- **Narrative Synthesis:** a structured narrative synthesis was conducted to integrate findings across studies. This approach emphasized recurrent predictors of severe RSV outcomes, such as young age, prematurity, and congenital heart disease, while also highlighting rare but clinically relevant conditions (e.g., cystic fibrosis, sepsis). The synthesis focused on consistency of associations across different populations and healthcare settings, rather than exhaustive tabulation of individual study data.
- **Risk of Bias Assessment:** risk of bias and methodological quality were assessed using the Newcastle-Ottawa Scale (NOS) for cohort studies. The NOS evaluates three domains: selection of participants (0–4 points), comparability of cohorts (0–2 points), and outcome assessment

(0–3 points), resulting in a total score ranging from 0 to 9 [11].

- **Meta-Analysis:** all analyses were conducted in R version 4.5.1 [12]. Meta-analyses were performed using the `meta` package [13], with additional customization of forest plots supported by `metafor` [14]. Odds ratios (OR) and 95% confidence intervals (CI) from individual studies were log-transformed, and standard errors (SE) were calculated using Equation 1.

$$SE = \frac{\log(\text{Upper}) - \log(\text{Lower})}{2 \cdot 1.96} \tag{1}$$

Random-effects models were applied using the inverse variance method (`metagen` function, `meta` package). Forest plots were generated to display study names, effect sizes, and confidence intervals, with redundant columns removed for clarity. Heterogeneity was assessed using the Q statistic, τ^2, and the I^2 index, with thresholds of 25%, 50%, and 75% interpreted as low, moderate, and substantial heterogeneity, respectively. Study weights were calculated using the inverse-variance random-effects model and are represented graphically by the size of the squares in the forest plots.

Meta-analyses were restricted to risk factors that demonstrated the strongest associations with severe RSV outcomes and for which at least three independent studies reported odds ratios (OR). Only OR estimates were pooled to ensure methodological consistency, while studies reporting relative risks (RR) or hazard ratios (HR) were described narratively but not included in quantitative synthesis.

When multiple severe outcome estimates were reported from the same cohort, only one estimate was included in each pooled analysis. Ventilatory support was prioritized over ICU admission because it was the most consistently reported severe outcome across studies and represents an objective marker of severe respiratory deterioration.

Additionally, sensitivity analyses were performed for pooled factors presenting substantial heterogeneity by sequentially excluding individual studies and recalculating the pooled effect estimates.

III. Results

A. Study Selection Process

A total of 252 records were identified across the databases consulted. After removing 40 duplicates, 212 studies remained for title and abstract screening. During this phase, 195 studies were excluded for addressing non-eligible populations (adults or adolescents), infections by other viruses, unrelated diseases, or outcomes outside the inclusion criteria (purely epidemiological studies, drug or vaccine efficacy, absence of multivariate analysis, or heterogeneous severity definitions).

Seventeen articles were selected for full-text review. Of these, nine met all eligibility criteria and were included in the review. The remaining eight were excluded—six due to inconsistent definitions of disease severity and two for evaluating populations outside the established age range (children older than five years or non-RSV infections).

The study selection process is summarized in Figure 1, following the PRISMA 2020 framework, illustrating the flow from identification to inclusion.

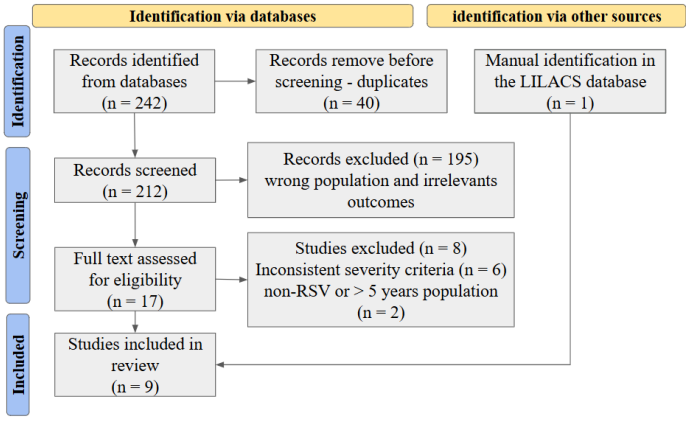

Fig. 1: PRISMA 2020 flow diagram for new systematic reviews [9].

B. Synthesis of Results

The characteristics of the included studies and their main predictors of severe RSV outcomes are summarized in Table II. The studies included in this systematic review span diverse countries and clinical contexts. Collectively, the included studies consistently identified a set of recurring risk factors associated with severe RSV outcomes. Although the specific endpoints differ — ICU admission, mechanical ventilation, ventilatory support, or death — the findings consistently highlight a set of recurrent predictors, with occasional but striking outliers.

In Australia, Anderson et al. (2021) showed that apnea (OR = 4.5; 95% CI: 3.1–6.5), feeding difficulty (OR = 4.5; 95% CI: 3.1–6.5), and increased work of breathing (OR = 3.2; 95% CI: 2.1–5.0) were strong predictors of ventilatory support, particularly in infants under two months (OR = 2.3; 95% CI: 1.6–3.3) [15].

Data from the United States (Brenes-Chacón et al., 2023) reinforced the vulnerability of young infants: age < 6 months predicted ICU admission (OR = 2.27; 95% CI: 1.84–2.81) and was the strongest factor for mechanical ventilation (OR = 5.43; 95% CI: 3.69–8.00). Prematurity also contributed (e.g., 29–34 weeks: OR = 1.78; 95% CI: 1.45–2.20; mechanical ventilation OR = 3.01; 95% CI: 2.29–3.96), as did neuromuscular disease (ICU: OR = 2.71; 95% CI: 1.63–4.48; ventilation: OR = 3.49; 95% CI: 1.69–7.19), viral coinfection (OR = 1.40–1.41), and fever (ICU: OR = 1.84; 95% CI: 1.59–2.14; ventilation: OR = 3.93; 95% CI: 3.02–5.14) [16].

The German cohort studied by Cai et al. (2019) highlighted extreme risks, with cystic fibrosis (OR = 35.13; 95% CI: 1.76–700.59), hepatic disease (OR = 14.99; 95% CI: 1.49–150.82), and perinatal respiratory or cardiovascular disorders

(OR = 4.97; 95% CI: 3.36–7.34) strongly associated with ICU admission. Neurological disease (OR = 6.48; 95% CI: 3.76–11.18) and cardiovascular disease (OR = 5.19; 95% CI: 2.77–9.72) were also important predictors, with similar patterns observed for mechanical ventilation [17].

In Norway, Havdal et al. (2022) found age < 3 months (OR = 6.73; 95% CI: 2.71–16.7) to be the strongest predictor of ventilatory support, followed by comorbidity (OR = 2.40; 95% CI: 1.35–4.24) and sibling exposure (OR = 1.65; 95% CI: 1.05–2.59) [18].

Evidence from Canada (Kirolos et al., 2025) showed elevated risk for ICU admission, ventilation, or death in infants < 3 months (RR = 2.34; 95% CI: 1.43–3.84) and those aged 3–6 months (RR = 2.79; 95% CI: 1.65–4.70). Neurodevelopmental disorders (RR = 1.89; 95% CI: 1.03–3.49) and chronic pulmonary disease (RR = 3.01; 95% CI: 1.79–5.06, in older children) also contributed [19].

A smaller study in France (Mulot et al.) suggested a protective effect of corrected age in preterm infants (OR = 0.77; 95% CI: 0.62–0.93), while bronchopulmonary dysplasia and palivizumab use were not statistically significant [20].

The large Japanese cohort analyzed by Okubo et al. ($N = 50{,}482$) revealed that having ≥ 2 chronic conditions markedly increased risk (RR/OR = 6.91; 95% CI: 5.81–8.21). Respiratory disease (RR = 3.50; 95% CI: 2.71–4.53), prematurity (RR = 3.11; 95% CI: 2.14–4.54), and neuromuscular disease (RR = 2.48; 95% CI: 1.91–3.20) were also important [21].

Finally, studies from Colombia confirmed age < 6 months (Rodríguez et al., 2014: RR = 2.01; 95% CI: 1.70–2.38; Rodríguez-Martínez et al., 2022: OR = 2.94; 95% CI: 1.29–6.66) and prematurity (RR = 1.61; 95% CI: 1.20–2.17) as consistent predictors. Additional risk factors included congenital heart disease (RR = 2.03; 95% CI: 1.16–3.54; OR = 3.54; 95% CI: 1.41–8.84), adenovirus coinfection (RR = 2.09; 95% CI: 1.60–2.73), malnutrition (OR = 3.28; 95% CI: 1.15–9.37), and sepsis (OR = 45.79; 95% CI: 5.29–395.78) [8].

Taken together, the studies consistently demonstrate that young age (< 6 months) and prematurity are the most robust predictors of severe RSV outcomes, with effect estimates generally ranging from approximately 1.6 to 5.4. Comorbidities such as congenital heart disease (up to OR $\approx$ 3.5), neuromuscular or neurological disorders ($\approx$2.5–3.5), and chronic lung disease (RR up to 3.01) repeatedly amplify risk. Rare but severe conditions—including cystic fibrosis (OR = 35.13), hepatic disease (OR up to 14.99), and sepsis (OR = 45.79)—confer extreme vulnerability. Clinical features such as apnea (OR = 4.5), feeding difficulty (OR = 4.5), and fever (up to OR = 3.93), as well as exposures such as siblings (OR = 1.65) or viral coinfections (OR $\approx$1.4–2.1), add further nuance.

Figure 2 presents a graph of the most frequent risk factors identified in this literature review, considering only those evaluated through multivariate analyses with statistically significant results and reported in at least three studies.

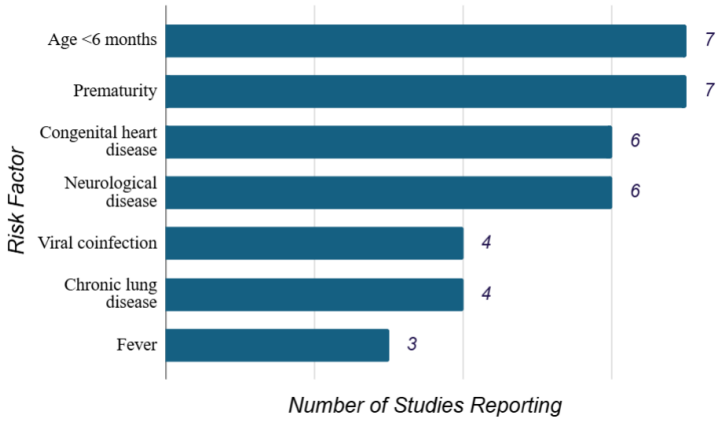

Fig. 2: Most Frequent Risk Factors for Severe RSV Outcomes

C. Risk of Bias Assessment

Risk of bias assessment using the Newcastle-Ottawa Scale is presented in Table III. Eight studies were classified as high quality (scores 7–9), while one study (Mulot et al.) was classified as moderate quality (score 6). Lower scores were mainly related to limited sample size, reduced representativeness, and fewer adjustments for potential confounding factors. Overall, the methodological quality of the included evidence was considered satisfactory.

D. Meta-Analysis

The random-effects meta-analysis demonstrated significant associations between several risk factors and severe RSV outcomes (Figure 3).

