization protocol in post-processing. We aligned the synchronized datasets by identifying the absolute onset peak of the initial transient oscillation, utilizing cross-correlation to achieve sample-to-sample synchronization. This dual-acquisition strategy allowed us to obtain a synchronized dataset, enabling a direct comparison between the measurements.

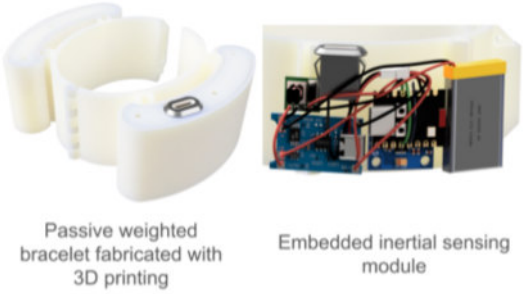

Fig. 1. Overview of the proposed wearable system. On the left, the passive weighted bracelet fabricated via additive manufacturing, with its weight-distribution containers. On the right, the embedded inertial sensing module detailing the ESP32-C3 microcontroller, the triaxial accelerometer, and the power supply.

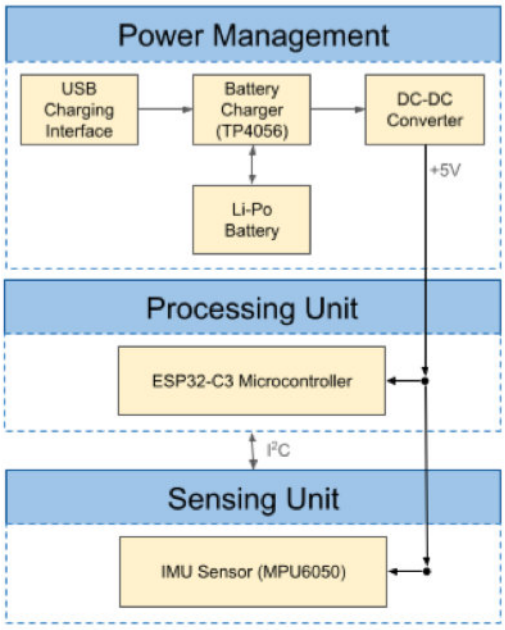

Fig. 2. Functional block diagram of the embedded sensing module. The architecture is divided into a power management unit (battery charger and DC-DC converter), a processing unit (ESP32-C3), and a sensing unit (MPU-6050), illustrating the 5V power supply lines and the I2C communication protocol.

B. Mass-Induced Frequency Reduction Evaluation

To evaluate whether the sensor can detect changes in oscillation frequency resulting from the addition of mass to the bracelet, we added mass to the mass-spring system. Increasing the mass of the system decreases its natural frequency of oscillation.

We started testing the system using Spring 1 with the bracelet's weight compartment empty. Next, we ran the test again with the weight compartment completely filled by adding 137g of lead. We conducted additional tests using different configurations (other springs and alternating the weight compartment between full and empty) to assess the consistency of the embedded system in detecting frequency changes associated with the addition of mass.

C. Frequency-Domain Validation Protocol

To evaluate the frequency measurement performance of the low-cost sensor, we processed the synchronized kinematic signals from both devices in the frequency domain. Because the mechanical oscillation of the suspended spring-mass system occurred strictly along a single vertical axis, we selected only the vertical acceleration component (a_z) of the MPU-6050 for analysis, thereby eliminating uninformative noise from the orthogonal axes.

First, we removed the Direct Current (DC) component from both the PASCO angular displacement and the accelerometer signals by subtracting their respective mean values to eliminate baseline offsets. To mitigate spectral leakage and windowing

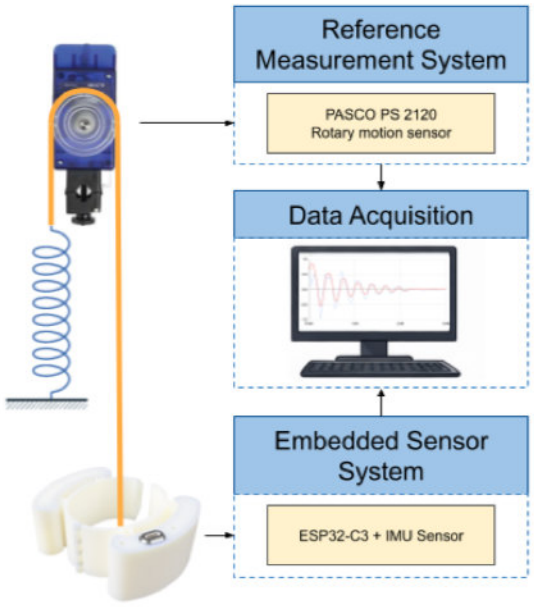

Fig. 3. Setup of the damped harmonic oscillator bench test connecting the mass-spring system to the bracelet, carried out to validate the bracelet's embedded sensing module. The functional block diagram shows that data from the bracelet's sensing module is collected simultaneously with data

artifacts, we applied a Hann window to the time-domain signals prior to spectral analysis.

We then calculated the frequency spectrum using the Fast Fourier Transform (FFT) with a window size of N=1024 points. Although each trial was recorded for a continuous duration of 15 s, not all samples were used in the frequency-domain analysis. From each 15-s recording, we manually selected a 1024-sample segment (10.24 s at 100 Hz) corresponding to the free-decay portion of the oscillation. Specifically, we excluded the initial interval in which the bracelet was still being manually displaced from equilibrium — during which acquisition had already started but release had not yet occurred — as well as the final interval in which the oscillation had already decayed to a near-flat signal. This selection ensured that the analyzed segment captured the actual damped oscillatory motion while excluding the pre-release handling artifact and the low-amplitude tail, both of which could otherwise degrade the accuracy of the FFT-based peak detection. At a sampling rate of 100 Hz, this configuration yielded a spectral resolution of approximately 0.098 Hz, allowing for fine frequency discrimination when comparing peak locations. The dominant frequency of oscillation was mathematically extracted by identifying the bin corresponding to the maximum absolute magnitude within the single-sided power spectrum density (PSD) of each signal.

III. Results

A. Mass-Induced Frequency Reduction

The bench results showed that the embedded sensing module was able to detect the frequency reduction associated with the addition of mass. According to the mass-spring dynamic model, the addition of mass decreases the system's natural oscillatory frequency. As detailed in the frequency-domain analysis (Table I), the reference PASCO sensor recorded a clear frequency drop from 2.97 Hz with the empty bracelet (trial 1a) to 1.66 Hz when the 137g mass was added (trial 1b). The proposed embedded system detected this frequency shift, measuring 3.00 Hz and 1.67 Hz, respectively. Similar attenuation patterns were recorded across the other spring configurations tested (e.g., trials 2a and 2b). The results are consistent with the expected mass-dependent reduction in the natural frequency of the oscillator and demonstrate the capability of the low-cost sensor to detect this change. **Fig. 4** shows the alignment between the reference signals of the PASCO sensor and the signals measured by the embedded accelerometer over time, visually confirming their synchronization.

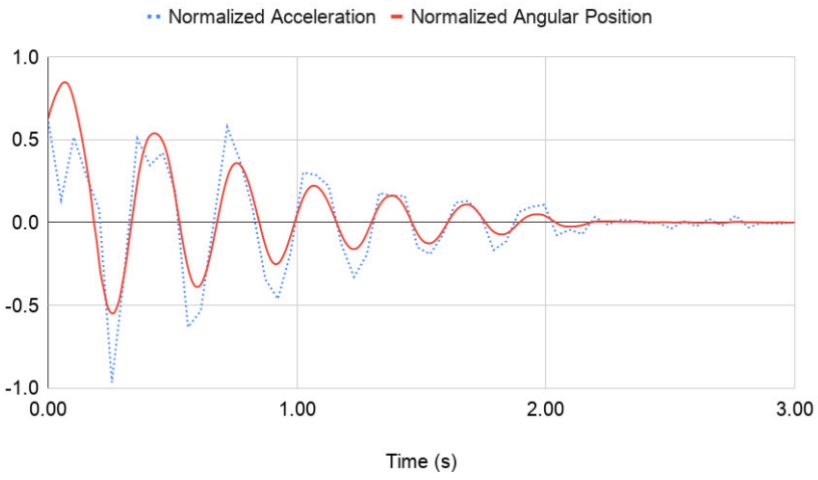

Fig. 4. Comparison between the normalized signals collected by the PASCO reference sensor (solid red line) and the embedded sensing module (dashed blue line) over time. The peak-to-peak alignment visually validates the metrological capability of the low-cost hardware.

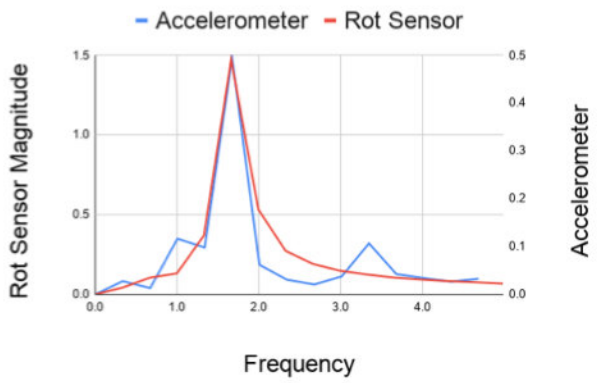

Fig. 5. Frequency spectrum magnitude obtained via Fast Fourier Transform (FFT) for trial 1b (Spring 1 with 137 g mass). The solid red line represents the reference spectrum from the rotary motion sensor (left y-axis), while the solid blue line represents the equivalent spectrum from the embedded accelerometer (right y-axis). The close alignment of the dominant frequency peaks at approximately 1.66 Hz illustrates the close agreement between the dominant frequency estimates obtained from the two sensors.

B. Frequency-Domain Performance Evaluation

To assess the frequency measurement performance of the low-cost accelerometer when compared to the reference laboratory PASCO sensor, the raw data from the 12 bench trials, which represented distinct experimental configurations rather than 12 independent repetitions of the same condition, were analyzed using the Fast Fourier Transform (FFT). **Table I** shows the dominant frequencies extracted from both measurement systems. **Fig. 5** shows the alignment of the dominant frequency between the data extracted from the PASCO sensor and the accelerometer data extracted in trial 1b.

TABLE I. DOMINANT FREQUENCIES EXTRACTED VIA FFT

Trial	*Reference Sensor (Hz)*	*Embedded Sensor (Hz)*	*Difference (%)*
1a	2.970	2.997	0.91%
1b	1.661	1.672	0.66%
2a	1.998	1.964	-1.70%
2b	1.314	1.335	1.60%
3a	1.679	1.697	1.07%
3b	1.000	1.003	0.30%
4a	1.329	1.338	0.68%
4b	0.498	3.344	571.49%
5a	0.738	1.003	35.91%
6a	1.990	1.998	0.40%
6b	1.329	1.332	0.23%
7a	2.993	2.991	-0.07%

For the tested oscillations at or above approximately 1.00 Hz, the embedded sensor showed good agreement with the laboratory reference sensor. However, the experiments did not cover the full 2-10 Hz frequency range important to essential tremor. Within the portion of this range that was reproduced by the bench setup (approximately 2–3 Hz), the frequency differences between the embedded and reference sensors were below 2%.

To provide aggregate error measures for the tested configurations, we calculated aggregate error metrics across these ten trials. The system achieved a Mean Absolute Error (MAE) of 0.0136 Hz, a Root Mean Squared Error (RMSE) of 0.0171 Hz, and an overall Mean Absolute Percentage Error (MAPE) of 0.76%. The maximum absolute deviation recorded was 0.0340 Hz (a 1.70% error in trial 2a). These aggregate metrics characterize the overall performance across the tested configurations and should not be interpreted as estimates of within-condition repeatability.

Conversely, the two trials below the 1.00 Hz threshold—specifically trials 4b and 5a—revealed significant deviations . In trial 5a, the embedded sensor estimated 1.003 Hz compared with 0.738 Hz from the reference sensor, resulting in a 35.91% difference. Although this represents a considerable relative error, the estimated frequency remained in the same general low-frequency region as the reference. In contrast, trial 4b showed a much larger discrepancy, with the embedded sensor indicating 3.344 Hz while the reference sensor measured 0.498 Hz. This result is more consistent with a frequency-peak misidentification than with a simple frequency estimation error, since the dominant peak detected by the FFT did not correspond to the fundamental oscillation observed by the reference sensor. At such low frequencies, the reduced acceleration amplitude may cause the fundamental component to become less prominent relative to noise and other spectral components, increasing the likelihood of selecting an unrelated peak as the dominant frequency.

IV. DISCUSSION

The data from the bench tests support the preliminary technical feasibility of the proposed sensing module under controlled conditions investigated. Using a damped harmonic oscillator model, we evaluated the low-cost accelerometer's ability to detect mass-induced changes in oscillation frequency. According to mass-spring dynamics, increasing the system's mass decreases its natural frequency of oscillation. The embedded sensor was able to register this shift. For instance, the frequency dropped from 3.00 Hz to 1.67 Hz between trials 1a and 1b, and from 1.96 Hz to 1.34 Hz between trials 2a and 2b. Observing these variations indicates that the accessible hardware captures the dynamic changes caused by the added mass.

To further investigate the sensor's frequency measurement performance, we analyzed the signals in the frequency domain using the Fast Fourier Transform (FFT). A direct comparison with the laboratory reference sensor highlighted a critical performance threshold. For oscillations below 1.00 Hz, the embedded system produced substantial different behavior from the reference sensor. In trial 5a, the measured frequency was 1.003 Hz, compared with 0.738 Hz from the reference,

corresponding to a 35.91% difference. In trial 4b, however, the discrepancy was much larger: the reference sensor measured 0.498 Hz, whereas the embedded sensor identified a dominant frequency of 3.344 Hz. This large deviation should therefore not be interpreted simply as a large frequency estimation error. Rather, it suggests that the FFT-based peak-selection procedure may have identified a different spectral component instead of the fundamental oscillation. This distinction is important because the reference frequency was close to 0.5 Hz, where the oscillatory acceleration is expected to be much smaller than at higher frequencies. Under these conditions, the fundamental component may become less distinguishable from noise and other spectral components, increasing the possibility of selecting an unrelated peak as the dominant frequency.

The results from trials 4b and 5a therefore suggest a limitation of the current frequency-identification approach at very low frequencies, rather than a uniform degradation of frequency accuracy. Further experiments with controlled low-frequency excitation and additional signal-quality analysis will be necessary to determine the extent to which sensor noise, spectral leakage, or other mechanical disturbances contribute to this behavior.

These low-frequency results are outside the typical frequency range considered for essential tremor and therefore do not directly limit the intended 2–10 Hz application range. Nevertheless, they are relevant for characterizing the operating limits of the proposed sensing approach and indicate that additional signal-processing strategies may be required when the system is exposed to very slow oscillations. More importantly, the present experiments do not cover the complete 2–10 Hz range relevant to essential tremor, so the observed performance cannot yet be generalized to the entire clinical frequency range.

Essential Tremor is clinically defined by involuntary oscillations usually within the 2.00 to 10.00 Hz frequency band. For the frequencies tested above 1 Hz, the measured errors remained below 2%. However, because the experimental setup was limited to approximately 3 Hz, these results cannot be extrapolated to the entire 2–10 Hz clinical range.

Despite these promising results, a physical limitation of our gravity-driven suspended mass-spring setup must be addressed. While the clinical window for Essential Tremor usually spans from 2.00 Hz to 10.00 Hz, our bench trials were physically constrained to a maximum frequency of approximately 3.00 Hz.

Due to the mass-spring dynamic relation ($f_n = \frac{1}{2\pi}\sqrt{k/m}$), simulating stable oscillations up to 10.00 Hz is restricted by the minimum mass of our physical wearable prototype (approximately 150 g). Forcing higher frequencies would require an extremely stiff spring, resulting in a negligible static deflection that cannot sustain clean, manually excited harmonic oscillations under gravity.

Consequently, while this study successfully verifies the sensor's frequency measurement behavior and low error margins (<2%) starting from 1.00 Hz, validation across the full 2–10 Hz clinical frequency range, particularly above 3 Hz, remains a priority. Future work will overcome this setup limitation by utilizing an active, motorized mechanical shaker table to generate high-frequency controlled sweeps, paving the way for upcoming clinical trials with volunteers.

The validation demonstrates that low-cost wearable hardware can bridge the gap between passive assistive devices and complex, high-cost monitoring systems [10]. The developed system shows potential for frequency-based tremor monitoring, subject to further validation. The observed frequency reduction with increased mass supports the feasibility of investigating mass-dependent mechanical tuning in future studies.

Future studies should also characterize practical aspects of wearable operation, including acquisition latency, communication stability, power consumption, and longer-term continuous operation. These measurements were outside the scope of the present bench validation, which focused primarily on the agreement between the embedded sensor and the laboratory reference in the frequency domain.

V. Conclusion

In this work, we performed a preliminary bench characterization of a low-cost, 3D-printed wearable inertial sensing module integrated into a weighted bracelet. We evaluated the system using a damped harmonic oscillator and compared it with a laboratory reference sensor through frequency-domain analysis based on the Fast Fourier Transform (FFT).

The embedded accelerometer was able to detect the frequency reduction associated with the addition of mass to the oscillating system. For the tested frequencies between approximately 1 and 3 Hz, the measured dominant frequencies showed good agreement with the laboratory reference sensor, with differences below 2% for the tested frequencies above 1 Hz. In contrast, substantial deviations were observed below 1 Hz, which were attributed primarily to the reduced acceleration amplitude and lower signal-to-noise ratio at very low frequencies.

These results support the preliminary technical feasibility of the sensing module for frequency characterization under controlled bench conditions. However, the present study does not constitute clinical validation and does not cover the complete 2–10 Hz frequency range relevant to essential tremor. Further studies should evaluate the system across the full frequency range using controlled excitation, different motion amplitudes and directions, repeated measurements, and ultimately human subjects and clinically relevant reference instrumentation.

***Resumo*—O zumbido (tinnitus) é a percepção de um som na ausência da fonte sonora e pode comprometer severamente a qualidade de vida de muitos indivíduos, desencadeando distúrbios de sono e ansiedade. Barreiras econômicas no mercado brasileiro limitam o acesso a dispositivos eletrônicos com geradores de ruído integrados, enquanto o sistema público de saúde frequentemente disponibiliza aparelhos focados apenas na amplificação sonora para perda auditiva. Este trabalho tem o objetivo de desenvolver a especificação do projeto, a modelagem arquitetônica e os requisitos de segurança de um sistema assistivo de baixo custo baseado em IoT que pode ser utilizado na Terapia de Habituação do Zumbido (Tinnitus Retraining Therapy - TRT). O sistema proposto possui um aplicativo móvel e um hardware auricular minimalista baseado no microcontrolador ESP32, utilizando acoplamento acústico de canal aberto (open-fit) para evitar o efeito de oclusão. Portanto, sendo um estudo focado na concepção arquitetônica e especificações de projeto, este manuscrito estabelece os requisitos técnicos e detalha um plano de validação eletroacústica, de segurança do paciente e de conformidade regulatória para orientar o desenvolvimento físico e ensaios clínicos futuros.**

Palavras-chave: Zumbido; Tinnitus; Tecnologia Frugal; Internet das Coisas; Terapia Sonora; Dispositivo Auricular.

I. Introdução

O zumbido, também denominado tinnitus, é um sintoma de grande prevalência na população mundial caracterizado pela percepção de um som, na ausência de uma fonte sonora externa correspondente [1]. Embora possa apresentar diferentes características acústicas, intensidade e duração, em alguns indivíduos o zumbido assume caráter persistente gerando um impacto em dimensões funcionais, físicas e emocionais [2]. Apresenta fisiopatologia multifatorial, podendo envolver desde alterações na atividade neural ao longo das vias auditivas, como estar relacionada a modificações no input sensorial periférico, além de causas metabólicas e vasculares [3], [4], [5].

Existem diversos fatores associados ao desenvolvimento ou agravamento do zumbido como, por exemplo, a perda auditiva; a exposição a altos níveis de pressão sonora; uso de medicamentos; acidentes e entre outros [3], [4]. Além dessa questão auditiva, o sintoma pode impactar negativamente a qualidade de vida, gerando alterações no sono, dificuldade de

concentração e complicações emocionais, como ansiedade e depressão em casos mais graves [6], [7].

Entre as estratégias terapêuticas utilizadas para o manejo do zumbido, destaca-se a Terapia de Habituação do Zumbido (Tinnitus Retraining Therapy – TRT). A TRT envolve aconselhamento terapêutico associado ao enriquecimento sonoro, buscando favorecer a habituação à percepção do zumbido e reduzir seu impacto emocional e atencional. O uso de estímulos sonoros contínuos ou estruturados constitui, portanto, um dos recursos empregados no processo de manejo do sintoma, considerando os mecanismos de adaptação e neuroplasticidade do sistema auditivo [8], [9], [7].

Apesar da disponibilidade de diferentes tecnologias para terapia sonora, o acesso a dispositivos com recursos específicos para o manejo do zumbido pode ser limitado por fatores econômicos e tecnológicos. Equipamentos de Amplificação Auditivos de Sonora Individual (AASI) com recursos de geração ou controle de estímulos terapêuticos para o zumbido podem apresentar custo elevado, enquanto aqueles disponibilizados em determinados contextos de atenção à saúde podem ter como finalidade principal a amplificação da fala e não necessariamente contemplar estratégias específicas de enriquecimento sonoro para o zumbido [10], [8], [11].

Diante disso, é observada a importância de alcançar soluções assistivas que conciliam a funcionalidade, usabilidade, acessibilidade econômica e que alcancem resultados significativos e benéficos aos usuários. Por isso, questões como ergonomia, conforto, dimensões do dispositivo, adaptação ao conduto auditivo e controle do efeito de oclusão são importantes para garantir bons resultados e adesão ao uso. Evitando, assim, a percepção de sons internos e o comprometimento do conforto acústico do usuário [6].

Nesse processo, a atuação fonoaudiológica torna-se importante para caracterizar o zumbido a partir da avaliação auditiva, no qual é possível definir o tipo, intensidade e frequência do zumbido que vão permitir a seleção e adaptação do dispositivo de acordo com as necessidades individuais de cada usuário. Dessa forma, o desenvolvimento de uma solução tecnológica para terapia sonora requer a integração de requisitos clínicos, acústicos, ergonômicos e de usabilidade. A definição desses requisitos constitui uma etapa importante para a construção de um sistema que possa posteriormente ser prototipado e submetido a avaliações de desempenho e usabilidade [6].

Em relação ao contexto nacional para esse sintoma, existem milhões de brasileiros que apresentam algum grau de zumbido, com diferentes causas. [10], [8], [6]. Para essa situação, aparelhos de amplificação são oferecidos de forma gratuita pela rede pública mediante fila de espera. Porém, estes aparelhos normalmente são direcionados prioritariamente ao público com perda auditiva e, em apenas alguns casos, esses dispositivos possuem função de redução de zumbido. Essa questão faz com que um grande número de pessoas que possuem zumbido, principalmente aquelas que não sofrem de perda auditiva, permaneçam sem o tratamento necessário para seu sintoma. Além disso, o alto custo financeiro de aparelhos no mercado impede o acesso de grande parte da população a essa tecnologia [8], [11].

Para contornar as questões econômicas e tecnológicas, este trabalho tem como objetivo apresentar a especificação técnica de projeto, a engenharia de requisitos e a modelagem arquitetônica de uma plataforma assistiva de baixo custo baseada em Internet das Coisas (IoT) direcionada à Terapia de Habituação do Zumbido (Tinnitus Retraining Therapy – TRT) [8], [11].

O projeto busca desenvolver um ecossistema integrado por um hardware auricular vestível (centrado no microcontrolador ESP32-PICO-MINI com conectividade BLE), um aplicativo móvel para o paciente (responsável pelo offloading computacional de áudio e registro diário) e uma plataforma web de gerenciamento, destinada ao acompanhamento por fonoaudiólogos e engenheiros [12]. Além disso, será utilizada adoção de acoplamento acústico de canal aberto (open-fit) em invólucro de silicone biocompatível para eliminar o efeito de oclusão e garantir o conforto durante o uso prolongado [3], [6]. Por fim, vale ressaltar que esse projeto se trata de uma estruturação e planejamento iniciais para o desenvolvimento de software e hardware, tendo este trabalho como base para tratar especificações técnicas, os requisitos de biossegurança auditiva e o enquadramento regulatório, estruturando o projeto a fim de orientar a futura prototipagem física e ensaios clínicos do sistema.

II. Materiais e métodos

DELINEAMENTO DO ESTUDO:

Trata-se de um estudo de especificação arquitetônica, modelagem de sistema e engenharia de requisitos aplicado ao desenvolvimento de uma tecnologia assistiva em saúde [8] [13]. Previamente ao desenvolvimento do dispositivo físico, foram definidas as características dos estímulos a serem empregados, com ênfase no uso de estímulos de banda larga, bem como estabelecidas as diretrizes de calibração e os fluxos de software necessários para orientar a futura montagem do protótipo e a realização dos ensaios de bancada.

PROTOCOLO TERAPÊUTICO:

Previamente à utilização do dispositivo, é necessária uma avaliação fonoaudiológica individualizada, incluindo audiometria tonal limiar e de altas frequências, logoaudiometria, acufenometria e emissões otoacústicas. Esses procedimentos permitem caracterizar a função auditiva e coclear, bem como as características psicoacústicas do zumbido, subsidiando a definição dos parâmetros de estimulação do dispositivo [5], [7], [6].

Esse processo possibilita o acompanhamento contínuo do paciente e a caracterização das principais características psicoacústicas do zumbido, incluindo seu tipo, frequência (pitch) e intensidade (loudness), permitindo o ajuste dos parâmetros terapêuticos de acordo com as características individuais do sintoma [6].

O dispositivo proposto tem como foco principal a emissão de ruído para auxílio no manejo desse sintoma específico. Para o projeto, será adotado o uso do ruído branco de banda larga e, em casos específicos, a banda estreita personalizada [7]

[9]. Esta escolha se dá devido à viabilidade computacional no microcontrolador e por utilizar um padrão validado na literatura para a Terapia de Habituação do Zumbido (TRT) [8], [13], [6].

O nível de pressão sonora do ruído deve ser ajustado no ponto de mistura (mixing point), no qual o ruído terapêutico e o zumbido podem ser percebidos simultaneamente, possibilitando a estimulação necessária para a habituação neural [6], [9].

Além disso, para garantir a personalização do estímulo sonoro, os testes e uso serão realizados apenas após uma avaliação fonoaudiológica detalhada [6], [7]. Além da audiometria convencional, serão realizadas analises do Limiar de Desconforto Sonoro e a acufenometria para identificar a frequência exata e o nível de intensidade do zumbido em cada paciente [5], [6].

PROJETO ACÚSTICO DE ACOPLAMENTO ABERTO (OPEN-FIT):

Na região externa do dispositivo, o hardware deverá apresentar geometria compatível com a anatomia auricular, de modo a minimizar pontos de atrito e pressão durante o uso. Para essa finalidade, está sendo avaliada a possibilidade de fabricação da estrutura por impressão 3D em silicone, visando proporcionar maior maleabilidade, além de propriedades hipoalergênicas e biocompatibilidade [6].

Adicionalmente, será utilizado acoplamento acústico do tipo open-fit (oliva de canal aberto), que favorece a ventilação do meato acústico externo e reduz o efeito de oclusão, que pode produzir alterações na percepção sonora durante a utilização do dispositivo [6], [11], [3]. O sinal analógico será gerado pelo conversor digital-analógico (DAC) integrado ao microcontrolador e, posteriormente, encaminhado ao transdutor eletroacústico, responsável pela conversão do sinal elétrico em estímulo sonoro [11] .

REQUISITOS DE SEGURANÇA:

Para garantir a segurança auditiva e a integridade do usuário durante o uso diário, o projeto estabelece requisitos específicos de controle da exposição sonora. Será implementada uma limitação do nível de pressão sonora (SPL), com mecanismos de proteção em software e hardware, de modo a impedir que o nível de saída ultrapasse 80 dB SPL no conduto auditivo externo. Essa medida visa reduzir o risco de exposição sonora excessiva e, consequentemente, de danos à função auditiva decorrentes de níveis elevados de estimulação sonora [4], [13].

O controle de volume disponível no aplicativo do paciente contará com um mecanismo de segurança do tipo failsafe, mantendo o nível de saída restrito ao limite máximo previamente configurado pelo fonoaudiólogo no software de gerenciamento [11], [7].

Na etapa de alimentação, o circuito contará com um sistema de gerenciamento da carga associado à bateria recarregável, com mecanismos de proteção contra sobretensão, curto-circuito e aquecimento excessivo. Além disso, o módulo de radiofrequência associado à conectividade Bluetooth deverá incorporar medidas de blindagem e isolamento adequadas, a fim de minimizar a interferência eletromagnética e a indução de ruídos elétricos no circuito analógico de áudio [4].

Ou seja, sob a perspectiva da biossegurança e conformidade regulatória, a arquitetura de hardware e firmware incorpora mecanismos estritos de proteção auditiva para prevenir episódios de trauma acústico ou perda auditiva induzida por ruído [4]. A saída sonora no conduto auditivo é travada em um limite máximo de 80 dB SPL, impedindo que os ruídos causem lesões às células ciliadas da cóclea [4], [13].

CARACTERIZAÇÃO ELETROACÚSTICA:

Para a futura etapa de desenvolvimento e validação em bancada, foi estabelecido um plano de caracterização eletroacústica da cadeia de sinal. O protocolo prevê a análise do espectro de frequência dos sinais gerados pelos canais DAC de 8 bits do ESP32 e a determinação da Distorção Harmônica Total mais Ruído (THD+N), tanto na saída do circuito quanto no sinal encaminhado ao transdutor eletroacústico [3], [11].

A faixa de frequência de estimulação será previamente estabelecida entre 250 a 8000Hz, contemplando a faixa de interesse para a caracterização e o tratamento do zumbido. Os parâmetros de estimulação serão definidos individualmente pelo fonoaudiólogo no software de gerenciamento, de acordo com as características audiológicas e psicoacústicas de cada paciente [11], [5], [4].

ARQUITETURA DO SISTEMA (SOFTWARE DE GERENCIAMENTO E APLICATIVO):

A arquitetura do projeto propõe que as tarefas de processamento mais pesadas sejam transferidas para o smartphone do paciente (offloading computacional), permitindo a emissão de ruídos sem sobrecarregar ou gerar elevado consumo energético no dispositivo auricular.

Um esquema do funcionamento é apresentado nas figuras 1 e 2 a seguir.

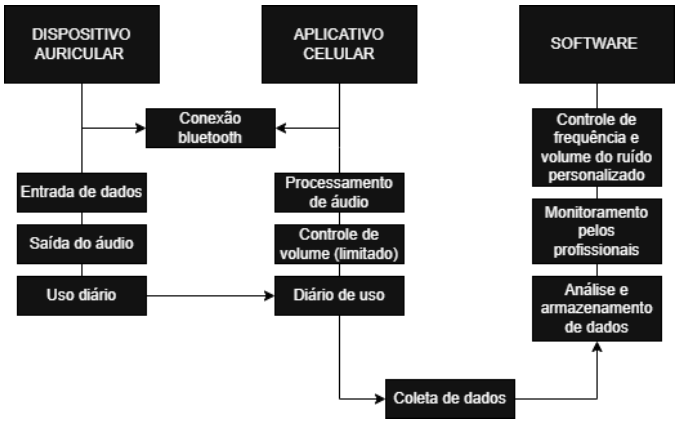

Fig. 1. Autoria própria - Diagrama de blocos da arquitetura do ecossistema assistivo, ilustrando a integração digital e fluxo de dados entre o dispositivo auricular, aplicativo e software.

Para a implementação do ecossistema, o software de gerenciamento será destinado aos profissionais envolvidos, incluindo engenheiros e fonoaudiólogos, para o acompanhamento dos testes e das sessões terapêuticas [8], [13], [7].

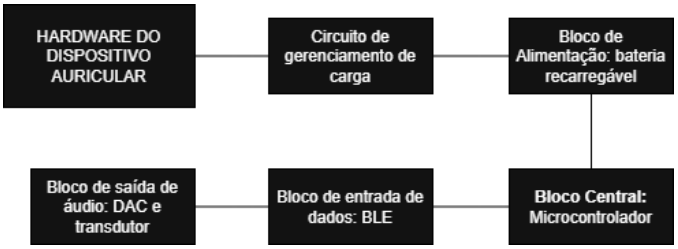

Fig. 2. Autoria Própria - Diagrama para representação do fluxo de funcionamento e arquitetura de hardware projetada para o dispositivo auricular

O módulo permitirá organizar, visualizar e ajustar as informações individuais relacionadas ao zumbido de cada paciente, além de configurar os arquivos de áudio e os parâmetros de estimulação sonora de acordo com as características clínicas e psicoacústicas identificadas.

Paralelamente, a arquitetura prevê o emprego de offloading computacional, transferindo para o smartphone do paciente as tarefas de maior demanda relacionadas ao processamento de áudio [13], [12], [11].

A aplicação permitirá ativar e desativar os estímulos, realizar o ajuste de volume dentro dos limites previamente configurados pelo profissional e registrar diariamente o uso do dispositivo e a percepção de incômodo relacionada ao zumbido. Esses dados serão armazenados em nuvem, possibilitando o acompanhamento longitudinal da utilização e das respostas do paciente ao longo das sessões terapêuticas [12], [6].

Ao transferir parte do processamento de sinais para o smartphone, o dispositivo auricular deverá apresentar menor demanda computacional e potencial redução do consumo energético, favorecendo sua autonomia durante o uso prolongado [11], [12].

O hardware auricular será composto por conectividade Bluetooth Low Energy (BLE), responsável pela comunicação com o smartphone, e terá como unidade central o microcontrolador ESP32, na variante miniaturizada ESP32-PICO-MINI. O sistema contará ainda com dois canais de conversão digital-analógica (DAC) para geração dos sinais, um transdutor eletroacústico de alta impedância e uma bateria recarregável dimensionada de acordo com os requisitos de autonomia estabelecidos para o uso terapêutico.

ENQUADRAMENTO REGULATÓRIO:

O projeto foi estruturado considerando o alinhamento com as normas de dispositivos médicos assistivos (RDC/ANVISA e ISO 13485) [8], [13].

Para o software e comunicação sem fio, será necessário seguir os requisitos da Lei Geral de Proteção de Dados (LGPD) ao implementar criptografia no protocolo BLE, autenticação de acesso na plataforma web e anonimização dos registros de saúde armazenados em nuvem.

III. RESULTADOS ESPERADOS E DISCUSSÕES

A análise da literatura possibilitou um embasamento teórico robusto para a definição dos parâmetros do sistema, demonstrando que a estimulação auditiva contínua com ruídos calibrados pode atuar com eficácia na modulação cortical e na habituação neural para redução do zumbido [8], [6].

Por se tratar de uma especificação de arquitetura e engenharia de requisitos, a discussão trata sobre a viabilidade e maturidade do projeto para o desenvolvimento físico.

Planejar a transferência do processamento de áudio para o aplicativo celular busca reduzir a carga computacional no microcontrolador ESP32, permitindo utilizar células de bateria menores e leves no hardware auricular, possibilitando dimensões reduzidas e o conforto durante o uso do dispositivo.

Além disso, a integração entre o acompanhamento profissional prévio e contínuo, a oliva de canal aberto (open-fit) e o gerenciamento prático pelo aplicativo celular visa reduzir as principais causas de abandono da terapia sonora relatadas na literatura médica: o desconforto induzido pela oclusão mecânica do conduto auditivo e a falta de acompanhamento clínico ao longo do tratamento [3], [6].

Com a arquitetura fundamentada, os próximos passos do projeto contemplam o desenvolvimento da Placa de Circuito Impresso (PCI) em software EDA e a fabricação dos protótipos para a realização dos ensaios de caracterização eletroacústica em bancada.

IV. CONCLUSÃO

A partir das análises e especificações realizadas, concluise que a modelagem arquitetônica apresentada fornece uma estrutura fundamentada para o futuro desenvolvimento de um dispositivo assistivo de baixo custo voltado para a Terapia de Habituação do Zumbido (TRT). O projeto visa alcançar um ecossistema que concilia um dispositivo auricular open-fit, um aplicativo móvel para o paciente e um software de gerenciamento para profissionais. Espera-se, então, por meio dessa tecnologia assistiva planejada, que conta com uma vasta multidisciplinaridade, proporcionar uma melhor qualidade de vida a um público não amplamente alcançado atualmente.

***Abstract*—Mental health disorders and psychological distress are highly prevalent among individuals undergoing medical treatment and may negatively affect treatment adherence, recovery, and quality of life. Exposure to green spaces and natural environments has been associated with improvements in psychological well-being and reductions in stress; however, evidence involving adults receiving medical care remains fragmented across clinical conditions and healthcare settings.**

This article presents the protocol for a systematic review aiming to evaluate the effects of direct contact with green spaces on mental health outcomes among adults under medical treatment. The protocol follows the Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols (PRISMA-P) recommendations and was prospectively registered in PROSPERO (CRD420261427698).

Initial searches in six databases identified 2,941 records, of which 1,788 remained after duplicate removal. Primary outcomes are perceived stress and psychological well-being. Methodological refinements introduced after protocol registration and screening initiation are being documented as protocol amendments and will be transparently reported in the final review.

The findings of this review may contribute to understanding green spaces as supportive healthcare environments and may support the development of nature-based strategies for mental health promotion and patient-centered healthcare design.

***Index Terms*—green spaces, mental health, nature exposure, stress, psychological well-being, healthcare environments, systematic review.**

I. Introduction

Mental disorders are among the leading causes of disability worldwide and constitute a major public health challenge. According to the World Health Organization, nearly one billion people live with mental disorders, and psychological distress contributes substantially to disability, reduced quality of life, and increased healthcare utilization [1]. Individuals undergoing medical treatment frequently experience elevated levels of stress, anxiety, emotional distress, and reduced psychological well-being, which may negatively affect treatment adherence, recovery, and clinical outcomes.

The healthcare environment itself may influence psychological responses during treatment. Hospitalization, chronic disease management, rehabilitation programs, and long-term medical follow-up may generate emotional burden and stress among patients. Consequently, complementary approaches capable of promoting psychological well-being and reducing psychological distress have received increasing attention.

Natural environments have emerged as potentially beneficial settings for health promotion. A study conducted in the 1980s investigating the relationship between healthcare environments and exposure to nature showed that postoperative patients with views of trees had shorter hospital stays and required fewer analgesics than patients whose rooms faced brick walls [2]. Since then, a growing body of evidence has suggested that contact with natural environments may contribute to psychological restoration and stress reduction.