Infants aged < 6 months showed a markedly increased risk of severe outcomes (pooled OR = 3.42; 95% CI: 2.23–5.27), although substantial heterogeneity was observed across studies (I^2 = 71.9%, τ^2 = 0.1550, p = 0.0066), suggesting variability in effect estimates according to study characteristics and outcome definitions. A leave-one-out sensitivity analysis was conducted for age below six months. The pooled association remained statistically significant after sequential exclusion of each individual study, with pooled ORs ranging from 2.67 to 3.92. These findings indicate that the observed association was robust and not driven by any single study (Figure 4).

Prematurity was also significantly associated with severe RSV outcomes (pooled OR = 1.80; 95% CI: 1.30–2.49), with no observed heterogeneity (I^2 = 0.0%, τ^2 = 0, p = 0.4219), indicating highly consistent findings across studies.

Children with congenital heart disease had significantly higher odds of severe RSV outcomes (pooled OR = 2.56; 95% CI: 1.46–4.51). Moderate heterogeneity was observed (I^2 = 46.4%, τ^2 = 0.1219, p = 0.1547), suggesting some variation in effect size while maintaining a consistent direction of association.

For chronic lung disease, the pooled estimate suggested increased odds of severe RSV outcomes; however, the association did not reach statistical significance (pooled OR = 1.30; 95% CI: 0.79–2.14). No heterogeneity was detected among studies (I^2 = 0.0%, $\tau^2 < 0.0001$, p = 0.4609).

TABLE II: Characteristics of included studies and main predictors of severe RSV outcomes

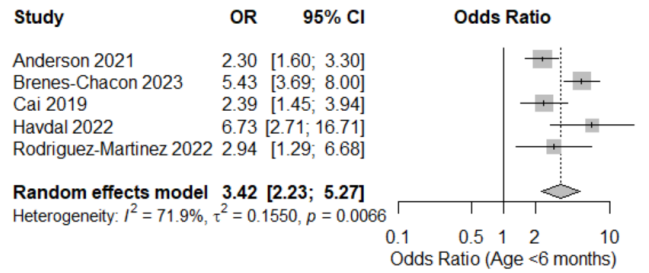
Study	Country	N	Age Range	RSV Confirmation	Severe Outcome	Main Predictors
Anderson et al., 2022	Australia	970	< 2 y	Laboratory-confirmed	Ventilatory support	Age < 2 months; apnea; feeding difficulty
Brenes-Chacón et al., 2024	USA	5143	< 5 y	Virologically confirmed	ICU admission / mechanical ventilation	Age < 6 months; prematurity; neuromuscular disease
Cai et al., 2020	Germany	8761	< 5 y	Hospital RSV records	ICU admission / mechanical ventilation	Prematurity; cardiovascular disease; neurological disease
Havdal et al., 2022	Norway	1096	< 59 months	Laboratory-confirmed	Ventilatory support	Age < 3 months; comorbidity; sibling exposure
Kirolos et al., 2025	Canada	452	< 2 y	Laboratory-confirmed	Ventilatory support, ICU admission or death	Age < 6 months; prematurity; neurodevelopmental disorder
Mulot et al., 2022	France	86	Preterm infants (< 12 corrected months)	Laboratory-confirmed	Ventilatory support	Lower corrected age for prematurity
Okubo et al., 2024	Japan	50482	< 5 y	Administrative database	Ventilatory support, ICU admission or death	Multiple chronic conditions; respiratory disease; prematurity
Rodríguez et al., 2014	Colombia	2147	< 5 y	RSV-positive testing	ICU admission	Age < 6 months; prematurity; congenital heart disease
Rodríguez-Martínez et al., 2022	Colombia	1215	< 5 y	Confirmed RSV-ALRI	Ventilatory support, ICU admission or death	Sepsis; congenital heart disease; malnutrition

TABLE III: Newcastle-Ottawa Scale Quality Assessment of Included Studies

Study	Selection	Comparability	Outcome	Total	Quality
Anderson et al., 2022	4	2	2	8	High
Brenes-Chacón et al., 2024	4	2	3	9	High
Cai et al., 2020	4	2	2	8	High
Havdal et al., 2022	4	2	3	9	High
Kirolos et al., 2025	4	2	3	9	High
Mulot et al., 2022	3	1	2	6	Moderate
Okubo et al., 2024	4	2	3	9	High
Rodríguez et al., 2014	3	2	2	7	High
Rodríguez-Martínez et al., 2022	3	2	2	7	High

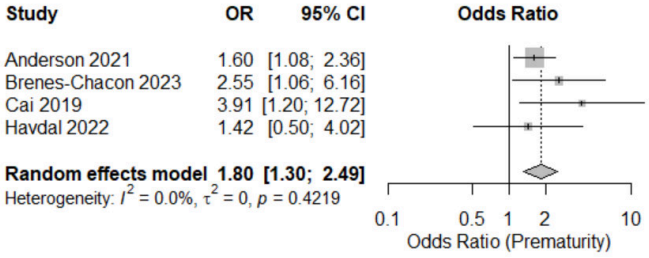
Overall, younger age, prematurity, and congenital heart disease demonstrated consistent associations with severe RSV outcomes. Although substantial heterogeneity remained for age below six months, the direction of effect was consistent across studies.

IV. Discussion



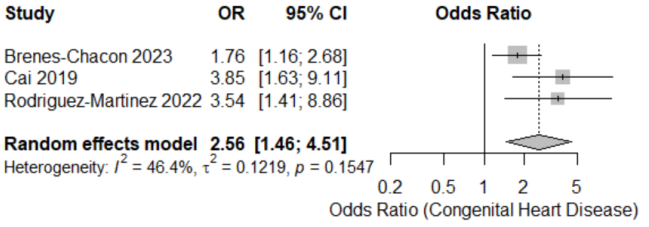
This systematic review and meta-analysis identified a consistent set of predictors associated with severe RSV outcomes in infants and young children. Across diverse geographic settings and healthcare systems, younger age, prematurity, congenital heart disease, chronic lung disease, and underlying comorbidities emerged as the most relevant determinants of disease severity. These findings reinforce the substantial vulnerability of specific pediatric subgroups and support the development of targeted prevention strategies. [1], [7], [8]

Among all factors evaluated, young age was the most consistent predictor of severe outcomes. Individual studies repeatedly demonstrated increased risks among infants younger than six months, while the pooled analysis showed that this age group was associated with more than a threefold increase in the odds of severe RSV disease. This observation is biologically plausible, given the immaturity of the infant immune system, smaller airway caliber, and limited pulmonary reserve during early life. The elevated burden observed in the first months of life also supports current strategies focused on passive immunization and maternal vaccination to provide protection during this critical period. [4], [5]

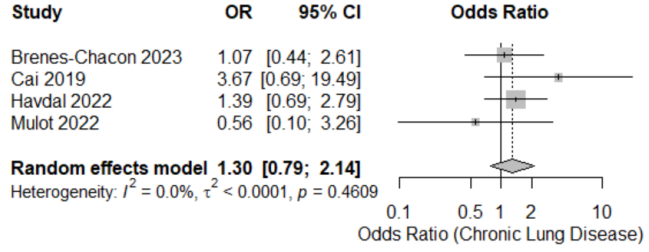


Prematurity was another recurrent predictor identified across studies and was significantly associated with severe RSV outcomes in the pooled analysis. Premature infants frequently present impaired lung development, reduced maternal antibody transfer, and increased susceptibility to respiratory complications. Although the magnitude of association varied among studies, the direction of effect was remarkably consistent, resulting in relatively low heterogeneity compared with other pooled analyses.

Congenital heart disease was consistently associated with increased risk of severe RSV outcomes. Although chronic lung disease is traditionally recognized as a high-risk condition, the pooled estimate in the present review did not demonstrate a statistically significant association, which may reflect the limited number of available studies and the imprecision of some effect estimates. These findings are consistent with the historical recognition of these populations as high-risk groups and partially explain their prioritization in preventive programs. Importantly, several studies also identified neurological, neuromuscular, and multisystem chronic conditions as major contributors to severity, suggesting that risk stratification should extend beyond the traditionally recognized high-risk groups.



The narrative synthesis additionally highlighted several clinical characteristics associated with severe disease, includ-



(a) Age $<$ 6 months

(b) Prematurity

(c) Congenital Heart Disease

(d) Chronic Lung Disease

Fig. 3: Forest plots summarizing pooled odds ratios for major risk factors.

ing apnea, feeding difficulty, fever, and increased work of breathing. While these factors are not suitable for preventive targeting before infection occurs, they may contribute to early identification of children at increased risk of clinical deterioration following hospitalization.

Despite the substantial heterogeneity observed for age below six months, sensitivity analysis demonstrated that the pooled association remained stable after sequential removal of individual studies, supporting the robustness of the findings.

Quality assessment using the Newcastle-Ottawa Scale indicated that most included studies were of high methodological

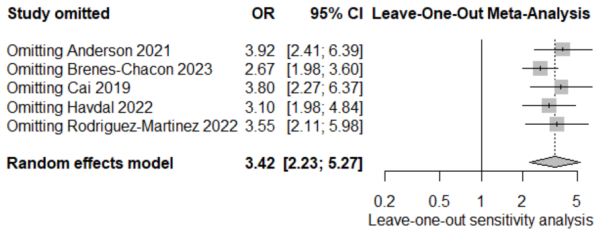


Fig. 4: Leave-one-out sensitivity analysis for age below six months.

quality. However, the observational nature of the evidence warrants cautious interpretation due to the possibility of residual confounding.

Despite its strengths, this review has some limitations. Screening and data extraction were conducted by a single reviewer, which may have introduced selection bias. Additionally, substantial heterogeneity was observed for some risk factors, likely reflecting differences in study design, population characteristics, and definitions of severe RSV outcomes. The relatively small number of studies included in some meta-analyses limited the exploration of publication bias and subgroup effects. Furthermore, the inclusion of studies from different healthcare settings may have influenced the comparability of effect estimates. These limitations should be considered when interpreting the pooled results.

Beyond supporting the identification of high-risk groups, the predictors consistently identified in this review may contribute to the development of future predictive models for severe RSV outcomes. Variables such as age below six months, prematurity, congenital heart disease, chronic lung disease, and neurological comorbidities demonstrated consistent associations with disease severity across different settings and therefore represent potential candidate predictors for risk stratification tools. Future studies should evaluate the performance of multivariable prediction models integrating these factors to support early identification of children at increased risk of severe disease

V. Conclusion

This systematic review and meta-analysis demonstrated that age below six months, prematurity, and congenital heart disease are important predictors of severe RSV outcomes in children. Additional risk was observed among patients with neurological, neuromuscular, and multiple chronic conditions.

The pooled analyses confirmed significantly increased odds of severe disease among infants younger than six months, premature infants, and children with congenital heart disease. These findings may help identify populations at increased risk of severe RSV outcomes and support future research on preventive strategies and clinical risk assessment tools.

As new RSV prevention technologies become increasingly available, understanding the factors associated with severe disease may contribute to improving risk awareness and informing future predictive models in pediatric populations.

VI. ACKNOWLEDGMENT

The authors acknowledge the Graduate Program in Biomedical Engineering (PPG-EBM) at the Federal University of ABC (UFABC) for supporting the development of this research.