Two major theoretical frameworks help explain these effects. Stress Reduction Theory proposes that natural environments promote psychophysiological recovery from stress through positive emotional and physiological responses [3]. Attention Restoration Theory suggests that natural environments facilitate recovery from mental fatigue and restore directed attention capacity [4]. These theoretical perspectives have substantially influenced research on restorative environments and therapeutic landscapes.

Exposure to green spaces, including parks, gardens, and forests, has been associated with multiple health benefits.

This work received no specific external funding.

Forest bathing and nature therapy have shown favorable physiological and psychological effects, including reductions in stress-related biomarkers and improvements in mood states [5], [6]. In addition, a broad systematic review and meta-analysis reported consistent associations between green-space exposure and improved health outcomes, including mental health indicators [7].

From an ecosystem-services perspective, natural environments may support mental health through different pathways, including stress reduction, social interaction, physical activity, attention restoration, and environmental quality [8]. These mechanisms may be particularly relevant to individuals undergoing medical treatment, who often experience physical and emotional vulnerability.

Despite the growing body of evidence, studies involving adults under medical treatment remain dispersed across different clinical conditions, healthcare settings, and types of nature exposure. Existing reviews often focus on healthy populations, community settings, specific age groups, or broad environmental exposures. Consequently, the role of direct contact with green spaces among adults receiving medical care remains insufficiently understood.

Furthermore, the incorporation of restorative environments, therapeutic gardens, and biophilic principles into healthcare facilities has attracted increasing interest in healthcare design and biomedical engineering. Understanding the effects of nature exposure on mental health outcomes may support the development of patient-centered care environments and contribute to evidence-based environmental interventions.

Therefore, this systematic review aims to synthesize the available evidence on the effects of direct contact with green spaces on mental health outcomes among adults under medical treatment.

II. Methods

A. Protocol and Registration

This protocol was developed in accordance with the Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols (PRISMA-P) statement [9]. The final systematic review will be conducted and reported in accordance with the PRISMA 2020 statement [10].

The review was registered in the International Prospective Register of Systematic Reviews (PROSPERO) under registration number CRD420261427698 [11]. Following registration and the initiation of screening, methodological refinements identified during implementation will be documented as justified protocol amendments.

B. Research Question

The review question was operationalized according to the PECOS framework (Population, Exposure, Comparator, Outcomes, and Study Design):

- Population: adults under medical treatment or follow-up in healthcare services.
- Exposure: direct contact with green spaces.
- Comparator: usual care, pre-intervention condition, or a concurrent comparator, when applicable.
- Outcomes: perceived stress and psychological well-being (primary), anxiety and depression (secondary).
- Study designs: RCTs with a comparator, controlled quasi-experimental studies, and uncontrolled pre-post studies, according to the methodological amendment.

The research question is:

What are the effects of direct contact with green spaces on mental health outcomes among adults under medical treatment?

C. Eligibility Criteria

Primary quantitative studies involving adults aged 18 to 64 years who are undergoing medical treatment or follow-up in healthcare services will be eligible for inclusion. Eligible healthcare settings include hospitals, outpatient clinics, rehabilitation centers, primary healthcare services, and other healthcare environments. This age range was defined to delimit the target adult population and reduce heterogeneity related to the clinical, functional, and healthcare characteristics of aging.

The exposure of interest consists of direct contact with green spaces, including:

- parks;
- gardens;
- therapeutic gardens;
- healing gardens;
- hospital gardens;
- forests;
- forest therapy;
- forest bathing.

Studies involving only virtual, simulated, or indirect exposure to nature, including photographs, videos, digital environments, or virtual reality, will be excluded.

Primary outcomes include:

- perceived stress;
- psychological well-being.

Primary outcomes will be assessed using validated instruments, including the Perceived Stress Scale (PSS) and the World Health Organization Five Well-Being Index (WHO-5).

Secondary outcomes include:

- anxiety;
- depression.

The following publication types will be excluded:

- reviews;
- editorials;
- conference abstracts without full text;
- case reports;
- case series;
- protocols.

Review articles, systematic reviews, and meta-analyses will be excluded from eligibility and used only for manual reference checking to identify potentially relevant primary studies not retrieved through the electronic searches.

Studies involving healthy populations, children, and adolescents will be excluded. Studies including participants aged 65 years or older will be eligible only when data for participants aged 18 to 64 years can be identified separately. Interventions centered on horticulture/therapeutic gardening or physical exercise in green spaces will also be excluded. Following PROSPERO registration and the initiation of screening, the study-design criteria were refined as a methodological amendment. The final synthesis will include RCTs with a comparator, controlled quasi-experimental studies, and uncontrolled pre-post studies; the latter will be analyzed separately and without causal attribution.

TABLE I
PECOS FRAMEWORK OF THE REVIEW

Component	Description
Population	Adults aged 18–64 years under treatment or follow-up in healthcare services.
Exposure	Direct contact with green spaces.
Comparator	Usual care, pre-intervention condition, or a concurrent comparator, when applicable.
Outcomes	Perceived stress, psychological well-being, anxiety, and depression.
Study designs	RCTs with a comparator, controlled quasi-experimental studies, and uncontrolled pre-post studies; refinement documented as an amendment.

D. Information Sources

Electronic searches were conducted in six databases:

- PubMed;
- Scopus;
- Embase;
- Web of Science Core Collection;
- Virtual Health Library (BVS);
- LILACS.

The searches were conducted between May and June 2026, with no restriction on publication year. Language restrictions were applied to English, Portuguese, and Spanish for operational feasibility, reflecting the languages in which the review team can independently and reliably assess full-text articles. The potential for language bias will be considered in the interpretation. No systematic search of the gray literature was planned because the review focuses on published and indexed primary studies with sufficient methodological information for critical appraisal. However, this decision may increase the risk of publication bias and will be acknowledged as a limitation. Relevant reviews will be used for manual reference checking of primary studies.

E. Search Strategy

The initial search combined controlled vocabulary and free-text terms related to three conceptual domains:

1) green spaces and nature exposure;
2) mental health outcomes;
3) adults receiving medical care.

The PubMed search strategy was:

(("Parks, Recreational"[Mesh] OR "Gardens"[Mesh] OR "Forests"[Mesh] OR "green space*"[tiab] OR "urban green space*"[tiab] OR "nature exposure"[tiab] OR "nature contact"[tiab] OR "natural environment*"[tiab] OR "therapeutic garden*"[tiab] OR "healing garden*"[tiab] OR "hospital garden*"[tiab] OR "forest therapy"[tiab] OR "forest bathing"[tiab] OR "shinrin-yoku"[tiab] OR "biophilic design"[tiab]) AND ("Mental Health"[Mesh] OR "Stress, Psychological"[Mesh] OR "Anxiety"[Mesh] OR "Depression"[Mesh] OR "mental health"[tiab] OR "mental well-being"[tiab] OR "psychological well-being"[tiab] OR "emotional well-being"[tiab] OR stress[tiab] OR "perceived stress"[tiab] OR "stress reduction"[tiab] OR anxiety[tiab] OR depression[tiab]) AND (patient*[tiab] OR "adult patient*"[tiab] OR "in medical treatment"[tiab] OR "medical care"[tiab] OR healthcare[tiab] OR hospitalized[tiab] OR hospitalised[tiab] OR inpatient*[tiab] OR outpatient*[tiab] OR ambulatory[tiab] OR "chronic disease"[tiab] OR "chronic illness"[tiab] OR cancer[tiab] OR oncology[tiab] OR rehabilitation[tiab] OR dialysis[tiab] OR "cardiac rehabilitation"[tiab] OR "cardiovascular disease"[tiab] OR diabetes[tiab]))

Equivalent strategies were adapted for Embase, Scopus, Web of Science, BVS, and LILACS according to the indexing characteristics of each database.

During review implementation, the sensitivity of this strategy began to be reassessed, particularly regarding the clinical condition/population block and the retrieval of previously known potentially relevant studies. Any search refinements will be documented as protocol amendments, with dates and justification, and will be fully reported in the final review, while clinical and age criteria will remain part of the eligibility assessment to preserve methodological traceability.

F. Study Selection

All records retrieved from the databases were imported into Rayyan for duplicate identification and study selection [12].

Study selection will be performed independently by two reviewers in two stages:

1) title and abstract screening;
2) full-text assessment.

Disagreements will initially be resolved through discussion and consensus between the reviewers. If consensus cannot be reached, disagreements will be resolved by the supervising researchers.

The two primary reviewers are:

- Fernanda Santos de Carvalho;
- Michelle Luciana de Sousa.

The reviewers responsible for resolving disagreements are:

- Aldira Guimarães Duarte Dominguez;
- Glécia Virgolino da Silva Luz.

G. Data Extraction

Data extraction will be performed independently by two reviewers using a standardized form.

The following variables will be collected:

- author and year;
- country;
- study design;
- participant characteristics;
- clinical condition;
- healthcare setting;
- type of green-space exposure;
- duration and frequency of exposure;
- outcome measures;
- assessment instruments;
- main findings.

Missing essential data will be recorded as not reported and, when feasible, study authors may be contacted; unreported results will not be imputed. Potentially overlapping publications will be compared according to authors, study location, recruitment period, and sample characteristics and, when they refer to the same population, will be treated as a single study unit.

TABLE II
VARIABLES EXTRACTED FROM ELIGIBLE STUDIES

Variable	Description
Author and year	Study identification
Country	Study location
Population	Participant characteristics
Clinical condition	Disease or treatment context
Exposure	Type of green space
Outcome	Mental health measures
Setting	Healthcare environment
Main findings	Main results

H. Risk of Bias Assessment

Methodological quality and risk of bias will be assessed independently by two reviewers using the appropriate Joanna Briggs Institute critical appraisal tools according to study design [13].

Risk-of-bias judgments will be considered during interpretation. Studies at higher risk will not be automatically excluded solely on this basis; when a sufficient number of comparable studies is available, sensitivity analyses may be performed.

I. Certainty of Evidence

The certainty of evidence will be assessed by outcome using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach, including secondary outcomes when sufficient evidence is available for synthesis [14].

The certainty of evidence will be classified as:

- high;
- moderate;
- low;
- very low.

J. Data Synthesis

The primary synthesis will be narrative and structured by study design: (1) randomized controlled trials with a comparator; (2) controlled quasi-experimental studies; and (3) uncontrolled pre-post studies. Within each group, clinical condition, healthcare setting, type and duration of exposure, and assessment instrument will be considered. Pre-post studies will be described using non-causal language.

Meta-analysis will be considered only when at least two studies are sufficiently comparable in terms of population, exposure, comparator, outcome, and assessment time point. The decision to pool studies will prioritize clinical and methodological compatibility in addition to statistical heterogeneity. When the number of studies permits, subgroup analyses by clinical condition, healthcare setting, and type of exposure may be explored; otherwise, a structured narrative synthesis will be maintained.

III. PRELIMINARY RESULTS

The electronic searches identified a total of 2,941 records across the six databases. After duplicate identification and removal using Rayyan, 1,153 duplicate records were excluded, resulting in 1,788 unique records for title and abstract screening.

Table III presents the number of records retrieved from each database. These figures correspond to the initial search and may be updated if sensitivity checking leads to refinement of the search strategy before the final synthesis.

TABLE III
RECORDS RETRIEVED FROM EACH DATABASE

Database	Records
PubMed	214
Scopus	659
Embase	581
Web of Science	812
BVS	646
LILACS	29
Total	2,941

The screening process is ongoing. The final study-selection process will be presented using the PRISMA 2020 flow diagram.

IV. IMPLICATIONS FOR BIOMEDICAL ENGINEERING

The potential contribution of this review to Biomedical Engineering lies in translating evidence on restorative environments into recommendations for healthcare-environment planning.

If supported by the final results, the findings may inform design guidelines for therapeutic and hospital gardens, criteria for incorporating natural elements into healthcare environments, clinical guidance on contact with green spaces as a therapeutic practice, and the development of patient-centered environmental technologies. The interface with soft technologies in health,

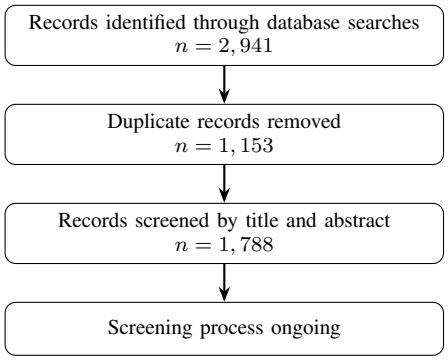

Fig. 1. Preliminary PRISMA flow diagram.

as conceptualized by Merhy and Franco [15], will be treated as a complementary dimension of care.

V. Methodological Challenges and Research Gaps

Heterogeneity is expected across clinical populations, environments and exposure protocols, psychological assessment instruments, and study designs with different levels of control. Another challenge is balancing search sensitivity and specificity: overly restrictive terms may omit relevant studies, whereas generic environmental terms may retrieve a large volume of irrelevant records.

A lack of standardization is also expected in reporting the duration, frequency, and intensity of contact with green spaces. These gaps will be mapped without anticipating conclusions regarding effectiveness, and clinical diversity will be treated as a source of heterogeneity rather than as evidence of a uniform effect.

VI. Discussion

This protocol was designed to synthesize a potentially heterogeneous body of literature. Organizing the evidence by study design will distinguish studies with concurrent comparators from pre-post studies. Interpretation will be proportional to the strength of the study design and risk of bias.

The breadth of clinical conditions increases the scope and relevance of the review but limits generalizability. Therefore, the synthesis will explicitly describe differences among populations, settings, and exposure modalities. Anticipated limitations include language restrictions and the absence of a systematic gray-literature search, with potential language and publication bias.

VII. Conclusion

This protocol describes a systematic review registered in PROSPERO and guided by PRISMA-P. Procedures have been defined for independent study selection, risk-of-bias assessment, certainty-of-evidence evaluation, management of heterogeneity, and assessment of search sensitivity. Conclusions regarding effectiveness and implications for healthcare-environment design will be formulated only after completion of the review.

Acknowledgment

The authors thank the Graduate Program in Biomedical Engineering at the University of Brasília for institutional support.

Resumo— **As próteses mioelétricas transradiais apresentam baixa adesão ao uso cotidiano, em grande parte, devido à ausência de realimentação somatossensorial. Este estudo propõe e avalia preliminarmente um protocolo de reabilitação baseado na realimentação de força por estimulação elétrica senoidal (ES). O protocolo envolveu a padronização da força de preensão em 30 participantes hígidos, a avaliação da instrumentação experimental e a codificação de quatro níveis de força por estimulação elétrica senoidal. Os níveis utilizados corresponderam a 5%, 20%, 35% e 50% da Contração Voluntária Máxima (CVM), por apresentarem conforto e reprodutibilidade sem causar fadiga. A ES de 3 kHz foi gerada por um estimulador elétrico, permitindo o controle combinado de amplitude e duração do *burst* para codificação dos níveis de força. Foram obtidas taxas médias de 87% para percepção de força e 88% para execução de força. A percepção apresentou melhora progressiva ao longo da sessão, atingindo 100% de acerto no último bloco do Teste de Retenção de Aprendizagem (TRA), o que sugere um processo de aprendizagem sensório-motora intrassessão. O Estímulo de 35% da CVM apresentou o menor desempenho relativo. Como perspectivas futuras, prevê-se a integração de sinais eletromiográficos (EMG), eletroencefalográficos (EEG) e mecanomiográficos (MMG), bem como a aplicação do protocolo em indivíduos com amputação transradial.**

Palavras-Chave— **Prótese mioelétrica, realimentação somatossensorial, controle de força de preensão, reabilitação.**

I. INTRODUÇÃO

As funções motoras desempenham papel fundamental na sobrevivência e na realização das atividades de vida cotidiana. Sua perda, decorrente de amputações traumáticas ou de doenças neuromusculares, compromete significativamente a independência funcional e a qualidade de vida dos indivíduos. Nesse contexto, tecnologias assistivas, especialmente as próteses mioelétricas, têm sido desenvolvidas para restaurar parcialmente a funcionalidade motora por meio da conversão de sinais eletrofisiológicos em comandos [1]. Estudos recentes indicam que o controle mioelétrico exige maior esforço cognitivo-motor do que alternativas mecânicas, o que reforça a necessidade de estratégias que facilitem a internalização desse tipo de controle pelo sistema nervoso [2]. Apesar dos avanços tecnológicos, a adesão ao uso cotidiano dessas próteses permanece limitada. Um dos principais fatores associados a essa baixa utilização é a escassez ou ausência de realimentação somatossensorial, o que impede o usuário de perceber adequadamente a força aplicada durante a manipulação de objetos [3]. Como consequência, a precisão das tarefas de preensão é reduzida, dificultando a execução de atividades de vida diária. Além disso, a falta de retorno sensorial compromete a incorporação da prótese à imagem corporal e é frequentemente apontada como uma das principais causas de abandono do dispositivo [4, 5]. Entre as estratégias investigadas para suprir essa lacuna, destaca-se a estimulação eletrotátil, que atua sobre mecanorreceptores via corrente controlada

na pele, ativando seletivamente fibras Aβ sem recrutar fibras nociceptivas [6]. Estudos demonstraram que é possível codificar até 13 sensações eletrotáteis distintas com acurácia superior a 85%, por meio da modulação combinada de parâmetros de pulso [7]. A ES senoidal de 3 kHz, em particular, tem demonstrado potencial para induzir sensações artificiais graduadas e modular oscilações corticais na banda alfa [8]. Essas características tornam a técnica promissora para a codificação de variáveis sensoriais, como a força de preensão, por meio da manipulação de parâmetros de amplitude e temporização dos *bursts* de estimulação. Com base nesse contexto, o presente trabalho propõe e avalia preliminarmente um protocolo de realimentação somatossensorial de força utilizando ES senoidal em participantes hígidos, como etapa preparatória para futuras aplicações em usuários de próteses mioelétricas transradiais. A hipótese central é que a ES senoidal seja capaz de codificar de forma confiável quatro níveis distintos de força de preensão por meio de combinações específicas de amplitude e parâmetros temporais dos *bursts* de estimulação. Dessa forma, espera-se que participantes hígidos consigam discriminar, reproduzir e reter esses níveis de força após uma única sessão de treinamento, mesmo na ausência de *biofeedback* visual. A confirmação dessa hipótese poderá fornecer subsídios para o desenvolvimento de sistemas de controle mioelétrico com realimentação sensorial aplicados a próteses mioelétricas transradiais.

II. Materiais e métodos

A. Participantes

Os critérios de inclusão compreenderam indivíduos com idade igual ou superior a 18 anos, sem comprometimentos cognitivos ou neuromusculares que pudessem interferir na execução das tarefas propostas. Foram excluídos participantes com doenças neuromusculares, alterações cognitivas, uso de medicações capazes de modificar a força muscular ou a sensibilidade somatossensorial, bem como condições associadas à degeneração sensorial, como diabetes mellitus e esclerose lateral amiotrófica (ELA). A elegibilidade foi verificada por meio de anamnese estruturada. Todos os participantes eram voluntários hígidos. O projeto foi aprovado sob o código CAEE 53366621.0.0000.5257 pelo comitê de ética em pesquisa do Hospital Clementino Fraga Filho (HUCFF - UFRJ) no dia 16/01/2022.

B. Equipamentos

O sistema de medição de força foi composto pelo Dinamômetro de Força Manual EMGSystem, selecionado em comparação preliminar com um dinamômetro de mão e pinça. O modelo adotado apresentou maior superfície de contato para preensão palmar, suporte integrado para o antebraço e maior estabilidade postural durante as coletas, sendo conectado a um computador para aquisição contínua dos dados de força.

A estimulação elétrica senoidal de 3 kHz foi gerada por um equipamento de neuroestimulação *Dual Channel Electrical Stimulato*r [9], utilizado como fonte de corrente controlada. O modo corrente é preferível ao modo tensão em aplicações de estimulação cutânea por ser independente da variação de impedância da pele, garantindo maior previsibilidade na carga elétrica efetivamente entregue aos tecidos [6]. O sistema permitiu o ajuste independente de amplitude e dos parâmetros temporais dos *bursts* (T-ON e T-OFF), essenciais para a codificação dos níveis de força.

A interface entre o estimulador e a pele foi realizada por eletrodos de ouro, cuja escolha se justifica pela baixa impedância de contato.

C. Força de Preensão

Esta seção descreve o protocolo de medição da força de preensão e a identificação dos níveis de força utilizados nas etapas subsequentes. Participaram 30 voluntários hígidos (19 homens e 11 mulheres). A dominância manual foi determinada pelo Inventário de Lateralidade de Edinburgh (EHI).

Cada participante realizou cinco contrações voluntárias máximas (CVM) de preensão utilizando o Dinamômetro de Força Manual EMGSystem, com intervalo de um minuto entre as tentativas e o cotovelo mantido a 90° de flexão. A CVM individual foi calculada pela média das cinco tentativas. A normalização pela CVM é procedimento consagrado na literatura para comparação entre indivíduos e controle da intensidade relativa do esforço [10].

A partir desses valores, foram avaliadas diferentes intensidades relativas de força. Os níveis correspondentes a 5%, 20%, 35% e 50% da CVM foram selecionados por apresentarem melhor equilíbrio entre conforto e capacidade de reprodução pelos participantes durante o tempo exigido pelo protocolo. Esses níveis permitiram a execução sustentada da tarefa sem indução significativa de fadiga, além de apresentarem diferenças perceptíveis entre si.

D. Configuração Experimental

Todos os experimentos foram conduzidos no Laboratório de Engenharia Neural (NTIEB/COPPE/CT – UFRJ), em ambiente com temperatura controlada (25 ± 1°C). O posicionamento dos participantes seguiu as recomendações da *American Society of Hand Therapists* (ASHT): quadris e joelhos flexionados a 90°, pés apoiados no solo, ombro em posição neutra, cotovelo flexionado a 90°, antebraço em posição neutra e punho entre 0° e 30° de extensão.

O membro utilizado para a instrumentação foi definido por meio de randomização computacional implementada em Python, utilizando geração de números equiprováveis: o valor 1 correspondia ao membro esquerdo e o valor 2 ao membro direito, garantindo igual probabilidade de seleção para cada participante. Esse membro segurava o dinamômetro conectado ao computador para aquisição dos dados de força, com a tela mantida fora do campo visual do participante. A randomização foi adotada para tornar o protocolo independente da lateralidade, considerando a futura aplicação em indivíduos com amputação transradial, nos quais a perda do membro pode ocorrer tanto no lado dominante quanto no não dominante.

E. Determinação do Limiar de Sensibilidade

Antes da associação entre estimulação elétrica e força de preensão, foi determinado individualmente o limiar de sensibilidade (LS) para a estimulação senoidal de 3 kHz. O procedimento foi composto por duas etapas [8]: inicialmente um protocolo de rampa, no qual a amplitude era progressivamente aumentada até a percepção do estímulo, definindo o Limiar Rampa (LR). Em seguida, foi aplicado um protocolo de rastreamento iniciado em LR/2, com incrementos de LR/4 quando não havia percepção e decrementos de LR/8 quando o estímulo era percebido, até atingir uma resolução final de 20 μA.

A frequência de 3 kHz foi selecionada por apresentar maior seletividade para fibras Aβ de grande calibre, com menor probabilidade de recrutar fibras nociceptivas ou produzir sensações dolorosas [8]. O LS foi utilizado como referência para definir as amplitudes empregadas na codificação dos níveis de força, permitindo calibrar a estimulação às características sensoriais de cada participante. As amplitudes utilizadas permaneceram dentro da faixa operacional do estimulador, cujo limite máximo de corrente é de 10 mA. Nenhum participante relatou dor ou desconforto significativo durante o protocolo.

F. Codificação dos Níveis de Força pelo Estímulo

Cada nível de força previamente definido foi associado a uma combinação específica de amplitude e duração do *burst* de estimulação (T-ON), mantendo-se constante o intervalo sem estímulo (T-OFF = 0,5 s): 5% da CVM (1,2 × LS; T-ON = 0,5 s), 20% da CVM (1,5 × LS; T-ON = 0,8 s), 35% da CVM (2,0 × LS; T-ON = 1,0 s) e 50% da CVM (2,5 × LS; T-ON = 1,2 s). A combinação simultânea de amplitude e duração foi adotada para ampliar a distinção perceptiva entre níveis adjacentes de força.

G. Protocolo de Treinamento

Após a calibração, os participantes realizaram 10 blocos de treinamento. Não foram realizadas tentativas adicionais de familiarização além dos blocos de treinamento descritos no protocolo. Em cada bloco, os quatro níveis de força foram apresentados em ordem crescente (5%, 20%, 35% e 50% da CVM), mantendo-se essa ordem em todos os blocos, sem contrabalanceamento. Para cada nível, o participante executava uma preensão sustentada de 20 s com auxílio de *biofeedback* visual exibido na tela do computador. O estímulo elétrico correspondente era aplicado durante os 10 s finais da tarefa.

H. Teste de Retenção de Aprendizagem (TRA)

Após um período de cinco minutos sem estimulação, previamente estabelecido como intervalo de retenção de curto prazo, foi realizado o Teste de Retenção de Aprendizagem (TRA), composto por cinco blocos. Diferentemente da etapa de treinamento, o TRA foi conduzido sem qualquer *biofeedback* visual. Em cada tentativa, um dos quatro estímulos elétricos previamente associados aos respectivos níveis de força durante o treinamento era apresentado durante os primeiros 10 s. A ordem de apresentação dos quatro estímulos em cada bloco foi definida por randomização computacional em Python, gerando permutações sem repetição dos quatro estímulos, de modo que cada estímulo fosse apresentado exatamente uma vez por bloco, em ordem imprevisível para o participante. Após a apresentação do estímulo, o participante deveria identificar qual estímulo havia recebido e, a partir da associação estabelecida durante o treinamento, indicar o nível de força correspondente. Nos 10 s subsequentes, sem estimulação, o participante deveria reproduzir a força associada ao estímulo apresentado.

Ao final de cada tentativa, o participante informava verbalmente o estímulo percebido e o respectivo nível de força associado, além de descrever a sensação experimentada. As sensações relatadas pelos participantes foram consistentemente descritas como vibrações de intensidade variável, correspondendo qualitativamente aos diferentes estímulos apresentados. Em seguida, o nível correto era informado pelo pesquisador como forma de *feedback*. Os pesquisadores responsáveis pela aplicação do protocolo não foram cegados quanto à ordem dos estímulos apresentados. O desempenho foi analisado segundo duas métricas principais: *(i)* percepção de força, definida como a identificação correta do estímulo apresentado e do nível de força a ele associado; e *(ii)* execução de força, definida como a reprodução correta da força correspondente ao estímulo apresentado, na ausência de *biofeedback* visual. Os resultados foram expressos como médias entre os participantes.

III. Resultados

Participaram do estudo 30 voluntários hígidos, sendo 19 homens (idade: 33,3 ± 11,9 anos; CVM: 35,9 ± 6,7 kgf) e 11 mulheres (idade: 34,3 ± 14,0 anos; CVM: 22,1 ± 6,7 kgf). A CVM média geral foi de 30,8 ± 9,4 kgf. Os valores foram obtidos de forma consistente entre os participantes, indicando a adequação dos quatro níveis de força selecionados (5%, 20%, 35% e 50% da CVM) para as etapas subsequentes.

Durante o protocolo de treinamento, todos os participantes completaram os 10 blocos sem intercorrências, não havendo desistências ou exclusões após o início do protocolo. O *biofeedback* visual foi progressivamente associado ao estímulo elétrico correspondente a cada nível de força, permitindo a familiarização com os parâmetros de codificação. Nenhum participante relatou desconforto significativo relacionado à estimulação ao longo das sessões.

As Tabelas I e II apresentam os resultados obtidos no TRA. A Tabela I apresenta a acurácia de Percepção de Força, definida como a identificação correta do estímulo apresentado e do nível de força a ele associado. A Tabela II apresenta a acurácia de Execução de Força, definida como a reprodução correta da força correspondente sem auxílio de *biofeedback* visual.

Médias						**87%**

TABELA II - *Acurácia de Execução de Força por nível de estímulo (linhas) ao longo dos cinco blocos (colunas).*

Estímulo	**Bloco 1**	**Bloco 2**	**Bloco 3**	**Bloco 4**	**Bloco 5**	**Total**
1	100%	100%	100%	100%	100%	**100%**

2	100%	66%	100%	100%	100%	**93%**
3	100%	66%	100%	66%	66%	**80%**
4	66%	66%	66%	100%	100%	**80%**
Médias						**88%**

Para a Percepção de Força (Tabela I), a média geral foi de 87%. O Estímulo 1 (5% da CVM) apresentou o maior desempenho global, atingindo 93% de acerto, enquanto o Estímulo 3 apresentou a menor acurácia total (80%). Observou-se melhora progressiva ao longo dos blocos de avaliação, com destaque para o Bloco 5, no qual todos os estímulos atingiram 100% de identificação correta.

Para a Execução de Força (Tabela II), a média geral foi de 88%. O Estímulo 1 apresentou desempenho máximo em todos os blocos, atingindo 100% de acerto total. Os Estímulos 3 e 4 apresentaram as menores médias gerais (80%), porém ambos demonstraram melhora ao longo do teste. O Estímulo 4 iniciou com 66% de acerto nos três primeiros blocos e atingiu 100% nos Blocos 4 e 5. De forma semelhante, o desempenho geral da execução manteve-se elevado ao longo do protocolo, atingindo 100% de acerto nos blocos finais para a maioria dos níveis de força.

IV. Discussão

Os resultados obtidos constituem uma avaliação preliminar da viabilidade do protocolo proposto. A padronização da força de preensão em 30 participantes permitiu estabelecer níveis de esforço confortáveis e reproduzíveis, em linha com valores de referência descritos na literatura para população adulta hígida [10], [11]. No TRA, a ES apresentou médias de acerto de 87% para Percepção de Força e 88% para Execução de Força, indicando capacidade preliminar de transmitir informações relacionadas à magnitude da força de preensão.

Na Percepção de Força, observou-se aumento da discriminação dos estímulos ao longo dos blocos, atingindo 100% de acerto no último bloco. Esse comportamento é compatível com uma possível aquisição de associações sensório-motoras de curto prazo [8], [12]. Entretanto, o *feedback* verbal fornecido após cada tentativa do TRA impede atribuir essa melhora exclusivamente às associações estabelecidas durante o treinamento. Os resultados também apresentam desempenho compatível com estudos de estimulação eletrotátil que demonstraram elevada capacidade de discriminação de diferentes padrões de estimulação [7], embora diferenças entre os protocolos devam ser consideradas.

O Estímulo 3 (35% da CVM), apresentou o menor desempenho, com 80% de acerto tanto para Percepção quanto para Execução de Força. Esse resultado pode estar relacionado a uma pista perceptiva menos distinta em relação aos níveis adjacentes ou à maior variabilidade do controle graduado da força em níveis intermediários [13]. Contudo, o delineamento não permite determinar a origem desse menor desempenho. Além disso, como amplitude e duração do *burst* foram modificadas simultaneamente, esses parâmetros podem ter atuado como pistas perceptivas para a identificação dos estímulos, não sendo possível determinar a contribuição individual de cada parâmetro para sua discriminação.

Algumas limitações devem ser consideradas. Embora a ordem dos estímulos no TRA tenha sido definida por randomização computacional, reduzindo a possibilidade de antecipação baseada na sequência, não se pode excluir a influência de expectativas decorrentes das associações estabelecidas durante o treinamento. Os pesquisadores também não foram cegados quanto à ordem dos estímulos, constituindo possível fonte de viés de observação. Durante o treinamento, os níveis de força foram apresentados em ordem fixa e crescente, sem contrabalanceamento, de modo que efeitos de ordem ou prática não podem ser completamente excluídos. A ausência de uma condição controle também limita a distinção entre os efeitos específicos da ES e aqueles decorrentes da prática e do *biofeedback* visual. O intervalo de cinco minutos sem estimulação entre o treinamento e o TRA caracteriza uma avaliação de retenção de curto prazo, não permitindo avaliar a manutenção das associações em períodos mais prolongados.

Os resultados do TRA foram preservados de forma agregada, não estando disponíveis registros individuais das respostas. Assim, análises retrospectivas em nível individual, incluindo matrizes de confusão, modelos de efeitos mistos, estimativas de tamanho de efeito e respectivos intervalos de confiança, não puderam ser realizadas. Os achados devem, portanto, ser interpretados como evidências descritivas e preliminares da viabilidade do protocolo.

Por fim, a avaliação foi realizada exclusivamente em participantes hígidos, não permitindo afirmar que os resultados se traduzam diretamente para usuários de próteses mioelétricas transradiais, nos quais alterações das vias sensoriais, sensações ou dor fantasma e a experiência decorrente do uso prolongado de próteses podem influenciar a percepção e o desempenho. Estudos

posteriores deverão incluir essa população e condições controle, além de investigar separadamente os parâmetros de estimulação por análises de sensibilidade e comparar a ES com modalidades vibrotáteis e mecanotáteis. A integração com registros de EMG, EEG e MMG também poderá contribuir para a investigação dos mecanismos neuromusculares e corticais envolvidos.

V. Conclusões

A combinação de amplitude e tempo de ativação do *burst* foi capaz de produzir estímulos perceptivamente discrimináveis associados a diferentes níveis de força, com médias de acerto de 87% para percepção e 88% para execução, fornecendo evidência preliminar de viabilidade do protocolo proposto. Assim, a principal contribuição deste estudo consiste na calibração e avaliação preliminar de um protocolo de realimentação somatossensorial que poderá subsidiar estudos posteriores em usuários de próteses mioelétricas transradiais. Como perspectivas futuras, o protocolo será integrado a registros de EMG, EEG e MMG, e posteriormente aplicado a indivíduos com amputação transradial, visando investigar os mecanismos neuromusculares e corticais associados ao desempenho e avaliar sua aplicabilidade clínica.

Agradecimentos

Os autores agradecem aos voluntários que participaram do estudo, à equipe do Laboratório de Engenharia Neural (NTIEB/COPPE/CT – UFRJ) pelo suporte, e às agências financiadoras CAPES (PROEX), CNPq, FAPERJ (E-26/204.393/2024) e FINEP (Convênio 01.24.0122.00).

***Abstract*—Automatic recognition of Libras can contribute to the development of more accessible technologies for the deaf community. In this work, a system was developed to classify nine isolated signs from videos. The MediaPipe Hands and MediaPipe Pose computer vision modules were used to detect and track landmarks on the hands and upper body. An LSTM (Long Short-Term Memory) network then analyzed the sequences of these points throughout the signs. Three input configurations were compared for the model: 171 coordinates provided directly by MediaPipe, 155 features related to hand configuration, its location relative to the body, and movement, and the combination of both representations, totaling 326 attributes per frame. In the evaluation, these representations achieved accuracies of 86.41%, 91.35%, and 93.82%, respectively, with the concatenated representation achieving the best performance, with a macro F1-score of 93.81%. The concatenated representation was integrated into a webcam-based application capable of automatically identifying the onset and offset of signs. The results show that the engineered features complement the MediaPipe coordinates and can support the development of future assistive technologies and communication interfaces between Libras and Portuguese.**

***Index Terms*—Brazilian Sign Language (Libras), sign language recognition, Long Short-Term Memory (LSTM), formational parameters.**

I. Introduction

Brazilian Sign Language (Libras) is fundamental to the autonomy, social participation, and access to information of the Brazilian deaf community. However, linguistic barriers still hinder communication in essential services, especially when interpreters or professionals proficient in Libras are unavailable [1]. For many users of this language, written Portuguese is acquired as a second language [2], which can make activities such as writing, reading, formulating questions, and understanding everyday, health-related, and public-service information more difficult [3]. Recently, with the advancement of assistive technologies, digital resources supporting communication and accessibility have been developed, although these resources are still not robust enough to replace interpreters or other forms of linguistic accessibility [4].

Different studies have investigated the development of applications that, with the aid of artificial intelligence and the use of cameras, enable the identification and recognition of sign languages. Wadhawan and Kumar observed that most of the systems developed focused on isolated, static, one-handed signs [5]. In the context of Libras, Silva et al. compared models capable of analyzing image sequences for the real-time recognition of three signs [6]. Samaan et al. used hand, body, and face landmarks to represent ten dynamic signs and track their execution throughout the video [7]. Varshini and Rukmani employed a similar approach in a webcam-based application to recognize 20 American Sign Language signs [8].

Although these studies demonstrate the feasibility of sign recognition using conventional cameras, they differ in terms of datasets, sign languages, and representations used. Silva et al. worked with three isolated Libras signs based on image sequences [6], while Samaan et al. used hand, body, and face landmarks to represent ten dynamic signs [7]. Varshini and Rukmani, in turn, employed landmarks in a webcam-based application for the recognition of 20 American Sign Language signs [8]. In addition to the differences in the number of signs and the language considered, these studies use different ways of representing information, such as image sequences and landmark coordinates. Consequently, their results do not allow a direct determination of which representation is most suitable for Libras recognition. On the other hand, engineered features can explicitly represent aspects of the sign, such as hand distances and angles, spatial relationships with the body, and movement trajectories, although they may omit information present in the original coordinates. This motivates the investigation of representations based on intrinsic characteristics of Sign Language, such as hand shape, signing location, and movement [9]. Representing these elements may help distinguish signs that share some of these parameters.

Given this, the objective of this work is to develop and

evaluate a system based on a Long Short-Term Memory (LSTM) neural network for the classification of nine isolated Libras signs. To investigate the influence of sign representation on model performance, three input forms are compared: 171 coordinates provided directly by MediaPipe, 155 features engineered from hand configuration, its position relative to the body, and movement, and a concatenated representation combining both, totaling 326 attributes per frame. In addition to the experimental evaluation, the concatenated representation is integrated into a webcam-based application, in which a state machine automatically identifies the onset and offset of each execution. This work thus seeks to evaluate the contribution of the different representations to sign classification and the feasibility of the system in real time.

II. Theoretical Background

A. MediaPipe Hands and MediaPipe Pose

MediaPipe is a computer vision framework designed for real-time image and video processing [10]. In this work, MediaPipe Hands and MediaPipe Pose were combined to extract reference points known as *landmarks*. These points correspond to anatomical positions identified in the image, such as finger joints, wrists, shoulders, and elbows, represented by spatial coordinates. MediaPipe Hands estimates 21 points per hand, with x, y, and z coordinates, in addition to tracking them across frames and identifying handedness [11]. MediaPipe Pose, based on BlazePose, estimates 33 body points, including references for the head, shoulders, arms, and torso [12]. The combination of both solutions makes it possible to represent hand configuration and its position relative to the body.

The use of landmarks reduces input dimensionality by replacing video pixels with structured coordinates, emphasizing the geometric and temporal relationships of the sign while reducing the influence of background and clothing. It also enables real-time processing with a conventional RGB camera, although landmark extraction may be affected by occlusions, hand overlap, rapid movements, inadequate lighting, and partial framing.

B. Long Short-Term Memory Networks

Dynamic signs depend on the temporal evolution of movements, making frame-by-frame analysis insufficient. RNNs process sequential information but may struggle with long-term dependencies due to vanishing and exploding gradients [13]. LSTM networks address these limitations through gated memory mechanisms that regulate which information is retained, updated, or discarded [14]. This makes them suitable for modeling the temporal sequences of MediaPipe landmarks used in this work [7].

In this work, the LSTM was chosen because the *landmarks* extracted by MediaPipe form sequences that describe the execution of the signs. While HS and LOC are mainly associated with the spatial relationships between the hands and the body, MOV depends on the changes observed across frames. Thus, MediaPipe provides the spatial representation, while the LSTM models its temporal evolution. The architecture and hyperparameters used are presented in the Methodology Section.

C. Formational Parameters of Libras

Libras has a visuospatial modality, in which information is produced by the hands, the body, and non-manual expressions. Stokoe was a pioneer in proposing that signs can be decomposed into sublexical units formed by Handshape, Location, and Movement [15]. Later, Battison incorporated palm orientation [16], and other studies recognized the participation of facial and body expressions. Thus, the description of Libras frequently considers five parameters: Handshape (HS), Location or Place of Articulation (LOC), Movement (MOV), Orientation (O), and Non-Manual Expressions (NME) [9], [17], [18]. Changes in one or more of these parameters can distinguish signs or modify their meanings.

HS corresponds to the shape and arrangement of the fingers; LOC indicates the region of the body or signing space where the hands are located; and MOV describes trajectory, direction, repetition, and displacement. Orientation represents the direction of the palm and fingers, while NME comprise movements of the face, head, and body with linguistic functions [17], [18]. As an example, Table I presents the decomposition of the signs LEARN and FAMILY according to the variants described in the consulted source.

TABLE I
Parametric description of Libras signs

Param.	**Signs**	
	LEARN	**FAMILY**
HS	Hand in C configuration	Both hands in F configuration
LOC	Forehead	Neutral space at chest height
MOV	Repeated opening and closing	Symmetric, semicircular movement, bringing the hands together
O	Palm oriented sideways	Palms facing each other
NME	Neutral expression	Dependent on communicative context

Source: Adapted from [20].

This work focuses on HS, LOC, and MOV due to their direct relationship with the geometric and temporal information obtained from the hands and body pose. These parameters guided the construction of descriptors based on distances, angles, spatial relationships, and landmark trajectories. The proposed representation does not constitute a direct linguistic annotation of the parameters, but rather a computational approximation of aspects associated with them, detailed in the Methodology Section.

III. Methodology

The methodology was organized into four stages: data acquisition and extraction, sign representation, model training and evaluation, and real-time application. Fig. 1 presents an overview of the developed process.

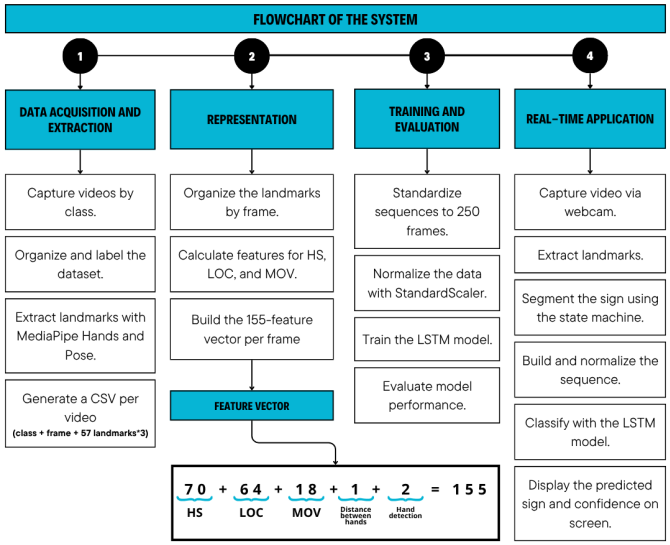

Fig. 1. Flowchart of the system stages.

TABLE II
SAMPLE DISTRIBUTION IN THE DATASET

Sign	Number of samples
Love	45
Learn	46
Study	45
I	56
Family	36
Man	54
Woman	55
Work	54
You	40
Total	**431**

A. Dataset construction and landmark extraction

The dataset was constructed with public YouTube videos and original recordings, the latter accounting for more than half of the samples. Signs with variations in Handshape, Location or Place of Articulation, and Movement were selected. The original recordings captured the upper body and were performed at a resolution of 1920×1080 pixels and a frame rate of 30 frames per second.

To expand the dataset, horizontally mirrored versions of the videos were generated. This augmentation was considered linguistically valid for the selected signs because their identity is preserved under laterality inversion: none of the selected signs specifies the dominant hand or presents a lateral asymmetry that would change the sign when mirrored, which is consistent with the parametric description of Libras signs [9], [17]. The mirroring procedure was applied to the entire dataset, resulting in additional samples while preserving the characteristics of the original executions. The final dataset comprised 431 samples, distributed as shown in Table II.

The videos were manually trimmed to contain only the execution of the sign, keeping all frames within the selected interval. Reading was performed with OpenCV, and each frame was converted to RGB before processing by MediaPipe.

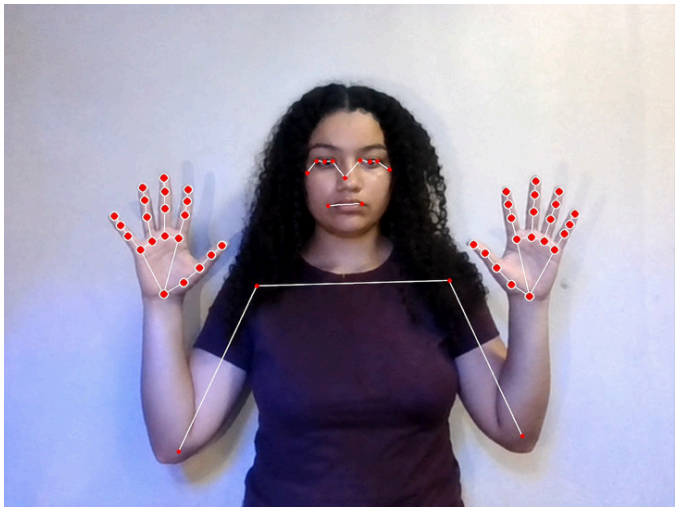

Fig. 2. Hand and pose *landmarks* selected for sign representation. 21 *landmarks* were extracted for each hand and 15 points pose. *Source: Authors' own elaboration.*

Extraction used MediaPipe Hands and MediaPipe Pose with minimum confidence thresholds of 50% for detection and tracking of reference points. 21 *landmarks* were extracted for each hand and 15 pose points, corresponding to indices 0 to 14, which include references for the face, shoulders, and elbows. These points can be better visualized in Fig. 2.

Each frame was represented by 57 *landmarks*, totaling 171 coordinates (x, y, z). When a hand or the pose was not detected, the corresponding values were filled with zeros. For each video, a CSV file was generated with one row per frame and 173 columns: the label, the frame index, and the 171 extracted coordinates.

B. Sign representation

Based on the landmarks, three input representations were evaluated. The first directly used the 171 coordinates extracted per frame. The second transformed these coordinates into 155 geometric and temporal features inspired by the HS, LOC, and MOV parameters. The third concatenated both representations, totaling 326 attributes per frame.

To represent HS, distances and angles between hand points were used, describing the arrangement of the fingers and their relationships with the wrist and thumb. LOC was represented by distances between the hands and pose references, such as the facial region, shoulders, and elbows. For MOV, frame-to-frame displacements and trajectory measures of the hand centroids were calculated, such as length, distance relative to the initial position, tortuosity, and convex hull properties.

The constructed vector contains 70 HS features, 64 LOC features, and 18 MOV features, in addition to the distance between the hands and two detection indicators, totaling 155 values per frame.

These features do not constitute a direct linguistic annotation, but rather a computational approximation of aspects associated with the formational parameters. Hand orientation

was not encoded separately, and non-manual expressions were not modeled.

C. Training and evaluation

Three input representations were compared: 171 raw coordinates, 155 engineered features, and the concatenation of both, with 326 attributes per frame. The dataset was stratified and split into 65% for training, 15% for validation, and 20% for testing, using random seed 42.

Due to the variable duration of the videos, the sequences were limited to 250 frames, considering the video with the longest duration. To standardize the length of the sequences, padding frames were added to samples with shorter duration, a process referred to as *padding*. For the 171- and 155-feature representations, -1 was used as padding, whereas -10 was adopted for the concatenated representation because -1 could coincide with valid values after processing. In both cases, a *Masking* layer identifies and ignores the padding frames during LSTM processing. In both cases, a *Masking* layer, that is, a mask applied to the network input, identifies the padding frames and disregards them during processing by the LSTM.

Each set of attributes was standardized using *StandardScaler*, a method that adjusts the data to have zero mean and unit standard deviation, reducing scale differences between features. This adjustment considered only the valid training frames and was subsequently applied to the validation and test sets. Frames added by *padding* retained the padding values. The labels were encoded in *one-hot* format, in which each class is represented by a binary vector, and class weights were employed to compensate for residual imbalance.

The architecture, kept the same across the three experiments, consisted of a *Masking* layer, responsible for identifying and disregarding the padding frames, followed by an LSTM with 64 units and two *Dropout* layers, which randomly deactivated 20% of the neurons during training, reducing the possibility of overfitting. This was followed by a dense layer with 64 neurons and ReLU activation, and a *softmax* output layer with nine neurons, corresponding to the classes. Training used the Adam optimizer, categorical cross-entropy as the loss function, batches of four samples, and up to 200 epochs. To reduce overfitting, *EarlyStopping* was employed, which stops training when the validation loss shows no improvement for ten epochs and restores the best weights. In addition, a *checkpoint* saved the model with the lowest validation loss.

D. Real-time application

The model based on the 326 features (concatenated representation) was integrated into an application for classifying signs captured via webcam, having been chosen because it presented the best experimental performance among the evaluated representations. The application was developed with OpenCV, a computer vision library used for image capture and processing, for acquiring frames from the webcam; with MediaPipe for detecting and tracking reference points; and with TensorFlow, a platform for developing and running machine learning models, for classifying the signs. The same trained model, class encoder, and normalizer used during training were employed.

The camera was configured to operate at 30 frames per second. The captured frames were horizontally mirrored, converted to the RGB color system, and processed by MediaPipe Hands and MediaPipe Pose, with thresholds of 50% for detection and tracking. To automatically segment the signs, a state machine was implemented based on the displacement of the hand centroids between consecutive frames, calculated as the Euclidean distance between the normalized coordinates provided by MediaPipe. When both hands were visible, the hand with the greater displacement per frame was considered; when only one was detected, the displacement of that hand was used.

For the operation of the state machine, states and events representing the stages of the capture process were defined. In the `WAITING` state, the system monitored displacement without storing frames. When the displacement reached the threshold of 0.025 per frame, the system transitioned to the `CAPTURING` state and began storing the *landmarks*. Capture was ended when the displacement remained less than or equal to 0.02 per frame for 12 consecutive frames (0.4 s), when both hands remained absent for eight consecutive frames (approximately 0.27 s), or when the sequence reached 250 frames (approximately 8.33 s).

Sequences with fewer than ten frames (approximately 0.33 s) generated the `DISCARDED` event and were ignored; the remaining sequences generated the `FINALIZE` event and were forwarded to the classifier. The *buffers* and counters were then reset, and the system returned to the `WAITING` state.

The stored *landmarks* were converted into the same 155 features used during training and concatenated with the 171 *landmark* coordinates. The resulting representation was normalized with *StandardScaler* and padded with vectors of value -10 until reaching 250 frames.

The resulting input was organized as a tensor of dimension $1\times250\times326$, corresponding, respectively, to a sequence of one sample, 250 frames, and 326 attributes per frame. This input was fed to the LSTM. The *softmax* output layer, responsible for producing a score for each of the nine classes, was used to determine the class corresponding to the highest score. The prediction was presented together with its score, expressed in the interval $[0, 1]$. Since no rejection threshold was adopted, every valid sequence was assigned one of the nine classes. The interface also displayed the capture state, the number of stored frames, and the *landmarks* detected in real time.

IV. Results and Discussion

A. Comparison of input representations

To evaluate the influence of sign representation on classifier performance, three input configurations were compared: raw coordinates, engineered features, and the concatenated representation. The three configurations were evaluated on the same test set, comprising 81 samples, while keeping the same LSTM architecture and the remaining training parameters unchanged.

Table III presents the overall accuracy and macro F1-score obtained for each representation, while Fig. 3 presents the respective confusion matrices.

TABLE III
PERFORMANCE OF THE REPRESENTATIONS ON THE TEST SET

Representation	Dim.	Accuracy (%)	Macro F1 (%)
Raw coordinates	171	86,41	85,93
Engineered features	155	91,35	91,61
Concatenated representation	326	93,82	93,81

The representation based on raw coordinates presented the lowest performance among the three configurations, with an accuracy of 86.41% and a macro F1-score of 85.93%. The main confusions occurred among the classes STUDY, MAN, and WOMAN, in addition to errors involving FAMILY and LEARN. With the use of the engineered features, accuracy increased to 91.35% and the macro F1-score to 91.61%, corresponding to gains of 4.94 and 5.68 percentage points, respectively. This result indicates that transforming the coordinates into features related to configuration, location, and movement provided more discriminative information for the classification process.

The concatenated representation presented the best performance among the three configurations, reaching 93.82% accuracy and 93.81% macro F1-score. Relative to the raw coordinates, gains of 7.41 percentage points in accuracy and 7.88 percentage points in macro F1-score were observed. When compared to the engineered features, the concatenated representation showed additional gains of 2.47 percentage points in accuracy and 2.20 percentage points in macro F1-score. This behavior suggests that the raw coordinates and the engineered features provide complementary information to the model: while the former directly preserve the spatial information of the reference points, the latter incorporate descriptors related to the formational parameters of the signs.

For the representation based on raw coordinates, 11 errors were observed in the test set. With the engineered features, this number was reduced to 7, while the concatenated representation presented only 5 errors. In this last configuration, the main confusions occurred between STUDY and LOVE, MAN and LEARN, MAN and STUDY, WOMAN and STUDY, and WORK and WOMAN. The concentration of errors in these classes indicates greater overlap among the feature patterns extracted for these signs.

B. Analysis by class

The individual analysis of the classes makes it possible to identify which signs present greater classification difficulty and which features may be related to the observed errors. Table IV presents the metrics obtained for each of the nine classes using the concatenated representation, which presented the best overall performance, with 93.82% accuracy and 93.81% macro F1-score.

The classes I, FAMILY, and YOU presented maximum performance across all metrics. LOVE, LEARN, and WORK

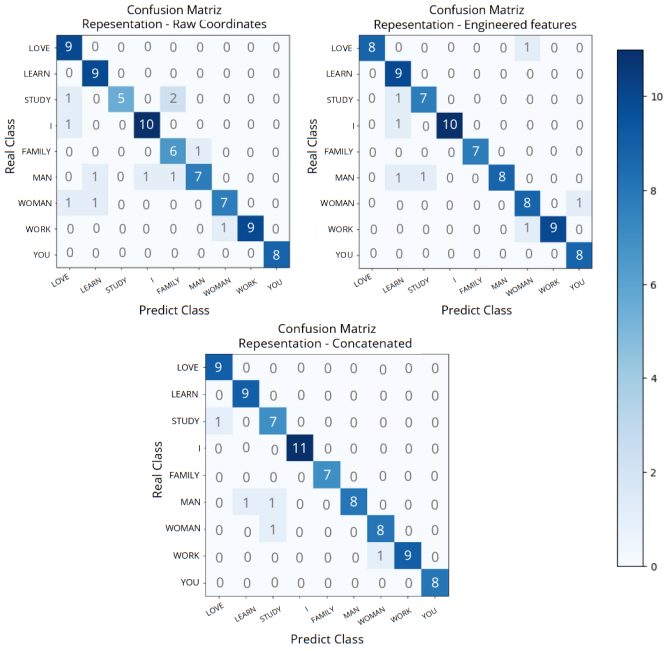

Fig. 3. Confusion matrices on the fixed-split test set for the three representations: raw coordinates, engineered features, and concatenated representation.

TABLE IV
PER-CLASS PERFORMANCE METRICS FOR THE CONCATENATED REPRESENTATION

Class	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
I	100.00	100.00	100.00	100.00
FAMILY	100.00	100.00	100.00	100.00
YOU	100.00	100.00	100.00	100.00
LOVE	98.77	90.00	100.00	94.74
LEARN	98.77	90.00	100.00	94.74
WORK	98.77	100.00	90.00	94.74
WOMAN	97.53	88.89	88.89	88.89
MAN	97.53	100.00	80.00	88.89
STUDY	96.30	77.78	87.50	82.35

also presented high performance, with an F1-score of 94.74%. The greatest difficulties were observed for STUDY, WOMAN, and MAN, with F1-scores of 82.35%, 88.89%, and 88.89%, respectively. These results are consistent with the confusion matrix, in which these classes appear among the ones most involved in the errors.

STUDY presented the lowest precision among the classes, at 77.78%, and a *recall* of 87.50%, indicating the occurrence of both samples from the class itself being assigned to other classes and false positives. MAN and WOMAN presented *recall* of 80.00% and 88.89%, respectively, showing that part of their samples were confused with other signs.

The main confusions may be related to the partial overlap of spatial and temporal features. Figure 4 presents some of the signs involved in these errors. It can be observed that I, LOVE, and MAN may present, at certain moments, a closed hand configuration directed toward the chest region, while STUDY is also performed in the upper body region, although it presents

Fig. 4. Visual representation of signs involved in the main confusions observed by the classifier. The sign names shown in the images correspond to EU [I], HOMEM [MAN], AMOR [LOVE], ESTUDAR [STUDY], and MULHER [WOMAN]. *Source: images b), c), and e) extracted from [19]; images a) and d) generated by Artificial Intelligence.*

differences in configuration and movement trajectory. This similarity may reduce separability between some classes. This is, however, a hypothesis, since the model does not provide explicit measures of the importance of these features.

Overall, the per-class analysis confirms the high performance of the concatenated representation, but shows that performance is not uniform across signs, especially for classes with greater similarity in their spatial and temporal patterns.

C. Generalization across signers

To evaluate the generalization capability for individuals not observed during training, a *cross-signer* experiment was conducted, in which one signer was used exclusively for testing. 16 repetitions of each of the nine signs were planned and, after processing, 141 samples were effectively evaluated. The model achieved 83.69% overall accuracy and 82.83% macro F1-score, compared to 93.82% and 93.81%, respectively, in the fixed split, corresponding to reductions of 10.13 and 10.98 percentage points.

Table V presents the per-class performance. Maximum performance is observed for LEARN, STUDY, FAMILY, and WORK, while MAN presented the lowest F1-score (31.58%), followed by I (60.38%) and LOVE (66.67%). For MAN, the low *recall* rate (18.75%) indicates that a large portion of the true samples were not recognized, while for I, the *recall* of 100.00% was accompanied by a precision of 43.24%, indicating a higher occurrence of false positives.

Overall, the performance reduction relative to the fixed split shows that variation between signers constitutes a challenge for the model's generalization, reinforcing the importance of datasets with greater signer diversity.

D. Feature ablation test

To evaluate the contribution of the different feature groups to classifier performance, an ablation test was conducted based on the engineered representation. Four configurations were evaluated: the complete model, containing 155 features, and three configurations obtained by individually removing the groups related to hand configuration (HS), location (LOC), and movement (MOV). The results are presented in Table VI.

TABLE V
PER-CLASS PERFORMANCE METRICS IN THE *cross-signer* EVALUATION

Class	Accuracy	Precision	Recall	F1-score
LEARN	100.00	100.00	100.00	100.00
STUDY	100.00	100.00	100.00	100.00
FAMILY	100.00	100.00	100.00	100.00
WORK	100.00	100.00	100.00	100.00
WOMAN	99.29	100.00	93.33	96.55
YOU	97.87	87.50	93.33	90.32
LOVE	94.33	100.00	50.00	66.67
I	85.11	43.24	100.00	60.38
MAN	90.78	100.00	18.75	31.58

TABLE VI
RESULTS OF THE FEATURE ABLATION TEST

Configuration	No. of features	Accuracy (%)	Macro F1 (%)
Complete	155	91.36	91.61
Without HS	85	71.60	72.51
Without LOC	90	86.42	86.49
Without MOV	137	91.36	91.86

TABLE VII
COMPARISON WITH RELATED WORK

Work	Model	Result
Silva et al. [6]	LSTM and Bi-LSTM	84.71% with LSTM
Samaan et al. [7]	MediaPipe with GRU, LSTM, and Bi-LSTM	100% with GRU
Alves et al. [22]	OpenPose and ResNet-18	93% on MINDS-Libras and 82% on LIBRAS-UFOP
Rego et al. [21]	MediaPipe and Bi-LSTM	$92\% \pm 3$
Varshini and Rukmani [8]	MediaPipe and LSTM	94.38% on the test set
This work	**LSTM with concatenated representation**	**93.82%**

Removing the hand configuration (HS) features produced the largest performance drop, with decreases of 19.76 percentage points in accuracy and 19.10 percentage points in macro F1 relative to the complete model. Removing the location (LOC) features also resulted in a reduction, although smaller, of 4.94 percentage points in accuracy and 5.12 percentage points in macro F1. On the other hand, removing the movement (MOV) features did not reduce accuracy and produced a positive change of 0.25 percentage points in macro F1.

The results indicate that, in the evaluated set, the HS features presented the greatest contribution to performance, followed by the LOC features, while the MOV features showed a smaller impact when removed in isolation. However, this comparison should be interpreted considering the distinct number of attributes in each group.

E. Comparison with the literature

Table VII presents a comparison between the results obtained in this work and those reported in related studies. The studies were selected because they present approaches based on *landmarks*, recurrent networks, or sign recognition strategies comparable to the one employed in this study.

The performance obtained falls within the range reported by studies based on landmarks and recurrent networks, such as Rego et al. and Alves et al. However, direct comparisons are limited by differences in the number of classes, signers, datasets, and evaluation protocols. Superior results, such as those of Samaan et al. and Varshini and Rukmani, should also be interpreted considering the acquisition conditions and splits of their respective datasets. In this context, the cross-signer result obtained in this work shows that generalization to new signers remains a challenge.

F. Real-time application evaluation

The real-time application was evaluated considering the state machine's ability to identify the onset and offset of executions, the occurrence of false triggers, and the classifier's inference latency. For the trigger evaluation, a signer remained in front of the application, with visualization of the classification result and the state machine states (*WAITING* and *CAPTURING*). 10 repetitions of each of the nine signs were requested, performed in a paused and individual manner, waiting for the return to the *WAITING* state before the start of the next execution. A second evaluator manually recorded, by means of a button, the onset and offset instants of each sign, taking into account in this procedure the reaction error associated with manual marking. A tolerance of ± 500 ms between the manual and automatic markings was adopted to consider the detection correct. After processing the records, 92 occurrences were considered in the comparison between the manual and automatic markings.

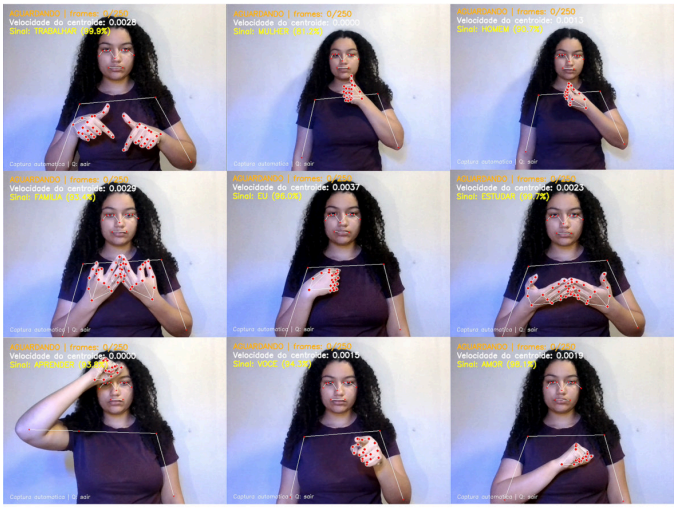

Fig. 5. Examples of real-time classification for the nine sign classes. The interface displays the detected *landmarks*, the predicted class, and the highest *softmax* probability. The interface labels are presented in Portuguese: *AGUARDANDO* [WAITING], *Sinal* [Sign], *Velocidade do centroide* [Centroid speed], *Captura automática* [Automatic capture], and *Q: sair* [Q: quit]. The predicted sign names shown in the images correspond to TRABALHAR [WORK], MULHER [WOMAN], HOMEM [MAN], FAMÍLIA [FAMILY], EU [I], ESTUDAR [STUDY], APRENDER [LEARN], VOCÊ [YOU], and AMOR [LOVE]. *Source: Authors' own elaboration.*

TABLE VIII
EVALUATION OF FALSE TRIGGERS UNDER DIFFERENT ACTIVITY CONDITIONS

Condition	**1**	**2**	**3**	**4**	**5**
Duration (min)	5.48	5.08	7.14	5.20	5.15
False triggers	0	36	17	38	78
Average speed/frame	0.0013	0.0092	0.0040	0.0084	0.0114
Average softmax output (%)	–	73.86	80.05	84.94	88.64

To evaluate the occurrence of false triggers, five activity blocks were performed, each with an approximate duration of five minutes. The first block corresponded to rest; the second, to everyday movements with no communicative intent, such as touching one's hair, touching the nose, scratching, and yawning; the third, to cell phone use; the fourth, to activities involving objects and hand movements close to the body, such as flipping through and reading a book, writing, holding a pen, and keeping a book close to the chest; and the fifth, to drinking water and performing natural movements of raising and lowering the hands, simulating displacement between the resting position and the sign execution region. The exact durations and the results obtained are presented in Table VIII.

In the trigger evaluation, the state machine presented a correct detection rate of 77.17%, considering the established tolerance. Among the detections considered correct, the mean error in identifying the onset was -132.6 ± 178.5 ms, and for the offset, 187.3 ± 212.0 ms. The negative sign in the first case indicates that, on average, capture began before the manual reference, while the positive value in the second indicates that termination occurred afterward.

In the false trigger evaluation, no activations were observed during rest. Among the other conditions, the highest occurrence was observed in the fifth block, with 78 activations, followed by the fourth, with 38. This result indicates that natural hand repositioning movements and activities performed close to the body may present sufficient characteristics to trigger the state machine, even without the intentional execution of a sign.

Inference latency was measured in an independent session, considering the interval between the classifier receiving the data and the emission of the class and its respective confidence. 194 predictions were analyzed, yielding an average latency of 50.5 ± 42.7 ms, with values ranging from 44.3 to 643.6 ms. This result indicates that the classifier's response time is short for most inferences, although occasional instances of higher latency were observed.

G. Limitations

This study has limitations that should be considered when interpreting the results. Although the horizontal mirroring used to expand the dataset is linguistically valid for the selected signs, samples derived from the same recording may not be

fully independent; since all input representations were evaluated on the same test set, however, any residual bias introduced by this augmentation is common to all configurations and does not compromise the relative comparison among them. The experimental evaluation relied on a single stratified split (81 test samples), and the *cross-signer* experiment involved a single held-out signer; absolute performance values should therefore be interpreted with caution, and cross-validation and *leave-one-signer-out* protocols constitute natural extensions of this evaluation. In addition, the real-time application did not include a rejection mechanism, favoring recall in automatic segmentation at the cost of false triggers — an acceptable trade-off for an exploratory assistive system, to be addressed through confidence-based rejection thresholds before deployment. Finally, the ablation test was conducted only on the engineered representation, since the formational-parameter groups (HS, LOC, and MOV) are semantically defined only in this configuration.

V. Conclusion

This work presented a system for the classification of isolated Libras signs using landmarks extracted by MediaPipe Hands and MediaPipe Pose, combined with features related to hand configuration, location, and movement, and classified by an LSTM network. Different data representations were evaluated, with the concatenated representation presenting the best performance, with 93.82% overall accuracy and 93.81% macro F1-score.

The per-class analysis showed that the model presented high performance for most signs, although some classes concentrated the classification errors. The *cross-signer* experiment presented 83.69% accuracy and 82.83% macro F1-score, showing a performance reduction when the model is applied to a signer not observed during training. The ablation test also indicated a greater contribution from the hand configuration features, whose removal resulted in the largest performance reduction among the evaluated groups.

In the real-time application, the state machine presented 77.17% of detections within the ± 500 ms tolerance, while the false trigger evaluation showed greater sensitivity to natural hand repositioning movements and activities performed close to the body. The average inference latency was 50.5 ms in an independent session, indicating a response time compatible with real-time operation, although occasional instances of higher latency were observed.

As future directions, the expansion of the dataset with greater diversity of signers and execution conditions stands out, as well as the improvement of automatic segmentation to reduce false triggers and improve the identification of sign boundaries. These advances can contribute to increasing the generalization capability and robustness of the system in usage scenarios closer to real applications.

***Abstract*—Sample-size planning is a prerequisite for confirmatory trials of rehabilitation technologies such as serious games, yet the parametric power formulas in common tools assume normality and an externally specified effect size—assumptions that cannot be verified in the small, non-normal pilots typical of this field and that mismatch the non-parametric tests usually planned for analysis. We describe a reproducible, distribution-free workflow that estimates statistical power by resampling pilot data with replacement and applying the planned Mann–Whitney U test, yielding power curves derived directly from the observed data structure. A compact Python implementation (fewer than 15 lines of core code, using only widely available scientific Python libraries, runnable in Google Colab) is provided in full. As a worked case study we use a non-randomised pilot of a serious-games motor–cognitive protocol versus conventional physiotherapy in 22 adults with Parkinson's disease (control n=10, experimental n=12). Across five outcomes, four reached $\geq 80\%$ power—strictly conditional on the pilot effect—at current sizes, whereas the six-minute walk test (6MWT) required $n \approx 24$ per group; every estimate carries a Monte Carlo confidence interval. We emphasise the central caveat: resampling removes distributional and test-mismatch problems but not the large effect-size uncertainty inherent to tiny, non-randomised pilots, so estimates must be read as conditional and buffered, and do not replace validation in a larger sample. Positioned within the development–validation–translation pathway of a marker-less serious-games system, the workflow offers a transparent, test-matched sample-size justification for confirmatory evaluation.**

***Index Terms*—statistical power, sample size, bootstrap, resampling, serious games, neurorehabilitation, Parkinson's disease, Mann–Whitney U, reproducible research**

I. Introduction

Serious games and exergames are increasingly used as rehabilitation technologies in movement and cognitive disorders, including Parkinson's disease (PD), where they target balance, mobility and executive function through engaging, sensor-mediated tasks [1]. Moving such a system from a feasibility pilot to a confirmatory randomised controlled trial (RCT) requires a defensible sample-size justification, increasingly expected by regulators, ethics committees and journals [2], [3]. For rehabilitation-engineering groups, this places a statistical bottleneck on the translational path of the technology they develop: a feasibility-validated device cannot progress to confirmatory evaluation without a credible recruitment target.

Standard power calculation—for example Cohen's d with normal-distribution assumptions, or dedicated software such as G*Power [4], [5]—requires the analyst to specify an expected effect size, a standard deviation, and a distributional family. In the small pilots typical of game-based rehabilitation ($n < 30$ per group), these quantities are estimated with high uncertainty and normality cannot be reliably tested [6]. Worse, the non-parametric tests appropriate for small, bounded, ceiling-prone outcomes—particularly the Mann–Whitney U test—are not directly supported by many parametric power tools, mismatching the calculation and the planned primary analysis.

Resampling-based power simulation offers a distribution-free alternative [7]. Instead of a parametric model, it uses the observed pilot data as a non-parametric estimate of the population distribution and simulates the power of the planned test by repeatedly resampling from that empirical distribution. In this sense the procedure generates synthetic data: each resample is a synthetic cohort drawn from the pilot's empirical distribution, and power is read off the planned test across these cohorts. This requires no distributional assumptions, naturally handles non-normal and bounded outcomes, and uses the same test that will be reported. It is important to state at the outset what the method does *not* do: because the pilot is small and non-randomised, the underlying effect size is itself estimated with substantial error, and resampling propagates—rather than removes—this uncertainty [8]–[10]. We therefore treat the resulting power estimates as conditional on the pilot, report their Monte Carlo precision explicitly, and stress that they are a planning aid rather than a substitute for validation in a larger, randomised sample.

This paper contributes: (1) a rationale for distribution-free power simulation in serious-games trials; (2) a complete, reproducible Python workflow using only widely available scientific libraries (`numpy`, `scipy`); (3) a worked PD case study for five outcomes with Monte Carlo intervals; and (4) a quantitative discussion of when the estimates are trustworthy, with recommendations for a confirmatory trial.

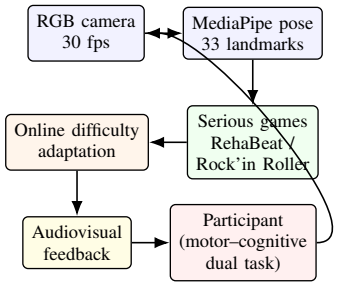

Fig. 1. Architecture of the ReabNet system. A standard webcam feed is converted to a 33-landmark whole-body pose by MediaPipe (BlazePose), in the browser; the pose drives the games, whose difficulty adapts online, closing a real-time audiovisual feedback loop. The bounded, dual-task, sensor-derived outcomes it produces are the non-normal variables the resampling workflow plans around.

II. Methods

A. Case Study Dataset and Intervention Context

We use data from a non-randomised controlled pilot trial comparing a serious-games motor–cognitive rehabilitation protocol with conventional physiotherapy in 22 adults with mild-to-moderate PD (control n=10, experimental n=12; Hoehn & Yahr stages 1–3; mean age 66.5 ± 7.9 years). Five outcomes were assessed: MoCA, Berg Balance Scale, six-minute walk test (6MWT), Trail Making Test Part A (TMT-A) and Digit Span Forward; pre–post change scores (Δ = post − pre) were the analytical variables. Ethical approval: UFU Research Ethics Committee (CAAE 83857524.7.0000.5152); the de-identified dataset and code are openly available [15]. The trial was *not* randomised and exhibited baseline imbalance (notably greater initial aerobic capacity in the experimental group); because change scores are analysed under this imbalance, the estimates carry a regression-to-the-mean risk whose implications are addressed in Sections III-C and IV-C.

B. Serious-Games Rehabilitation System and Protocol

The experimental intervention used ReabNet, a markerless serious-games platform for motor–cognitive rehabilitation (Fig. 1). Body motion is captured from an ordinary webcam and converted to a 33-landmark whole-body pose estimate in real time by MediaPipe (BlazePose) [14], running client-side in the browser; no markers or wearables are attached to the participant. Tracking accuracy was characterised against a Vicon optical reference (mean positional error 2.3 cm), adequate for game control. Two purpose-built games drive the therapy: RehaBeat, a rhythm game eliciting bilateral upper-limb reaching synchronised to audiovisual cues, and Rock'in Roller, a weight-shifting platform game eliciting medio-lateral and antero-posterior transfers, partial squats and lateral steps to train dynamic, closed-chain balance and anticipatory postural adjustments. Both embed a cognitive–motor dual-task component, and difficulty is adapted online from the hit rate of the last 50 actions (raised above 80%, lowered below 60%).

The experimental group completed 16 physiotherapist-supervised sessions over 8 weeks (two 50-min sessions/week: warm-up, RehaBeat 3×5 min, Rock'in Roller 3×5 min, cool-down); adherence exceeded 96%. The control group received dose-matched individualised physiotherapy (same frequency and length, without interactive technology).

TABLE I
Power-estimation approaches for small-sample rehabilitation trials.

Criterion	Param. (t)	G*Power	Sim. (normal)	Resampling
Distributional assumption	Normal	Normal	Specifiable	None (empir.)
Requires external effect size	Yes	Yes	Yes	No (data)
Suitable for $n < 30$/group	Poor	Poor	Partial	Yes
Matches non-param. test	No	No	Partial	Yes
Resolves effect-size unc.	No	No	No	No†

†No method overcomes effect-size imprecision from a small pilot; resampling makes this explicit and is paired with a buffer (Section III-C).

As Fig. 1 makes explicit, the outcomes that this system produces are bounded, dual-task and sensor-derived—exactly the non-normal, ceiling-prone variables for which parametric power formulas are least appropriate. This is where the contribution connects to biomedical engineering. ReabNet follows a development–validation–translation pathway, and the resampling workflow operates at the validation-to-translation interface: it converts the device's bounded, test-matched outcomes into a defensible recruitment target, so sample-size planning becomes an integral engineering deliverable of the platform rather than an external afterthought.

C. Resampling Power Simulation Algorithm

For a target per-group sample size n, N_{sim} pairs of bootstrap samples are drawn with replacement from the pilot data—one sample of size n from the control group and one from the experimental group. The planned Mann–Whitney U test is applied to each pair, and the proportion of replicates with $p < \alpha$ estimates power at n. Repeating across a grid of candidate sizes yields a power curve. Table I positions this approach against parametric and normal-simulation alternatives on the dimensions that matter for small rehabilitation samples.

D. Reproducible Python Implementation

The core routine accepts two pilot arrays and returns power across a range of sample sizes (Listing 1); it depends only on `numpy` and `scipy.stats` [13], both widely available in standard scientific Python environments.

Listing 1. Core resampling power-simulation function.

```
import numpy as np
from scipy import stats
def power_simulation(ctrl, exp, n_range=range(8,51,2),
                     n_sim=2000, alpha=0.05, seed=42):
    rng = np.random.default_rng(seed)
    powers = []
    for n in n_range:
        sig = 0
        for _ in range(n_sim):
            c = rng.choice(ctrl, size=n, replace=True)
            e = rng.choice(exp,  size=n, replace=True)
            _, p = stats.mannwhitneyu(e, c,
                        alternative='two-sided')
            sig += (p < alpha)
        powers.append(sig / n_sim)
```

TABLE II
PILOT EFFECT SIZE (RANK-BISERIAL r WITH CASE-RESAMPLING 95% CI) AND RESAMPLING POWER (%) PER OUTCOME ($N_{\text{SIM}} = 2{,}000$, SEED 42; MONTE CARLO 95% CI HALF-WIDTH $\leq \pm 2.2$ PP). POWER AT n=12, 20 IS SHOWN IN FIG. 2.