***Abstract*—Este artigo apresenta o desenvolvimento e a avaliação preliminar de um protótipo de sistema especialista baseado em regras, implementado em CLIPS (C Language Integrated Production System), para apoio à análise ergonômica de postos de trabalho. O sistema integra uma base de conhecimento derivada de itens selecionados da Norma Regulamentadora NR-17 (Ergonomia) com uma interface de aquisição de dados em Python. Diferentemente de modelos baseados em aprendizado profundo de caixa-preta, a abordagem em regras prioriza a explicabilidade e a rastreabilidade jurídica, emitindo diagnósticos diretamente associados às cláusulas regulamentares. Testes preliminares em múltiplos cenários simulados demonstraram a consistência da árvore de inferência e a capacidade de resolução de conflitos por prioridades. O trabalho atua como prova de conceito e ferramenta de triagem preliminar, fornecendo diretrizes estruturadas para futuras validações clínicas e ocupacionais com especialistas.**

***Index Terms*—Sistemas especialistas, CLIPS, ergonomia ocupacional, NR-17, saúde do trabalhador.**

I. Introdução

Na área de saúde e segurança ocupacional, os Distúrbios Osteomusculares Relacionados ao Trabalho (DORT) configuram uma das principais causas de absenteísmo e incapacidade laboral crônica. A detecção precoce de inadequações posturais e ambientais é essencial para mitigar o desenvolvimento crônico destas lesões, exigindo o emprego de ferramentas de triagem eficientes [10]. No Brasil, a Norma Regulamentadora NR-17 estabelece os parâmetros técnicos para a adaptação das condições de trabalho às características psicofisiológicas dos trabalhadores. Contudo, a realização da Análise Ergonômica do Trabalho (AET) depende substancialmente de inspeções manuais. Segundo a literatura clássica de ergonomia brasileira, esse processo analítico exige elevada especialização, configurando-se como uma atividade custosa, que demanda tempo prolongado de observação *in loco* e está sujeita à variabilidade interavaliador [4].

Nesse cenário, os sistemas especialistas baseados em regras representam uma solução determinística e transparente. Estudos recentes no contexto nacional apontam que a aplicação de sistemas especialistas na área da saúde otimiza a triagem diagnóstica e padroniza condutas clínicas [5].

Este artigo propõe o desenvolvimento e a avaliação de um protótipo de sistema especialista implementado em linguagem CLIPS acoplado a uma interface Python para suporte à triagem ergonômica preliminar baseada na NR-17 [2]. O escopo do trabalho assume estritamente o caráter de prova de conceito técnica, visando verificar a consistência das regras, a resolução de conflitos na agenda de execução e a rastreabilidade normativa, sem a pretensão de substituir a avaliação integral conduzida por ergonomistas certificados.

II. Metodologia

A arquitetura do sistema divide-se em três etapas: modelagem da base de conhecimento a partir da NR-17, codificação do motor de regras no CLIPS e implementação da camada de entrada de dados em Python.

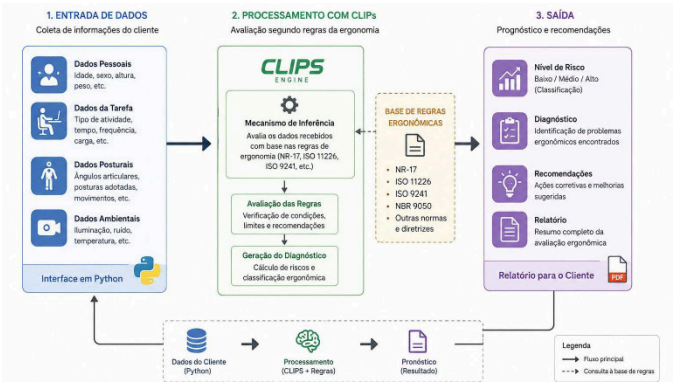

Fig. 1. Arquitetura proposta para o Sistema de Avaliação Ergonômica, detalhando o fluxo de integração entre a interface de aquisição de dados em Python, o motor de inferência CLIPS fundamentado em normas técnicas e a geração do relatório diagnóstico.

A. Engenharia de Conhecimento e Rastreabilidade Normativa

A base de conhecimento foi estruturada pela tradução de cláusulas selecionadas da NR-17 e de seus anexos específicos em proposições lógicas. Os limiares de alcance horizontal que disparam os alertas posturais no motor de

inferência foram definidos cruzando as restrições da NR-17 com dados antropométricos clássicos [11]. Adicionalmente, a interpretação técnica impressa nos alertas de temperatura e iluminação baseia-se nos impactos fisiológicos documentados na literatura ergonômica fundamental [12]. Para assegurar a auditabilidade do sistema e provar sua aderência à norma, a Tabela I detalha a matriz de rastreabilidade implementada no CLIPS, abrangendo os limites exatos de conforto ambiental e exigências antropométricas.

NR-17 (17.8.4.1.2)	Ruído de fundo	$>$ 65 dB(A)	Alerta Normativo (Estresse Auditivo)
NR-17 (17.8.4.2)	Temperatura ambiente	Fora da faixa de 18–25°C	Alerta Normativo (Desconforto)
NR-17 (17.4.3.1)	Pausas de recuperação	Atividade repetitiva sem pausa	Alerta Normativo (Risco de DORT)
NR-17 (Anexo I)	Operadores de Checkout	Sem ensacador / Mobiliário fixo	Alerta de Sobrecarga (Específico)
NR-17 (Anexo II)	Telemarketing	Sem headset / Sem pausa	Alerta Ergonômico (Específico)
Critério Clínico	Dor subjetiva (0–10)	Escore ≥ 4	Triagem Preventiva (Sem infração)

Ressalta-se que a NR-17 veda o transporte manual de cargas que comprometa a integridade física do trabalhador sem fixar um limite numérico estático de peso. Para viabilizar a inferência computacional, o limiar de 25 kg foi adotado nesta prova de conceito como regra heurística de triagem, baseado nos parâmetros de segurança da Equação de Levantamento do NIOSH [13], devendo ser calibrado parametricamente em estudos futuros. Adicionalmente, o sistema destaca-se por incorporar as resoluções dos Anexos I e II da referida norma, garantindo diagnósticos contextualizados para funções críticas como teleatendimento e caixas de supermercado. A estruturação dos níveis de severidade dos alertas gerados inspira-se em metodologias consagradas de avaliação de risco biomecânico [15]. Para a variável ambiental de luminância, o sistema utiliza como limiar técnico a NHO-11 da Fundacentro [3], uma vez que a atual redação da NR-17 delega a esta norma a fixação dos valores quantitativos adequados a cada atividade.

B. Implementação no CLIPS e Interface Python via Visão Computacional

A arquitetura computacional do protótipo é dividida em duas camadas operacionais operando em tempo real: aquisição de dados via Visão Computacional (Python) e inferência simbólica (CLIPS).

A camada de aquisição atua como a interface de monitoramento do trabalhador. Utilizando as bibliotecas OpenCV e MediaPipe [8], o sistema mapeia a cinemática do usuário por meio de inferência de marcos articulares (esqueleto digital). O algoritmo calcula matematicamente os ângulos de flexão e inclinação de segmentos corporais críticos (pescoço, tronco, ombro, braço e punho). Simultaneamente, dados organizacionais (como carga levantada e pausas) são informados no sistema.

Esses parâmetros angulares e ambientais são exportados dinamicamente para um arquivo no formato `.facts`, populando a memória de trabalho estática inicial do sistema de acordo com os moldes estruturados (`deftemplate`):

```
(deftemplate dados
(slot nome (type STRING))
(slot repetitiva (type SYMBOL))
(slot braco_direito (type INTEGER))
(slot pescoco (type INTEGER))
(slot tronco (type INTEGER))
(slot carga (type INTEGER))
(slot distancia_alcance (type INTEGER))
(slot pausas (type SYMBOL))
(slot iluminacao (type INTEGER))
(slot temperatura (type INTEGER))
(slot ruido (type INTEGER))
(slot funcao (type SYMBOL))
(slot ensacador (type SYMBOL))
(slot headset (type SYMBOL))
)
```

A modelagem dos fatos posturais (como os ângulos de braço e pescoço capturados pela IA) foi estruturada visando compatibilidade direta com métodos consolidados de avaliação rápida de postura dos membros superiores, como o método RULA [14].

Uma vez que o Python atualiza o arquivo de fatos, o motor de inferência assume o processamento. O encadeamento para frente (*forward chaining*) orienta as deduções lógicas. Para evitar inconsistências no diagnóstico, a propriedade `salience` organiza a hierarquia de execução, garantindo que as variáveis biomecânicas mais críticas sejam processadas de forma prioritária [1].

C. Extensões Futuras (Lógica Difusa e Aprendizado de Máquina)

A integração de Lógica Difusa (*fuzzy*) para tratamento de transições posturais graduais e classificadores *Random Forest* para sinais fisiológicos constitui proposta de extensão futura, não integrando a base de testes da atual prova de conceito.

III. RESULTADOS E DISCUSSÃO

O protótipo foi submetido a uma bateria de testes sintéticos cobrindo doze cenários operacionais para averiguar a sensibilidade das regras, a ausência de disparos indevidos (falsos positivos) e o funcionamento das regras específicas de função (Anexos I e II). A Tabela II resume os casos testados.

TABLE II
RESULTADOS DA AVALIAÇÃO EM CENÁRIOS SIMULADOS COM BASE NA ÁRVORE DE INFERÊNCIA

Cenário	Parâmetros Simulados	Diagnóstico Emitido pelo CLIPS
C1	Posto Padrão (Carga=15kg, Pausa=sim, Temp=22°C)	Nenhum alerta gerado (Conforme)
C2	Carga = 28 kg (Heurística $>$ 25 kg)	Alerta NR-17.5.1: Reduzir peso
C3	Distância de Alcance = 70 cm ($>$ 60 cm)	Alerta NR-17.5.2.1: Alcance excessivo
C4	Atividade Repetitiva = sim, Pausas = não	Alerta NR-17.4.3.1: Ausência de pausas
C5	Mobiliário Ajustável = não	Alerta NR-17.6.1: Risco postural/lombar
C6	Iluminação = 250 lux ($<$ 300 lux)	Alerta NR-17.8.3: Iluminação inadequada
C7	Ruído de Fundo = 75 dB(A) ($>$ 65 dB)	Alerta NR-17.8.4.1.2: Estresse auditivo
C8	Temperatura = 16°C ou 28°C (Fora de 18–25°C)	Alerta NR-17.8.4.2: Desconforto térmico
C9	Função = checkout, Ensacador = não	Alerta Anexo I (4.3): Sobrecarga do operador
C10	Função = checkout, Mobiliário Ajustável = não	Disparo múltiplo: Anexo I (3.1) e NR-17.6.1
C11	Função = telemarketing, Headset = não	Alerta Anexo II: Risco de cervicalgia
C12	Múltiplas: Telemarketing, Sem pausa, Ruído=70	Disparo conjunto de 3 alertas específicos

Fig. 4. Teste do segundo cenário: detecção de posturas nocivas e inconformidades ambientais, resultando na emissão de alertas estruturados pelo sistema especialista baseados na NR-17.

A análise do tempo de execução confirmou uma latência média de processamento de aproximadamente 23 ms por posto analisado, atestando viabilidade para sistemas de monitoramento contínuo.