Outcome	r	95% CI	n=8	n=10	n@80%
MoCA	0.80	[0.51, 1.00]	89.7	96.8	< 8
Berg	0.90	[0.69, 1.00]	99.0	100.0	< 8
6MWT	0.44	[0.00, 0.88]	34.1	41.2	24
TMT-A	0.68	[0.33, 1.00]	75.0	85.0	10
Digit Span	0.66	[0.29, 1.00]	69.1	80.7	10

```
    return list(n_range), powers
```

The function is applied per outcome, and the minimum n reaching the target power is extracted; the complete multi-outcome driver and plotting code are in the repository [15].

E. Simulation Parameters and Uncertainty

We used n = 8–50 per group (step 2), $N_{\text{sim}} = 2{,}000$, $\alpha = 0.05$, a power target of 80%, and a fixed seed for reproducibility. The full run (22 sizes $\times$ 5 outcomes $\times$ 2,000 iterations) completes in $\approx$ 8 min on the Google Colab free tier.

Two distinct sources of uncertainty must be separated. The Monte Carlo error of a power estimate $\hat{\pi}$ is binomial, $\text{SE} = \sqrt{\hat{\pi}(1-\hat{\pi})/N_{\text{sim}}}$, which at $N_{\text{sim}} = 2{,}000$ never exceeds ± 2.2 percentage points (95%); this is controllable by increasing N_{sim}. For $\hat{\pi}$ near 0 or 1 the symmetric binomial interval is inaccurate, so near-ceiling estimates use Wilson score intervals, which are asymmetric and narrower toward the bound. The far larger and *irreducible* source is the sampling error of the effect size itself, inherited from the small pilot; this is not reflected in the Monte Carlo interval and is the basis for the conservative buffer recommended later.

F. Simulator Validation

Applied to normal data with a known effect (d=0.8), the routine tracked the analytical two-sample power within 4 percentage points across n=8–30, sitting slightly below it as expected from the relative efficiency of Mann–Whitney under normality. The simulator thus recovers the correct power when assumptions hold, isolating the pilot dependence as the only remaining source of error. Its bias and confidence-interval miscalibration across distributions, effect sizes and pilot sizes are characterised in a companion calibration study [16].

III. RESULTS

A. Power at the Current Sample Size

Table II reports power at selected sizes and the minimum n for 80% power. Conditional on the pilot effect, four outcomes (MoCA, Berg, TMT-A, Digit Span) were adequately powered at current sizes, whereas the 6MWT was underpowered (41.2%) and required $n \approx 24$ per group (N=48). The very high power of Berg and MoCA already at n=8 must be read with explicit caution (Section IV-C): in a small, non-randomised sample, a near-ceiling estimate is more plausibly

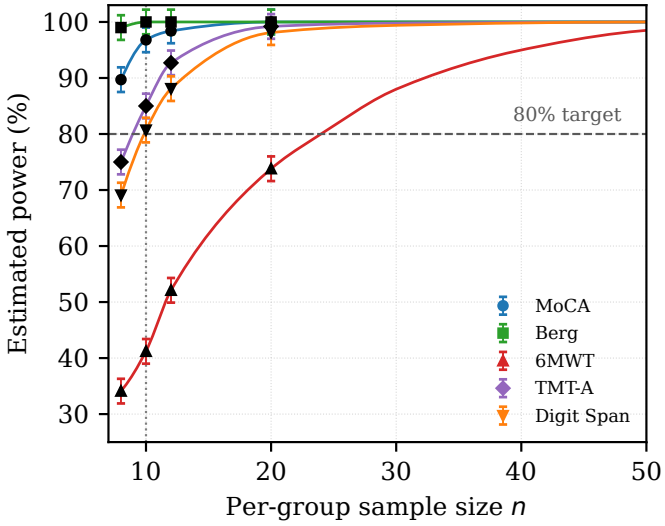

Fig. 2. Resampling-based power curves for five outcomes. Markers are simulated estimates at the reported sizes; whiskers are Monte Carlo 95% confidence intervals; connecting lines are monotone interpolation. Dashed line: 80% target; dotted line: current $n \approx 10$ per group. The 6MWT crosses 80% at $n \approx 24$.

a symptom of an over-stated pilot effect than evidence of a robust, replicable difference, and should not be reported as the latter. Table II lists these effects: r is large for the cognitive and balance scales (0.66–0.90) and moderate for the 6MWT (0.44), yet every 95% CI is wide—reaching the r=1 bound for the ceiling outcomes and down to ≈ 0 for the 6MWT. The decisive power of Berg and MoCA thus rests on effect estimates barely distinguishable from near-perfect separation: the quantitative basis for treating the power values as conditional.

B. Power Curves

Fig. 2 shows the five power curves with Monte Carlo confidence intervals. Cognitive and balance outcomes plateau near the ceiling at small n, consistent with strong ceiling effects in these bounded scales—but, as above, also with effect-size over-estimation in a tiny pilot. The 6MWT rises gradually without a plateau before $n \approx 24$; its monotone shape—rather than a flat curve near zero power—indicates a real but moderate effect, i.e. an underpowered rather than null result at the current size.

C. Implications for a Confirmatory Trial

The simulation supports the following plan for a confirmatory RCT. (1) Adopt the 6MWT as the primary endpoint. This choice is made on clinical and methodological grounds rather than because it is merely the power-limiting outcome: functional mobility measured by the 6MWT is a patient-relevant, guideline-endorsed target of gait/balance training in PD, has an established minimal clinically important difference [12], and is the least ceiling-prone of the five outcomes, so it best discriminates treatment response in a confirmatory setting. That it is also the outcome requiring the largest sample makes it the binding constraint for recruitment, which is convenient

but secondary to its clinical primacy. (2) Recruit $n = 24$ per group (N=48), with a 15–20% attrition and effect-uncertainty buffer (target N=56–58). (3) Retain MoCA, Berg, TMT-A and Digit Span as secondary endpoints, adequately powered at $n \geq 10$ per group conditional on the pilot effect.

Two safeguards follow from the pilot's weaknesses. Because it was non-randomised with baseline imbalance and used change scores, the confirmatory trial must randomise and pre-specify covariate adjustment (e.g. ANCOVA) to control regression to the mean [11]; the large effects on bounded scales may shrink once this is in place, a further reason to keep the buffer. These are planning estimates, not guarantees, and do not substitute for the larger, randomised validation they dimension.

IV. Discussion

A. What the Method Does—and Does Not—Solve

The workflow removes three problems of parametric planning: it makes no distributional assumption, requires no externally supplied effect size, and evaluates the exact non-parametric test to be reported—real advantages for bounded, ceiling-prone outcomes. However, it does not address the dominant limitation of any pilot-based plan: with $n = 10$–12 per group the effect size is estimated very imprecisely, and resampling treats the observed effect as if it were the truth [8], [9]. A second, method-specific caveat: resampling from only 10–12 distinct values cannot create variability beyond the observed support, so at larger candidate sizes the empirical distribution is reused rather than enriched and power near the bounds may be mildly optimistic. We therefore avoid describing the method as "assumption-free" in the colloquial sense: it is *distribution-free*, but it remains strongly conditional on the representativeness of the pilot. Consequently, near-ceiling power at very small n is best read as a signal of effect-size uncertainty, not of robustness—a behaviour characterised systematically in the companion calibration study [16]. We therefore report Monte Carlo intervals (bounding only simulation noise) separately from the buffer (which hedges the larger, unmodelled effect-size error).

B. Comparison with Parametric Calculation

For an approximately symmetric outcome such as MoCA, a Cohen's-d calculation from pilot moments yields power broadly comparable to the resampling estimate. For skewed, high-variance outcomes such as the 6MWT, parametric formulas tend to overstate power—where the distribution-free approach helps most, though neither escapes the imprecision of the pilot effect.

C. Limitations

First and foremost, power estimates are conditional on pilot composition; an atypical pilot biases them either way [10], and the small non-randomised design makes this more likely. We mitigate it with the buffer and by reporting every estimate as conditional. Second, the design was non-randomised with baseline imbalance, and between-group analysis of change scores under unequal baselines is vulnerable to regression to the mean [11]; within-group baseline–change correlations should therefore not be interpreted as treatment effect sizes, and the confirmatory trial should randomise and pre-specify covariate adjustment. Third, testing five outcomes raises multiplicity; the confirmatory design should pre-register one primary endpoint and control family-wise error. Fourth, the estimates are specific to the Mann–Whitney U test; another analysis (e.g. a mixed-effects model) requires re-running with that test—one line in Listing 1. Overall, the workflow should *dimension* a confirmatory study, not claim an effect is established.

V. Conclusion

Resampling-based power simulation is a practical, distribution-free and reproducible way to plan sample sizes for small trials of serious-games rehabilitation technologies, provided its estimates are read as conditional on the pilot. Applied to a PD pilot of a marker-less serious-games system, it identified four adequately powered secondary endpoints and one underpowered primary endpoint (6MWT), giving a concrete recommendation ($n = 24$ per group; $N = 48$, buffered to 56–58) for a confirmatory RCT. Its main value is transparency: it estimates power for the test actually planned and makes the dependence on the pilot effect explicit, so estimates are reported and buffered as conditional—never as a replacement for larger-sample validation. Embedded in the development–validation–translation pathway of a sensor-driven platform, it gives rehabilitation-engineering groups a test-matched element of pilot reporting when distributional assumptions cannot be verified and non-parametric analyses are planned.

***Abstract*—Hand gesture recognition from surface electromyography (sEMG) is a cornerstone of intuitive human–machine interfaces and myoelectric prosthesis control. This work presents *sEMGest*, an integrated and reproducible platform that spans custom acquisition hardware, a signal-processing and machine-learning pipeline, and a real-time three-dimensional digital twin of a prosthetic hand used for validation. A four-channel analog front-end based on INA333 instrumentation amplifiers and Sallen–Key active filters feeds an ESP32-S3 microcontroller sampling at 1 kHz with 12-bit resolution; the board was experimentally characterized, showing an approximate 25–540 Hz passband and a 49.5 µV RMS input-referred noise floor. Signals are band-pass filtered (20–500 Hz), segmented into 256 ms windows with 75% overlap, and described by the four time-domain features of the TD4 set. Three classifiers (linear discriminant analysis (LDA), a support vector machine with a radial basis function kernel (SVM-RBF), and random forest (RF)) were compared through grid search and cross-validation, first on the public NinaPro DB5 dataset and then on a proprietary two-participant dataset acquired with the developed hardware. Using repetition-grouped cross-validation, which prevents leakage between overlapping windows of the same repetition, SVM-RBF and RF are statistically tied intra-subject (macro-F1 0.69 on DB5; 0.53–0.60 on the proprietary data), whereas leave-one-subject-out evaluation collapses to 0.29–0.37, evidencing covariate shift and the need for per-user calibration; RF proves the most robust across subjects. The processing latency stays at 2.55 ms (95th percentile), so that the perceived response time is dominated by the 256 ms window-filling delay and remains within the 300 ms myoelectric-control budget. The digital twin renders the recognized gesture in real time, providing a hardware-independent tool for pipeline validation and, prospectively, user training.**

***Index Terms*—surface electromyography, hand gesture recognition, myoelectric prosthesis, digital twin, embedded systems, machine learning, real-time systems.**

I. Introduction

The human hand is among the most complex and versatile anatomical structures of the body, and the loss of an upper limb (by trauma, vascular disease or congenital causes) compromises daily activities and functional autonomy [1]. Myoelectric prostheses use surface electromyography (sEMG) as a control interface: electrodes placed over the skin capture the electrical potentials associated with muscle contraction and drive motorized actuators more directly than purely mechanical systems [5], [6]. Conventional myoelectric control relies mostly on signal amplitude and becomes insufficient when several functions must be controlled reliably; in contrast, pattern-recognition control infers the intended movement from features extracted from the sEMG, widening the command set and improving naturalness [3]. Nonetheless, upper-limb prosthesis abandonment rates between 23% and 45% are still reported, associated with insufficient perceived control and lack of naturalness [2], [4].

Two obstacles are particularly relevant. First, latency: delays above 100–125 ms start to degrade user performance in manipulation tasks and delays above 300 ms make control significantly harder [7], imposing a tight budget on acquisition, processing and classification. Second, robustness: classification performance measured under controlled laboratory conditions is hard to sustain in continuous use because of session variability, muscle fatigue and electrode repositioning [8]. Many systems are also validated only with specialized acquisition equipment and desktop processing, while reducing the number of channels (desirable for wearable devices) remains feasible when the pipeline is properly designed [9]. In parallel, the digital-twin concept, a virtual representation that mirrors a physical system in real time, has been explored in biomedical applications [11], [12] and, for prostheses, can validate control algorithms in a virtual environment before integration with hardware, while extended-reality interfaces support embodiment and training [10], [13].

This work proposes *sEMGest*, an integrated platform that combines sEMG acquisition, machine-learning gesture classification and a real-time digital twin, targeting practical applicability to upper-limb prosthesis control.[1] Its main contributions are:

- an **integrated and reproducible platform** joining a four-channel acquisition front-end (INA333, OPA4277 and ESP32-S3), a Python processing/classification pipeline

[1]Source code (processing pipeline, digital twin and trained models) is available at https://github.com/bmalinoski/sEMGest.

and a three-dimensional real-time visualization environment, in contrast with commercial black-box solutions;
- a **two-stage validation methodology**, first on the reference NinaPro DB5 dataset and then on a proprietary dataset acquired with the developed hardware;
- a **complete experimental characterization** of the hardware (per-channel frequency response, input-referred noise floor and end-to-end latency);
- **empirical evidence of covariate shift** across subjects and sessions, supporting a two-phase architecture with dedicated per-user models; and
- the application of a **digital twin** that renders the classified gesture in real time, acting both as a pipeline-validation instrument and as potential support for user training.

II. Related Work

Classical machine learning remains competitive for sEMG-based gesture recognition. Comparative studies report high intra-subject accuracy for LDA, SVM and RF [14]–[16], and time-domain feature sets are favored for their low computational cost and robustness in real-time pattern recognition [8], [17]. Segmentation parameters (window length, overlap and truncation) strongly influence performance and trade information for latency [18]. Public datasets such as NinaPro support reproducible benchmarking and setup comparison [19], [20], and embedded/real-time solutions with reduced acquisition have been demonstrated on prosthetic hands [21].

On the visualization side, extended-reality and virtual-prosthesis environments have been used mainly for training and embodiment, or, more recently, as myoelectric digital twins for fast and realistic modelling in deep-learning pipelines [10], [11], [13], [22]. In the present platform, the digital twin is coupled end-to-end with a custom low-cost front-end and is used online as a validation instrument for the full acquisition-to-decision chain, in addition to its role as a visualization and training aid.

III. Materials and Methods

A. System Overview

The platform is organized in three subsystems (Fig. 1): (i) a four-channel acquisition front-end with embedded firmware; (ii) a host processing pipeline in Python that performs digital filtering, segmentation, feature extraction and classification; and (iii) a digital twin that renders the classified gesture in real time. Evaluation followed two stages: pre-validation on NinaPro DB5 to establish an algorithmic performance ceiling, and validation on a proprietary dataset acquired with the developed hardware.

B. Acquisition Hardware

Each of the four channels implements a five-stage conditioning chain. An INA333 instrumentation amplifier (CJMCU-333 module, gain $2\times$) provides differential acquisition with high common-mode rejection, followed by a second-order Sallen–Key high-pass filter (20 Hz) and a second-order Sallen–Key low-pass filter (≈ 540 Hz) built with OPA4277 precision op-amps [23]. A non-inverting stage adds a fixed gain of $\approx 500\times$ (total chain gain $\approx 1000\times$), and a unity-gain subtractor centers the signal at 1.5 V to match the ADC input range. The board is powered by a battery through low-dropout regulators, with an on-board mid-supply reference biasing the analog chain. Digitization uses the 12-bit SAR ADC of an ESP32-S3 microcontroller at 1 kHz, obtained by $4\times$ oversampling of a 4 kHz timer. Electrode placement followed SENIAM recommendations [24].

The assembled printed circuit board was experimentally characterized (Fig. 2). The four channels showed a uniform passband of approximately 25–540 Hz, and the input-referred background noise, with inputs short-circuited and the system battery-powered, was 49.5 μV RMS. Considering that forearm sEMG amplitudes typically range from 100 to 500 μV [6], this noise floor is compatible with gesture recognition.

C. Embedded Firmware

The firmware runs on the ESP32-S3 under FreeRTOS. A high-resolution timer dispatches acquisition, and a set of second-order IIR biquads in Direct Form II Transposed applies a 20 Hz high-pass, a 480 Hz low-pass and a 60 Hz notch. Samples are packed into 15-byte binary frames with an XOR checksum and streamed to the host over USB-CDC.

D. Datasets and Acquisition Protocol

Pre-validation used the public NinaPro DB5 dataset (8-channel Myo armband, 200 Hz) [19], [20]. Seven classes were considered: rest and six functional gestures (closed fist, open hand, pinch, pointing, thumbs up and finger abduction).

The proprietary dataset was collected with the developed four-channel hardware from two participants: P1 (right-handed) and P2 (left-handed). To preserve an identical protocol, acquisition was always performed on the right forearm, which is the non-dominant limb for P2. Each gesture followed a cue schedule of 5 s of contraction and 3 s of rest, with 15 repetitions per gesture and participant. Windows were labeled by activity-envelope detection, which locates each contraction directly from the signal amplitude and thereby avoids the misalignment between the manually timed 5/3 s cue and the true contraction onset that a purely schedule-based labeling would introduce.

All experimental procedures involving human participants were conducted in accordance with the Declaration of Helsinki and approved by the Research Ethics Committee of the Federal University of Technology of Paraná (protocol no. 7.218.395). Both participants were members of the research team and provided written informed consent prior to data collection.

E. Signal Processing Pipeline

The host pipeline applies a 20–500 Hz band-pass filter and segments each channel into 256 ms windows with 75% overlap, parameters validated in the literature for real-time applications [18]. Each window is described by the four time-domain features of the TD4 set (MFL, MSR, WAMP and

Fig. 2: Experimental hardware characterization: (a) channel frequency response and (b) input-referred noise floor.

LS) [17], yielding 16 features per window (4 features $\times$ 4 channels). Features are normalized and class imbalance is mitigated by random undersampling of the majority (rest) class to the median of the minority classes.

F. Classifiers and Validation

Three classifiers were implemented with scikit-learn [25] and compared: LDA, SVM-RBF and RF. Hyperparameters were selected by nested grid search, and every cross-validation split, both the outer evaluation loop and the inner grid-search loop, was grouped by *repetition*, so that all windows originating from the same contraction stay in the same fold. This is essential because the 75% window overlap makes neighboring windows of one repetition nearly identical; a random split would place such near-duplicates in both training and test folds and inflate the scores. The intra-subject setting used repetition-grouped cross-validation computed *per subject* (each of the ten NinaPro DB5 subjects individually, and dedicated per-participant models for P1 and P2), reporting the mean and standard deviation across subjects. Cross-subject generalization used full Leave-One-Subject-Out (LOSO) over the ten DB5 subjects, rotating the held-out subject, and the two-direction LOSO between P1 and P2 on the proprietary dataset. For every protocol we report macro-F1, balanced accuracy, and a gesture-only macro-F1 (excluding the rest class), together with the exact per-class window counts and the proportion of rest in the test set.

G. Digital Twin

The digital twin materializes a virtual prosthetic hand that mirrors, in real time, the gesture predicted by the pipeline (Fig. 3). It was implemented in Python with a pygame event loop and legacy OpenGL (PyOpenGL) rendering, in a 1280×720 window split into a 3D viewport in the upper region and a signal panel showing the filtered EMG waveforms and per-channel RMS activation bars in the lower region.

The hand is a serial anthropomorphic kinematic chain of five fingers, with two joints for the thumb (MCP, IP) and three for each remaining finger (MCP, PIP, DIP), dimensioned from the proportions of the open-source OpenBionics model. Each gesture class is encoded as a vector of flexion and abduction joint angles, and phalanx positions are obtained by forward kinematics through the composition of homogeneous 4×4 transforms:

$$T_n = T_{\text{base}} \cdot \prod_{i=1}^{n} R_x(\theta_i)\, T_z(l_i), \tag{1}$$

where θ_i is the flexion angle of joint i, l_i the length of phalanx i, R_x a rotation about the x axis and T_z a translation along z. Bones are rendered as cylinders and joints as spheres, one color per finger. Transitions between successive poses are smoothed by a 200 ms *smoothstep* interpolation,

$$s(t) = t^2\,(3 - 2t), \quad t \in [0, 1], \tag{2}$$

applied to the joint angles to avoid abrupt motion of the 3D model.

The input layer follows a strategy pattern: a common interface abstracts three interchangeable sources feeding the same pipeline and renderer—a *replay* source that streams NinaPro DB5 recordings sample by sample, a *hardware* source fed by the four-channel USB-CDC stream of the ESP32-S3, and a *demo* source for manual pose inspection. A heads-up display overlays the classified gesture, its confidence, the classification latency and the frame rate, and the model can be rotated interactively for inspection. To suppress visual flicker when classifier confidence is low, the pose is updated only when the prediction exceeds a 90% confidence threshold—the previous pose is held otherwise, and the hand reverts to rest after a prolonged low-confidence interval. This acts as a low-cost persistence scheme in place of the heavier sliding-voting post-processing used elsewhere for output smoothing.

IV. Results and Discussion

A. Intra-Subject Classification on NinaPro DB5

Intra-subject performance was evaluated per subject and then averaged across the ten DB5 subjects. Crucially, the cross-validation folds are grouped by *repetition*: because the 256 ms windows overlap by 75%, neighboring windows of the same repetition are nearly identical, and a random split would place such near-duplicates in both the training and the test folds, measuring interpolation within a repetition rather than generalization to unseen repetitions. Grouping every window of a given repetition into the same fold (in both the outer loop and the inner grid-search loop) removes this optimistic bias. Under this protocol, SVM-RBF and RF are statistically tied, with macro-F1 of 0.691 ± 0.050 and 0.692 ± 0.051 respectively, both clearly ahead of LDA (0.656 ± 0.057); balanced accuracy follows the same ordering (Table I). The dispersion across subjects ($\sigma \approx 0.05$) reflects the genuine inter-individual variability of forearm sEMG.

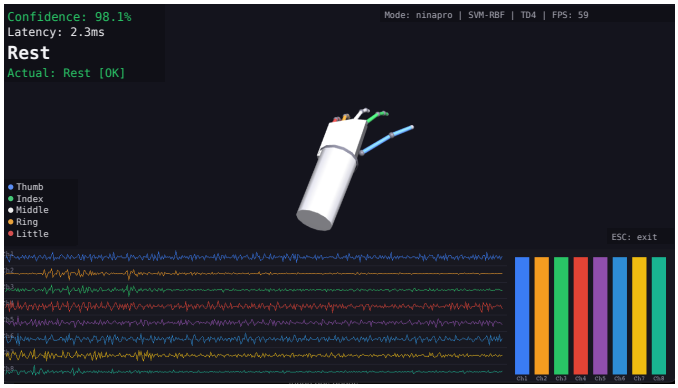

Fig. 3: Digital twin in operation, with the 3D viewport, the EMG signal panel with per-channel activation bars, and the informational HUD (classified gesture, confidence, latency and frame rate).

These figures are markedly lower than those obtained with a subject-aggregated, randomly split validation (macro-F1 up to 0.910), and the gap is precisely the inflation introduced by inter-window leakage between overlapping segments of the same repetition. The repetition-grouped values are therefore the ones that reflect deployment, where the model must classify contractions it has not seen during training. Across subjects, the residual errors concentrate between the lower-amplitude gestures and the rest class.

B. Results on the Proprietary Dataset

On the four-channel proprietary hardware, dedicated per-participant models were trained with the same repetition-grouped cross-validation. The classifier ordering seen on DB5 is preserved (Table I): RF and SVM-RBF are close, with RF marginally ahead (macro-F1 0.601 ± 0.033 vs. 0.590 ± 0.029 for P1; 0.528 ± 0.037 vs. 0.526 ± 0.054 for P2), and both clearly outperform LDA. Absolute values are lower than on DB5, consistent with a four-channel montage and a single acquisition session.

Fig. 4 shows the RF confusion matrix for P1. The dominant error is confusion between the gestures and the rest class in both directions: rest is recovered in only 44% of its windows, and pinch, the weakest gesture, in 51%, with about 31% of its windows assigned to rest. The higher-amplitude, topographically distinct gestures are recognized reliably (thumbs up 83%, finger abduction 78%, pointing 77%). This rest-boundary confusion, rather than confusion between biomechanically similar gesture pairs, is the main error mode on the four-channel montage.

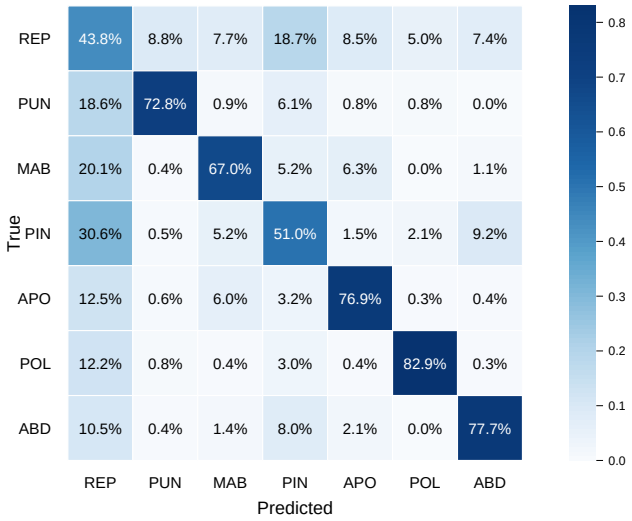

Fig. 4: Confusion matrix (true-class normalized) of the RF classifier for participant P1, from repetition-grouped cross-validation on the proprietary four-channel hardware. Classes: REP (rest), PUN (closed fist), MAB (open hand), PIN (pinch), APO (pointing), POL (thumbs up), ABD (finger abduction).

TABLE I: Repetition-Grouped Cross-Validation Results (Mean $\pm$ Std). Macro-F1 and Bal. Acc. are over all seven classes; F1 (gest.) is the macro-F1 over the six gestures, excluding rest.

Protocol	Clf.	Macro-F1	Bal. Acc.	F1 (gest.)
Intra-subject				
	LDA	0.656 ± 0.057	0.801 ± 0.066	0.611 ± 0.064
DB5	SVM-RBF	0.691 ± 0.050	0.829 ± 0.063	0.649 ± 0.058
	RF	0.692 ± 0.051	0.826 ± 0.061	0.650 ± 0.058
	LDA	0.495 ± 0.033	0.552 ± 0.045	0.510 ± 0.044
P1	SVM-RBF	0.590 ± 0.029	0.643 ± 0.041	0.603 ± 0.036
	RF	0.601 ± 0.033	0.657 ± 0.045	0.613 ± 0.042
	LDA	0.437 ± 0.031	0.492 ± 0.030	0.454 ± 0.032
P2	SVM-RBF	0.526 ± 0.054	0.565 ± 0.051	0.525 ± 0.059
	RF	0.528 ± 0.037	0.579 ± 0.037	0.529 ± 0.042
Inter-subject / inter-participant				
	LDA	0.360 ± 0.085	0.475 ± 0.119	0.275 ± 0.085
DB5 LOSO	SVM-RBF	0.288 ± 0.092	0.316 ± 0.118	0.180 ± 0.103
	RF	0.370 ± 0.106	0.474 ± 0.114	0.279 ± 0.113
	LDA	0.135	0.214	0.106
Own LOSO	SVM-RBF	0.168	0.210	0.132
	RF	0.228	0.278	0.191

The ≈ 6 percentage-point gap between P1 and P2, under identical hardware, pipeline and classifiers, is attributed to acquisition conditions rather than to the methodology. Two factors are consistent with the data: P2 is left-handed but was acquired on the right (non-dominant) forearm to preserve an identical protocol, which reduces the activation uniformity of the target muscles [26]; and a thicker layer of subcutaneous adipose tissue hindered palpation of the muscle bellies, suggesting slightly less precise electrode placement. The small participant count and single session place these figures at the level of a proof of concept rather than a population estimate.

C. Inter-Subject and Inter-Session Generalization

Generalization to unseen subjects was assessed by leave-one-subject-out (LOSO) over all ten DB5 subjects, rotating the held-out subject (Table I). Performance collapses relative to the intra-subject case: the best classifier reaches only 0.370 ± 0.106 macro-F1 (RF), against 0.692 intra-subject. Balanced accuracy tells the same story, and on the gesture-only subset (excluding rest) it falls to 0.18–0.28. Notably, the classifier ranking *inverts* with respect to the intra-subject setting: RF (0.370) and LDA (0.360) now lead, while SVM-RBF drops to 0.288. Raw accuracy is uninformative in this regime: with $\approx 92\%$ of the test windows being rest, SVM-RBF's 0.865 is in fact below the 0.923 of a trivial rest-only predictor, while its balanced accuracy of 0.316 exposes the poor gesture discrimination. The inter-participant LOSO on the proprietary dataset reproduces both the collapse and the inversion (RF 0.228 vs. SVM-RBF 0.168 macro-F1).

Two conclusions follow. First, the collapse is the expected signature of covariate shift (systematic mean and scale changes of the TD4 space across subjects, electrode placement and skin-electrode impedance) which violates the assumption that training and test share the same distribution [4], [8], and it motivates a two-phase architecture with an individualized calibration stage. Second, the flexible RBF boundaries that are competitive within a subject are the least robust across subjects, whereas the simpler decision surfaces of RF and LDA transfer slightly better, an argument for preferring RF as the deployed classifier, since it is both the best (tied) intra-subject and the most robust across subjects.

D. Real-Time Latency

The end-to-end responsiveness of the system is the sum of two contributions of different natures, summarized in Table II: a fixed *windowing* delay imposed by the segmentation scheme, and the *computation* time spent turning a window into a decision. The computation time (feature extraction, normalization and inference) was measured on the proprietary hardware over more than 1,000 consecutive classifications, yielding a mean of 1.79 ms and a 95th percentile of 2.55 ms. This term is negligible next to the windowing delay: because a decision can only be issued once a full 256 ms window is available, the first decision is inherently delayed by 256 ms, and subsequent decisions follow every 64 ms (the 25% step of a 256 ms window with 75% overlap). The serial transfer of each 15-byte frame over the native USB-CDC link adds a sub-millisecond term (one frame per millisecond at 1 kHz) that is likewise negligible. The 200 ms *smoothstep* pose interpolation is a visual animation applied after the decision and does not delay the classification.

The perceived latency is therefore dominated by the 256 ms window-filling delay rather than by computation, and the relevant figure for real-time control is this windowing term plus the few milliseconds of processing, within the 300 ms budget established for myoelectric prostheses by Farrell and Weir [7], although with a smaller margin than the 2.55 ms processing time alone would suggest.

TABLE II: End-to-End Latency Budget of the Real-Time Loop.

Stage	Contribution	Nature
Window filling (first decision)	256 ms	Structural
Inter-decision step (steady state)	64 ms	Structural
USB-CDC frame transfer	< 1 ms (est.)	Estimated
Feature extraction + inference (mean)	1.79 ms	Measured
Feature extraction + inference (p95)	2.55 ms	Measured
Pose interpolation (smoothstep)	200 ms (visual)	Animation

E. Digital-Twin Operation

The digital twin is the component that turns the pipeline into an interactive system, and it played two complementary roles in the evaluation. As a *paired visual-validation instrument*, fed in replay mode with restimulus-labeled DB5 windows from held-out subjects, its online accuracy matched the corresponding offline result within measurement margin, confirming that the streaming implementation faithfully reproduces the algorithmic behavior and ruling out buffer-synchronization or run-time feature-extraction bugs; it thereby complements the confusion matrices with a qualitative, temporal view of the classifier output. As an *online twin of the prosthetic hand*, fed by the four-channel USB-CDC stream, it anticipates the behavior expected once the trained model is embedded in a physical device, with transitions stabilized by the 200 ms smoothstep interpolation and the 90% confidence threshold.

Online operation with the proprietary hardware was evaluated qualitatively: because the target gestures were not logged synchronously, accuracy, macro-F1 and confusion matrices cannot be computed for this phase. Under visual inspection of the rendered pose, predictions oscillated among neighboring gestures (chiefly rest, pointing and open hand) more often than the offline cross-validation suggested, mainly because the exact electrode placement of the training session was not preserved between sessions: the same covariate-shift mechanism, now manifested within the same user across sessions. The confidence threshold and pose smoothing attenuated the visual flicker but did not remove the underlying degradation, reinforcing the need for a brief per-session recalibration. Beyond validation, this hardware-independent embodiment of the recognized gesture also provides a basis for user training and prosthesis-control prototyping before hardware integration, in line with virtual-prosthesis and extended-reality approaches reported in the literature [10], [13], [22].[2]

It should be made explicit what the digital twin mirrors in the present work: it reflects, in real time, the *intended gesture* inferred from the user's muscular activity, mapped onto the kinematic posture of a prosthetic-hand model. It does not yet model the mechanics or dynamics of a physical prosthesis (actuator response, contact forces or joint compliance) which would require a bidirectional coupling to an instrumented device. Establishing that physical, bidirectionally synchronized twin is left as future work; the current system is thus best understood as a real-time virtual hand serving as a validation and visualization instrument, and the user-training role is a prospect its architecture enables rather than a claim evaluated here.

[2]Demonstration videos of the system in real-time operation are available at: https://youtube.com/shorts/pkRm3E10lTw, https://youtube.com/shorts/_bxdrktQDjc and https://youtube.com/shorts/W6CeXGm7YlE.

F. Comparison with the Literature

Table III positions the results against representative sEMG gesture-classification works. Direct comparison requires caution, and not only for the usual differences in channels, dataset, number of gestures and protocol: many reported accuracies rely on randomly split windows, which, as shown above, inflate intra-subject scores when segments overlap. The repetition-grouped 0.69 macro-F1 reported here is therefore conservative by construction, and the more relevant message is the large intra-to-inter-subject gap, whose LOSO collapse reproduces the widely documented behavior of sEMG models without individual calibration [4], [8].

G. Limitations

Results must be read in light of the study's limitations. Pre-validation relied on NinaPro DB5, which differs from the target scenario in sampling rate (200 Hz vs. 1 kHz), number of channels (8 vs. 4), ADC resolution (8 vs. 12 bits) and sensor type; the reported numbers set an algorithmic ceiling, but effective performance still depends on acquisition quality. The proprietary collection comprises only two participants (both members of the research team) in a single session, without contractile-force control, professional anatomical assistance or preservation of electrode placement between sessions. The seven-class set also falls short of the ten or more grasps required by modern multifunction prostheses [19], and online performance was assessed only qualitatively.

H. Practical Implications and Clinical Applicability

Two findings carry the clearest practical weight. First, the intra-subject scores reported under repetition-grouped validation (≈ 0.69 on DB5) are a more realistic estimate of deployed behavior than the higher numbers common in the literature, and they set expectations accordingly: a low-cost four-channel platform is viable as an assistive and training tool, but not yet as a drop-in multifunction controller. Second, and more decisive for clinical use, the inter-subject collapse means a factory-trained, one-size-fits-all model is not usable; any deployment must include a short per-user (and, given the inter-session drift observed with the digital twin, per-session) calibration step, and should favor the more transfer-robust RF over SVM-RBF. For rehabilitation, the immediate value is less as a final prosthesis controller and more as an accessible platform for gesture-based training and biofeedback: the real-time virtual hand lets a user or therapist see the decoded intention without a physical device, and the open, reproducible hardware lowers the barrier for clinical research groups. Reaching routine clinical use would still require larger and more diverse cohorts, amputee participants, a richer grasp set, and the fast on-device calibration outlined above.

TABLE III: Comparison of the Results of this Work with the Literature.

Work	Channels	Gestures	Classifier	Result
Englehart & Hudgins [3]	4	4	LDA	$> 95\%$ acc.
Pizzolato *et al.* [19]	16	52	RF/SVM	70–92% acc. (DB5)
Dellacasa Bellingegni *et al.* [15]	6	7	SVM/LDA	30 amputees
Xue *et al.* [16]	–	10	RF	91.67% acc.
Yang *et al.* [21]	2	7	–	93% (real time)
Mendes Junior *et al.* [18]	8	6	SVM-RBF	$\approx$99% acc.
This work (DB5, intra, per subj.)	8	7	RF/SVM	0.69 macro-F1
This work (own hw., intra)	4	7	RF/SVM	0.53–0.60 macro-F1
This work (DB5, LOSO)	8	7	RF	0.37 macro-F1

V. Conclusion

This work proposed and implemented *sEMGest*, an integrated platform for hand gesture classification from sEMG comprising a four-channel acquisition front-end, a processing/classification pipeline and a real-time three-dimensional digital twin of a prosthetic hand. The hardware was experimentally characterized (25–540 Hz passband, 49.5 μV RMS input-referred noise). Under repetition-grouped cross-validation, RF and SVM-RBF tied intra-subject (macro-F1 ≈ 0.69 on NinaPro DB5, 0.53–0.60 on the proprietary hardware), with a processing latency of 2.55 ms at the 95th percentile and a perceived response time dominated by the 256 ms window-filling delay, within the 300 ms real-time budget. Inter-subject and inter-session evaluations revealed a collapse caused by covariate shift (with RF emerging as the most robust classifier across subjects) justifying a two-phase architecture with dedicated per-user models preceded by a calibration step. As a proof of concept with two participants and a qualitatively evaluated online stage, the results indicate the technical feasibility of the platform, with the digital twin serving as a hardware-independent instrument for pipeline validation and potential user training.

Future work includes enlarging the participant pool, developing a fast per-session calibration procedure and online incremental adaptation to mitigate covariate shift [27], [29], expanding the gesture set, integrating the classifier with a physical robotic hand, adding proportional force control [28], and instrumenting synchronous labeling to quantify online performance.

***Abstract*—This work investigates the efficacy of a control strategy to address the nonlinear and time-varying characteristics of hybrid FES/exoskeleton systems. The proposed approach relies on robust controller synthesis within a quasi-Linear Parameter Varying (quasi-LPV) framework, where the nonlinear dynamics are reformulated as a linear system whose state-space matrices vary as functions of state-dependent parameters. While similar control strategies have been successfully applied to underactuated manipulators, helicopters, and projectiles, their application to hybrid rehabilitation systems remains largely unexplored. Two control scenarios are analyzed: (i) when the varying parameter depends on both a muscle fatigue index and the musculoskeletal model; and (ii) when only the fatigue index evolves over time. Preliminary simulations on a human knee–exoskeleton model demonstrate that the proposed controllers regulate muscle activation via FES and robotic torque according to the muscle fatigue level, highlighting the potential of the approach for adaptive rehabilitation strategies.**

I. INTRODUCTION

Robotic rehabilitation involves a series of tasks focused on the motor recovery of individuals using robot-assisted devices [1]. Unlike traditional therapy, these robotic devices offer uniformity in repeating long-term routines, reliable recording of measured variables, and motivation for patient participation through interactive environments [2]. Under this premise, powered orthoses, robotic exoskeletons, and robotic platforms, in general, have been constantly improved due to the evolution of hardware and software technologies that address human-robot interaction challenges [3].

In these applications, ensuring safe interaction between humans and robots despite inter-subject variability is crucial. The uncertain nature of human dynamics complicates this task, compromising the stability of interaction control due to unpredictable and sudden movements of human joints [4] and [5].

The combination of robotic systems with muscle electrical stimulus, such as Functional Electrical Stimulation (FES), named as hybrid configuration, further complicates the interaction [4]. New parameters and variables, such as muscle fatigue and musculoskeletal model, add nonlinearity and time variability to the problem. To address these challenges, researchers have investigated the use of adaptive and nonlinear controllers. An adaptive hybrid controller was implemented for [6]. The *triadic collaboration* among a human, exoskeleton, and FES in gait rehabilitation was designed to overcome the challenges associated with muscle fatigue and the coordination of assistance provided by robotic devices and FES. The proposed controller automatically adapts the stimulation levels based on the patient's performance and muscle fatigue, prioritizing the patient's voluntary movements to encourage their active participation and enhance rehabilitation outcomes. In [4], iterative learning techniques are used to design a shared control of a hybrid powered exoskeleton and FES system, while in [7], the same research group presents a solution based on model predictive controller and dynamic control allocation.

In this paper, we investigate the feasibility of a novel control solution to deal with the nonlinearities and time-varying conditions of the hybrid FES/exoskeleton system. The proposed approach is based on robust controller synthesis for quasi-Linear Parameter Varying (quasi-LPV). The main idea is to represent the nonlinear system as a linear system where the matrices of the state-space model vary as function of given set of state-dependent parameters. This kind of control solution has already been applied to underactuated robotic manipulators [8], helicopters [9], and projectiles [10].

For our control problem, two cases are considered: in the first case, the varying parameter is defined as function of the muscle fatigue index and the musculoskeletal model; in the second one, only the fatigue index is assumed to vary over time. Preliminary results of the application of the proposed controllers in a knee human/exoskeleton simulated model show that the muscle activation associated with the FES and

the robot torque are automatically adjusted according to the level of muscle fatigue.

This paper is organized as follows: Section II describes the modeling of the hybrid FES/exoskeleton system, including the fatigue index and the musculoskeletal model; Section III presents the robust state-feedback controller design for LPV systems; Section IV the quasi-LPV representation of the hybrid FES/exoskeleton model; Section V presents the simulated results and a discussion about the feasibility of the proposed solution; Finally, conclusions are given in Section VI.

II. MODELING OF THE HYBRID FES/EXOSKELETON SYSTEM

The dynamic model of the hybrid FES/exoskeleton system is based on the right knee actuator of the exoskeleton Exo-TAO shown in Fig. 1. The rotary series elastic actuator (SEA), described in [11], can provide a torque-controlled actuation, and has been used to evaluate different robust control solutions, including model predictive [12] and Markovian [13] controllers.

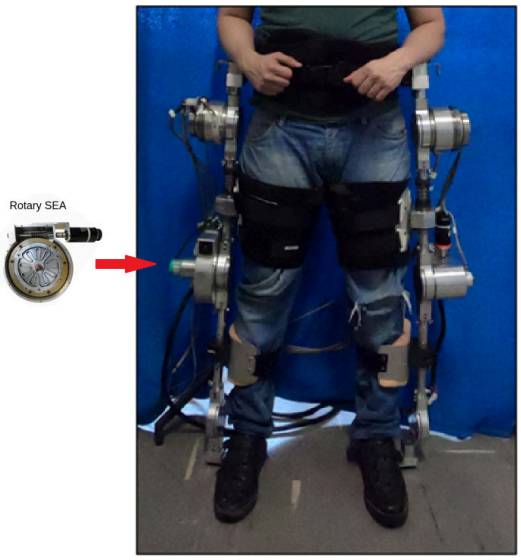

Fig. 1. Exoskeleton Exo-TAO, with the knee actuator.

Consider the following dynamic model:

$$M\ddot{q} + C\dot{q} + G(q) = \tau_r + \tau_f, \tag{1}$$

where q is the knee angle, M is the moment of inertia, $C\dot{q}$ is the torque generated by viscous damping, $G(q)$ is the torque due to gravity, and τ_r is the torque generated by the robot. The torque generated by the musculoskeletal system due to the application of FES, τ_f, is given by:

$$\tau_f = \sigma(q, \dot{q})\mu u_f,$$

where $\sigma(q, \dot{q})$ is the function corresponding to the musculoskeletal model, $u_f \in [0, 1]$ is the muscle activation induced by FES, and $\mu \in [\mu_{min}, 1]$ is the fatigue index that models muscle fatigue.

For the musculoskeletal model, we are considering a simplified muscle contraction model to compute the muscles forces, with active components depending only on muscle length and velocity, that is:

$$\sigma(q, \dot{q}) = f_A(\tilde{l}^m) f_V(\dot{\tilde{l}}^m) F_0^m cos(\phi) r^m,$$

where $f_A(\tilde{l}^m)$ is the normalized active force-length function, $f_V(\dot{\tilde{l}}^m)$ is the normalized force-velocity function, F_0^m is the maximum isometric force at optimal muscle fiber length l_o^m, r^m is the moment arm, $\tilde{l}^m$ is the normalized muscle fiber length, $\tilde{l}^m = \frac{l^m}{l_0^m}$, where l^m is the muscle fiber length, where ϕ is the angle between the orientation of muscle and tendon fibers, named pennation angle, which can be compute by:

$$\phi = arcsin\left(\frac{l_0^m sin\phi_0}{l^m}\right), \tag{2}$$

where ϕ_0 is the pennation angle at optimal fiber length. All musculoskeletal model's functions ($f_A(.)$ and $f_V(.)$) and parameters (F_0^m, l_0^m, and ϕ_0), for given values of q and $\dot{q}$, were obtained using the software OpenSim (version 4.4).

A. Fatigue Modeling and Estimation

The fatigue index is a mathematical representation employed to characterize the state of muscle fatigue during FES application [14]. The primary objective of this modeling is to assess the relationship between the level of muscle activation and the recovery process over time, under different intensities of electrical stimulation current. The dynamics of muscle fatigue are represented by the variable μ, which denotes the functional capacity of the muscle. When $\mu = 1$, the muscle operates under ideal conditions, without fatigue. Conversely, μ_{min} corresponds to the minimum level of muscle performance, below which functionality is substantially impaired. The temporal evolution of μ is described by the following differential equation:

$$\dot{\mu} = \frac{(\mu_{min} - \mu)u_f}{T_f} + \frac{(1 - \mu)(1 - u_f)}{T_r}, \tag{3}$$

where T_f is the time constant associated with muscle fatigue, determining the rate of decline of μ under continuous activation, and T_r is the recovery time constant, which governs the rate of muscle recovery when activation is suspended.

The fatigue index's parameters, T_f and T_r, can be obtained by the experimental methodology proposed by [14]. For the knee joint case, an experiment was conducted as shown in Fig. 2, where the setup includes a chair equipped with a force sensor attached to the subject's leg to measure the generated force. The stimulation signal comprises two parts: the first part is a constant stimulation lasting 180 seconds, followed by an intermittent stimulation with cycles of 10s of rest and 1s of activity. This pattern is repeated for an additional 180s, resulting in a total duration of 360s. This sequence aims to assess the effects of fatigue and subsequent muscle recovery. The protocol was approved by the University of São Paulo Ethics Committee (EEFERP-USP) under protocol No. 411150620.70000.5659 and decision statement

No. 4.579.836. Written informed consent was obtained from the participant.

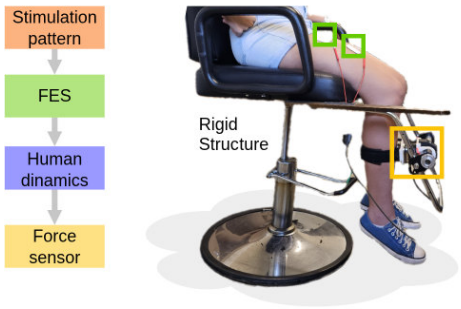

Fig. 2. Setup for muscle fatigue identification.

Initially, the force generated during the subject's maximum voluntary contraction is recorded. Immediately following this, the stimulation sequence is applied. This procedure is repeated three times across four different days to ensure the consistency and reliability of the collected data.

Figure 3 shows the behavior of muscle capacity to generate force in response to constant and discrete stimulation. At the top is the pulse width $P_w(t)$, and below, in gray, is the generated muscle force response. On the other hand, the fatigue index curve $\mu(t)$, is divided into two sections, the green line represents the decay of muscle fatigue caused by constant stimulation ($t < 180$s), and the orange line represents muscle recovery. The ranges of $\mu_(t)$ and T_h were normalized with the maximum voluntary force.

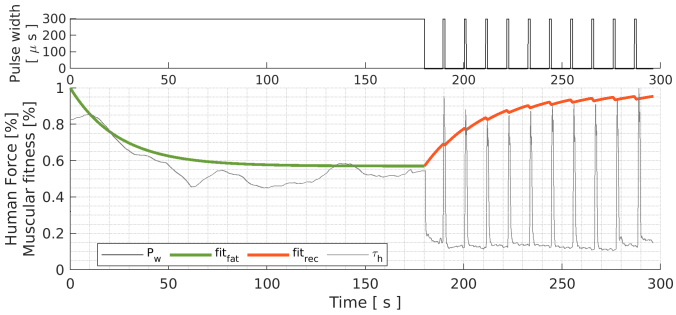

Fig. 3. Behavior of muscle capacity to generate force in response to constant and discrete stimulation.

Table I show the time constant associated with muscle fatigue, T_f and the recovery time constant, T_r, obtained considering the fatigue model, Eq. (3), and the experimental data.

TABLE I
TIME CONSTANTS FOR MUSCLE FATIGUE (T_f) AND RECOVERY (T_r)

Time constant	Value[s]
T_f	32.1
T_r	54.7

III. STATE FEEDBACK $\mathcal{H}_\infty$ CONTROL FOR QUASI-LPV SYSTEMS

Consider the following quasi-LPV model:

$$\begin{bmatrix} \dot{x} \\ z_1 \\ z_2 \end{bmatrix} = \begin{bmatrix} A(\rho(x)) & B_1(\rho(x)) & B_2(\rho(x)) \\ C_1(\rho(x)) & 0 & 0 \\ C_2(\rho(x)) & 0 & I \end{bmatrix} \begin{bmatrix} x \\ w \\ u \end{bmatrix}, \tag{4}$$

where x is the state vector, u is the control input vector, w is the external input vector, $z = [z_1\ z_2]^T$ is the output vector, and $\rho(x)$ is the parameter varying vector. Assume that the underlying parameter $\rho(x)$ varies in the allowable set:

$$F_P^\nu = \left\{\rho(x) \in \mathcal{C}^1(\Re^n, \Re^m) : \rho(x) \in P,\ |\dot{\rho}_i| \leq \nu_i\right\}, \tag{5}$$

for $i = 1, \ldots, k$, where $P \subset \Re^m$ is a compact set, $\nu = [\nu_1 \cdots \nu_m]^T$ with $\nu_i \geq 0$ and $\underline{\nu}_i(\rho) \leq \dot{\rho}_i \leq \overline{\nu}_i(\rho)$, $i = 1, \ldots, m$. We denote by $\mathcal{C}^1(\Re^n, \Re^m)$ the set of continuously differentiable functions that map $\Re^n$ to $\Re^m$. The state feedback control problem considered here aims at finding a continuous function $F(\rho)$ such that the closed loop system has an $\mathcal{L}_2$ gain less than or equal to γ, that is, $\int_0^T \|z(t)\|^2\, dt \leq \gamma^2 \int_0^T \|w(t)\|^2\, dt$, under a state feedback law $u = F(\rho)x$.

According to [15], if there exists a continuously differentiable matrix function $X(\rho(x)) > 0$ that satisfies:

$$\begin{bmatrix} E(\rho(x)) & X(\rho(x))C_1^T(\rho(x)) & B_1(\rho(x)) \\ C_1(\rho(x))X(\rho(x)) & -I & 0 \\ B_1^T(\rho(x)) & 0 & -\gamma^2 I \end{bmatrix} < 0, \tag{6}$$

where

$$E(\rho(x)) = -\sum_{i=1}^{m} \overline{\nu}_i(\rho) \frac{\partial X(\rho(x))}{\partial \rho_i} - B_2(\rho(x))B_2^T(\rho(x)) + \widehat{A}(\rho(x))X(\rho(x)) + X(\rho(x))\widehat{A}(\rho(x))^T$$

and $\widehat{A}(\rho(x)) = A(\rho(x)) - B_2(\rho(x))C_2(\rho(x))$, then the closed loop system has $\mathcal{L}_2$ gain $\leq \gamma$ under the state feedback control law, $u(t) = -K(\rho(x))x(t)$, where:

$$K(\rho(x)) = B_2^T(\rho(x))X^{-1}(\rho(x)) + C_2(\rho(x)). \tag{7}$$

A practical scheme was developed in [15] to compute these linear matrix inequalities based on basis functions related to the $X(\rho(x))$ and on the grid of the parameter set P. First we need to choose a set of $\mathcal{C}^1$ basis functions $\{\psi_i(\rho)\}_{i=1}^M$ for $X(\rho(x))$ in order to rewrite it as:

$$X(\rho(x)) = \sum_{i=1}^{M} \psi_i(\rho(x))X_i, \tag{8}$$

where $X_i \in S^{n\times n}$ is the coefficient matrix for $\psi_i(\rho(x))$. To solve this infinite dimensional optimization problem, we can grid the parameter set P along L points $\{\rho_k\}_{k=1}^L$ in each dimension. Since Equation (6) consists of 2^m entries, a total of $(2^m + 1)L^m$ matrix inequalities in terms of the matrices $\{X_i\}$ should be solved.

IV. QUASI-LPV REPRESENTATION OF THE HYBRID FES/EXOSKELETON MODEL

Considering the hybrid FES/exoskeleton model given by Eq. (1), and a given desired trajectory, q^d and its derivatives, the following state-space representation can be obtained:

$$\dot{x} = \begin{bmatrix} 0 & 1 \\ 0 & -\frac{C}{M} \end{bmatrix} x + \begin{bmatrix} 0 \\ \frac{1}{M} \end{bmatrix} w + \begin{bmatrix} 0 & 0 \\ \frac{1}{M} & \frac{\sigma(q,\dot{q})\mu}{M} \end{bmatrix} u \quad (9)$$

where $x = [q^d - q, \dot{q}^d - \dot{q}]^T$, $u = [-\tau_r + G(q), -u_f]^T$, and $w = M\ddot{q}^d + C\dot{q}^d$. Here, we are assuming the desired trajectory and its derivatives are bounded, so the disturbance w is also bounded.

Considering that the controller's gains are obtained from Eq. (7) as:

$$K(\rho(x)) = \begin{bmatrix} K_r & B_r \\ K_f & B_f \end{bmatrix},$$

the robotic control input is defined as:

$$\tau_r = K_r(q_d - q) + B_r(\dot{q}^d - \dot{q}) + G(q).$$

The FES control input is given by:

$$u_f = K_f(q_d - q) + B_f(\dot{q}^d - \dot{q}).$$

For the application of the quasi-lpv control described in Section III, two possible definitions for the variant parameter, $\rho(x)$ are considered, as in the cases below.

A. Case 1 - $\rho(x) = \sigma(q, \dot{q})\mu$

First, the varying parameter is defined as the combination of the musculoskeletal model and the fatigue index, that is, $\rho(x) = \sigma(q, \dot{q})\mu$, and Eq. (9) can be rewritten as:

$$\dot{x} = \underbrace{\begin{bmatrix} 0 & 1 \\ 0 & -\frac{C}{M} \end{bmatrix}}_{A} x + \underbrace{\begin{bmatrix} 0 \\ \frac{1}{M} \end{bmatrix}}_{B_1} w + \underbrace{\begin{bmatrix} 0 & 0 \\ \frac{1}{M} & \frac{\rho(x)}{M} \end{bmatrix}}_{B_2(\rho(x))} u. \quad (10)$$

We also consider the following matrices to complete the quasi-LPV model, Eq. (4): $C_1 = I_2$, and $C_2 = 0_2$.

B. Case 2 - $\rho(t) = \mu$

In this case, we assume that $\sigma(q, \dot{q}) = \bar{\sigma}$, where $\bar{\sigma}$ represents the average value of $\sigma(q, \dot{q})$ along the knee extension/flexion movement. In this case, the varying parameter is defined only as the fatigue index, i.e., $\rho(t) = \mu$, and Eq. (9) can be rewritten as:

$$\dot{x} = \underbrace{\begin{bmatrix} 0 & 1 \\ 0 & -\frac{C}{M} \end{bmatrix}}_{A} x + \underbrace{\begin{bmatrix} 0 \\ \frac{1}{M} \end{bmatrix}}_{B_1} w + \underbrace{\begin{bmatrix} 0 & 0 \\ \frac{1}{M} & \frac{\bar{\sigma}\rho(t)}{M} \end{bmatrix}}_{B_2(\rho(t))} u. \quad (11)$$

Actually, in this case, the system is considered as a LPV one, since the varying parameter depends only on the time. The controller's design procedure presented in Section III can also be applied to LPV systems.

V. RESULTS

This section presents the simulated results of the application of the proposed controllers to the knee actuator, considering the human is in a seated position, as shown in Fig. 4. The simulation was performed using Matlab, with data (mass, inertia, lengths, muscle parameters, etc.) obtained from the OpenSim software for a person with 75 kg.

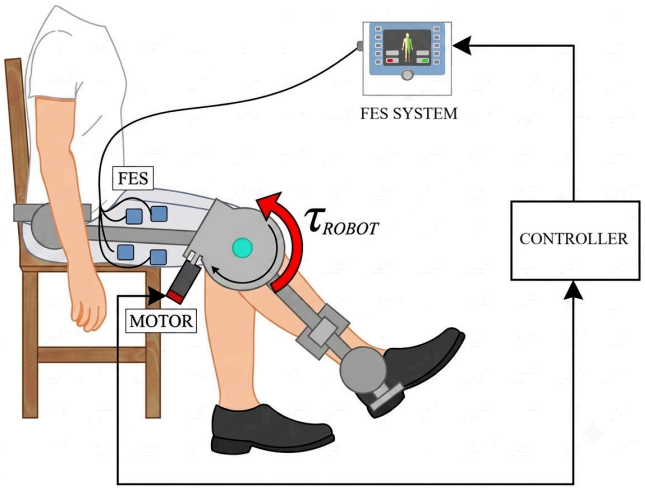

Fig. 4. Human/knee-exoskeleton system.

A. Case 1

For Case 1, the varying parameter is defined as the combination fo the musculoskeletal model and the fatigue index, that is, $\rho(x) = \sigma(q, \dot{q})\mu$. As shown in Section III, we need to grid the parameter set P along L points. Considering that the fatigue index, μ, can assume values in the set $\mu \in [0.2; 1]$, we defined 9 points to grid this parameter, that is, $\mu \in 0.2, 0.3, \cdots, 0.9, 1$. For the musculoskeletal model, $\sigma(q, \dot{q})$, we considered only the extension's muscular group (Rectus Femoris, Vastus Medialis, Vastus Lateralis). According to data provided by the OpenSim for an extension/flexion movement, $\sigma(q, \dot{q})$ varies from 10 to 40. For this function, we defined 7 points to grid this parameter that is, $\sigma(q, \dot{q}) \in 10, 15, \cdots, 35, 40$. Overall, it was defined 63 points to represent the variation of parameter $\rho(x)$. The basis functions were defined as $\psi_1 = 1$ and $\psi_2 = \sigma(q, \dot{q})\mu$.

B. Case 2

For Case 2, we defined $\bar{\sigma} = 25$, representing the average value of $\sigma(q, \dot{q})$ along the knee extension/flexion movement. Since, in this case, $\rho(x) = \mu$, we again defined 9 points to grid this parameter, that is, $\mu \in 0.2, 0.3, \cdots, 0.9, 1$. The basis functions were now defined as $\psi_1 = 1$ and $\psi_2 = \mu$.

C. Simulation Conditions

The desired trajectory to be followed by the human/exoskeleton system is a sinusoidal function with peak-to-peak amplitude of 90°, representing the flexion and extension of the knee, with a frequency of $0.5Hz$, that is, the extension/flexion movement takes 2 seconds.

To highlight the effect of the quasi-LPV controller for different conditions of muscle fatigue, the muscle recovery was not considered in the simulation, that is, the recover constant, T_r, was assumed to have a high value. Additionally, the time constant associated with muscle fatigue was assumed to be small, T_f = 0.2 s. This constitutes an artificially imposed stress scenario that does not accurately reflect physiological conditions. Consequently, the fatigue indicator, μ, decreases rapidly from 1 to approximately 0.5. Figure 5 shows the values of the fatigue index, μ, for Cases 1 and 2.

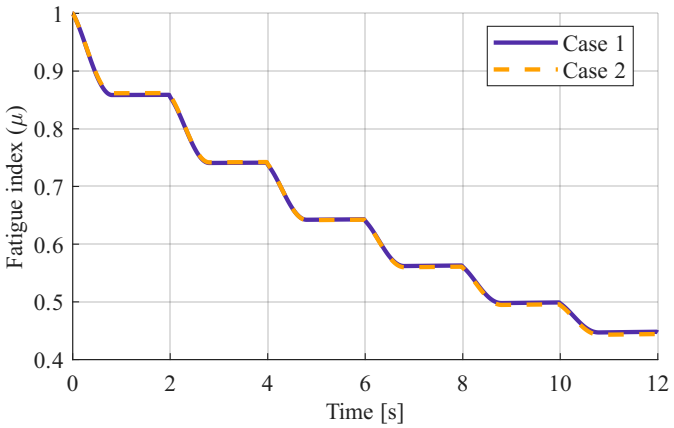

Fig. 5. Fatigue index, μ, for Cases 1 and 2.

Figures 6 to 8 show, respectively, the muscle activation, u_f, the torque applied by the exoskeleton (not considering the gravity compensation), τ_r, the torque generated by the muscle due to the FES stimulation, τ_m, and the controller's gains for Case 1.

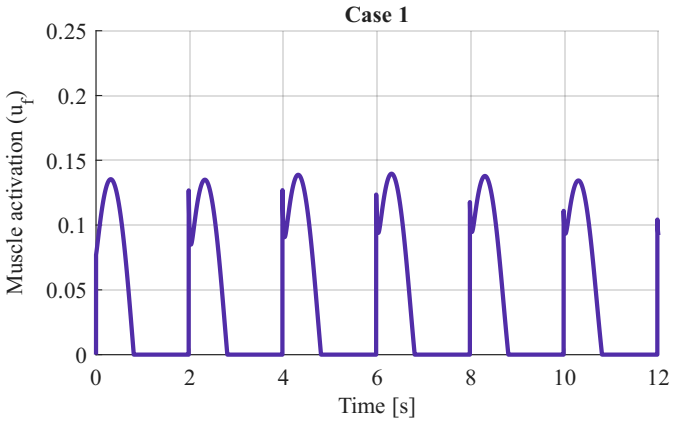

Fig. 6. Muscle activation, u_f, for Case 1.

Note from Fig. 6 that the proposed controller slightly increases the level of muscle activation at the first phases of muscle fatigue increase (decrease of the fatigue index), trying to maintain the muscle torque even with muscle fatigue. At the same phase, the robot torque also slightly increases. However, at the later phases, where the muscle fatigue is higher, the controller strongly and automatically increases

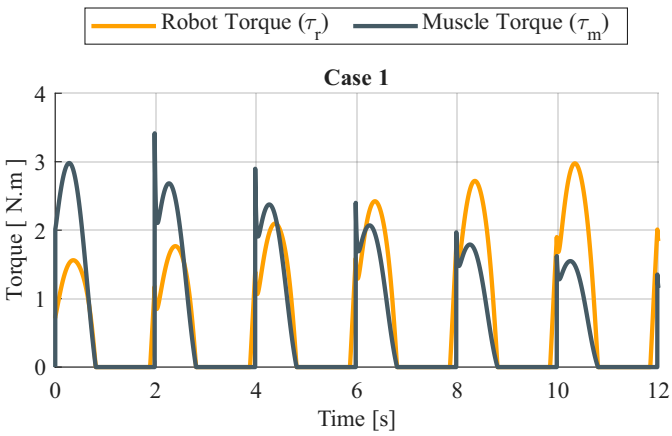

Fig. 7. Torques, τ_r and τ_m, for Case 1.

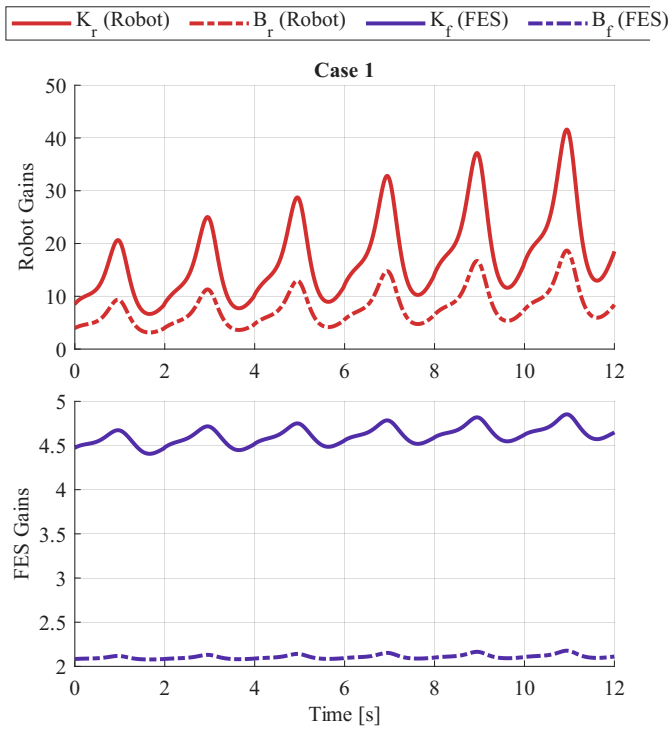

Fig. 8. Controller's gains for Case 1.

the robot actuation, decreasing the muscle activation. These changes of level of muscle activation and robot actuation, reflecting on the muscle and robot torques, can be seen at Fig. 7.

Fig. 8 shows the changes of the values of the gains within the phases and within a single extension movement. As seen from the figure, the gains change during the extension movement, mainly due the change in the musculoskeletal model, $\sigma(q, \dot{q})$.

Figures 9 to 11 show, respectively, the muscle activation, u_f, the torque applied by the exoskeleton (not considering the gravity compensation), τ_r, the torque generated by the muscle due to the FES stimulation, τ_m, and the controller's gains for

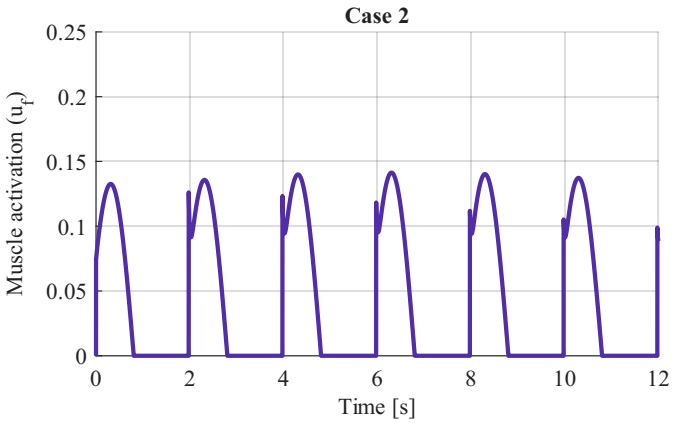

Fig. 9. Muscle activation, u_f - Case 2.

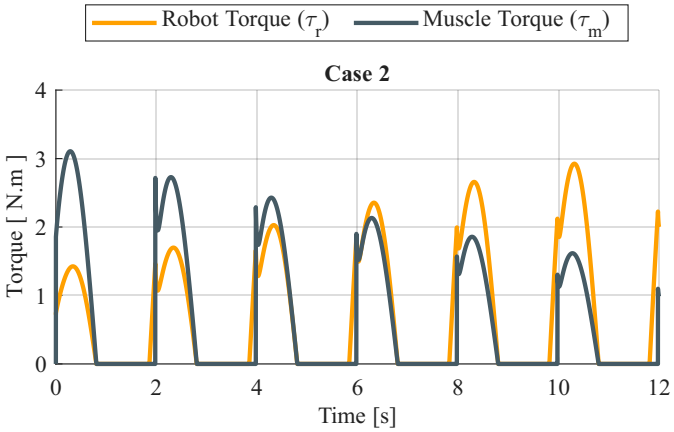

Fig. 10. Torques, τ_r and τ_m - Case 2.

Case 2.

The main difference between Cases 1 and 2 is concentrated in the variation of the gain values during a single extension movement. In case 2, the gains also change within the phases, but are kept constant during a single extension movement, as show in Fig. 11 .

VI. CONCLUSIONS

This work evaluated a quasi-LPV robust control approach to address the nonlinearities and time-varying dynamics of hybrid FES/exoskeleton systems. Two cases were investigated: one considering both the muscle fatigue index (fatigue index) and the musculoskeletal model as varying parameters, and another relying solely on the fatigue index. Simulations with a knee human–exoskeleton model demonstrated that the proposed controllers automatically adjusted FES-induced muscle activation and robotic torque according to fatigue levels. The main distinction observed between the two cases was in the gain variation during a single extension movement: while case 1 exhibited variations, case 2 maintained gains nearly constant. Future work will focus on experimental validation and extending the approach to multi-joint systems.

Sinais faciais embarcados em smartphones: reprodutibilidade entre SoCs e desempenho na detecção de nictação e oscitação

P. Neri de Oliveira[1,2] e F. J. Fraga da Silva[2]
[1]*Waker Inova Simples IS*, Santo André, Brasil
[2]*Universidade Federal do ABC (UFABC)*, Santo André, Brasil

***Resumo*—Movimentos oculares e da boca são manifestações observáveis associadas a estados como fadiga e sonolência, cuja aquisição convencional exige instrumentação dedicada. Este trabalho avalia a extração de sinais faciais integralmente executada em smartphones, sem armazenamento de imagem e sem conexão de rede, sobre três dispositivos Android com sistemas em um chip (SoCs) de arquiteturas distintas (Snapdragon 730, Exynos 1380 e Exynos 2400e). Como caso de teste, um detector de nictação, fechamento ocular prolongado e oscitação, baseado em razões de aspecto geométricas sobre malha facial de 468 pontos, foi avaliado nos 29 vídeos de câmera veicular do conjunto público YawDD, contra anotação temporal consensual de 1002 eventos. Os três dispositivos produziram detecções idênticas ao evento (índice de Jaccard 1,000). A 10 quadros/s, taxa de operação do sistema, obteve-se F1 de 0,830 para nictação (sensibilidade 0,748; valor preditivo positivo 0,932), 0,634 para oscitação (sensibilidade 0,833) e 0,584 para fechamento prolongado. A sensibilidade de oscitação supera os 60 % reportados pelos autores do YawDD nos mesmos vídeos. Um desenho fatorial 2×2 mostrou que a resolução de entrada não afeta a latência e que a vantagem entre GPU e CPU depende do SoC; a diferença entre desktop e dispositivo foi decomposta em taxa de amostragem, causalidade e plataforma, esta última respondendo por 0,035 de F1. Os resultados constituem prova de conceito técnica, sem alegação de validade clínica.**

***Palavras-chave*—sinais faciais; visão computacional; processamento embarcado; smartphone; nictação; oscitação.**

I. Introdução

Sinais faciais como a frequência e a duração de piscadas, o fechamento ocular sustentado, base da métrica PERCLOS [10], e o bocejo são utilizados como indicadores comportamentais de fadiga e sonolência em contextos como o monitoramento de condutores [4], [8]. Sua aquisição em campo depende, em geral, de câmeras dedicadas e processamento externo, o que limita a portabilidade e levanta questões de privacidade quando a imagem do rosto precisa sair do local de captura.

Smartphones reúnem câmera, processador e acelerador gráfico num único dispositivo, e modelos de malha facial otimizados para GPU móvel [1] tornam viável extrair esses sinais localmente. A questão investigada não é se um detector de piscada funciona, o que a literatura estabeleceu há uma década [2], [7], mas se a extração completa pode ser executada no aparelho, de forma reprodutível entre arquiteturas distintas, com custo compatível com operação contínua e desempenho mensurável contra referência humana.

Neste texto, *sinal facial* designa uma medida derivada da geometria do rosto, como a razão de aspecto do olho ou da boca, tratada como indicador comportamental. Nenhuma alegação de validade clínica é feita; a associação entre esses sinais e estados fisiológicos é assumida da literatura e não é avaliada aqui.

As contribuições são: (i) a demonstração de que três sistemas em um chip (SoCs) de fabricantes e famílias de GPU diferentes produzem detecções idênticas ao evento sobre os mesmos quadros; (ii) um desenho fatorial que separa o efeito do acelerador do efeito da resolução de entrada; (iii) a decomposição da diferença de desempenho entre implementação de desktop e embarcada em três parcelas mensuráveis; (iv) uma avaliação em nível de evento contra anotação temporal consensual, com o protocolo, as exclusões e os modos de falha declarados.

II. Materiais e Métodos

A. Arquitetura

O pipeline (Fig. 1) recebe quadros da câmera frontal, obtém a malha facial de 468 pontos e os coeficientes de expressão do MediaPipe Face Landmarker [1], [9], calcula razões de aspecto geométricas e as submete a máquinas de estado que emitem eventos discretos. Todo o processamento ocorre no dispositivo; nenhum quadro é armazenado ou transmitido. O sistema em produção opera a 10 quadros/s sobre entrada de 320×240 pixels. Ele passou por iterações desde uma versão inicial (v1.24, maio de 2025), cujo detector foi avaliado internamente apenas por contagem de eventos por vídeo, sem instantes; a versão corrente (v40) é a que fornece o detector de nictação comparado ao de referência na Seção III-F. Nenhuma dessas avaliações anteriores foi publicada; os dados que as sustentam integram o material depositado.

Para esta avaliação, o mesmo modelo de malha facial e as mesmas regras de detecção foram implementados em duas plataformas: (a) uma referência em Python sobre computador (macOS, Apple M2), que processa os vídeos a 30 quadros/s com acesso ao vídeo inteiro; (b) uma implementação Kotlin embarcada nos três dispositivos Android, que processa os mesmos vídeos a 10 quadros/s de forma causal, como faria com a câmera. A paridade das regras entre as duas implementações foi verificada parâmetro a parâmetro. A comparação entre elas

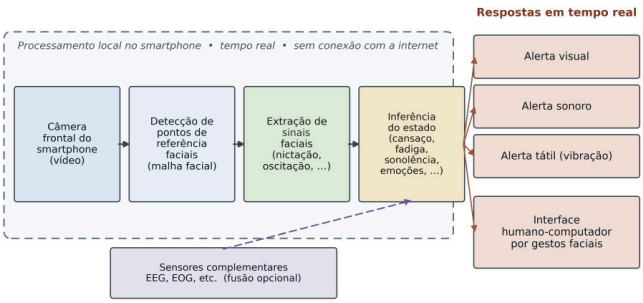

Figura 1. Arquitetura do sistema. Os três primeiros blocos, até a extração dos sinais faciais, são objeto deste trabalho. A inferência de estado e as respostas não são avaliadas. Sensores complementares indicam trabalho futuro.

isola, portanto, a plataforma e a estratégia de amostragem, e não o algoritmo.

O sistema também possui uma etapa de inferência de estado (fadiga, sonolência) que combina os eventos com regras temporais. Essa etapa *não* é avaliada neste trabalho: o YawDD não contém anotação de sonolência, e qualquer número nesse sentido seria inventado.

B. Extração dos sinais

A razão de aspecto do olho (EAR) segue Soukupová e Čech [2], com seis pontos por olho e média entre os dois olhos (Fig. 2):

$$\mathrm{EAR} = \frac{\|p_2 - p_6\| + \|p_3 - p_5\|}{2\,\|p_1 - p_4\|}, \tag{1}$$

sobre coordenadas convertidas a pixels antes do cálculo das distâncias, para evitar distorção pela razão de aspecto não quadrada do quadro. Na Fig. 2, as normas $\|p_2 - p_6\|$ e $\|p_3 - p_5\|$ aparecem expandidas como distâncias euclidianas d_1 e d_2, $\|p_1 - p_4\|$ como a largura w, e a razão é denotada AR; o cálculo é o mesmo, feito para cada olho e, posteriormente, calculou-se a média. A razão de aspecto da boca (MAR) segue a mesma construção com três distâncias verticais v_1, v_2, v_3 do contorno interno dos lábios sobre duas vezes a largura w_M:

$$\mathrm{MAR} = \frac{v_1 + v_2 + v_3}{2\,w_M}. \tag{2}$$

A pose da cabeça (yaw, pitch, roll) é obtida da matriz de transformação facial do modelo.

Os sinais são normalizados por um *baseline* (linha de base) individual, porque a EAR de olho aberto variou de 0,259 a 0,417 entre os 29 participantes, razão de 1,6, o que inviabiliza limiar absoluto. Na implementação de desktop, o baseline é o percentil 75 da EAR sobre o vídeo inteiro. Na implementação embarcada, causal, o detector inicia com um valor *a priori* populacional (0,29, mediana dos baselines individuais do conjunto de referência) e o substitui pelo percentil 75 da janela crescente de quadros válidos e frontais a partir do décimo quadro. Para a boca, o baseline é a mediana da janela crescente a partir do trigésimo quadro, sem valor a priori, porque o bocejo é raro e longo e um valor a priori errado produziu falsos positivos em teste preliminar.