A. *Discussão e Limitações do Protótipo*

O principal ganho metodológico do sistema reside na sua rastreabilidade determinística: para cada alerta, o operador recebe o trecho exato da norma violada e a interpretação biomecânica correspondente. Diferentemente de modelos conexionistas, o sistema não opera como caixa-preta [9].

Como limitações da presente etapa, pontua-se: 1) A base de conhecimento abrange apenas uma parcela dos requisitos previstos na NR-17. 2) A validação ateve-se a cenários gerados sinteticamente, não substituindo a coleta in loco. 3) Variáveis contínuas limítrofes (como temperatura de 17,8°C) exigem a incorporação futura de inferência por lógica difusa (*fuzzy*) para modelagem de incertezas.

IV. Conclusão

O protótipo desenvolvido comprovou a viabilidade técnica da utilização do CLIPS para a estruturação de um sistema especialista explicável aplicado à triagem de não conformidades

da NR-17. A separação clara entre parâmetros normativos mandatórios e heurísticas complementares forneceu robustez à arquitetura.

Trabalhos futuros focarão na expansão integral da base de regras normativas, na integração da biblioteca `clipspy` para inferência difusa e na realização de estudos de validação clínica em ambientes ocupacionais reais, avaliando a concordância do sistema frente a avaliações periciais especializadas via Coeficiente Kappa de Cohen.

AGRADECIMENTOS

Os autores agradecem à Universidade de Brasília (UnB), ao Programa de Iniciação Científica PIBIC/UnB e à FAPDF pelo suporte institucional que viabilizou este projeto.

***Abstract*—Oral Squamous Cell Carcinoma (OSCC) is the most common form of oral cancer, and early diagnosis plays a critical role in improving patient prognosis. Fourier Transform Infrared (FTIR) spectroscopy combined with machine learning has emerged as a promising non-invasive approach for identifying disease-related biochemical alterations in biological samples. This study evaluated the influence of different spectral preprocessing strategies on the classification of salivary FTIR spectra obtained from healthy individuals and patients with OSCC. The proposed computational workflow combined baseline correction (IASLS, ModPoly, and AirPLS), Savitzky–Golay smoothing, second-derivative transformation, spectral region selection, Principal Component Analysis (PCA), and supervised machine learning algorithms, including Linear Discriminant Analysis, Random Forest, Support Vector Machine, and K-Nearest Neighbors. Model performance was assessed using repeated stratified five-fold cross-validation with ten repetitions. The results showed that second-derivative preprocessing exerted the greatest influence on predictive performance by enhancing subtle spectral features, whereas PCA provided comparatively limited benefits for the evaluated dataset. Random Forest achieved the most robust performance across the investigated preprocessing configurations. Permutation feature importance analysis indicated that the most discriminative information was concentrated within the fingerprint region, particularly in spectral bands associated with proteins, lipids, carbohydrates, and nucleic-acid-related molecular vibrations. Overall, the findings demonstrate that optimizing spectral preprocessing is as important as classifier selection for developing robust and reproducible FTIR-based diagnostic workflows and reinforce the potential of salivary FTIR spectroscopy combined with machine learning as a rapid, non-invasive approach to support the diagnosis of Oral Squamous Cell Carcinoma.**

***Index Terms*—Oral Squamous Cell Carcinoma, FTIR spectroscopy, Saliva, Spectral preprocessing, Machine learning, Random Forest.**

I. Introduction

Oral Squamous Cell Carcinoma (OSCC) is the most common malignant neoplasm of the oral cavity, accounting for approximately 90% of oral cancer cases worldwide. Because patient prognosis is strongly associated with the stage at diagnosis, early detection remains one of the main factors influencing treatment success and survival. Conventional diagnosis relies primarily on clinical examination followed by histopathological analysis, procedures that may delay definitive diagnosis in some situations. Consequently, there is growing interest in complementary diagnostic approaches based on minimally invasive biological samples.

Among these biological matrices, saliva has attracted considerable attention because it can be collected easily, non-invasively, and at low cost while containing molecular information associated with both local and systemic diseases [1]. Fourier Transform Infrared Spectroscopy (FTIR) has emerged as a promising analytical technique for investigating these biochemical alterations due to its ability to characterize biological samples through their vibrational molecular signatures [2]–[4]. In addition to being rapid and relatively inexpensive, FTIR requires minimal sample preparation and can simultaneously capture information from multiple classes of biomolecules, making it particularly attractive for biomedical applications.

FTIR spectroscopy has been widely applied to the analysis of biological materials, including saliva, blood, urine, and cerebrospinal fluid [4]. In salivary samples, previous studies have demonstrated its applicability in the investigation of psoriasis [1], Burning Mouth Syndrome [5], peri-implantitis [6], COVID-19 [7], and biochemical alterations associated with smoking and illicit drug use [8], [9]. More recently,

salivary FTIR spectroscopy has also been explored for the identification of biochemical signatures associated with OSCC progression and staging. Collectively, these studies highlight the versatility of FTIR spectroscopy for identifying disease-related biochemical alterations. However, they also reveal considerable variability in the computational strategies adopted for spectral preprocessing and data analysis.

Reliable interpretation of FTIR spectra depends on appropriate preprocessing to minimize baseline distortions, instrumental noise, and signal intensity variations before exploratory or predictive analyses are performed [11], [12]. Common preprocessing procedures include baseline correction, smoothing, normalization, derivative transformation, spectral region selection, and dimensionality reduction. Although these techniques are routinely employed in FTIR studies, there is still no consensus regarding the most appropriate combination for different biomedical applications. Since machine learning models learn directly from the spectral representation of the data, preprocessing choices may substantially influence predictive accuracy, model robustness, and reproducibility.

Machine learning has become an important component of FTIR-based biomedical studies because it enables the automatic identification of spectral patterns that are often imperceptible through visual inspection alone. Most published investigations, however, focus primarily on evaluating classification algorithms or identifying potential biomarkers, whereas comparatively fewer studies systematically assess the impact of preprocessing decisions on model performance. As a result, the contribution of individual preprocessing steps to the final predictive outcome remains insufficiently understood, limiting the reproducibility and comparability of FTIR-based computational workflows.

Motivated by this gap, the present study evaluates the influence of different spectral preprocessing strategies on the classification of salivary FTIR spectra obtained from healthy individuals and patients diagnosed with Oral Squamous Cell Carcinoma. Different combinations of baseline correction methods, spectral smoothing, second-derivative transformation, spectral region selection, Principal Component Analysis (PCA), and supervised machine learning algorithms were investigated. By systematically comparing these preprocessing pipelines, this study aims to identify strategies that improve spectral discrimination and predictive performance while contributing to the development of more robust and reproducible computational workflows for FTIR-based salivary analysis.

II. Materials and Methods

A. Dataset

The experiments were conducted using a previously published dataset composed of 158 salivary Fourier Transform Infrared (FTIR) spectra, including 77 spectra obtained from healthy controls and 81 spectra obtained from patients diagnosed with Oral Squamous Cell Carcinoma (OSCC) [10]. The spectra and associated class labels were derived from the study reported by Jimenez et al. [10], which investigated salivary biochemical markers associated with OSCC staging using FTIR spectroscopy.

To investigate the influence of spectral region selection on classification performance, two spectral configurations were evaluated. The first considered the complete spectral range (700–6000 cm^{-1}), whereas the second was restricted to the fingerprint region (900–1800 cm^{-1}), which contains absorption bands associated with proteins, lipids, nucleic acids, carbohydrates, and other biomolecules commonly explored in FTIR-based biomedical studies [4].

The present work represents a secondary computational analysis of a previously published dataset. Individual-level metadata linking spectra to specific participants were not available during the computational analyses. Consequently, the number of spectra acquired per participant, the existence of replicated measurements, and the possibility of performing patient-wise data partitioning could not be assessed. Therefore, each spectrum was treated as an independent observation throughout the study.

Detailed information regarding participant recruitment, sample collection procedures, FTIR instrumentation, spectral acquisition parameters, and ethical approval is available in the original publication describing the dataset [10]. The present study focused exclusively on evaluating the impact of different spectral preprocessing strategies and machine learning models on classification performance using the published spectra.

B. Computational Workflow

The entire computational workflow was implemented in Python (version 3.14.3). Figure 1 summarizes the computational workflow adopted in this study. Starting from the raw FTIR spectra, the data were sequentially subjected to spectral preprocessing, spectral region selection, dimensionality reduction, supervised classification, model training and validation, and performance evaluation.

Different preprocessing strategies were combined with the two spectral region configurations (full spectrum and fingerprint region). The resulting datasets were either used directly or transformed using Principal Component Analysis (PCA) before training the supervised machine learning models. Each combination of preprocessing strategy, spectral region, and classification algorithm defined an independent computational pipeline, allowing their individual contributions to classification performance to be systematically evaluated.

C. Spectral Preprocessing

Spectral preprocessing was performed before exploratory analyses and supervised classification to minimize baseline distortions, instrumental noise, and signal intensity variations commonly observed in FTIR spectra [11], [12].

Three baseline correction methods were evaluated using the Pybaselines library: Improved Asymmetric Least Squares (IASLS), Modified Polynomial Fitting (ModPoly) with a third-order polynomial, and Adaptive Iteratively Reweighted Penalized Least Squares (AirPLS). These algorithms estimate the

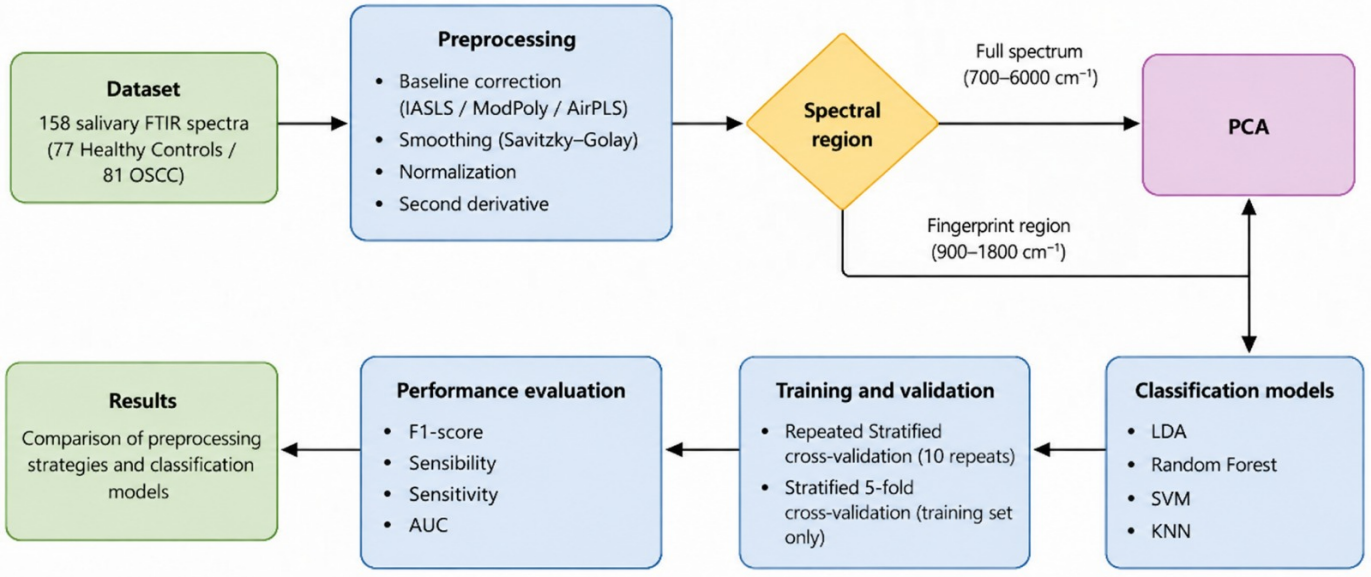

Fig. 1. Overview of the computational workflow adopted in this study. Raw salivary FTIR spectra were subjected to spectral preprocessing, followed by spectral region selection, Principal Component Analysis (PCA), supervised classification, model training and validation, and performance evaluation. The workflow summarizes the sequence of computational steps used to investigate the influence of different preprocessing strategies on the classification of healthy controls and patients with Oral Squamous Cell Carcinoma (OSCC).

spectral baseline using different mathematical approaches, allowing their impact on downstream classification performance to be systematically evaluated.