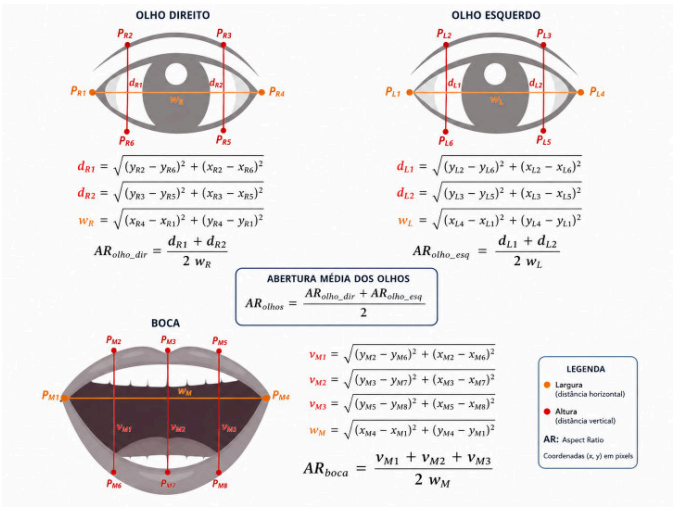

Figura 2. Pontos de referência e razões de aspecto. Olhos: seis pontos por olho, duas distâncias verticais sobre duas vezes a largura, com média entre os dois olhos. Boca: três distâncias verticais sobre duas vezes a largura. Coordenadas em pixels.

C. Regras de detecção

Um evento ocular inicia quando a EAR normalizada cai abaixo de 0,70 e termina quando volta acima por mais de 60 ms. A duração é estimada como o intervalo entre o primeiro e o último quadro abaixo do limiar mais um intervalo de amostragem, para que um evento capturado em um único quadro receba a duração de um intervalo em vez de zero. Eventos de até 500 ms são nictação se a EAR mínima atingiu 0,60 do baseline; eventos mais longos são fechamento prolongado se a mediana da EAR durante o evento ficou abaixo de 0,50, e fechamento parcial caso contrário. Um período refratário de 100 ms separa nictações consecutivas. O bocejo inicia quando a MAR normalizada excede 2,2, com histerese de saída em 1,6, e é contabilizado como oscitação se sustentado por ao menos 1000 ms. Os limiares de 0,70 e 2,2 foram fixados antes da anotação de referência existir; a varredura posterior (Seção III-C) confirmou 0,70 como ótimo para nictação.

Os limiares de profundidade (0,60 para nictação, 0,50 para prolongado) foram introduzidos após análise dos falsos positivos em rodada preliminar no dispositivo: os falsos positivos tinham EAR mínima entre 0,59 e 0,65, contra 0,29 a 0,33 nos verdadeiros, e o critério de anotação exige cobertura de mais de metade da pupila. A confirmação por coeficiente de expressão (*blendshape*) foi testada como alternativa e como complemento em ambos os casos e não superou a profundidade geométrica; o resultado negativo é reportado na Seção III-G.

D. Parâmetros de operação

A Tabela I consolida os parâmetros das Seções II-B e II-C. Todos são idênticos nas duas implementações e foram verificados um a um antes das rodadas; qualquer divergência entre desktop e dispositivo é, portanto, atribuível à plataforma ou à estratégia de amostragem, e não a diferença de configuração.

Tabela I
PARÂMETROS DE OPERAÇÃO, IDÊNTICOS NAS DUAS IMPLEMENTAÇÕES.

Modelo de malha facial	MediaPipe Face Landmarker
Confiança mínima	0,6
Resolução de entrada	320×240; 640×480
Taxa de amostragem	10 quadros/s
Aquecimento descartado	1000 ms
Baseline ocular	p75; prior 0,29 (embarcado)
Limiar de nictação	EAR/base $< 0{,}70$; mín. $< 0{,}60$
Duração de nictação	70 a 500 ms
Período refratário	100 ms
Fechamento prolongado	> 500 ms; med. EAR/base $< 0{,}50$
Limiar de oscitação	MAR/base $> 2{,}2$ (saída $1{,}6$)
Duração de oscitação	1000 a 10000 ms

E. Conjunto de dados

A avaliação utilizou os 29 vídeos do YawDD [5], [6] gravados com a câmera instalada no painel, 640×480 a 30 quadros/s, totalizando 2151 s. Os arquivos AVI foram convertidos a MP4 H.264 sem perda perceptível (fator de taxa constante, CRF, igual a 16) e identificados por SHA-256 no manifesto, o que resolve a ambiguidade de onze vídeos com duração arredondada idêntica. Cada vídeo contém as fases de condução normal, fala e bocejo, com o veículo parado. A composição da amostra está na Tabela II.

Tabela II
COMPOSIÇÃO DA AMOSTRA (29 PARTICIPANTES).

Atributo	Categorias	n
Sexo	Feminino / Masculino	13 / 16
Óculos	Com / Sem	15 / 14
Tom de pele [12]	Monk 01–04 / 05–10	20 / 9

F. Anotação de referência

Um observador anotou início e fim de cada evento nos 29 vídeos, com ferramenta de navegação quadro a quadro e candidatos automáticos pré-populados por dois detectores independentes: o MediaPipe Face Landmarker (versão 0.10.14), o mesmo modelo do sistema avaliado, e o preditor de 68 pontos do dlib (versão 19.24) [3], que é o detector do trabalho original da EAR [2]. Os candidatos serviam apenas para orientar a navegação; a decisão sobre cada evento foi do observador. O critério para nictação é a cobertura de mais de metade da pupila no ápice, com início no fechamento e fim na reabertura completa; fechamentos acima de 500 ms constituem classe separada. A oscitação é a abertura ampla e sustentada da boca; fala com boca aberta não é contabilizada.

Um subconjunto de seis vídeos, escolhido para cobrir os extremos de taxa de nictação, uso de óculos e tom de pele, foi revisado por um segundo observador com acesso à marcação inicial. O procedimento caracteriza anotação por consenso e não permite estimar concordância entre anotadores independentes, o que é declarado como limitação. A revisão acrescentou 28 eventos e removeu 3 sobre 268, taxa de omissão de 9,6 % na passada única, valor que deve ser considerado ao interpretar as métricas sobre os 23 vídeos não revisados.

A anotação original do YawDD classifica cada vídeo inteiro; trabalho contemporâneo produziu anotação por quadro para bocejo, com pipeline semiautomático e verificação humana, e mostrou o ganho de rótulos temporais finos para treinamento em plataformas de borda [16]. A anotação aqui é por evento, com início e fim, e cobre também nictação e fechamento prolongado, que aquele trabalho não trata. O gabarito final contém 1002 eventos: 882 nictações, 78 oscitações e 42 fechamentos prolongados. As taxas de nictação resultantes (mediana de 24 por minuto, entre 7 e 56) são compatíveis com a variação individual descrita na literatura [11], elevada pela fase de fala presente em todos os vídeos. Um vídeo (participante com óculos escuros) foi excluído das métricas oculares por impossibilidade de estabelecer referência, permanecendo na de oscitação; a exclusão e seu motivo constam do material suplementar.

G. Métricas

A avaliação é em nível de evento, seguindo o protocolo de pareamento com tolerância temporal estabelecido para detecção de piscada [13] e aplicado recentemente ao mesmo par MediaPipe e EAR sobre o Eyeblink8 [15]. Uma detecção é verdadeiro positivo (VP) quando seu centro dista do centro de um evento anotado até 250 ms para nictação, 500 ms para fechamento prolongado e 1000 ms para oscitação, com pareamento um a um. Detecções sem par são falsos positivos (FP); eventos anotados sem par, falsos negativos (FN). Reportam-se sensibilidade $S = \mathrm{VP}/(\mathrm{VP}+\mathrm{FN})$, valor preditivo positivo $\mathrm{VPP} = \mathrm{VP}/(\mathrm{VP}+\mathrm{FP})$ e

$$F1 = \frac{2\,S \cdot \mathrm{VPP}}{S + \mathrm{VPP}}. \tag{3}$$

Para comparação com a versão v1.24, que registrou apenas contagens por vídeo, usa-se a concordância de contagem $C = \max(0,\, 1 - |Q_{\mathrm{ref}} - Q_{\mathrm{det}}|/Q_{\mathrm{ref}}) \times 100$, normalizada pela referência. A concordância entre implementações em dispositivos distintos é medida pelo índice de Jaccard sobre os conjuntos de eventos, com tolerância de 100 ms.

H. Custo computacional

Seguindo a prática de benchmarking de inferência em SoCs móveis [14], [17], cada dispositivo processou os 29 vídeos em quatro configurações, num desenho fatorial 2×2: acelerador (GPU ou CPU do MediaPipe) e resolução de entrada (320×240 ou 640×480), na ordem GPU-CPU-GPU-CPU com pausa de 60 s entre configurações. Mediu-se a latência de cada inferência, a memória proporcional do processo (*Proportional Set Size*, PSS) e o tempo de CPU do processo por `/proc/self/stat`. O estrangulamento térmico foi verificado comparando a latência mediana do primeiro e do último terço de cada rodada. O consumo de bateria não é medido neste protocolo, porque o processamento de vídeo armazenado não representa a operação com aquisição de imagem da câmera em tempo real; sua medição em sessão ao vivo é reservada

a estudo futuro, junto com a análise de convergência com eletroencefalografia (EEG).

III. Resultados e Discussão

A. Reprodutibilidade entre dispositivos

Os três dispositivos produziram exatamente as mesmas detecções sobre os mesmos quadros. Na resolução de produção (320×240), usando CPU, nictação resultou em VP 660, FP 48 e FN 222 no Galaxy M51 (Snapdragon 730, Adreno 618), no Galaxy A54 (Exynos 1380, Mali-G68) e no Galaxy S24 FE (Exynos 2400e, Xclipse 940). O índice de Jaccard mediano entre pares de dispositivos foi 1,000 para nictação. Entre GPU e CPU no mesmo dispositivo, as detecções diferiram em no máximo quatro eventos de cerca de 660, atribuíveis a precisão de ponto flutuante.

Esse resultado sustenta a afirmação central do trabalho: o modelo e as regras produzem saída idêntica em três famílias de GPU e três gerações de CPU. Ele não implica invariância a câmeras distintas, não testadas.

B. Desempenho na detecção

Tabela III
Desempenho por evento e fonte, 29 vídeos. Dispositivos a 10 quadros/s, 320×240, CPU; os três dão valores idênticos e são reportados uma vez.

Evento	Fonte	VP	FP	FN	S	VPP	F1
Nictação	Desk. 30 q/s	742	48	140	0,841	0,939	0,888
	Desk. 10 q/s	720	50	162	0,816	0,935	0,872
	Desk. 10 causal	710	50	172	0,805	0,934	0,865
	Disp. 10 q/s	660	48	222	0,748	0,932	0,830
Oscitação	Desk. 10 q/s	70	42	8	0,897	0,625	0,737
	Desk. 10 causal	64	65	14	0,821	0,496	0,618
	Disp. 10 q/s	65	62	13	0,833	0,512	0,634
Fech. prol.	Desk. 10 q/s	35	25	7	0,833	0,583	0,686
	Desk. 10 causal	35	24	7	0,833	0,593	0,693
	Disp. 10 q/s	33	38	9	0,786	0,465	0,584

A Tabela III organiza as fontes de modo que a diferença entre linhas consecutivas isole um fator. Para nictação, passar de 30 para 10 quadros/s no desktop custa 0,016 de F1; tornar o baseline causal custa 0,007; e a plataforma embarcada custa 0,035. A parcela da plataforma corresponde à cadeia de decodificação de vídeo e conversão de cor no Android, distinta do OpenCV no desktop, e ao *build* Android do MediaPipe. O VPP permanece em 0,93 em todas as fontes: a diferença é integralmente de sensibilidade, e não de falsos positivos.

Para oscitação, a taxa de amostragem não pesa (bocejo dura segundos), mas a estimativa causal do baseline custa 0,12 de F1, todo em VPP. O mecanismo é o viés de fase: os vídeos iniciam com a boca fechada, a mediana crescente permanece baixa e o limiar de 2,2× fica abaixo da abertura da fala que vem depois. A implementação de desktop, com a mediana sobre o vídeo inteiro, não sofre esse viés. Mesmo assim, a sensibilidade de 0,833 no dispositivo supera os 60 % reportados pelos autores do YawDD [5] com Viola–Jones nos mesmos vídeos.

A Fig. 3 ilustra a cadeia avaliada sobre um fechamento prolongado real no dispositivo. O fechamento prolongado é o evento de pior desempenho, com VPP de 0,465. Os falsos positivos residuais são fechamentos sustentados com EAR entre 0,50 e 0,60 do baseline, que o critério de profundidade não separa. Antes desse critério, o VPP era 0,29; os 58 eventos reclassificados como fechamento parcial correspondem aos falsos positivos de sonolência evitados.

Figura 3. Cadeia avaliada, sobre um fechamento prolongado: captura, malha facial, EAR normalizada cruzando o limiar de entrada (0,70) e permanecendo abaixo de 0,50 por mais de 500 ms, e registro do evento no dispositivo. O alerta visual, sonoro ou por vibração é funcionalidade implementada do sistema, acionada pela detecção; sua avaliação não é objeto deste trabalho.

A taxa de detecção de rosto foi 99,7 % dos quadros nas duas plataformas, contra 93 % reportados pelos autores do YawDD com Viola–Jones; a de boca, 99,7 % contra 78 %.

C. Varredura de limiar

A Fig. 4 mostra sensibilidade, VPP e F1 em função do limiar, no desktop a 30 quadros/s. Para nictação, o F1 é máximo em 0,70, valor fixado antes da anotação existir. Para oscitação, o F1 cresce até o fator 3,3 sem atingir máximo, à custa de sensibilidade; o valor de 2,2 foi mantido por priorizar sensibilidade, dado que a omissão de bocejo é o erro de maior consequência para a aplicação.

D. Análise por subgrupo

A Tabela IV estratifica a nictação por uso de óculos e por sexo, e a oscitação por sexo, no desktop a 30 quadros/s. Óculos de grau não degradam a detecção de nictação: a diferença de F1 entre os grupos com e sem óculos é de 0,02, dentro da variação entre participantes.

Óculos escuros, presentes em um participante, impedem a observação do olho; nesse vídeo, os dois detectores usados na anotação produziram saída espúria (1 evento com MediaPipe, 35 com dlib) sem sinalizar a impossibilidade, modo de falha silencioso que um sistema em produção precisa detectar explicitamente; o sistema de origem possui modo dedicado a essa condição, não avaliado aqui. A oscitação

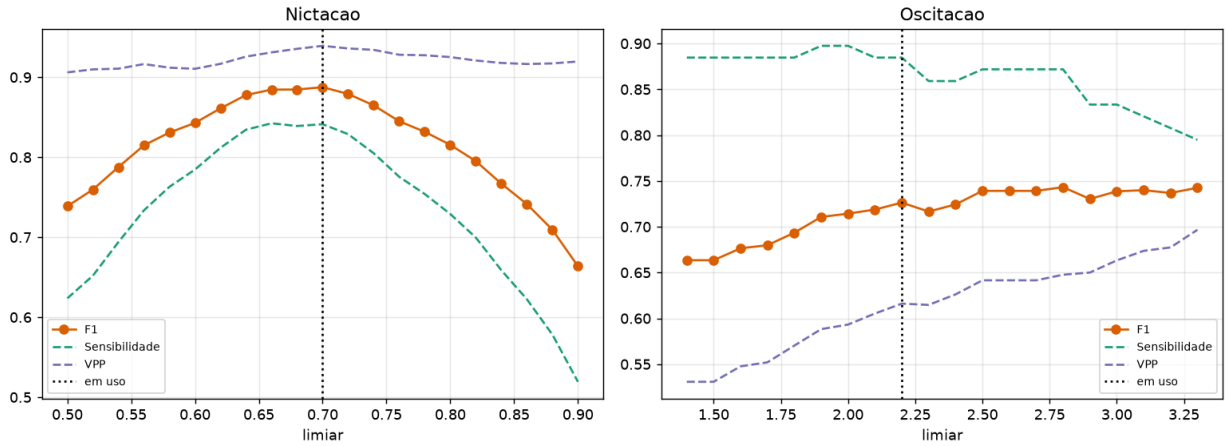

Figura 4. Sensibilidade, VPP e F1 em função do limiar, desktop 30 quadros/s. Esquerda: nictação, limiar sobre EAR/baseline. Direita: oscitação, fator sobre MAR/baseline. Linha pontilhada: valor em uso.

Tabela IV
DESEMPENHO POR SUBGRUPO, DESKTOP 30 QUADROS/S.

Evento	Subgrupo	n	S	VPP	F1
Nictação	Sem óculos	14	0,844	0,959	0,898
	Com óculos	15	0,838	0,917	0,876
	Feminino	13	0,880	0,948	0,913
	Masculino	16	0,796	0,928	0,857
Oscitação	Feminino	13	0,853	0,617	0,716
	Masculino	16	0,909	0,615	0,734

não é estratificada por óculos: lentes não afetam a boca, e a estratificação preliminar produziu diferença confundida com a distribuição de participantes que estão conversando.

E. Custo computacional

Tabela V
CUSTO COMPUTACIONAL, DESENHO FATORIAL 2×2, 21 530 QUADROS POR CONFIGURAÇÃO.

Dispositivo	Res.	Acel.	Lat. (ms)	p95 (ms)	q/s	PSS (MB)
Galaxy A54	320	GPU	36	42	27,8	314
	320	CPU	26	31	38,5	286
	640	GPU	40	43	25,0	323
	640	CPU	27	32	37,0	298
Galaxy M51	320	GPU	71	84	14,1	282
	320	CPU	66	113	15,2	258
	640	GPU	73	86	13,7	280
	640	CPU	71	116	14,1	257
Galaxy S24 FE	320	GPU	63	87	15,9	320
	320	CPU	102	145	9,8	300
	640	GPU	65	89	15,4	319
	640	CPU	118	152	8,5	307

Três achados emergem da Tabela V. Primeiro, a resolução de entrada não afeta a latência (razões entre 0,92 e 1,06 nas seis combinações): o modelo redimensiona internamente, e a escolha de 320×240 em produção não custa nem tempo nem acurácia, tendo dado F1 marginalmente superior ao de 640×480. Segundo, todos os dispositivos sustentam a taxa de 10 quadros/s com folga em ao menos um acelerador, com o uso de CPU do processo entre 110 e 128 % de um núcleo. Terceiro, a vantagem entre GPU e CPU depende do SoC: no A54 a CPU foi 28 % mais rápida, no M51 os dois se equivalem, e no S24 FE a GPU foi 38 % mais rápida, variabilidade consistente com a documentada em benchmarks de inferência móvel, nos quais a relação entre latência de CPU e de GPU não se mantém entre plataformas [14], [17]. No S24 FE, a CPU operou entre 1,4 e 1,5 GHz, cerca de metade da frequência máxima do núcleo, com a thread alocada consistentemente aos núcleos de desempenho; a prioridade de thread não alterou o resultado, o que aponta para política de energia do sistema operacional. O comportamento, em que o governador mantém a CPU em frequência subótima durante inferência contínua, é observado aqui em um modelo de visão de pequeno porte, o que sugere que o mecanismo é do sistema operacional e não da carga. A escolha de acelerador, portanto, não pode ser fixada em tempo de compilação.

O estrangulamento térmico dentro de cada rodada foi ausente em dez das doze configurações. O A54 em GPU a 320×240 apresentou aumento de 22 % na latência entre o primeiro e o último terço; o S24 FE em GPU a 640×480 apresentou redução de 59 %, de 70 para 29 ms, comportamento consistente com governador de frequência que atinge o regime após período de carga sustentada. A sensibilidade das medições a esse efeito é reconhecida na literatura de benchmarking móvel, que recorre a resfriamento ativo e fixação de frequência para obter latências estáveis [17]; aqui optou-se por medir na condição de uso, sem essas intervenções, e reportar a variação.

F. Evolução do sistema

A versão v1.24, avaliada à época por contagem sobre os mesmos vídeos, foi reavaliada contra o gabarito atual e obteve concordância de contagem média de 61,2 % para nictação. O

detector de nictação da versão corrente (v40), executado nos mesmos quadros no dispositivo, obteve 77,1 %, e em nível de evento F1 de 0,740 (VP 610, FP 157, FN 272). As regras de referência deste trabalho, nos mesmos quadros (GPU), obtiveram F1 de 0,832 com FP 45: a diferença está no uso do coeficiente de expressão de um único olho sem filtro de profundidade na v40, contra a EAR geométrica dos dois olhos com filtro. Combinar as duas fontes, aceitando candidatos rasos da referência confirmados pela v40, elevou o F1 a 0,842 (sensibilidade 0,779, VPP 0,917); a combinação foi escolhida após a análise e é reportada como variante, não como método principal.

G. Lições aprendidas

O detector foi refinado em ciclos de análise de falha contra a anotação de referência: cada mudança partiu de um padrão observado nos falsos positivos ou negativos, foi implementada nas duas plataformas e reavaliada. Os achados abaixo são reportados porque se aplicam a qualquer detector de eventos faciais operando em fluxo, e porque os resultados negativos delimitam o que não funcionou.

Duração a partir de amostras esparsas. A 10 quadros/s, uma piscada de 100 a 150 ms cabe em um único quadro. Estimar a duração como a diferença entre o primeiro e o último quadro abaixo do limiar dá zero para esses casos, e o piso de 70 ms os descarta: 30 % das corridas abaixo do limiar eram perdidas assim. Somar um intervalo de amostragem, estimativa de viés mínimo, recuperou-as sem alterar a classificação dos eventos longos.

Baseline em fluxo. A EAR de olho aberto varia 1,6 vez entre pessoas, o que exige normalização individual. Em fluxo, o baseline só pode ser estimado do passado. A primeira implementação esperava 120 quadros antes de detectar, 4 s para operações com 30 quadros/s, porém 12 s operações com 10 quadros/s, e deixava 18,7 % de cada vídeo cego, tornando inalcançáveis 158 das 882 nictações. Reduzir a janela para 30 quadros recuperou a maior parte; iniciar com um valor a priori populacional e refiná-lo pelo percentil da janela crescente eliminou o período cego. Para a boca, o mesmo valor a priori produziu falsos positivos, porque a fala inicial excedia um limiar calibrado sobre repouso; ali, esperar 4 s custa poucos bocejos, que são raros e longos, e é a escolha correta. A estratégia de baseline depende, portanto, da estatística do evento.

Profundidade do fechamento. Os falsos positivos de nictação e de fechamento prolongado tinham em comum EAR mínima entre 0,59 e 0,65 do baseline, contra 0,29 a 0,33 nos verdadeiros: cruzavam o limiar de entrada mas não fechavam. Exigir profundidade mínima (0,60 no ápice para nictação; mediana abaixo de 0,50 para prolongado) elevou o VPP de 0,884 para 0,944 e de 0,29 para 0,50, respectivamente, com perda de sensibilidade inferior a 0,01. Pose da cabeça (*pitch*) foi testada como discriminador alternativo e não separou os grupos.

Coeficiente de expressão. O *blendshape* de piscada, usado como sinal primário, foi testado como confirmação e como alternativa à geometria, em ambos os eventos oculares. Não superou a profundidade da EAR em nenhum caso; para fechamento sustentado, o coeficiente de um único olho deu F1 de 0,34 contra 0,58 da EAR bilateral. Uma hipótese é que o coeficiente reconhece o gesto de piscar, rápido e ativo, e não a pálpebra caindo devagar, que é geometria distinta.

Limiar sem medida. Uma versão anterior do sistema usava limiar de 0,80 sobre um coeficiente cujo máximo observado no sinal era 0,80, e produziu uma única detecção em 1496 quadros. Limiares devem ser derivados da distribuição medida do sinal, não de estimativa.

H. Limitações

O YawDD contém 29 participantes, expressões atuadas e veículo parado; a generalização a condução real, com iluminação variável e vibração, não foi testada. A anotação é consensual, sem medida de concordância entre observadores independentes. O baseline causal da boca sofre viés de fase, com custo de cerca de 0,1 de F1 no dispositivo. Óculos escuros impedem a extração ocular e o sistema não sinaliza a condição nas implementações avaliadas. A etapa de inferência de estado não foi avaliada, por ausência de referência. A implementação iOS existe e não foi avaliada. O consumo de bateria em operação com câmera é reservado a estudo futuro.

IV. Conclusões

Um detector de nictação, fechamento prolongado e oscitação baseado em razões de aspecto sobre malha facial foi executado integralmente em três smartphones Android com SoCs de arquiteturas distintas e produziu detecções idênticas ao evento nos três. Contra anotação temporal consensual de 1002 eventos em 29 vídeos do YawDD, obteve-se F1 de 0,830 para nictação e 0,634 para oscitação a 10 quadros/s, com sensibilidade de oscitação superior à reportada pelos autores do conjunto. A diferença de desempenho entre desktop e dispositivo foi decomposta em taxa de amostragem, causalidade e plataforma, com esta última respondendo por 0,035 de F1. Um desenho fatorial mostrou que a resolução de entrada não afeta a latência e que a vantagem entre GPU e CPU depende do SoC. Os resultados constituem prova de conceito técnica da extração embarcada; sua validade clínica não é objeto deste trabalho.

A extração embarcada de sinais faciais é agnóstica à aplicação. Uma linha em estudo é a avaliação de dor em pacientes não verbais por escalas como a PSPI (*Prkachin and Solomon Pain Intensity*) [18], ainda sem avaliação. Está em curso, sem resultado no momento da submissão, a investigação da convergência entre os sinais faciais aqui extraídos e sinais de EEG, com atenção ao artefato ocular no EEG frontal, que correlaciona com a piscada por construção e não por mecanismo neural.

Disponibilidade de dados e código

A anotação temporal consensual, o manifesto com SHA-256 dos vídeos, o arquivo de exclusões, a implementação de referência em Python, o detector embarcado em Kotlin, a ferramenta de anotação e os CSVs de saída dos três dispositivos

estão depositados em https://github.com/NeriOliveira/artigo_cbeb_2026 (SWHID: swh:1:rev:e35c7c3a3a4563734ea5351a34e17166b5755c7f), o que permite reproduzir integralmente as Tabelas III a V. Os vídeos do YawDD não são redistribuídos e devem ser obtidos na fonte [6]; o manifesto permite verificar a correspondência exata dos arquivos. O detector da versão corrente do sistema comercial, usado apenas na comparação da Seção III-F, não é distribuído; os eventos que ele produziu constam dos CSVs depositados.

AGRADECIMENTOS

Os autores agradecem à Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) pelo financiamento por meio dos processos 2023/04821-0 e 2024/13300-7, ao Grupo de Pesquisa de Processamento de Sinais da UFABC e à Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES).

CONFLITO DE INTERESSE

O primeiro autor é sócio da Waker Inova Simples IS, empresa que desenvolve o sistema cujo pipeline de extração é avaliado neste trabalho. A anotação de referência, o protocolo de avaliação, os dados e o código de análise estão publicamente disponíveis para verificação independente, conforme a seção de disponibilidade. O segundo autor declara não haver conflito de interesse.

***Abstract*—Population aging and the increasing prevalence of neurodegenerative diseases have increased the need for technological solutions capable of supporting health monitoring and preventing adverse events, particularly falls among individuals with cognitive impairment. This paper presents a technical proof-of-concept wrist-worn smartband that combines embedded TinyML with a post-classification, multi-stage physical verification pipeline for automatic fall detection. The proposed system integrates an M5Stack AtomS3R-Ext microcontroller with an embedded Inertial Measurement Unit (IMU), a 1D convolutional neural network (CNN) quantized to 8-bit integer (int8) and trained via Edge Impulse, and a three-stage physical verification method designed to reduce false positives beyond the performance of the CNN alone. Communication is handled through the Message Queuing Telemetry Transport (MQTT) protocol, enabling alerts via a companion mobile application. On an internal validation split automatically held out during training (n=849 windows), the embedded model reached 95.2% accuracy and a ROC-AUC of 0.951, with a mean inference time of 7 ms and a computational load of 0.7%. In practical on-device trials (10 per fall type, performed by the two healthy adult authors who also contributed to the training data), detection rates were 100% for forward falls, 80% for backward falls, and 70% for lateral falls, with one false positive recorded. These results indicate that fully on-device inference combined with multi-stage physical verification is computationally feasible on resource-constrained wearables. However, given the small, non-independent, and self-collected dataset, clinical suitability for the target population requires further evaluation with leakage-free, subject-level data and cohorts representative of older adults with cognitive impairment.**

***Index Terms*—fall detection, embedded artificial intelligence, wearable devices, Edge Impulse, elderly monitoring, cognitive impairment**

I. Introduction

Population aging is a growing global trend, with the proportion of people aged 60 or older expected to double by 2050, according to the World Health Organization (WHO) [1]. In Brazil, approximately 8.5% of the elderly population live with some form of dementia, a figure projected to rise from 1.8 million to 5.7 million by 2050 [2]. Neurodegenerative diseases impair cognitive and functional abilities, substantially increasing the risk of falls. In this context, cognitive impairment refers to deficits in functions such as memory, attention, spatial orientation, judgment and autonomy, which may increase fall risk and hinder the ability to seek help after

an adverse event. Studies report annual fall rates of 40-60% among elderly individuals with dementia [3], [4], compared to roughly one-third of the general older population [1].

Falls are a leading cause of morbidity and mortality among this population, making reliable, fast-response detection systems desirable [1]. Wrist-worn wearables equipped with Inertial Measurement Units (IMUs) are particularly attractive due to their unobtrusiveness, continuous monitoring capability, and high user acceptance [5], [6]. When combined with machine learning (ML), such devices have been reported to distinguish fall events from activities of daily living with high accuracy [7], [8]. However, several fall-detection systems still rely on offline processing or cloud-based inference [9], [11], which introduces latency and privacy concerns, and increases energy consumption. Edge Artificial Intelligence (AI), executing ML models directly on the microcontroller, addresses these limitations by enabling local, real-time inference without constant server dependency [10], [12].

A. Related Work

Several studies have explored wearable-based fall detection using ML across different body placements, as summarized in Table I. Marques et al. [7] evaluated classical ML algorithms on a wrist-worn device, while Nunez et al. [8] compared waist and wrist placements, reporting that wrist sensors exhibit higher classification ambiguity than trunk-mounted alternatives. Jang et al. [9] employed a dual-stream CNN with self-attention for waist devices, and Li et al. [10] reviewed a decade of progress, highlighting trends toward embedded AI. Most of these approaches rely on the classifier's output alone to trigger an alert, which makes them susceptible to false positives whenever daily activities produce IMU signatures similar to a fall.

The most comparable study is that of Volochtchuk and Bassai [11], who reported 92.31% accuracy using Edge Impulse, but conducted their final tests with the device connected to a computer, without autonomous deployment. In contrast, the main methodological contribution of this work is not the CNN classifier in isolation, but its integration with a three-stage, rule-based physical verification pipeline (temporal voting, impact detection, and post-impact immobility check) executed entirely on-device after inference. As described in Section III, this pipeline is what allows high-intensity activities such as running and jumping, which produce CNN-detectable acceleration peaks comparable to those associated with falls, to be rejected before an alert is issued, a capability that a CNN-only or threshold-only approach does not provide. This work also advances toward fully autonomous embedded deployment and integrates Wi-Fi-based geofencing, prioritizing wrist placement for user acceptance. Beyond falls, wandering behaviors [13] and IMU-derived fall-risk parameters [14] further motivate the relevance of this line of work, although wandering detection is not evaluated in this study.

This paper presents a wrist-worn smartband technical proof-of-concept built around the M5Stack AtomS3R-Ext microcontroller, combining a 1D convolutional neural network (CNN) quantized to 8-bit integer (int8) and deployed via the Edge Impulse platform [15] with a multi-stage physical verification method intended to reduce false positives beyond those produced by the classifier alone.

II. MATERIALS AND METHODS

A. System Architecture

The system comprises three main layers: (1) a wrist-worn embedded device responsible for data acquisition, on-device ML inference, and fall confirmation; (2) Message Queuing Telemetry Transport (MQTT)-based communication layer for event-driven messaging; and (3) a mobile application specially designed to generate and deliver alert notifications to caregivers following a confirmed fall event. Fig. 1 illustrates the overall system architecture, while Fig. 2 shows the mobile application interface.

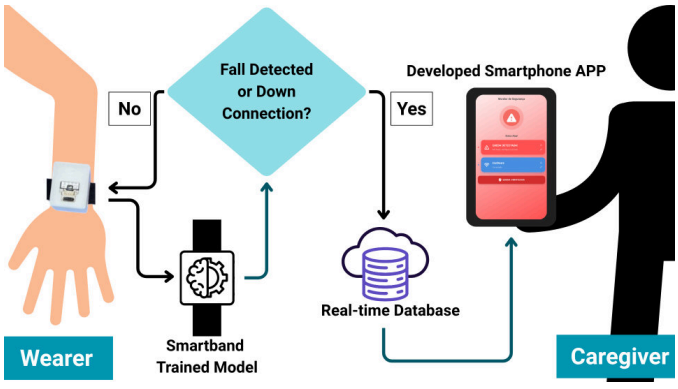

Fig. 1. System architecture: the embedded device acquires IMU data, runs on-device ML inference, and publishes fall or geofencing events via MQTT to a cloud backend, which triggers push notifications to the caregiver's mobile application.

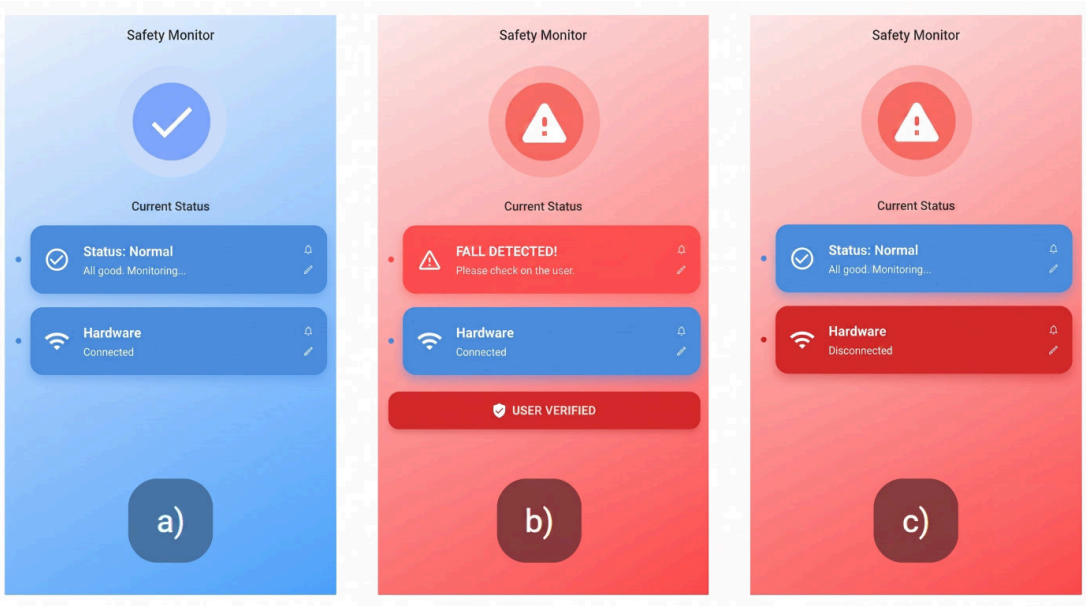

Fig. 2. Mobile application dashboard showing three operating states: (a) normal operation, with the wearable device connected and monitoring active; (b) fall detected, displaying an alert and confirmation button; (c) device disconnected, indicating loss of communication with the smartband.

During normal activity, no data are published to the broker, minimizing network traffic and energy consumption. A fall event triggers a compact MQTT message to the backend, which updates the Firebase real-time database and dispatches a push notification via Firebase Cloud Messaging (FCM) to the caregiver's Flutter application.

B. Hardware Device

The M5Stack AtomS3R-Ext [16] was selected as the embedded platform due to its combination of compact form factor (24 × 24 × 13 mm), built-in IMU (three-axis BMM150 geomagnetic sensor and a six-axis BMI270 attitude sensor), dual-core Xtensa® LX7 processor at up to 240 MHz, 8 MB of Flash, 8 MB of PSRAM, native Wi-Fi connectivity, and low cost (approximately US$14.50). These characteristics make it well suited for a wrist-worn wearable requiring on-device ML inference and wireless communication. The device was also selected due to its native compatibility with Edge Impulse, an edge AI platform that provides an integrated workflow for the entire ML pipeline on embedded systems, including data acquisition, model training, optimization, and deployment. This integration enables the deployment of optimized TinyML models directly onto microcontrollers, reducing development complexity and computational overhead. The selected microcontroller and its battery module are shown in Fig. 3, respectively. An Atomic Battery Base (200 mAh, 24 × 24 × 27 mm) was used solely to provide autonomous power during data collection and testing; battery-life optimization was beyond the scope of this work and is left for future development. A custom 3D-printed PLA enclosure fixed the device to the wrist via a Velcro strap, yielding a total wearable mass of 35 g, as shown in Fig. 4 and 5.

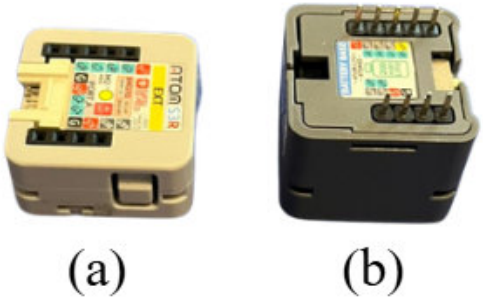

Fig. 3. Hardware used in the prototype: (a) the M5Stack AtomS3R-Ext microcontroller and (b) the Atomic Battery Base module.

Fig. 4. Prototype of the wrist-worn smartband: M5Stack AtomS3R-Ext enclosed in a 3D-printed PLA case and fixed to the wrist via a Velcro strap.

C. Signal Acquisition and Filtering

The IMU outputs accelerometer data in multiples of gravitational acceleration (g) and gyroscope data in degrees per second (°/s). A moving-average filter with window size N was applied to attenuate high-frequency noise:

$$y[n] = \frac{1}{N} \sum_{k=0}^{N-1} x[n-k] \tag{1}$$

Fig. 5. Smartband worn on the wrist during operation.

where $y[n]$ is the filtered output at sample n, $x[n]$ is the raw sensor signal, and N is the window size. Windows of $N \in \{1, 5, 10, 20\}$ were evaluated. $N = 5$ provided the best trade-off between noise suppression and dynamic response preservation, and was adopted as the definitive filter parameter.

1) Dataset Collection: A pilot experimental protocol was conducted with two healthy adult volunteers, both authors of this work, simulating fall events and activities of daily living (ADL). This is a significant limitation of the present study: the dataset was neither collected from the target population (older adults with cognitive impairment) nor from an independent, larger cohort, and results should therefore be interpreted strictly as a technical proof-of-concept. Fall events (forward, lateral, and backward) were recorded, resulting in 100 simulated fall trials per subject, totalling 200 labelled fall trials. ADL samples, walking, light running, jumping, sitting, dishwashing, and arm raising, were also recorded (approximately 10 samples per activity per subject). Raw IMU signals were then segmented into windowed samples of 1000 ms with a 250 ms stride (75% overlap) at a 20 Hz sampling frequency, yielding a total of 490 windowed samples distributed between two classes: *fall* and *non-fall*. The Edge Impulse platform split these 490 windows randomly at the window level into 386 for training and 104 for testing, with both volunteers contributing to both subsets.

Because adjacent windows were extracted with 75% overlap, highly correlated segments from the same fall or ADL event can appear in both the training and test subsets. This constitutes data leakage at the window level and is considered the most critical methodological limitation of this study: it may substantially inflate the accuracy reported in Section III, since the model can partially memorize event-specific patterns rather than learning fall dynamics that generalize to unseen events or subjects. In addition, the classification metrics reported in this paper (Section III) correspond to an internal validation split of $n = 849$ windows automatically held out by the Edge Impulse training pipeline from the 386 training windows, rather than to the independently reserved 104-window test set. A fully independent, leakage-free evaluation on that test set was not performed and is identified as a priority for future work. A rigorous evaluation should instead partition data by event and by subject (e.g., leave-one-subject-out), ensuring that no windows from the same fall event appear in both training and evaluation splits.

Furthermore, falls in older adults may exhibit kinematic signatures different from those of healthy young adults, due to factors such as reduced movement speed, impaired protective reflexes, and altered gait patterns. Given the small sample (two subjects), the window-level data leakage described above, and the absence of participants from the target population, the dataset and the results derived from it should be regarded strictly as a proof-of-concept, and validation with independent, subject-diverse, and target-population data remains necessary before any clinical interpretation. Fig. 6 illustrates a representative IMU signal sample recorded during a forward fall trial, showing the characteristic pattern of accelerometer and gyroscope responses across the three phases: motionless, fall, and post-fall motionless.

2) Model Architecture: The model was developed on the Edge Impulse platform. Raw six-axis IMU signals were segmented into 1000 ms windows with a 250 ms stride (75% overlap) at 20 Hz, resulting in 20 samples per axis and 120 input values per window. Time-domain raw data were used directly, without spectral transformation, since falls are transient and non-periodic events better represented in the temporal domain [17]. A 1D CNN was employed, as illustrated in Fig. 7. The architecture consists of an input layer (120 features), a reshape layer to organize the 120 input values according to the six IMU axes, two 1D conv/pool blocks (24 filters, kernel size of 5; followed by 48 filters, kernel size 3), a flatten layer, a dense layer (32 neurons), and a 2-class softmax output layer. Training was performed for 120 epochs with a learning rate of 0.0005, selected empirically to ensure stable convergence without overshooting the loss minimum.

After training, the model was quantized to int8 and exported as an optimized C++ library integrated directly into the device firmware. The int8 version was selected for embedded deployment to reduce memory footprint and inference cost on the microcontroller, enabling real-time operation within the resource constraints of the M5Stack AtomS3R-Ext.

D. Multi-Stage Fall Confirmation

To reduce false positives inherent to wrist-worn sensors, a three-stage verification pipeline was implemented after the CNN inference. All thresholds were determined empirically based on the analysis of IMU signal plots collected during the same limited experimental protocol described in Section II-C1, selecting values that maximized fall detection while minimizing false positives in ADL scenarios. Because these thresholds were calibrated using the same small, self-collected dataset used for model development, they may be overfitted to the specific movement patterns of the two subjects and the specific

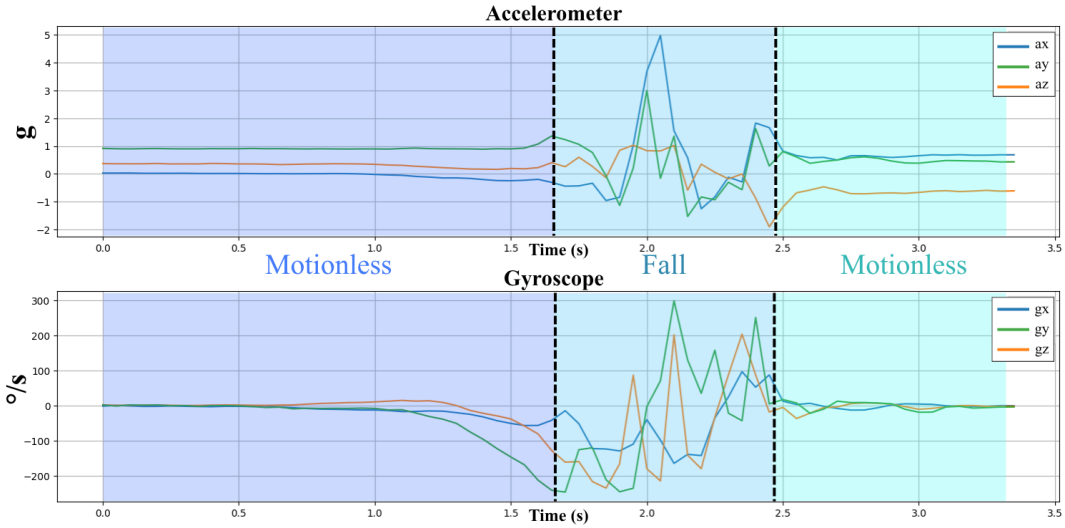

Fig. 6. Representative IMU signals during a experimental forward fall sample: accelerometer (top) and gyroscope (bottom) responses across three phases: motionless, fall, and post-fall motionless.

Fig. 7. 1D CNN architecture deployed on the M5Stack AtomS3R-Ext comprising an input layer (120 features), a reshape layer, two 1D convolution/pooling blocks, a flatten layer, a dense layer (32 neurons), and 2-class output layer.

ADL repertoire recorded, and their generalization to other individuals and activities has not been verified.

Stage 1 – K-of-M temporal voting: a fall suspicion is raised when at least $K = 1$ of the last $M = 2$ inference windows exceeds a fall probability threshold of 0.85. These values were determined empirically: more conservative configurations (e.g., $K = 2$, $M = 2$) caused genuine fall events to be missed, since requiring multiple high-probability windows within such a short sequence is overly restrictive given that a fall is a brief, transient event spanning few windows. While increasing M could potentially reduce false positives during high-intensity activities, it would also delay or suppress the detection of real falls, compromising the system's primary safety objective. The selected $K = 1$, $M = 2$ configuration prioritizes detection sensitivity, with false-positive suppression delegated to the subsequent physical verification stages.

Stage 2 – Impact verification: within a 1.8 s window following suspicion, either (a) acceleration magnitude exceeds 3.80 g, or (b) acceleration magnitude exceeds 3.40 g simultaneously with angular velocity magnitude exceeding 380 °/s.

Stage 3 – Post-impact immobility: over a minimum 1 s interval, angular velocity must remain below 20 °/s and acceleration magnitude variation must stay within 0.12 g of the reference value, confirming that the subject is motionless after impact.

Only events satisfying all three stages are classified as confirmed falls and trigger an MQTT alert.

III. Results

A. Model Validation Performance

The Edge Impulse platform automatically reserves a fraction of the 386 training windows described in Section II-C1 as an internal validation split during model training; this split, rather than the independently held-out 104-window test set, comprised the $n = 849$ windows evaluated below. Because this validation split is drawn from the same pool of events used for training, and given the window-level overlap described in Section II-C1, the metrics reported here should be interpreted as an upper-bound, in-distribution estimate of model performance rather than as evidence of generalization to unseen subjects or events. The float32 version achieved 95.5% accuracy and a ROC-AUC of 0.956. The int8-quantized version, used for embedded execution, achieved 95.2% accuracy and a ROC-AUC of 0.951, indicating that quantization introduced negligible performance degradation relative to the float32 version on the same validation split. Per-class metrics for the int8 model are summarized in Table II.

The confusion matrix (Fig. 8) shows that 504 of 528 non-fall samples and 304 of 321 fall samples were correctly classified. t-distributed Stochastic Neighbor Embedding (t-SNE) was used to visualize the learned feature space and

TABLE II
PER-CLASS PERFORMANCE METRICS – INT8 MODEL (INTERNAL VALIDATION SPLIT, $n = 849$)

Class	Precision	Recall	F1-score
Non-fall	97.5%	95.3%	0.964
Fall	92.5%	96.0%	0.942

assess class separability in a 2D representation, suggesting clear class separation, with misclassifications concentrated at the decision boundary, as shown in Fig. 9. Training and validation accuracy curves stabilized above 95% by epoch 20, indicating adequate convergence within 120 epochs, as shown in Fig. 10; the divergence between training and validation loss visible after approximately epoch 40 is consistent with mild overfitting, expected given the limited and non-independent dataset.

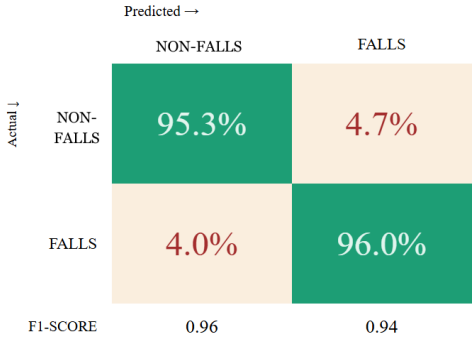

Fig. 8. Confusion matrix of the int8-quantized model evaluated on the internal validation split (849 samples).

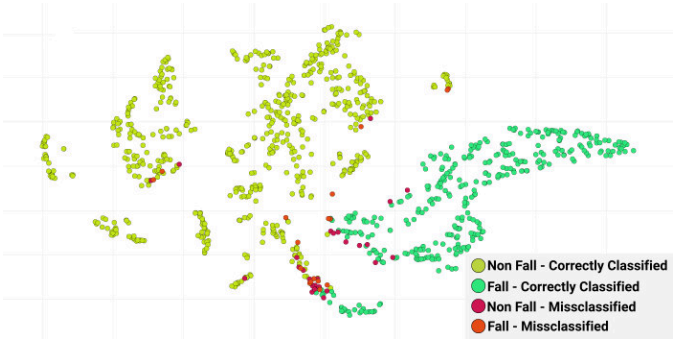

Fig. 9. t-SNE two-dimensional projection of the internal validation split showing class separability. Non-fall and fall samples are largely grouped in distinct clusters, with misclassified samples concentrated at the decision boundary.

B. Experimental Results – Fall Detection

Ten trials of each fall type were conducted with the device operating autonomously on the microcontroller, performed by the same two adult authors who also contributed to the training data. This sample size (10 trials per fall type) is too small to provide a statistically robust estimate of sensitivity, and the results below should be read as an indicative, not conclusive, characterization of on-device performance. Results are summarized in Table III.

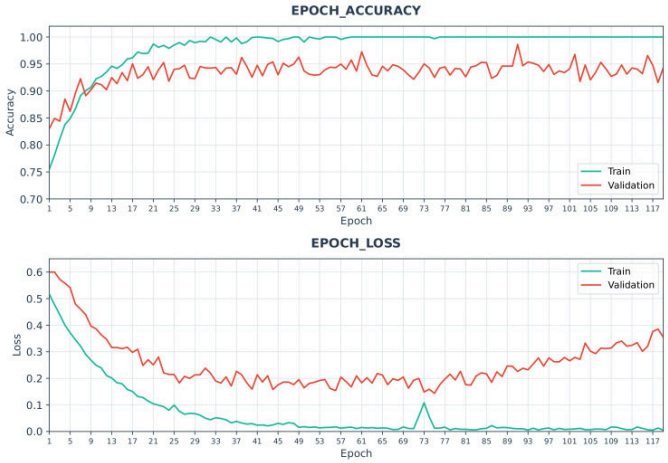

Fig. 10. Training and validation accuracy (top) and loss (bottom) curves over 120 epochs. Both metrics stabilize by epoch 20, with the divergence between training and validation loss indicating mild overfitting, expected given the limited dataset size.

TABLE III
FALL DETECTION PERFORMANCE IN PRACTICAL ON-DEVICE TESTS

Fall Type	Trials	Detected	Detection Rate
Forward	10	10	100%
Backward	10	8	80%
Lateral	10	7	70%

Forward falls were detected in all ten trials. Lateral falls showed the lowest detection rate (70%): in the three missed trials, wrist impact attenuation by the arm reduced peak acceleration below the Stage 2 threshold. Consequently, although the CNN correctly flagged a fall suspicion, the physical verification stage rejected it. This limitation appears to be associated with wrist-worn placement rather than with the classifier itself. These results suggest that a single, subject-independent acceleration threshold may not be adequate across all fall types, and two mitigation strategies are proposed for future work: (i) fall-type-adaptive thresholds, learned or calibrated separately for lateral falls, and (ii) a complementary sensing modality, such as a barometric pressure sensor, capable of detecting the altitude change associated with a real fall independently of arm-bracing behavior. One false positive was recorded during a rapid arm movement followed by immediate immobility on a surface, a motion that structurally mimics a fall signature and cannot be disambiguated from wrist-worn inertial data alone. The same barometric-sensing strategy could help distinguish this case, since an isolated arm gesture does not involve a change in whole-body height.

A qualitative comparison was made against a simple

threshold-only baseline (a fall was flagged whenever acceleration exceeds 3.80 g, with no temporal voting or post-impact verification). During the practical trials, high-intensity ADL such as running and jumping produced peak accelerations exceeding this threshold, which would have triggered false alerts under the baseline approach; the full pipeline correctly rejected these events at Stage 1 or Stage 3. However, sensitivity, specificity, and false-positive rate were not systematically computed over a dedicated test set, and this quantitative comparison is identified as a priority for future work rather than reported here as a complete result.

C. Computational Performance

Table IV summarises the embedded computational metrics observed during continuous autonomous operation. The system operated continuously during the practical test sessions without resets or critical failures. The 0.7% CPU load confirms that inference does not compromise concurrent tasks (MQTT communication, geofencing, and sensor acquisition).

The int8-quantized model itself, as estimated by the Edge Impulse platform, requires only 6.7 kB of peak RAM and 48.6 kB of Flash memory, with an estimated inference time of 6 ms. This compact footprint represents a small fraction of the total resources available on the M5Stack AtomS3R-Ext, demonstrating the effectiveness of int8 quantization in enabling TinyML deployment on resource-constrained microcontrollers.

TABLE IV
EMBEDDED COMPUTATIONAL PERFORMANCE – M5STACK ATOMS3R-EXT

Parameter	Value
Min. inference time	7 ms
Max. inference time	8 ms
Mean inference time	≈7.03 ms
Estimated ML CPU load	0.7%
Model peak RAM usage (int8)	6.7 kB
Model Flash usage (int8)	48.6 kB
Total SRAM (ESP32-S3)	512 kB
Typical free heap	≈243 kB
Firmware Flash usage	1,370,207 B (41%)
Static RAM usage	56,292 B (17.2%)

D. Geofencing Performance

In addition to fall detection, the Wi-Fi-based geofencing module was evaluated under realistic conditions, with the mobile application running in the background. This mechanism is limited to detecting the presence or absence of the preconfigured home Wi-Fi network and should not be interpreted as general spatial tracking or precise localization; it cannot indicate the wearer's position beyond the network's coverage area. The total time between the wearer leaving the configured perimeter and the caregiver receiving the notification was 21.78 s. This interval includes a 15 s confirmation window intentionally configured in the firmware to validate the disconnection and avoid false alerts caused by momentary signal loss, with the remaining time corresponding to the latency of the communication stack (MQTT publication, Firebase Cloud Messaging push delivery, and smartphone processing). The reconnection time, measured from the wearer's return to the perimeter until the status update in the application, was 4.45 s.

It is worth noting that both values are influenced by external factors, such as the quality of the local network infrastructure and the smartphone operating system's handling of background notifications, and therefore do not represent intrinsic limitations of the proposed embedded system.

IV. DISCUSSION

The experimental evaluation consisted of simulated fall tests performed by the two adult authors under controlled conditions, without the involvement of external participants, older adults, individuals with cognitive impairment, or clinical trials. Consequently, none of the findings reported here should be interpreted as evidence of clinical effectiveness. Although direct comparison is limited by differences in datasets and experimental protocols, the proposed system achieved 95.2% accuracy on its internal validation split, compared with the 92.31% reported by Volochtchuk and Bassai [11] using an Edge Impulse-based pipeline, while advancing to full autonomous embedded deployment. This comparison should nonetheless be read with caution, since neither study evaluated on a leakage-free, subject-independent test set. The 7 ms inference time and 0.7% CPU utilization demonstrate that 1D CNN inference is practical on a low-cost ESP32-S3 microcontroller, leaving ample headroom for other system tasks.

The wrist placement, while preferred for user acceptance, introduces inherent challenges: lateral falls produce lower-amplitude IMU signatures due to natural arm bracing, and rapid arm gestures can occasionally mimic fall dynamics. These limitations are consistent with findings from Nunez et al. [8], who reported that wrist sensors exhibit higher classification ambiguity than chest-mounted alternatives. Adaptive class thresholds or a complementary barometric pressure sensor could mitigate these issues in future work, since the altitude variation associated with a real fall would help distinguish it from isolated arm movements that do not involve a change in body height.

The system also integrates a Wi-Fi-based geofencing module, which detects whether the device remains within the configured home network perimeter and notifies the caregiver in case of a boundary breach, providing an additional monitoring functionality without requiring GPS hardware. As noted in Section III, this functionality is limited by Wi-Fi coverage and does not constitute general location tracking.

A. Lessons Learned and Research Gaps

Three practical lessons emerged from this work. First, window-level random splitting is inadequate for wearable fall-detection datasets built from short, repeated trials: with 75% window overlap, event- and subject-independent partitioning (e.g., leave-one-subject-out or leave-one-event-out) is necessary to obtain a trustworthy estimate of generalization, and

should be planned from the data-collection stage rather than applied post hoc. Second, a CNN classifier alone may be insufficient to suppress false positives from high-intensity, non-fall activities. The multi-stage physical verification pipeline used here shows that combining a learned classifier with interpretable, physics-based rules can provide an effective and computationally inexpensive strategy, though thresholds calibrated on a small development set risk overfitting to the specific subjects and activities recorded. Third, wrist placement, while potentially favorable for user acceptance, can weaken the acceleration signature of certain fall types (notably lateral falls) and may be vulnerable to arm-gesture false positives. These observations suggest that single-sensor wrist-only systems may need a complementary modality (e.g., barometric pressure) to reach clinically relevant sensitivity and specificity.

The main research gaps identified are: (i) the absence of a leakage-free, event- and subject-level evaluation of the trained model; (ii) the lack of data from the target population (older adults, particularly those with cognitive impairment), whose fall kinematics may differ from those of healthy young adults; (iii) the absence of quantitative sensitivity, specificity, and false-positive rate comparisons against baseline threshold methods over a common, dedicated test set; and (iv) the lack of usability, comfort, adherence, and battery-autonomy assessments, all of which are necessary before this proof-of-concept can be considered for real-world deployment with cognitively impaired users.

V. Conclusion

This paper presented a wrist-worn smartband combining fully embedded TinyML inference with a multi-stage physical verification pipeline for automatic fall detection. A 1D CNN quantized to int8 and deployed on an M5Stack AtomS3R-Ext reached 95.2% accuracy and a ROC-AUC of 0.951 on an internal validation split, with a 7 ms mean inference time and 0.7% CPU load, indicating that this class of on-device processing is computationally practical on a low-cost microcontroller. The study demonstrates a promising embedded TinyML proof of concept for wrist-based fall detection; however, its clinical validity has not been established and depends on: (i) leakage-free, event-level and subject-level evaluation on an independent test set; (ii) larger and more diverse cohorts; (iii) testing with older adults and individuals with cognitive impairment; (iv) longitudinal, real-world assessment; (v) battery-autonomy evaluation; and (vi) direct, quantitative comparison with baseline threshold methods and alternative sensor placements. The source code and embedded libraries are available at `https://github.com/rodbcl/Edge-AI-Smartband`.

Abstract —Surface electromyography (sEMG) is a non-invasive method for recording electrical activity associated with skeletal muscle activation. In rehabilitation, it supports functional assessment, therapeutic biofeedback, neuromuscular re-education, movement analysis, and recovery monitoring in neurological, musculoskeletal, and post-operative conditions. This review discusses current methodological principles, clinical applications, technical challenges, and future perspectives for the use of sEMG in physical therapy and rehabilitation science. The article emphasizes acquisition procedures, electrode placement, signal conditioning, normalization, interpretation, and integration with wearable systems, artificial intelligence, telerehabilitation, robotics, and virtual environments. Although sEMG offers relevant information regarding muscle synchronization, symmetry, fatigue, and motor control strategies, its clinical translation depends on standardized protocols, adequate professional training, transparent reporting, and careful interpretation regarding functional outcomes. The future of sEMG in rehabilitation is promising, especially when combined with multimodal assessment, patient-centered biofeedback, and reproducible digital health workflows.

Keywords— surface electromyography; rehabilitation; physical therapy; biofeedback; wearable sensors; signal processing; motor control.

I. INTRODUCTION

Surface electromyography (sEMG) has consolidated itself as an essential biophysical tool in sports science and rehabilitation, allowing for the non-invasive assessment of neuromuscular activity and the physiological mechanisms underlying motor performance [1], [2]. By capturing motor unit action potentials through the skin, sEMG offers a direct reflection of the central command sent to the muscles, making it indispensable for investigating coordination, muscle recruitment, and training adaptations [2], [3].

In clinical rehabilitation settings, monitoring neuromuscular alterations is fundamental for understanding functional deficits resulting from stroke, spinal cord injury, or post-operative musculoskeletal disorders [7]. A critical phenomenon evaluated by sEMG is muscle fatigue and activation timing, which directly reflects the neuromuscular system's capacity to sustain effort or coordinate movement during therapeutic exercises [4], [5]. Identifying these electromyographic changes allows physical therapists to tailor load progression, prevent secondary compensations, and optimize functional motor recovery [1], [2].

Standard fatigue and activation assessments traditionally rely on time-domain amplitude descriptors, such as the root mean square (RMS), and spectral frequency parameters, including mean and median frequencies [1], [5]. However, translating these parameters into routine physical therapy faces significant clinical and methodological challenges, such as signal crosstalk, anatomical variability, and the lack of standardized normalization protocols for patients with pain or neurological impairments [3], [6]. While advanced signal processing and machine learning approaches offer new opportunities to map motor control, their success critically depends on reproducible methodologies validated in clinical populations [7], [10].

This systematic review aims to evaluate the clinical application and methodological validity of surface electromyography (sEMG) in rehabilitation. Specifically, this study addresses the following PICO question: In patients undergoing physical rehabilitation (P), how does sEMG-assisted assessment or biofeedback (I) compare to conventional therapeutic evaluations or standard care (C)

in improving neuromuscular control and functional outcomes (O)?

II. BASIC PRINCIPLES OF SURFACE ELECTROMYOGRAPHY

Skeletal muscle contraction depends on action potentials generated by the activation of alpha motor neurons. When a motor unit is recruited, electrical activity propagates along the fibers, and surface electrodes detect the summation of these potentials. The recorded sEMG signal is an indirect representation of neuromuscular activation, highly influenced by physiological, anatomical, and technical factors [1], [2], [5]. The raw signal is generally bipolar, oscillating around a baseline. Its amplitude is affected by the number and firing rate of motor units, distance between fibers and sensors, tissue impedance, subcutaneous fat, and interference from adjacent muscles (cross-talk), while the frequency depends on conduction velocity and fatigue [1], [5].

Thus, sEMG does not directly measure isolated force, and high amplitudes do not necessarily indicate better muscle function; they can reflect compensations or inefficient motor strategies [1], [5]. Conversely, reduced amplitudes may signal weakness, inhibition, or greater technical efficiency. In rehabilitation, variables such as synchronization, symmetry, and mutual coordination are clinically more informative than isolated peaks, allowing for the assessment of, for example, quadriceps lag post-ligament reconstruction or gait asymmetry [1]. Because it is a non-invasive, accessible, and dynamic method, it applies to sports and ergonomic gestures but demands technical rigor. International guidelines, such as the SENIAM recommendations, remain fundamental for standardizing sensor placement and signal processing [1], [2], [3].

III. ACQUISITION METHODS AND ELECTRODE PLACEMENT

Quality in signal acquisition determines the validity of its interpretation. Sensors must be fixed over the muscle belly, parallel to the fibers, and respecting an adequate inter-electrode distance, after hair shaving, mild abrasion, and alcohol cleaning to mitigate impedance [3], [6]. Disposable Ag/AgCl bipolar configurations are the gold standard due to their stability and common-mode rejection, although textile and dry sensors are gaining ground in home-based wearable systems [5]. Placement requires caution in deep or overlapping structures (such as the forearm and paraspinal region) due to the risk of cross-talk [3], [6].

Dynamic tasks introduce artifacts from sweat and cable sway. Wireless devices minimize these impacts, requiring strict control over data packet loss and sampling rates (frequently above 1000 Hz) to record the entire physiological bandwidth [5]. Standard filtering utilizes band-pass filters to attenuate motion artifacts and high-frequency noise, associated with notch filters to eliminate power line interference (60 Hz), avoiding aggressive cut-offs that distort the signal phase [5]. For reliable longitudinal assessments, the clinician must meticulously document posture, load, and anatomical location, resorting to photographic records to prevent placement variations from masking real clinical progress [3], [6].

IV. SIGNAL PROCESSING AND INTERPRETATION

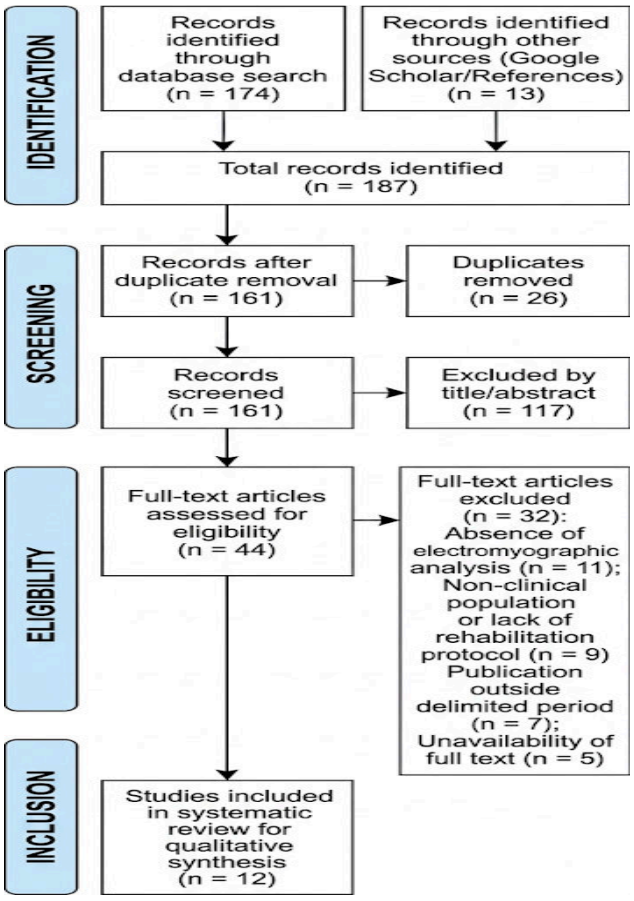
The raw signal initially undergoes a visual inspection for the exclusion of artifacts or saturation before being filtered, rectified, smoothed, and segmented [4], [5]. The most common time-domain descriptors are the root mean square (RMS), mean rectified value, and integrated EMG, while spectral descriptors (mean and median frequencies) are the basis for fatigue monitoring [4], [5]. The RMS reflects signal power in time windows whose durations balance time resolution and profile smoothness [1], [5].

Signal normalization is widely debated in the literature [3], [13], [14]. Because raw amplitudes vary due to non-physiological factors, Maximum Voluntary Isometric Contraction (MVIC) serves as the traditional reference, but fails in patients limited by pain or neurological dysfunctions. Alternative methods comprise submaximal reference contractions, peaks from the task itself, or dynamic normalizations [4], [5]. Furthermore, establishing sEMG assessment consistency across dynamic lower-limb tasks, such as vertical countermovement jumps, remains critical for ensuring measurement reliability in functional assessments [15]. Spectral analysis detects fatigue by shifting the spectrum toward lower frequencies due to the reduction in fiber conduction velocity, although in dynamic tasks, this interpretation suffers interference from variations in joint angles [1].

Machine Learning approaches have been proposed to classify movement intentions and predict fatigue [10]. By extracting features in the time and frequency domains, these models require rigorous internal validation processes and generalization tests to mitigate overfitting to specific training data [10]. For success in rehabilitation, however, the clinical interpretability of these algorithms and the integration of the sEMG signal into the patient's functional scenario—such as correlating hyperactivities with pain or dyskinesias—remain indispensable [1], [10].

V. RESULTS

A. Study Selection Results



The systematic search was conducted across six electronic databases (PubMed, SciELO, Frontiers, MDPI, Nature, and JSSM) using Medical Subject Headings (MeSH)

terms combined with Boolean operators for 'surface electromyography', 'rehabilitation', and 'neuromuscular control' [4], [11]. Methodological quality and risk of bias were independently evaluated by two reviewers using the PEDro scale for randomized trials and the ROBINS-I tool for non-randomized intervention studies, with consensus resolving any discrepancies [4], [12].

The search and article selection process followed the recommendations of the PRISMA 2020 protocol, as detailed in Flowchart 1. Initially, the automated search across the six selected databases (PubMed, SciELO, Frontiers, MDPI, Nature, and JSSM) resulted in 174 records. Additionally, 13 studies were identified through other sources, such as reference lists and Google Scholar, totaling 187 identified records.

Of the remaining 44 articles that advanced to full-text evaluation, 32 were excluded for the following specific reasons: absence of electromyographic analysis (n = 11); non-clinical population or lack of a rehabilitation protocol (n = 9); publication outside the delimited period (n = 7); and unavailability of the full text (n = 5). At the end of this process, 12 studies met the eligibility criteria and were included for qualitative synthesis.

Due to the high heterogeneity of protocols, evaluated muscles, and metrics used among the selected studies, conducting a statistical meta-analysis with a pooled effect size was not feasible.

VI. APPLICATIONS IN CLINICAL REHABILITATION

A. Neurological Rehabilitation

Dysfunctions resulting from Stroke, spinal cord injury, cerebral palsy, and Parkinson's disease severely alter patterns of coordination and selective motor control. sEMG operates by identifying whether functional restriction stems from insufficient recruitment, spasticity, or anomalous co-contractions [7]. In post-stroke patients, it assists in mapping dynamic asymmetries and muscle timing during the stance and swing phases of gait, supporting adjustments in orthoses and Functional Electrical Stimulation (FES) parameters [7].

sEMG biofeedback converts invisible electrical activity into real-time visual or auditory signals, providing concrete goals for patients with reduced proprioception, which accelerates motor learning and spasm relaxation [7]. Currently, robotic interfaces and exoskeletons utilize sEMG as an input signal to trigger movements based on user intent, directly stimulating neuroplasticity, provided they operate with low latency and robust filters against daily signal fluctuations [10].

B. Musculoskeletal and Sports Rehabilitation

In orthopedic dysfunctions, sEMG detects muscle inhibitions and protective guarding patterns. Post-anterior cruciate ligament reconstruction, it monitors quadriceps restoration and compensatory co-contractions during squatting and jumping, defining safe criteria for load progression [1]. In shoulder rehabilitation, it quantifies activation ratios between scapular stabilizers and the rotator cuff, allowing for the selection of lower-impact exercises [1]. In chronic low back pain conditions, biofeedback guides reconditioning and alleviates protective hyperactivity of the trunk [1]. In the sports sphere, wearable inertial sensors associated with sEMG enable kinematic and neuromuscular analyses directly on the field, allowing for the monitoring of asymmetries and predicting injury risks during complex sports gestures (such as running and throwing) outside the controlled laboratory environment [8].

C. Biofeedback and Motor Learning

The sEMG biofeedback transforms the signal into sensory stimuli that optimize muscle regulation. Its efficacy depends on controlled delivery: continuous feedback can induce dependence, requiring fading techniques (gradual reduction) to consolidate long-term retention [7]. Wearable technologies and integrated mobile applications extend these practices to the home environment, promoting greater therapeutic adherence [7], [9]. Furthermore, the insertion of virtual and gamified environments substantially elevates patient engagement by converting contractions and relaxations into interactive, playful commands, while addressing technological challenges related to usability, safety, and system latency [7].

VII. CHALLENGES, LIMITATIONS, AND FUTURE PERSPECTIVES

Despite its broad potential, sEMG exhibits critical limitations. The signal demonstrates extreme sensitivity to millimeter-level variations in placement, adipose tissues, and cross-talk, requiring rigorous documentation to enable longitudinal follow-up [3], [5]. The absence of a universal protocol limits direct comparisons, as established methodologies for healthy individuals rarely apply to

clinical populations with severe pain conditions [4], [6]. Another obstacle lies in the mistaken interpretation of amplitude as a direct synonym for force, disregarding factors of motor inefficiency or fear [1], [5]. Additionally, the high cost of equipment and the need for deep technical training in signal processing reduce its dissemination in daily clinical practice [4]. Continuous home monitoring via wearable sensors also imposes new ethical challenges regarding governance, privacy, and the security of physiological data [11], [12].

Future perspectives converge toward hardware miniaturization and the adoption of flexible and textile electrodes, mitigating motion artifacts and optimizing comfort during prolonged monitoring [9]. More than the raw time-series amplitude which currently holds limited standalone clinical value due to noise and impedance variability the true potential of modern sEMG lies in signal transformation into the frequency and time-frequency domains (e.g., via Fast Fourier Transform and Wavelet transforms). Spectral parameters, such as shifts in median (Fmed) and mean (Fmean) frequencies, serve as fundamental physiological biomarkers to objectively quantify neuromuscular fatigue, motor unit firing behavior, and fiber recruitment patterns well before structural performance deteriorates. Artificial intelligence algorithms stand out in supporting complex feature extraction and identifying subtle changes in muscle coordination during repetitive tasks, provided they are validated on representative data and structured comprehensibly for clinicians [10]. The consolidation of multimodal systems (sEMG combined with inertial and pressure sensors) provides a complete biomechanical mapping and drives telerehabilitation, allowing for remote and objective supervision of exercise routines [7], [8]. Finally, open science practices and the sharing of code pipelines and public databases are essential to mitigate literature heterogeneity and accelerate the clinical translation of these technologies, ensuring that innovations remain focused on functional gain and patient safety [11].

VIII. CONCLUSION

Surface electromyography is a valuable method for assessing and training neuromuscular function in rehabilitation. Its non-invasive nature, compatibility with movement, and potential for real-time feedback make it useful in neurological, musculoskeletal, sports, and post-operative contexts. It can support clinical reasoning by revealing activation synchronization, intensity, symmetry, fatigue, co-contraction, and motor control strategies that are not always visible through observation alone [1], [2].

At the same time, sEMG is not a simple or self-explanatory measurement. Its clinical value depends on careful acquisition, standardized protocols, adequate processing, cautious normalization, and contextual interpretation. Challenges such as crosstalk from adjacent muscles, motion artifacts, variability in electrode placement, limited standardization, and overinterpretation must be addressed through training and transparent reporting [3], [5], [6].

Future developments in wearable sensors, artificial intelligence, telerehabilitation, robotics, and virtual environments are driving sEMG beyond traditional laboratories and specialized clinics. Crucially, this transition relies on advancing beyond static, offline signal evaluation toward **real-time frequency-domain analysis**. Instantaneous spectral processing (e.g., real-time shifts in median and mean frequencies) allows for the continuous monitoring of motor unit fatigue, recruitment dynamics, and muscle coordination as movement happens. This enables immediate biofeedback and dynamic system adaptation in clinical and telerehabilitation settings. Ultimately, the most promising direction lies in patient-centered integration: systems that leverage real-time spectral metrics to help clinicians prescribe optimized exercises, mitigate injury risk, and enhance functional recovery. When used responsibly, surface electromyography becomes an intelligent bridge between neuromuscular physiology, real-time digital health, and functional rehabilitation [7], [9], [10].

TABLE I. CLINICAL USES OF sEMG IN REHABILITATION

Clinical Objective	sEMG Contribution	Example in Rehabilitation
Assessment	Quantifies activation synchronization, amplitude, symmetry, and fatigue	Comparing quadriceps activation after knee surgery
Biofeedback	Transforms muscle activity into real-time visual or auditory cues	Training upper trapezius relaxation in cervicalgia
Motor Control	Reveals co-contraction, delayed onset, or compensatory recruitment	Analyzing ankle dorsiflexor timing post-stroke
Exercise Selection	Compares muscle demand between therapeutic exercises	Selecting scapular stabilization exercises
Remote Monitoring	Supports home-based follow-up when integrated with wearable devices	Monitoring adherence and activation quality during telerehabilitation

ACKNOWLEDGMENTS

***Abstract*— The aim of this study was to systematize the current evidence of software, mobile devices and applications that promote assessment and intervention in postural misalignments, balance and postural control with a focus on individuals with neurological impairment. The study is a systematic review of studies published between 2015 and 2025 through the Cochrane Library, LILACS, PEDro, PubMed and Web of Science databases, using the descriptors posture, postural control, postural balance, postural correction, sitting posture, supine position, orthostatic position, neurological disorder, nervous system diseases, neurological rehabilitation, mobile applications and biomedical technology, following the PRISMA guidelines and registered in PROSPERO (CRD420261443761), with the data summarized in a descriptive table. Meeting the search requirements resulted in 1,089 studies, however, complying with the inclusion and exclusion criteria, 15 studies remained and had their results analyzed. Mobile technologies and sensor systems offer potential for the assessment, monitoring, and rehabilitation of postural control, alignment, and balance in individuals with neurological conditions. However, available evidence remains limited and heterogeneous regarding populations, devices, sensors, operating systems, tasks, and outcomes, making it difficult to draw clinically applicable conclusions. Thus, although some studies indicate favorable results concerning the validity, reliability, and feasibility of these technologies, further research characterized by greater methodological rigor, standardized protocols, and adequate sample sizes is still needed to establish their clinical effectiveness in neurological rehabilitation.**

Keywords*— *neurological rehabilitation, diseases of the nervous system, postural control, balance, mobile applications.