After baseline correction, spectral smoothing was performed using a Savitzky–Golay filter implemented in the SciPy library with a window size of nine points and a second-order polynomial. This procedure reduces high-frequency noise while preserving the position, width, and intensity of absorption bands, thereby maintaining the biochemical information contained in FTIR spectra [11], [12].

The spectra were subsequently normalized using the Rampy library and the intensity normalization method, reducing differences in signal amplitude among samples while preserving their relative spectral profiles. After normalization, a second-derivative transformation was computed using the Savitzky–Golay algorithm. This step enhances subtle spectral features, improves the resolution of overlapping absorption bands, and further reduces residual baseline effects, facilitating the detection of biochemical differences between classes.

Following preprocessing, all analyses were performed using both the complete spectral range (700–6000 cm^{-1}) and the fingerprint region (900–1800 cm^{-1}). The fingerprint region was evaluated separately because it contains several absorption bands associated with proteins, lipids, nucleic acids, and carbohydrates that are commonly used as biochemical markers in FTIR-based biomedical studies [4]. This comparison allowed the influence of spectral region selection to be assessed independently of the remaining preprocessing steps.

D. Dimensionality Reduction

Principal Component Analysis (PCA) was employed to project the spectra into a lower-dimensional feature space, reducing the dimensionality of the original spectral data while preserving the dominant sources of variation. PCA was used both as an exploratory visualization technique and as an optional feature extraction step before supervised classification.

To prevent information leakage during model evaluation, the PCA model was fitted exclusively on the training portion of each cross-validation iteration. The resulting transformation was subsequently applied to the corresponding validation fold without recalculating the principal components.

E. Classification Models

Four supervised machine learning algorithms were evaluated: Linear Discriminant Analysis (LDA), Random Forest (RF), Support Vector Machine (SVM), and K-Nearest Neighbors (KNN). These algorithms were selected because they represent complementary classification strategies frequently employed in biomedical machine learning studies.

LDA is a linear statistical classifier that maximizes class separability by projecting the data onto a discriminant subspace. Random Forest is an ensemble learning method that combines multiple decision trees to improve predictive performance and robustness. SVM constructs maximum-margin decision boundaries between classes, whereas KNN assigns class labels according to the similarity between neighboring samples in the feature space.

All models were implemented using the Scikit-learn library. To ensure a consistent comparison among preprocessing strategies, no hyperparameter optimization was performed, and all classifiers were evaluated using their default parameter settings.

F. Model Training and Validation

Model evaluation was performed using Repeated Stratified Five-Fold Cross-Validation. The dataset was partitioned into five stratified folds while preserving the proportion of healthy controls and OSCC spectra in each fold. This procedure was repeated ten times using different random partitions, resulting in a total of fifty validation iterations for each preprocessing configuration and classification model.

During each iteration, four folds were used for model training and one fold was reserved for validation. The repeated cross-validation strategy was adopted to reduce the influence of a single data partition and to provide a more robust estimate of predictive performance. The reported performance metrics correspond to the mean values obtained across all validation iterations.

To prevent information leakage, all preprocessing operations requiring parameter estimation, including Principal Component Analysis (PCA), were fitted exclusively using the training folds and subsequently applied to the corresponding validation fold within each cross-validation iteration.

All experiments were performed using a fixed random seed ($random_state = 42$), ensuring reproducibility of data partitioning and model evaluation.

G. Performance Evaluation

Model performance was assessed using accuracy, precision, recall, and F1-score. These complementary metrics were calculated for every computational pipeline, enabling a systematic comparison of the effects of baseline correction, derivative transformation, spectral region selection, dimensionality reduction, and classification algorithm on the discrimination between healthy controls and patients with OSCC. For each classifier and preprocessing configuration, the reported values correspond to the mean performance obtained across the fifty validation iterations generated by the repeated stratified five-fold cross-validation procedure.

III. Results and Discussion

A. Effect of Baseline Correction

Spectral preprocessing is essential in FTIR-based classification because baseline distortions, instrumental noise, and other acquisition-related artifacts may obscure biologically relevant spectral features. Figure 2 presents the average FTIR spectra in the fingerprint region (900–1800 cm^{-1}) after baseline correction using IASLS, ModPoly, and AirPLS, together with the unprocessed spectrum.

The raw spectrum exhibited noticeable baseline drift, whereas all three correction methods substantially reduced these distortions while preserving the main absorption bands. The corrected spectra showed highly similar peak positions and spectral profiles, indicating that baseline correction removed non-biological variability without significantly altering the biochemical information contained in the samples.

To further investigate the influence of preprocessing, the spectra were subjected to second-derivative transformation. As shown in Figure 3, this procedure enhanced subtle spectral features and improved the resolution of overlapping absorption bands. After derivative transformation, the spectral profiles obtained from the three baseline correction methods became even more similar, suggesting that derivative preprocessing reduced residual differences introduced during baseline estimation.

Derivative spectroscopy is widely employed in FTIR analysis because it improves spectral resolution and attenuates residual baseline effects. In the present study, derivative preprocessing produced a more homogeneous spectral representation regardless of the baseline correction method, indicating that subsequent classification models were less influenced by acquisition artifacts and more likely to capture biologically relevant variations.

Figure 4 shows the average spectra over the complete spectral range after baseline correction. Greater variability among preprocessing methods was observed at higher wavenumbers, particularly above 3800 cm^{-1}, whereas the fingerprint region exhibited substantially greater consistency.

Because the fingerprint region contains the most diagnostically relevant absorption bands associated with proteins, lipids, nucleic acids, and carbohydrates, these observations support its use as a complementary spectral configuration in the classification experiments.

Overall, IASLS, ModPoly, and AirPLS effectively corrected baseline distortions while preserving the characteristic molecular signatures of saliva. The application of second-derivative preprocessing further enhanced spectral consistency, generating suitable representations for the machine learning analyses presented in the following subsection.

TABLE I
Performance of the best computational pipelines obtained using repeated stratified five-fold cross-validation with ten repetitions.

Pipeline	F1 (%)	Sensitivity	Specificity	AUC
FP + Derivative + RF	100.0	100.0	100.0	1.000
FP + Derivative + SVM	100.0	100.0	100.0	1.000
Full + Derivative + RF	100.0	100.0	100.0	1.000
Full + Derivative + SVM	100.0	100.0	100.0	1.000
Full + Derivative + KNN	99.6	99.5	99.7	0.998

B. Classification Performance

Table I summarizes the performance of the best computational pipelines evaluated using repeated stratified five-fold cross-validation with ten repetitions. The reported metrics correspond to the mean performance obtained across fifty validation iterations. This evaluation strategy reduces the influence of a single data partition and provides a more robust estimate of model performance and stability.

The results demonstrate that spectral preprocessing played a critical role in determining classification performance. Although baseline correction was applied to all computational pipelines, the inclusion of second-derivative preprocessing consistently produced the greatest improvement in predictive performance. Across both spectral configurations, derivative transformation enhanced the discrimination between healthy

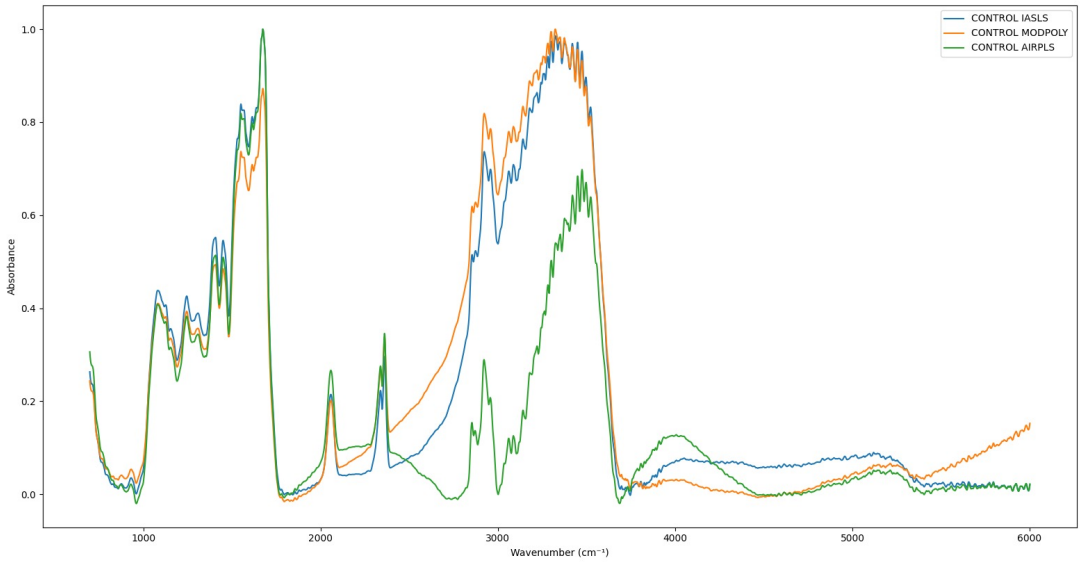

Fig. 2. Average FTIR spectra in the fingerprint region after baseline correction using IASLS, ModPoly, and AirPLS, compared with the unprocessed spectrum.