I. INTRODUÇÃO

De acordo com a Organização Mundial da Saúde (OMS), os distúrbios neurológicos constituem a principal causa de incapacidade e a segunda principal causa de mortalidade em todo o mundo [1]. Essas condições afetam o sistema nervoso central e/ou periférico, comprometendo significativamente o desempenho motor, sensorial, cognitivo e funcional dos indivíduos [2,3].

As doenças neurológicas envolvem a redução do controle motor, devido a degeneração ou lesão do sistema nervoso e neuromuscular, gerando déficits como perda de coordenação e a dificuldade em manter a postura e a marcha, assim são necessárias intervenções fisioterapêuticas voltadas para o alinhamento postural utilizando métodos ativos com o objetivo de corrigir deformidades da coluna e desalinhamentos corporais, ou ainda prevenir posturas inadequadas. Nesses tratamentos, o indivíduo é estimulado a realizar movimentos autocorretivos, exigindo consciência corporal e percepção postural [4,5,6,7,8,9].

O uso de tecnologia digital na avaliação do alinhamento, estabilidade postural e equilíbrio podem melhorar a precisão e a exatidão da medição e reduzem a variabilidade associada às diferenças na forma como os examinadores contabilizam os erros [10]. Uma solução emergente para superar as barreiras das intervenções domiciliares não supervisionadas é a implementação da tecnologia digital [11].

Com o uso de sensores inerciais (acelerômetros e giroscópios), métricas que compreendem o movimento de um indivíduo em aceleração no centro de massa demonstraram ter a capacidade de identificar significativamente o aumento da oscilação postural. Possíveis razões incluem maior tempo de configuração ou requisitos de processamento de dados *offline*, os quais interrompem o tempo e o fluxo de trabalho clínicos sempre limitados. Se comprovada a precisão, do uso de dispositivos móveis que contenham sensores inerciais para quantificar a oscilação postural, podem fornecer uma alternativa prática e de baixo custo às avaliações clínicas, substituindo plataformas de força e sistemas de análise óptica de movimento na quantificação da estabilidade postural, alinhamento postural e equilíbrio [9,11,12,13,14].

Assim devido à escassez de pesquisas acadêmicas a respeito da utilização de *softwares*, dispositivos móveis e aplicativos com enfoque no alinhamento postural, controle postural e equilíbrio na reabilitação neurológica, o presente estudo visa identificar através de uma revisão sistemática da literatura as tecnologias móveis utilizadas na reabilitação neurológica com enfoque no alinhamento postural, controle postural e equilíbrio.

II. METODOLOGIA

A busca iniciou-se em maio de 2025 e encerrou-se em outubro de 2025, e compreendeu os anos de 2015 a 2025, por meio das bases de dados Cochrane Library, LILACS, PEDro, PubMed e Web of Science, utilizando as seguintes palavras-chave de acordo com o DeCS (Descritores em Ciência da Saúde): *posture*, *postural balance*, *postural control*, *postural equilibrium*, *posture balance*, *sitting position*, *supine position*, *standing position*, *nervous system diseases*, *neurological rehabilitation*, *mobile applications* e *biomedical technology*, os geradores booleanos utilizados

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

para a busca foram AND e OR. A estratégia de busca utilizada para todas as bases de dados estão demonstradas na tabela 1.

Tabela 1: Estratégia de busca dos artigos selecionados.

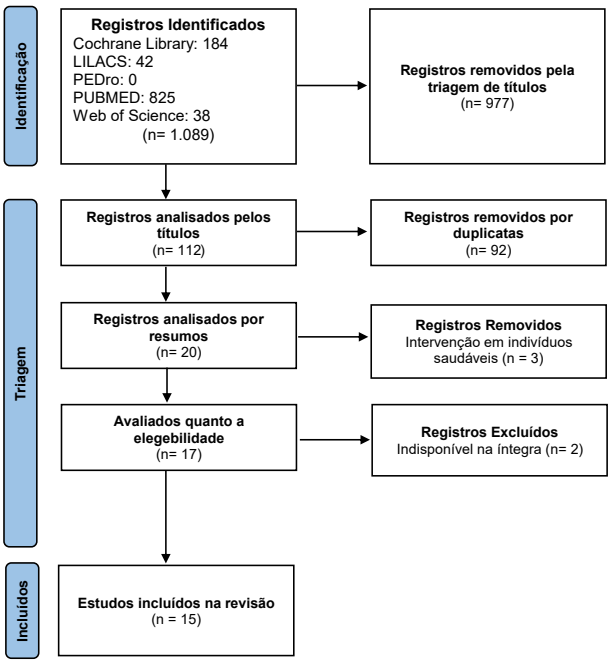
Bases de dados	Estratégia de Busca
Cochrane Library, LILACS, PEDro, PubMed e Web of Science	((((((((((posture) OR (postural balance)) OR (postural control)) OR (postural equilibrium)) OR (posture balance)) OR (sitting position)) OR (supine position)) OR (standing position)) AND (nervous system diseases)) AND (neurological rehabilitation)) AND (mobile applications)) AND (biomedical technology)

Seguindo os requisitos de inclusão foram considerados os estudos no idioma inglês, disponíveis na íntegra, que atendam os seguintes critérios: (1) população de indivíduos com diagnóstico ou comprometimento relacionado a condição neurológica; (2) utilização de tecnologias móveis ou sistemas tecnológicos portáteis para avaliação, monitoramento, feedback ou reabilitação do equilíbrio, controle postural, alinhamento postural, marcha ou função motora; (3) utilização de smartphones, tablets, dispositivos móveis, sensores inerciais, acelerômetros, giroscópios, inclinômetros, câmeras, sensores de profundidade ou plataformas tecnológicas portáteis; e (4) estudos que apresentam resultados relacionados à validade, confiabilidade, validação, usabilidade, desempenho, monitoramento ou eficácia da tecnologia.

Os critérios de exclusão englobam estudos realizados exclusivamente com indivíduos saudáveis, estudos que não apresentassem relação direta com avaliação, monitoramento ou reabilitação do controle postural e equilíbrio, estudos nos quais a tecnologia não fosse utilizada como instrumento de avaliação ou intervenção de interesse, revisões de literatura, editoriais, cartas ao editor, protocolos, trabalhos sem texto completo disponível e estudos duplicados.

Para seleção dos estudos seguiu-se as diretrizes PRISMA (*Preferred Reporting Items for Systematic Reviews and Meta-Analyses*), para melhor clareza e transparência do processo de revisão. O processo de seleção e análise dos artigos seguiu uma metodologia rigorosa, contando com a participação de dois pesquisadores independentes para seleção dos estudos. Inicialmente, realizou-se uma triagem com base nos títulos, seguida por uma análise mais aprofundada dos resumos e, posteriormente, a leitura completa dos textos selecionados.

Os artigos selecionados foram avaliados quanto a sua qualidade metodológica por dois revisores pelas escalas ROB 2 (*Risk of Bias Cochrane 2*) que avalia ensaios clínicos randomizados ou pela escala COSMIN (*COnsensus-based Standards for the selection of health Measurement INstruments*) que rastreia o risco de viés e descreve os elementos que auxiliam na construção de uma questão de pesquisa e fornece uma visão abrangente dos componentes da medida de resultados assim como os requisitos de projeto e métodos estatísticos preferidos sobre a confiabilidade e erro de medida dos instrumentos [15,16, 17]. Este protocolo foi devidamente registrado no Registro Prospectivo Internacional de Revisões Sistemáticas (PROSPERO), sob o número de registro: CRD420261443761.



A síntese dos principais achados foi analisada por dois pesquisadores e descrita de forma qualitativa. A análise dos dados foi organizada em uma tabela com identificação de autores, condição neurológica, tamanho amostral, tecnologia utilizada, dispositivo e sistema operacional (Tabela 2), e outra contendo sensores empregados, posicionamento do sensor, comparador, finalidade, e estágio de validação (Tabela 3).

III. Resultados e Discussão

Foram encontrados nas bases de dados 1.089 estudos, destes 825 foram encontrados na PubMed, 184 estudos na Cochrane Library, 42 na base de dados LILACS, 38 no *Web of Science* e 0 na base de dados PEDro.

Obedecendo aos critérios de inclusão e coerência com o tema do trabalho foram excluídos 977 estudos pela triagem inicial pela análise de títulos, permanecendo 112 estudos. Desses, 92 foram excluídos devido a duplicatas, permanecendo 20 estudos para análise pelos resumos, a análise foi realizada por dois avaliadores, assim dentre destes foram excluídos 3 por se tratarem de intervenção em indivíduos saudáveis, permanecendo assim 17 estudos para análise completa dos textos, onde 2 deles foram excluídos por indisponibilidade na íntegra. Desse modo, permaneceram-se 15 estudos (Figura 1).

Figura 1: Fluxograma PRISMA da revisão sistemática, evidenciando a forma de seleção dos artigos.

Com a finalidade de abordar detalhadamente os estudos científicos selecionados, foi elaborada uma tabela descritiva elucidando autores, condição neurológica e tamanho amostral, tecnologia, dispositivo e sistema operacional (Tabela 2).

Tabela 2: Descrição da população e condição neurológica investigada.

Dentre os 15 estudos muitos desfechos obtiveram dados que são considerados significativos, o nível de evidência deve ser levado em consideração, tendo em vista a ponderação dos desfechos com o risco de viés dos artigos analisados. Dos 15 artigos selecionados, 2 eram ensaios clínicos randomizados e os demais eram ensaios clínicos não randomizados.

Os ensaios clínicos randomizados foram analisados pela ferramenta ROB 2, ambos os estudos foram classificados como moderado risco de viés [29, 27]. Os problemas metodológicos mais encontrados envolveram à randomização, desvios da intervenção pretendida e na seleção dos resultados relatados (Figura 2).

Figura 2: Avaliação de Risco de Viés 2 (ROB 2).

Calcagni *et al.* [32]	±	?	+	?	?	±	±	±	A

Qualidade de desenvolvimento do estudo: "O" = ótima ou muito boa; "A" = adequada; "D" = duvidosa; "I" = inadequada. **Qualidade dos estudos sobre propriedades de medida:** "+" = suficiente; "–" = insuficiente; "?" = indeterminada; "±" = parcialmente suficiente.

Os estudos incluídos demonstram uma crescente aplicação de tecnologias móveis e sistemas instrumentados para avaliação e reabilitação do controle postural, equilíbrio e funcionalidade em diferentes condições neurológicas. Entretanto, a análise evidencia importante heterogeneidade quanto aos sensores empregados, posicionamento dos dispositivos, dispositivos móveis utilizados, sistemas operacionais, tarefas de avaliação, processamento dos sinais e finalidade tecnológica. Essa diversidade demonstra o potencial das tecnologias móveis para ampliar o acesso à avaliação objetiva do movimento, mas também evidencia desafios relacionados à padronização, reprodutibilidade, interoperabilidade e validação dos sistemas.

Os estudos podem ser compreendidos a partir de uma cadeia tecnológica composta por sensoriamento, aquisição do sinal, processamento, extração de parâmetros biomecânicos e interpretação clínica. Nesse contexto, o sensor não deve ser considerado isoladamente, uma vez que o resultado obtido depende também do dispositivo no qual está incorporado, do posicionamento corporal, das características de aquisição e do algoritmo utilizado para transformar o sinal em uma medida relacionada ao controle postural. Dessa forma, a análise dos estudos evidencia que a tecnologia deve ser compreendida como um conjunto sensor–*hardware*–*software*–algoritmo–protocolo–desfecho clínico.

Tecnologias inerciais na doença de Parkinson

Os estudos de Ozinga *et al.* [18–20] e Fiems *et al.* [21] destacaram-se pela utilização de sensores inerciais para avaliação da estabilidade e oscilação postural em indivíduos com DP. Nos estudos de Ozinga *et al.* [18,19], foram utilizados dispositivos móveis operados pelo sistema iOS, particularmente iPad, associados a sensores inerciais integrados (IMU). O aplicativo *CC-BApp*, desenvolvido pela Cleveland Clinic, foi empregado para captar medidas de equilíbrio estático em diferentes condições sensoriais e em três dimensões. A comparação com sistemas de referência demonstrou resultados positivos à utilização da tecnologia móvel para mensuração da estabilidade postural.

No estudo de Ozinga *et al.* [20], seguiu uma abordagem comparativa entre a acelerometria móvel e o sistema clínico Smart Balance Master da NeuroCom, utilizando o Sensory Organization Test (SOT). Foram analisadas as oscilações nos sentidos ântero-posterior (AP) e médio-lateral (ML), demonstrando que a acelerometria móvel pode constituir uma alternativa portátil para avaliação da instabilidade postural.

Fiems *et al.* [21] utilizaram o Sway Balance™ em um iPod Touch com iOS, empregando IMUs para mensurar a oscilação postural. O protocolo incluiu Romberg, semi-tandem, tandem e apoio unipodal, com variação da superfície e da condição visual. O estudo demonstrou forte confiabilidade teste-reteste e validade concorrente, reforçando o potencial das IMUs para avaliação objetiva e portátil do equilíbrio.

Os dados provenientes das IMUs foram processados por programas desenvolvidos em MATLAB R2009a. As acelerações foram adquiridas a 60 Hz e submetidas a um filtro Butterworth passa-baixa com frequência de corte de 3,5 Hz e processamento em fase zero (*zero-phase*). Posteriormente, foi calculada a variável JERK, considerando as componentes de aceleração AP e ML:

$$JERK = \frac{1}{t}\int_0^t \left[\left(\frac{dA_{CC_{AP}}}{dt}\right)^2 + \left(\frac{dA_{CCML}}{dt}\right)^2\right] dt$$

em que representa a aceleração na direção AP, a aceleração na direção ML e o período de aquisição. O JERK permite representar a taxa de variação da aceleração e, portanto, caracterizar a dinâmica da oscilação postural.

Esse procedimento evidencia que a medida biomecânica não é resultado exclusivamente do sensor. A frequência de aquisição, o filtro utilizado e o algoritmo empregado para obtenção do JERK fazem parte da própria definição do desfecho. Consequentemente, diferenças nesses parâmetros podem influenciar a comparabilidade entre estudos e dispositivos.

Assim, esses estudos representam uma transição de sistemas laboratoriais ou clínicos de maior complexidade para sistemas inerciais portáteis, capazes de registrar o movimento em condições mais acessíveis. Entretanto, as tecnologias foram avaliadas principalmente em dispositivos específicos e em condições controladas, sendo necessária maior investigação sobre a equivalência dos resultados

quando sensores semelhantes são empregados em diferentes modelos de dispositivos.

Sensores e avaliação do equilíbrio na Síndrome de Down

Hsieh *et al.* [22] utilizaram um *iPod Touch* de quarta geração, operado por iOS, associado a um sistema Arduino para sincronização dos dados. O acelerômetro do dispositivo foi utilizado para registrar o equilíbrio durante tarefas em ortostatismo e tandem, com olhos abertos e fechados. Os resultados apresentaram padrões semelhantes aos obtidos por plataforma de força, indicando potencial para utilização do dispositivo móvel na avaliação do equilíbrio.

Do ponto de vista tecnológico, a utilização de Arduino como elemento de sincronização demonstra uma arquitetura híbrida entre dispositivos móveis e sistemas eletrônicos externos. Essa abordagem amplia as possibilidades de aquisição, mas também introduz maior complexidade de hardware e dependência de componentes adicionais.

Assim, embora o *smartphone* ou *iPod* possa reduzir custos e aumentar a portabilidade, a necessidade de dispositivos auxiliares para sincronização ou aquisição pode diminuir parte da vantagem de um sistema totalmente integrado. Essa questão deve ser considerada no desenvolvimento de tecnologias destinadas ao uso clínico ou domiciliar, particularmente quando o objetivo é obter uma solução escalável e de fácil utilização.

Tecnologias móveis e sistemas de captura nas ataxias

Nos estudos envolvendo ataxias, foram identificadas duas estratégias tecnológicas distintas. Arcuria *et al.* [23] utilizaram *smartphones* com sistemas iOS/Android, equipados com sensores triaxiais posicionados no esterno, associados ao sistema *TechnoBody Pro-Kin-212-N*. O aplicativo *APP-Coo-Balance-Test* foi utilizado para quantificar oscilações posturais do tronco e déficits de equilíbrio estático e dinâmico. As tarefas incluíram pés juntos, base alargada, sedestação sem apoio dos pés e caminhada em linha reta.

O posicionamento no esterno é particularmente relevante, pois permite que o sensor acompanhe diretamente os movimentos do tronco. Entretanto, a escolha do local de posicionamento interfere na informação biomecânica obtida, uma vez que sensores localizados no esterno, região lombar, pelve ou membros inferiores estão sujeitos a diferentes componentes do movimento corporal.

Além do posicionamento, Arcuria *et al.* [23] apresentam uma estratégia de processamento diferente daquela utilizada por Fiems *et al.* [21] os testes foram iniciados e finalizados por sinais sonoros, sendo o teste estático realizado durante 10 segundos. Para o teste dinâmico, o participante foi orientado a caminhar em linha reta, em um percurso de 9 metros durante 10 segundos. A oscilação postural foi quantificada por meio do *APPBalScore*, calculado por:

$$APPBalScore = \left(\frac{p_x}{SCA_n} \times 10\right) + k$$

em que corresponde ao número de pixels percorridos pelo ponto vermelho associado ao sensor de aceleração na grade virtual durante o teste; corresponde ao número de *SC* *An* realizados durante o período de avaliação; e *K* representa a pontuação de entrada relacionada à dificuldade do teste.

Esse cálculo demonstra uma estratégia de transformação do sinal distinta da observada em Fiems *et al*. [21] enquanto o JERK representa a variação temporal da aceleração, o APPBalScore converte o deslocamento do sinal em uma pontuação relacionada ao desempenho postural. Portanto, mesmo quando tecnologias utilizam sensores inerciais ou acelerômetros, os resultados não são necessariamente diretamente comparáveis, pois os algoritmos de processamento determinam quais características do movimento serão representadas.

Summa *et al.* [28], por outro lado, desenvolveram o *SaraHome*, utilizando *Kinect v2* e *Leap Motion Controller*, associados a software em *C#* e banco de dados *CouchDB*. O sistema foi desenvolvido para monitoramento remoto de tarefas motoras de indivíduos com ataxia.

A comparação entre Arcuria *et al.* [23] e Summa *et al.* [28] evidencia duas arquiteturas distintas: uma baseada em sensores inerciais móveis e outra baseada em captura de movimento sem marcadores. Enquanto a primeira favorece portabilidade e simplicidade, a segunda possibilita uma caracterização mais ampla do movimento, porém depende de equipamentos específicos e de condições apropriadas para aquisição.

Sensores inerciais e dupla tarefa na doença de Alzheimer

Serra-Añó *et al.* [25] utilizaram o aplicativo *FallSkip* em um *smartphone* Android Xiaomi Redmi 4X, equipado com IMU de seis eixos. O dispositivo foi utilizado para avaliação do controle postural e funcionalidade da marcha em idosos com doença de Alzheimer, incluindo tarefas motoras associadas a tarefas cognitivas.

A utilização de uma IMU de seis eixos representa uma arquitetura adequada para avaliação do movimento corporal, pois combina informações provenientes de acelerômetros e giroscópios. Entretanto, o estudo demonstra que a quantidade de eixos do sensor não determina isoladamente a qualidade da medida. O posicionamento, a frequência de aquisição, as características do movimento e os algoritmos utilizados para processamento também interferem no resultado.

A incorporação da dupla tarefa representa uma evolução em relação aos protocolos exclusivamente estáticos, pois permite avaliar o comportamento motor diante de uma demanda cognitiva simultânea. Essa abordagem aproxima a avaliação tecnológica de situações funcionais observadas no cotidiano e pode aumentar a capacidade dos sistemas de identificar alterações que não são necessariamente evidentes durante tarefas motoras simples.

Tecnologias utilizadas no AVC

Nos estudos envolvendo AVC, observa-se maior diversidade de aplicações, incluindo tanto avaliação instrumental quanto intervenção terapêutica.

Shin [27] utilizou um iPhone 5 com iOS integrado ao sistema *Bal-90*, com acelerômetro e giroscópio para fornecer *feedback* visual em tempo real durante treinamento do controle de tronco. A avaliação foi realizada por meio da *Trunk Impairment Scale* (TIS) e de parâmetros espaço-temporais da marcha, incluindo velocidade, comprimento

do passo e cadência. Os resultados indicaram melhora do controle postural e da capacidade de marcha.

Nesse caso, o sensor deixa de exercer exclusivamente a função de instrumento de mensuração e passa a integrar um sistema de *biofeedback*. Essa mudança é importante, pois o sistema precisa realizar aquisição, processamento e apresentação da informação em tempo suficientemente rápido para fornecer *feedback* durante a execução da tarefa.

Hou *et al.* [26] desenvolveram um aplicativo para smartphone Android utilizando um ASUS Zenfone 3, com acelerômetro e giroscópio, para avaliação quantitativa do equilíbrio estático após AVC. A tecnologia foi comparada com a Escala de Equilíbrio de Berg e apresentou evidências de confiabilidade e validade.

Além dos resultados de validade, Hou *et al*. [26] apresentam uma contribuição importante para compreender como os dados dos sensores foram transformados em variáveis biomecânicas. Os autores calcularam as mudanças combinadas do vetor de aceleração nos eixos AP e ML:

$$A = \frac{1}{n-1}\sum_{i=2}^{n}\sqrt{(x_i - x_{i-\perp})^2 + (yi - yi_{-1})^2}$$

em que xi e yi correspondem às acelerações nos respectivos eixos, em m/s², e n corresponde ao número total de amostras. Nesse caso, maior alteração do vetor de aceleração representou maior instabilidade postural.

Os autores também utilizaram o giroscópio para avaliar a alteração da velocidade angular nos eixos de *pitch*, *roll* e *yaw*, permitindo estimar a inclinação corporal durante o teste. As velocidades angulares foram convertidas em deslocamento angular por integração numérica:

$$a_i = \frac{|\alpha_i|}{f} \times \frac{180}{\pi} \qquad b_i = \frac{\beta_i}{f} \times \frac{180}{\pi} \qquad c_i = \frac{y_i}{f} \times \frac{180}{\pi}$$

sendo o ângulo acumulado estimado por:

$$\theta = \sum_{i=1}^{n}(ai + b_i + c_i)$$

em que a_i , β_i e y_i correspondem às velocidades angulares instantâneas, f à frequência de amostragem e ao número de amostras. Nesse modelo, maior ângulo de inclinação corporal indicou menor controle postural.

A abordagem de Hou *et al.* [26] evidencia uma arquitetura multissensorial, na qual o acelerômetro fornece informações relacionadas à alteração do movimento linear, enquanto o giroscópio permite caracterizar o componente angular do movimento. Essa combinação é particularmente relevante para sistemas destinados à avaliação do alinhamento e controle do tronco.

Aphiphaksakul *et al.* [29] utilizaram o *Compass Inclinometer*, em um smartphone Android associado a um disco de equilíbrio, para fornecer *feedback* visual durante exercícios domiciliares. A tecnologia demonstrou potencial para melhorar o controle de tronco e o desempenho funcional.

Assim, nos estudos de AVC observa-se uma progressão tecnológica, partindo de sensores utilizados para mensuração do equilíbrio e chegando a sistemas de feedback visual, jogos e intervenção terapêutica. Essa evolução representa uma mudança do conceito de tecnologia como instrumento de avaliação para tecnologia como componente ativo da reabilitação.

Sensores utilizados no TCE e concussão

Nos estudos envolvendo TCE leve e concussão, as tecnologias foram utilizadas principalmente para avaliação de déficits neuromotores.

Linder *et al*. [24] desenvolveram um paradigma portátil de *dual-task* utilizando iPad e Arduino, com avaliação simultânea da estabilidade postural e função cognitiva. Foram avaliadas condições de apoio duplo e tandem, com olhos abertos e fechados, associadas a estímulos auditivos. A condição tandem com olhos fechados e estímulos apresentados a 60 estímulos/minuto foi identificada como uma condição adequada para avaliação de dupla tarefa.

Rhea *et al.* [30] desenvolveram o *AccWalker*, utilizando smartphones Android, como Moto X e Google Pixel, fixados na coxa. A tecnologia avaliou a tarefa de *stepping-in-place* com olhos abertos, olhos fechados e rotação da cabeça. O aumento da variabilidade do movimento foi utilizado como indicador de disfunção neuromotora.

Tirosh *et al.* [31] utilizaram o *TelePhysio* para avaliação remota do equilíbrio em pacientes com concussão aguda. O sistema analisou a magnitude da aceleração AP e ML durante condições de superfície firme e espuma, com olhos abertos e fechados. O estudo demonstrou a viabilidade da avaliação remota utilizando smartphones.

Esses estudos demonstram uma tendência importante: a miniaturização dos sistemas de aquisição permite transferir avaliações originalmente realizadas em laboratório para dispositivos portáteis e ambientes remotos. Entretanto, a aplicação remota exige que o sistema seja suficientemente robusto para lidar com variações de posicionamento, execução da tarefa e condições ambientais.

Processamento dos sinais e biomarcadores digitais

Calcagni *et al*. [32] representam uma etapa mais avançada dessa evolução ao utilizar o aplicativo *NeuFun-TS* e sensores incorporados a smartphones para obtenção de biomarcadores digitais. O sistema foi utilizado nos testes *Postural Sway* e *Pronator Drift* para avaliação da oscilação corporal e controle motor fino em indivíduos com diferentes doenças neurológicas.

Nesse estudo, os dados tridimensionais de cada teste foram inicialmente calibrados e transformados em duas séries temporais: ML e AP. Posteriormente, essas componentes foram combinadas em uma série de aceleração radial denominada *Net acceleration*.

A partir dessas séries foram extraídas medidas nos domínios temporal e de frequência. No domínio temporal, foi calculado o *Root Mean Square* (RMS):

$$RMS = \sqrt{\frac{1}{N}\sum_{i=1}^{N} a_i^2}$$

em que a_i representa a aceleração instantânea e N o número de pontos da série temporal. O RMS foi calculado para as componentes ML, AP e Net e representa a magnitude da aceleração.

Também foi calculado o Jerk, representando a taxa de alteração da aceleração em relação ao tempo:

$$Jerk = \int_0^t \left(\frac{dACC}{dt}\right)^2 dt$$

Além disso, foi calculado o Net Jerk, combinando as componentes ML e AP:

$$Net\ Jerk = \int_0^t \left[\left(\frac{dAcc_{ML}}{dt}\right)^2 + \left(\frac{dAcc_{AP}}{dt}\right)^2\right] dt$$

A análise foi posteriormente ampliada para o domínio da frequência. Os dados de aceleração foram submetidos à Transformada Discreta de Fourier, permitindo a obtenção de espectros de frequência e densidade espectral de potência (PSD). A partir desses espectros foram calculados o Spectral Centroid (SC) e o Spectral Spread (SS).

O centróide espectral foi calculado por:

$$SC = \mu_1 = \frac{\sum_{k=b1}^{b_2} f_k \boldsymbol{s}\, k}{\sum_{k=b_1}^{b2} s\, k}$$

representando a frequência central ponderada pela densidade espectral.

O *Spectral Spread* foi calculado por:

$$SS = \mu_2 = \frac{\sum_{k=b1}^{b_2} (f_{k-}\mu_1)^2 \boldsymbol{s}\, k}{\sum_{k=b_1}^{b2} s\, k}$$

representando a dispersão das frequências em torno do centróide espectral.

Essas medidas foram calculadas nas diferentes condições posturais, incluindo olhos abertos e fechados, e utilizadas para calcular a Razão de Romberg:

$$Romberg\ Ratio = \frac{Medida_{EC-FT}}{Medida_{EO-FT}}$$

Essa abordagem representa uma evolução importante em relação aos estudos que utilizam apenas uma variável de oscilação, pois combina características temporais e espectrais do movimento. Dessa maneira, o *smartphone* deixa de ser apenas um instrumento de aquisição e passa a constituir uma plataforma para geração de biomarcadores digitais quantitativos.

Comparação das estratégias de processamento

A análise conjunta dos estudos evidencia diferentes níveis de complexidade na transformação do sinal bruto em uma variável biomecânica. Em Fiems *et al.* [21], o processamento segue a sequência:

aceleração → filtragem → derivada temporal → JERK.

Em Arcuria *et al.* [23]:

aceleração → representação espacial → deslocamento em pixels → APPBalScore.

Em Hou *et al.* [26]:

aceleração → diferenças entre amostras → alteração do vetor de aceleração

e, paralelamente:

velocidade angular → integração numérica → ângulo de inclinação.

Em Calcagni *et al.* [32]:

aceleração tridimensional → calibração → componentes ML/AP → Net acceleration → RMS/Jerk → Transformada de Fourier → SC/SS.

Essa comparação evidencia que sensores semelhantes podem gerar biomarcadores completamente diferentes. Portanto, a informação clínica produzida por uma tecnologia não depende somente da presença de acelerômetro ou giroscópio, mas da combinação entre hardware, aquisição e processamento.

Dependência do dispositivo e do sistema operacional

Os estudos utilizaram iPad, iPod Touch e iPhone em ambiente iOS, enquanto outros empregaram smartphones Android de diferentes fabricantes, como ASUS, Xiaomi, Motorola e Google. Também foram observados sistemas baseados em Arduino, Kinect, Leap Motion e plataformas específicas.

Essa heterogeneidade significa que o smartphone não deve ser entendido apenas como uma interface para execução do aplicativo. Ele constitui parte do sistema de instrumentação, uma vez que seus sensores são responsáveis pela aquisição dos dados.

Assim, a arquitetura tecnológica pode ser representada como:

Movimento corporal → sensor → aquisição → processamento → algoritmo → aplicativo → dispositivo → sistema operacional → resultado biomecânico.

Uma alteração em qualquer uma dessas etapas pode modificar o resultado final. Consequentemente, a validação de um aplicativo em determinado modelo de smartphone não garante automaticamente equivalência de desempenho em outro dispositivo, mesmo que ambos utilizem o mesmo sistema operacional.

Essa questão é particularmente relevante para tecnologias destinadas ao uso domiciliar e remoto. A literatura apresenta poucas evidências de validação cruzada entre diferentes fabricantes, modelos de smartphones e sistemas operacionais, constituindo uma importante lacuna para a escalabilidade das soluções.

IV. CONCLUSÃO

As tecnologias móveis e os sistemas de sensores apresentam potencial para avaliação, monitoramento e reabilitação do controle e alinhamento postural, e equilíbrio em indivíduos com condições neurológicas. Entretanto, as evidências disponíveis ainda são limitadas e heterogêneas quanto às populações, dispositivos, sensores, sistemas operacionais, tarefas e desfechos, dificultando as conclusões clinicamente aplicáveis. Assim, embora alguns estudos indiquem resultados positivos quanto à validade, confiabilidade e viabilidade dessas tecnologias, o estudo contribui com um mapa de evidências, ressaltando que ainda são necessários estudos com maior rigor metodológico, protocolos padronizados e amostras adequadas para estabelecer a efetividade clínica.

Abstract—The use of digital technologies in healthcare has promoted new possibilities for monitoring and rehabilitating patients with functional limitations. In this context, this study proposes the development of a mobile application aimed at the physiotherapy monitoring of wheelchair-bound patients, with the objective of facilitating clinical monitoring, improving communication between professional and patient, and encouraging adherence to treatment. The methodology involves bibliographic research and prototype development. The app was initially modeled using the Figma tool, used to define the information architecture, navigation flows, and interface prototyping. Subsequently, the screens and functionalities were implemented using the Flutter framework, allowing the development of a multiplatform application focused on usability and accessibility. The application includes functionalities such as exercise recording, monitoring of functional progress, sending therapeutic guidelines, activity reminders, and collection of user feedback. The app is prepared to obtain user experience by using the System Usability Scale (SUS), which allows the identification of aspects related to efficiency, effectiveness, and satisfaction in the use of the tool. It is expected that the solution will contribute to expanding access to physiotherapy care, promoting continuity of care and fostering greater autonomy and quality of life for wheelchair-bound patients.

Keywords—digital physiotherapy; health technology; wheelchair; usability; mobile application.

I. INTRODUCTION

Technology has become an essential resource in promoting health, offering opportunities to expand access to care and treatment through digital health [1]. In Brazil, the wheelchair-using population faces daily challenges such as limited accessibility, chronic pain, contractures, pressure ulcers, and sedentary lifestyles, factors that directly compromise their quality of life [2].

Despite the advancement of digital health solutions favoring the prevention of complications, adherence to treatment and the promotion of autonomy [3], there is a scarcity of tele-rehabilitation applications specifically aimed at this purpose, particularly for wheelchair users. Physical disability represents an important global public health issue, especially due to the functional, social and psychological impact associated with motor limitations. Among individuals with physical disabilities, wheelchair users face challenges related to mobility, urban accessibility, social participation and continuous access to health services [4].

The use of a wheelchair, while promoting functional independence, is also associated with significant biomechanical changes, including upper limb overload, musculoskeletal pain, postural changes, pressure injuries, and reduced cardiovascular conditioning [5]. Therefore, continuous physiotherapy follow-up becomes essential for preventing secondary complications and maintaining functionality.

In recent years, there has been significant growth in the use of digital technologies applied to health. Telerehabilitation has emerged as a strategy capable of expanding access to physiotherapy treatment, especially for individuals with mobility difficulties and accessibility limitations [6].

The COVID-19 pandemic significantly accelerated the implementation of remote physiotherapy services, favoring the development of digital platforms, mobile applications, and remote monitoring systems. Studies demonstrate that tele-rehabilitation can present similar results to in-person care in several functional aspects, in addition to promoting greater therapeutic adherence and reducing healthcare costs [7].

In this context, mobile health applications have stood out as promising tools for prescribing home exercises, functional

monitoring, communication between professionals and patients, and promoting self-care [8].

According to the World Health Organization (WHO), an estimated 1.3 billion people worldwide live with some type of disability classified as significant. This number corresponds to a proportion of one in six people [16]. For wheelchair users, applications focused on Tele-rehabilitation can represent an accessible alternative for continuous physiotherapy monitoring, ergonomic support, prevention of secondary injuries, and encouragement of adapted physical exercise.

Thus, this project proposes the development of a tele-rehabilitation application aimed at prescribing home exercises and supporting the daily activities of wheelchair users, integrating physiotherapy resources, digital accessibility, and remote monitoring.

II. Theoretical Basis

According to Tweedy Beckman [9], individual's dependent on wheelchairs frequently present musculoskeletal, cardiovascular, and postural alterations resulting from sedentary lifestyles and long periods of sitting, making continuous physiotherapy follow-up indispensable. Among the main complications associated with prolonged wheelchair use are musculoskeletal pain, deformities, pressure injuries, muscle shortening, loss of physical conditioning, and reduced functional capacity. According to Gomes Neto [3], physiotherapy interventions aimed at muscle strengthening, therapeutic stretching, and functional training promote significant improvement in mobility and reduction of secondary complications in wheelchair patients.

In addition to conventional in-person treatments, advances in digital technologies have brought new possibilities for physiotherapy follow-up. In that context, telerehabilitation has been consolidating itself as an important strategy to expand access to care, especially for these individuals. In the article written by Kairy, Veras and Archambault [16], telerehabilitation programs demonstrate effectiveness in therapeutic continuity, adherence to treatment and functional monitoring.

In this way, mobile health applications have become relevant tools in physical rehabilitation programs. As described in the work [13], mobile health technologies have the potential to expand access to services and promote greater integration between professionals and patients. These platforms allow the sending of guidelines, explanatory videos, activity reminders and monitoring of clinical progress in real time.

Another important point is related to the personalization of physiotherapy treatment. According to Chen [3], monitoring integrated with digital platforms allows for faster therapeutic adjustments and better communication between patient and physiotherapist. However, despite the observed benefits, there are still challenges related to the use of these technologies in the health field. Issues such as digital accessibility, technological limitations, difficulties with internet connectivity, and the need for scientific validation of applications should be considered during the development of these tools.

In turn, the work of Turolla and colleagues [6] mentions that the development of health technologies should prioritize safety, usability and digital inclusion to ensure therapeutic efficacy and universal access.

Observed as a whole, those works highlights the fact that the integration between physiotherapy, telerehabilitation and mobile health applications represents an important contemporary trend in the physical rehabilitation of wheelchair users. More than that, the use of these technologies may promote therapeutic continuity, access to care and functional independence of wheelchair users, contributing significantly to improve the quality of life of these individuals.

III. Methodology

The methodology focuses on developing a telerehabilitation application for prescribing home exercises and supporting wheelchair users. To achieve this, we followed sequential steps, from identifying user needs to developing and testing a functional prototype. An exploratory study identified the main demands and barriers faced by wheelchair users. Next, the application's structure was defined, including exercise prescription, educational content, remote monitoring, and accessibility features. The interfaces and screen architecture were designed in Figma, emphasizing accessibility and intuitive navigation. The system was then implemented in Flutter using Dart, ensuring cross-platform compatibility and adaptations that help promote the autonomy of wheelchair users.

As for the App Architecture, the development process began with prototyping the screens on the Figma platform, allowing for the definition of the navigation flow, organization of visual elements, and preliminary validation of the user experience. Subsequently, the prototypes were converted into functional interfaces using Flutter, preserving the usability and accessibility principles defined in the design phase.

The developed screens include functionalities such as user authentication, patient registration and monitoring, access to therapeutic exercises, monitoring of clinical progress, and visualization of data from the physiotherapy monitoring system. The use of Flutter allowed the creation of reusable components, contributing to the visual standardization and maintenance of the application.

The application's architecture was structured in layers, comprising a user interface developed in Flutter, a logic layer responsible for processing information, and a data storage layer for managing clinical records and follow-up histories. This organization favors system scalability, code maintenance, and standardization related to the screens already assembled in Figma.

IV. Results

The following images demonstrate the organization of the screens previously created in Figma and programmed in Flutter. They show a user navigation flow, including registration, authentication, physiotherapy assessment, and video (exercise) recording, as well as screens specifying the bottom buttons that the user can click to access the saved exercises screen, a calendar to mark the physiotherapy day, check for any

messages from the physiotherapist, and notifications. Fig. 1 corresponds to the application's authentication flow screns. These screens allow the user to register and securely access the system by logging in with the email and password that the professional uses to register, and also to register the patient, through which they can later access the app.