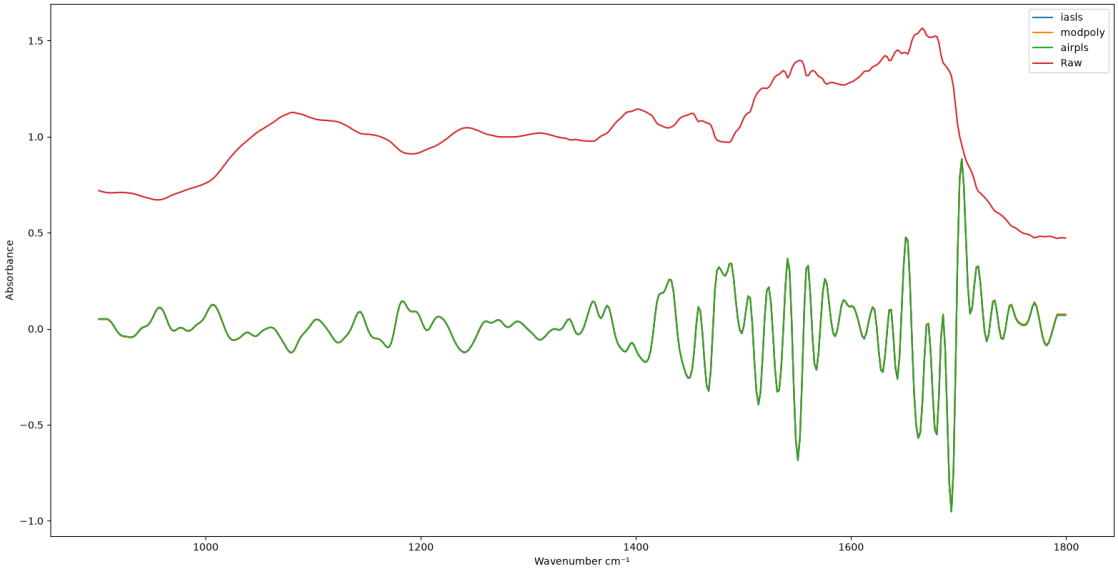

Fig. 3. Average FTIR spectra after second-derivative transformation using the three evaluated baseline correction methods.

controls and OSCC spectra, leading to substantial improvements in F1-score, sensitivity, specificity, and AUC. This behavior is consistent with the known ability of derivative spectroscopy to improve spectral resolution, reduce residual baseline effects, and enhance subtle absorption features that may be associated with disease-related biochemical alterations.

The influence of PCA was comparatively less pronounced. Although PCA is widely employed in spectroscopic studies to reduce dimensionality and minimize redundancy among spectral variables, its inclusion did not systematically improve classification performance in the present dataset. In several configurations, the results obtained with PCA were comparable to those achieved using the original spectral variables. These findings suggest that the FTIR spectra already contained sufficient discriminatory information for accurate classification and that dimensionality reduction was not a determining factor for predictive performance.

Among the evaluated classifiers, Random Forest exhibited the most robust and consistent behavior. The algorithm achieved perfect classification performance in both spectral

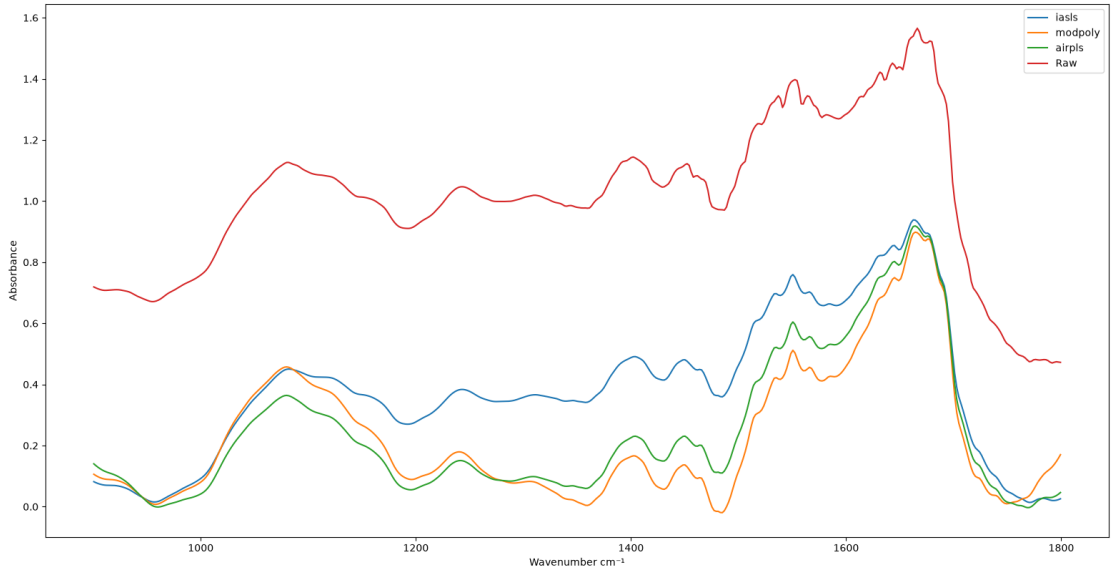

Fig. 4. Average FTIR spectra over the complete spectral range after baseline correction using IASLS, ModPoly, and AirPLS.

configurations when derivative preprocessing was applied, regardless of whether PCA was used. This stability likely reflects the ability of ensemble-based tree methods to model complex and non-linear relationships while remaining relatively insensitive to noise and irrelevant variables.

Support Vector Machine also achieved perfect classification performance when derivative preprocessing was applied, particularly in the fingerprint region. In contrast, its performance decreased considerably when derivative transformation was omitted, indicating a stronger dependence on the quality of the spectral representation. Similar behavior was observed for K-Nearest Neighbors, which benefited substantially from derivative preprocessing and achieved near-perfect classification performance under the best-performing configurations.

The comparison between the full spectral range (700–6000 cm^{-1}) and the fingerprint region (900–1800 cm^{-1}) revealed that both spectral representations contain relevant discriminatory information. The fingerprint region alone was sufficient to achieve perfect classification performance with Random Forest and Support Vector Machine, supporting the hypothesis that this spectral interval concentrates a large proportion of the biochemical information associated with OSCC. This observation is consistent with previous FTIR studies, which have shown that the fingerprint region contains absorption bands related to proteins, lipids, nucleic acids, and carbohydrates that are frequently altered in pathological conditions.

To further investigate the spectral regions contributing to model predictions, permutation feature importance was calculated for the best-performing Random Forest model. Figure 5 shows that the discriminatory information was not uniformly distributed throughout the spectrum. Instead, the highest importance values were concentrated within specific spectral intervals.

In particular, prominent contributions were observed between approximately 1000–1300 cm^{-1} and 1650–1750 cm^{-1}, both located within the fingerprint region. These intervals encompass absorption bands commonly associated with carbohydrates, phosphate-containing biomolecules, proteins, and lipid-related molecular vibrations. Additional contributions were observed between 2800 and 3600 cm^{-1}, a region associated with C–H, O–H, and N–H stretching vibrations. Conversely, the importance values decreased substantially above approximately 3700 cm^{-1}, suggesting that this portion of the spectrum contributed relatively little to the classification process.

The importance profile supports the classification results obtained using the fingerprint region and reinforces the biological plausibility of the proposed models. Rather than relying on isolated spectral variables, the classifiers appear to exploit multiple biochemical signatures distributed across several diagnostically relevant FTIR bands. Overall, these findings indicate that second-derivative preprocessing was the most influential preprocessing step, whereas Random Forest provided the most robust predictive performance. The results further demonstrate that accurate discrimination between healthy controls and patients with OSCC can be achieved through the combined optimization of spectral preprocessing and machine learning strategies.

C. Study Limitations

A limitation of this study is the absence of participant-level metadata associated with the spectral dataset. Consequently,

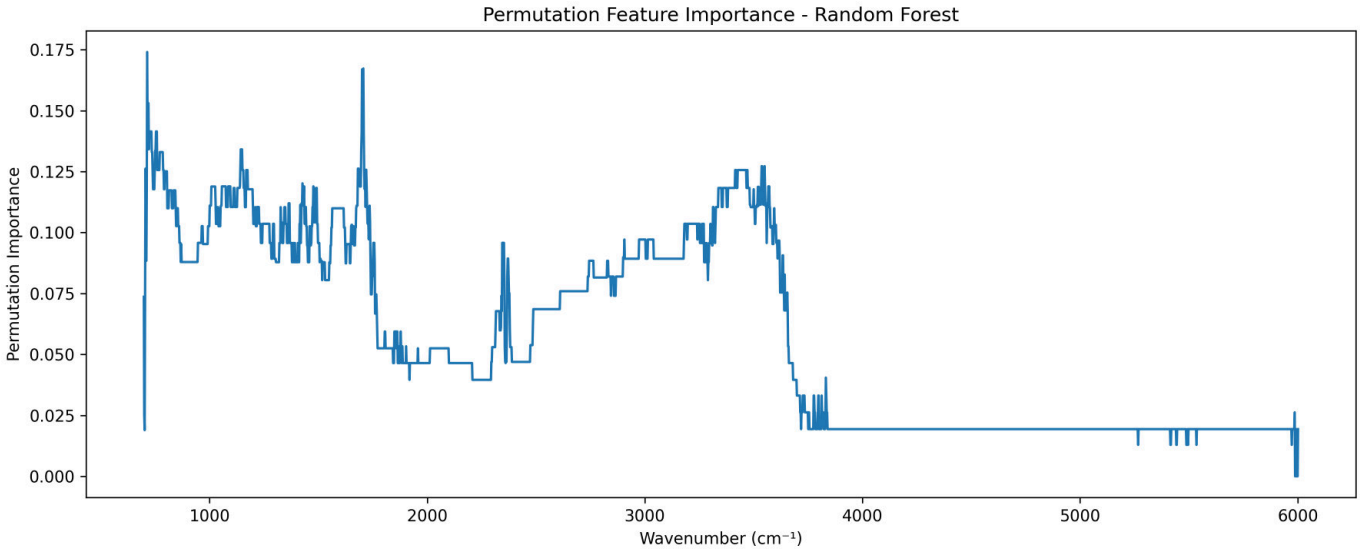

Fig. 5. Permutation feature importance profile obtained from the Random Forest classifier across the full FTIR spectral range (700–6000 cm^{-1}). Higher values indicate spectral variables whose permutation produced a greater decrease in model performance, suggesting a stronger contribution to the classification of healthy controls and patients with Oral Squamous Cell Carcinoma (OSCC).

it was not possible to determine whether multiple spectra originated from the same individual or to perform patient-wise partitioning during model training and validation. Therefore, each spectrum was treated as an independent observation throughout the computational analyses.

The dataset was obtained from a previously published study by Jimenez et al. [**?**], and only the processed spectra and corresponding class labels were available for the present investigation. Although this limitation does not affect the comparative evaluation of the preprocessing strategies investigated here, future studies should incorporate participant-level information to enable patient-wise validation and provide a more rigorous assessment of model generalization performance.

IV. Conclusion

This study evaluated the influence of different spectral preprocessing strategies on the classification of Oral Squamous Cell Carcinoma (OSCC) using salivary FTIR spectra. By systematically combining baseline correction methods, second-derivative transformation, spectral region selection, Principal Component Analysis (PCA), and supervised machine learning algorithms, it was possible to assess how different preprocessing choices affected classification performance.

The spectral analyses demonstrated that IASLS, ModPoly, and AirPLS effectively corrected baseline distortions while preserving the main biochemical characteristics of the salivary spectra. Although the corrected spectra exhibited only minor visual differences, the classification experiments revealed that preprocessing decisions substantially influenced predictive performance.

Among the evaluated preprocessing techniques, second-derivative transformation consistently produced the greatest improvement in classification performance, indicating that enhanced spectral resolution facilitated the identification of disease-related biochemical patterns. In contrast, PCA provided comparatively limited benefits, suggesting that the original spectral variables already contained sufficient discriminatory information for accurate classification.

Random Forest exhibited the most robust performance across the evaluated preprocessing configurations, while Support Vector Machine and K-Nearest Neighbors also achieved excellent results when derivative preprocessing was applied. The permutation feature importance analysis further indicated that the most informative spectral variables were concentrated within the fingerprint region and selected portions of the 2800–3600 cm^{-1} interval, highlighting the contribution of specific biochemical signatures to OSCC discrimination.

Although several computational pipelines achieved near-perfect classification performance, the results should be interpreted considering the limitations of the available dataset, particularly the absence of participant-level metadata that would allow patient-wise validation. Therefore, additional studies using larger and independent cohorts are necessary to further assess model generalizability and clinical applicability.

Overall, the findings demonstrate that spectral preprocessing can be as important as classifier selection in FTIR-based diagnostic workflows. This study contributes to the development of more reproducible computational strategies for salivary FTIR analysis and reinforces the potential of combining vibrational spectroscopy and machine learning as a rapid and non-invasive approach to support OSCC diagnosis.

Implementación y evaluación de un sistema de telemedicina integrado al sistema de información hospitalario para diagnóstico remoto en Paraguay

César José Yegros Acevedo[1], Eladio Quintana[1], Jorge Giubi[1]
Universidad Nacional de Asunción, San Lorenzo, Paraguay

Resumen—El acceso oportuno al diagnóstico especializado continúa siendo desigual en sistemas públicos de salud con población geográficamente dispersa. Este trabajo presenta la implementación y evaluación de una solución de telemedicina integrada al sistema de información hospitalario, complementada con geolocalización referencial para apoyar el diagnóstico remoto y la gestión sanitaria. El estudio prospectivo se realizó en un hospital universitario público de Paraguay entre septiembre de 2020 y diciembre de 2022. Se evaluaron la integración técnica, la usabilidad, la satisfacción profesional, la efectividad diagnóstica y aspectos económicos. Durante el piloto se analizaron 156.115 atenciones; 5.324 pacientes con COVID-19, dengue o leishmaniasis conformaron la muestra de evaluación diagnóstica. El porcentaje global ponderado de diagnósticos acertados con tratamiento adecuado fue 98,2%. La carga de geolocalización requirió en promedio 44,78 s y la satisfacción de los profesionales fue alta, aunque se identificaron dificultades de conectividad, capacitación y precisión de algunas direcciones. Los resultados muestran que integrar la telemedicina, el registro clínico digital y la geolocalización puede ampliar el acceso al especialista y generar información útil para la planificación, aprovechando la infraestructura disponible.

Palabras clave—*telemedicina, diagnóstico remoto, sistema de información hospitalario, geolocalización, salud digital.*

I. INTRODUCCIÓN

La distancia entre el paciente y el especialista sigue condicionando el acceso a servicios diagnósticos en varios países latinoamericanos. La telemedicina reduce parte de esa barrera, pero una consulta remota aislada tiene valor limitado si no se integra al registro clínico, a los procesos del hospital y a la capacidad de gestión del sistema de salud. En contextos con recursos restringidos, la solución tecnológica debe ser útil, sostenible y sencilla de incorporar al trabajo cotidiano [1]–[4].

El Hospital de Clínicas de la Universidad Nacional de Asunción implementó un sistema de información hospitalario (HIS) para digitalizar las fichas clínicas. Experiencias previas desarrolladas en Paraguay ya habían mostrado la factibilidad de implementar servicios de telesalud sobre infraestructura sanitaria disponible [10]. Sobre esa plataforma se desarrolló un módulo de telemedicina con geolocalización referencial. La propuesta agrega al registro del paciente datos de dirección y coordenadas, permite visualizar su ubicación y vincula esa información con el diagnóstico remoto. Así, el mismo dato utilizado durante la atención puede servir para conocer el origen territorial de la demanda y reconocer concentraciones de determinadas patologías.

Desde la Ingeniería Biomédica, el interés del proyecto radica en la integración: infraestructura informática, conectividad, dispositivos diagnósticos, profesionales y datos clínicos funcionan como un solo sistema. Este trabajo tuvo como objetivo implementar y evaluar dicha solución en condiciones reales, considerando desempeño técnico, usabilidad, aceptación profesional, efectividad diagnóstica e impacto económico-social.

II. MATERIALES Y MÉTODOS

Se realizó un estudio prospectivo con información de pacientes ambulatorios y de urgencias atendidos mediante diagnóstico remoto, desde la implantación del módulo de geolocalización, en septiembre de 2020 hasta diciembre de 2022. Para la evaluación clínica se incluyeron pacientes diagnosticados a distancia con COVID-19, dengue o leishmaniasis; se excluyeron los casos sin diagnóstico remoto asociado al sistema. El estudio fue aprobado por el Comité de Ética en Investigación de la Facultad de Ciencias Médicas de la Universidad Nacional de Asunción, mediante dictamen CEI N.º 48/2022, y contempló acceso autorizado a la base de datos, anonimización de la información y protección de la privacidad.

A. Integración tecnológica

El módulo fue incorporado al HIS existente, evitando crear una plataforma independiente. Se añadieron campos para dirección, ciudad, departamento, latitud y longitud, junto con una interfaz cartográfica. El desarrollo utilizó tecnologías web y bases de datos de código abierto, con un esquema modular y control de acceso por roles. Antes de la implementación se relevaron recursos disponibles o subutilizados, incluidos equipos diagnósticos, red, personal técnico e infraestructura informática.

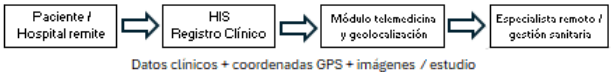

Fig. 1. Arquitectura funcional simplificada del sistema integrado de telemedicina, HIS y geolocalización.

B. Evaluación

La evaluación combinó cinco componentes. Primero, se verificó la implementación y funcionamiento del módulo. Segundo, se midió la usabilidad con 46 profesionales (7 médicos y 39 técnicos), considerando tiempo de tarea, número de pasos y errores. Tercero, se aplicó una encuesta semiestructurada con escala Likert de 1 a 5. Cuarto, la efectividad diagnóstica se estimó comparando el diagnóstico remoto con el diagnóstico presencial definitivo establecido por el especialista, utilizado como patrón de referencia. Se consideró el acierto cuando existió concordancia entre ambos diagnósticos y el tratamiento indicado fue considerado adecuado. Quinto, se analizaron costos de implantación y mantenimiento frente a costos asociados a la atención presencial, incluidos transporte, alimentación, costo de oportunidad e informe especializado. El enfoque económico siguió principios habituales de evaluación de tecnologías sanitarias [5]–[7]. Los resultados descriptivos se expresaron mediante frecuencias, porcentajes y medias. Para la proporción global de concordancia diagnóstica se estimó un intervalo de confianza del 95% a partir de los datos agregados disponibles.

III. RESULTADOS

La solución se integró al HIS y se mantuvo operativa durante el piloto. Los campos de ubicación quedaron asociados al registro clínico y pudieron consultarse individualmente o representarse en mapas. Durante el periodo analizado se registraron 156.115 atenciones médicas entre

consultas ambulatorias y teleconsultas. De ellas, 5.324 pacientes cumplieron los criterios para la evaluación diagnóstica; 41,0% fueron hombres y 59,0% mujeres, con edad media de 48 años.

TABLA I. EFECTIVIDAD DEL DIAGNÓSTICO REMOTO

Patología	N	Acierto y Tratamiento	Error
COVID-19	5099	98,3	1,7
Dengue	206	96,1	3,9
Leishmaniasis	19	84,2	15,8
Total	5324	98,2	1,8

Considerando el tamaño de cada grupo diagnóstico, la proporción global ponderada de concordancia diagnóstica con tratamiento adecuado fue 98,2% (IC95% aproximado: 97,8%–98,5%), con una proporción global de error de aproximadamente 1,8%. La diferencia entre patologías debe interpretarse junto con el tamaño desigual de los grupos, especialmente en leishmaniasis. Entre los factores que afectaron el desempeño se identificaron la experiencia clínica, diferencias entre dispositivos diagnósticos, la calidad de la transmisión y la experiencia del especialista remoto.

A. Usabilidad y aceptación

El tiempo medio para introducir dirección, ciudad y ubicación en el mapa fue 44,78 s, por debajo del objetivo de un minuto. La tarea requirió cinco pasos, dentro del rango considerado de alta eficiencia. Los 46 profesionales realizaron cinco tareas de carga cada uno, totalizando 230 tareas evaluadas. Se identificaron 68 errores (29,6%): 16 relacionados con la dirección (7,0%), 13 con la protección de datos (5,7%) y 39 con el posicionamiento en el mapa (17,0%). Este último componente concentró el 57,4% de todos los errores registrados. El problema fue más frecuente en domicilios fuera de Asunción y Gran Asunción, donde las direcciones postales pueden ser imprecisas.

Los 46 profesionales participantes (7 médicos especialistas y 39 técnicos sanitarios) respondieron la encuesta de satisfacción. Para la asistencia recibida de especialistas remotos, el promedio ponderado fue 4,5/5; para la calidad del servicio, 4,6/5; y para la valoración general de la unidad, aproximadamente 4,5/5. Las sugerencias se concentraron en reducir el tiempo de entrega de resultados, mejorar la velocidad de conexión y reforzar la capacitación.

TABLA II. INDICADORES PRINCIPALES DE IMPLEMENTACIÓN

Indicador	Resultado
Atenciones analizadas	156.115
Muestra diagnóstica	5.324
Tiempo medio de carga geográfica	44,78 s
Profesionales en usabilidad	46
Tareas de usabilidad evaluadas	230
Errores registrados	68 (29,6 %)
Error de dirección	16 (7,0 %)
Error de protección de datos	13 (5,7 %)
Error de posicionamiento en mapa	39 (17,0 %)
Satisfacción con servicio remoto	≈4,5/5

B. Costos e impacto

La evaluación económica tuvo un carácter descriptivo y permitió identificar los principales componentes de costo asociados a las modalidades de atención analizadas. En la atención presencial se consideraron costos que no recaen únicamente en la institución, como transporte, alimentación, jornada laboral perdida y acceso al especialista. Durante el periodo estudiado se registró un costo agregado de US$ 4.816,2 correspondiente a actividades de implantación, mantenimiento y evaluación remota del sistema. Por otra parte, para la atención presencial se estimó un costo promedio de US$ 130,6 por paciente.

Los registros disponibles no permitieron desagregar retrospectivamente los costos de implantación de los costos operativos atribuibles a cada atención remota. Por este motivo, no fue posible realizar un análisis económico incremental ni estimar un costo unitario directamente comparable entre las modalidades remota y presencial. En consecuencia, los valores obtenidos se presentan como indicadores descriptivos de la estructura de costos y no como una comparación de costo-efectividad entre ambas modalidades.

Durante la implantación también se identificaron barreras operativas relacionadas con la adecuación de interfaces entre equipos diagnósticos y computadoras, la capacitación de técnicos y especialistas, la resistencia inicial al uso de registros electrónicos y las diferencias de velocidad entre estaciones de la red. Con la infraestructura disponible fue posible transmitir y procesar imágenes y datos de forma satisfactoria durante el piloto; sin embargo, estos hallazgos muestran que un eventual escalamiento requiere fortalecer la conectividad, la interoperabilidad y la capacitación de los usuarios.

IV. DISCUSIÓN

Los resultados apoyan la factibilidad de integrar telemedicina y geolocalización al sistema de información hospitalario sin sustituir el flujo clínico existente. Este punto es relevante porque la sostenibilidad de la telesalud depende tanto de la tecnología como de su incorporación a procesos, recursos humanos y condiciones locales [2], [8]. El porcentaje global ponderado de acierto diagnóstico fue 98,2%, mientras que aproximadamente 1,8% correspondió a resultados clasificados como errores. La interpretación debe considerar la marcada diferencia en el tamaño de las muestras entre las tres patologías evaluadas y muestra que el desempeño remoto sigue condicionado por la calidad de la información, la conectividad y la experiencia clínica.

La conectividad apareció como una limitación práctica, en coincidencia con experiencias previas de telemedicina en regiones remotas y con la literatura sobre sistemas de información clínica a distancia [3], [4], [9]. La usabilidad presentó un comportamiento mixto: el tiempo de carga fue adecuado y el número de pasos fue reducido, pero la tasa de errores de georreferenciación fue elevada. Esto sugiere que el problema no está solamente en la interfaz. En Paraguay muchas direcciones carecen de nomenclatura uniforme, por lo que futuras versiones deberían incorporar validación de coordenadas, selección asistida y mecanismos de corrección.

La principal contribución del sistema es que el diagnóstico remoto no termina en la consulta. El dato clínico queda integrado al HIS y puede vincularse a su distribución territorial. Esto permite pensar en una plataforma que, además de acercar especialistas, apoye vigilancia, planificación y asignación de recursos. Para sistemas de cobertura universal en América Latina, donde la concentración de especialistas y

las distancias siguen siendo barreras, este tipo de integración puede ser más transferible que soluciones aisladas y costosas.

La posibilidad de personalizar el HIS y emplear componentes de código abierto fue relevante para reducir barreras de entrada. El modelo no exige que cada establecimiento disponga de todos los especialistas: organiza el acceso remoto a una capacidad diagnóstica compartida y deja la información dentro del expediente clínico. La capa geográfica añade una función de gestión que puede orientar cobertura, derivaciones y vigilancia. Esa combinación constituye el principal elemento de innovación aplicado al sistema público.

El estudio tiene limitaciones. Se realizó en una institución y con tres patologías; los tamaños de muestra fueron muy diferentes. La evaluación económica no fue un análisis incremental completo y algunas variables de impacto social se estimaron con información institucional. Tampoco corresponde extrapolar los resultados diagnósticos a otras especialidades sin nuevas validaciones. Aun así, la experiencia aporta evidencia de funcionamiento en condiciones reales y deja identificados los puntos que deben fortalecerse antes de escalar: conectividad, normalización de direcciones, capacitación, interoperabilidad y protocolos clínicos.

V. CONCLUSIÓN

Fue posible implementar un sistema de telemedicina integrado al HIS y complementado con geolocalización referencial en un hospital universitario público de Paraguay. El piloto reunió 156.115 atenciones y, en 5.324 pacientes evaluados para diagnóstico remoto, se observó una proporción global ponderada de 98,2% de diagnósticos acertados con tratamiento adecuado. La aceptación profesional fue alta y el tiempo de carga geográfica resultó compatible con el flujo asistencial, aunque persistieron errores de ubicación y limitaciones de conectividad.

La innovación propuesta no reside en una tecnología aislada, sino en conectar diagnóstico remoto, registro clínico y ubicación territorial dentro de una infraestructura disponible. Con validaciones adicionales, este enfoque puede apoyar la ampliación del acceso al especialista y ofrecer información útil para decisiones sanitarias en otros contextos latinoamericanos con recursos limitados.

***Abstract*—The growing use of artificial-intelligence (AI) models in healthcare has driven the development of specialized applications for distinct computer-vision tasks. However, the recurrent need to reimplement similar functionalities, authentication, image capture, inference, and result visualization, for each new model leads to fragmented, independent applications and duplicated effort. This paper presents VIZU, a mobile architecture proposal that centralizes computer-vision models for health behind a single, user-facing inference interface. Through VIZU, a user authenticates, submits an image from the device gallery or camera to a microservice, receives the model output (description, probability, and category), and acts upon it, archiving the analysis or disagreeing with the result, thereby contributing to model retraining, while visual feedback reports the connection and processing states. Prototyped with React Native and Expo for cross-platform compatibility, the proposed architecture could allow new models to be integrated into a shared model hub with minimal changes to the application. As an evolving prototype, its quantitative evaluation through usability testing and quality indicators is left as future work. The proposed approach favors the systematic reuse of components, offering a replicable foundation for research and development in computer vision applied to health.**

***Index Terms*—computer vision, artificial intelligence, medical imaging, mobile application**

I. Introduction

The application of Artificial Intelligence (AI) techniques in healthcare has expanded significantly in recent years, driven by advances in machine learning, computer vision, and the availability of large volumes of clinical and imaging data [1]. These technologies have been used in various contexts, including diagnostic support, disease prognosis, medical image segmentation, and clinical decision support, contributing to increased accuracy and efficiency in healthcare processes.

Among the various applications of AI in healthcare, specialized computer vision models designed for the analysis of imaging exams stand out. Deep neural networks have been used to identify patterns in X-rays [2], computed tomography (CT) scans [3], magnetic resonance imaging (MRI) scans [4], and clinical photographs [5] [6], assisting healthcare professionals in the early detection of pathologies and in conducting diagnostic evaluations. This trend has driven the development of specific solutions for different medical areas and types of exams.

At the same time, the growth of mobile technologies has fostered the spread of mobile health (mHealth) applications, which provide access to clinical tools directly through smartphones and tablets. These applications can expand the availability of computational resources for healthcare professionals, facilitate the collection and sharing of information, and support diagnostic and patient follow-up activities in different healthcare settings. [7]

Despite these advances, the development of mobile applications integrated with AI models often occurs in isolation, resulting in the creation of multiple systems that share similar functionalities. In many cases, different projects must reimplement mechanisms for authentication, image management, communication with inference services, and result visualization, leading to redundant development and maintenance efforts.

Existing ecosystems partially address model reuse, but from

a developer's perspective. Frameworks such as the Medical Open Network for AI (MONAI) standardize how medical-imaging models are built, shared, and deployed into clinical infrastructure [9], while general-purpose hubs centralize pretrained models for technical users. These solutions lower the effort of developing and deploying models, yet they do not provide a single, end-user-facing mobile interface through which a possibly non-technical user can run inference on a chosen model and act upon its results.

With this in mind, and based on the demands observed in previous projects conducted by the researchers, in which opportunities for component reuse and functionality standardization were identified, this paper presents Vizu, a unified mobile platform for the integration, validation, and visualization of computer vision models applied to healthcare. The proposal aims to centralize functionalities common to different AI-based applications, allowing for the incorporation of new models without the need to develop standalone applications for each solution.

As this is an evolving prototype, the contribution of this paper is primarily conceptual and architectural. Specifically, we: (i) identify the recurring requirements of mobile applications for AI-based image inference in health; (ii) propose an architecture that centralizes these functionalities behind a single interface and a model hub; and (iii) describe an initial prototype, discussing representative health use cases and outlining a plan for future evaluation. The remainder of this paper is organized as follows. Section II reviews related work on medical-AI frameworks and model hubs; Section III specifies the methodology used in this works; Sections IV and V present the the system requirements, architecture and the prototype; Section VI discusses use cases; Section VII outlines future work and the evaluation plan; and Section VIII concludes.

II. Related Work

The growing adoption of artificial intelligence models across various domains has driven the development of platforms, architectures, and systems designed to integrate, manage, and make these models available. These initiatives aim to reduce the complexity associated with the lifecycle of machine learning-based solutions by promoting reuse, scalability, and interoperability among different applications.

In the scientific context, DLHub [10] was proposed as a platform for publishing, sharing, and running machine learning models, allowing researchers to make models available along with their associated artifacts and metadata . The proposal seeks to address challenges related to the reproducibility, reuse, and availability of models for inference in different computational environments, offering standardized mechanisms for executing and sharing artificial intelligence solutions.

Similarly, ModelHub.AI [11] was developed as a platform focused on the structured dissemination of deep learning models. The proposed architecture uses containers and standardized interfaces to make models from different domains and computational frameworks available, with the goal of facilitating their reuse and integration by researchers and developers. The work highlights the need for mechanisms that reduce barriers related to interoperability and the sharing of artificial intelligence models.

In addition, several studies have investigated architectures focused on the lifecycle management of machine learning models. The Gallery system [12], developed by Uber, exemplifies this approach by providing an infrastructure for storing, versioning, monitoring, and orchestrating models at scale. The solution was designed to handle multiple models and heterogeneous applications, reducing the fragmentation of model management functions throughout the model lifecycle.

The literature also highlights the growing use of microservice-based architectures to support scalable artificial intelligence systems. In this approach, components responsible for distinct stages of the model lifecycle (training, inference, monitoring, and data processing) are decoupled into independent services, facilitating maintenance and the continuous evolution of solutions. Major industry platforms, such as TensorFlow Extended (TFX) [13], Michelangelo [14], and SageMaker [15], adopt similar principles to promote modularity and component reuse.

In the healthcare field, recent studies have emphasized the need for architectures capable of integrating multiple artificial intelligence models into complex clinical environments. Dedicated ecosystems such as the Medical Open Network for AI (MONAI) [9] provide frameworks, model zoos, and deployment SDKs that standardize how medical-imaging models are built, shared, and integrated into clinical infrastructure through standards such as DICOM and FHIR . In a complementary direction, the Health xAI [16] Implementation Framework proposes a structure for the development, deployment, monitoring, and maintenance of large-scale AI-based solutions, considering aspects such as modularity, integration between models, interpretability, and adaptation to the specific requirements of healthcare environments . The effective adoption of these technologies depends not only on the performance of the models but also on the existence of infrastructure that enables their integration into clinical workflows.

Although these studies make significant contributions to the sharing, management, and deployment of artificial intelligence models, it is evident that most proposals focus on the infrastructure for executing, publishing, or managing the lifecycle of these models. In contrast, less attention has been paid to providing a standardized mobile layer that allows for the testing, validation, and visualization of different computer vision models in healthcare through a single interface. In this context, this paper contribution lies in the proposal of a replicable mobile architecture aimed at integrating computer vision models applied to healthcare, seeking to reduce the need to develop specific applications for each solution and to promote the reuse of components across different projects.

Table I summarizes the reviewed works according to six dimensions relevant to the problem addressed in this paper: focus on the health domain, provision of an end-user interface (as opposed to a developer-oriented one), existence of a mobile

layer, focus on computer vision, support for user-driven model testing, and the use of end-user feedback to support retraining. As shown, the existing solutions concentrate on the infrastructure for publishing, serving, or managing the lifecycle of models, and each addresses only a subset of these dimensions. In particular, none of them combines a mobile, end-user-facing layer with the testing and visualization of computer-vision (CV) models in healthcare, which characterizes the gap explored in this work.

III. METHODOLOGY

The development of the proposed architecture and the Vizu application was conducted using the Interdisciplinary Method for the Development of Health-Focused Technologies (MIDTs) [8], a user-centered method geared toward developing technological solutions for the healthcare context. MIDTs integrates principles of interdisciplinarity, Design Science, and User-Centered Design, and is structured into six stages (Figure 1): (i) understanding the context of the problem, (ii) identifying needs and establishing requirements, (iii) ideation and design, (iv) prototyping, (v) solution evaluation, and (vi) academic and market documentation and actions. The method was adopted because it provides a systematic approach to identifying real-world demands, defining requirements, and building technological solutions aligned with user needs and research objectives.

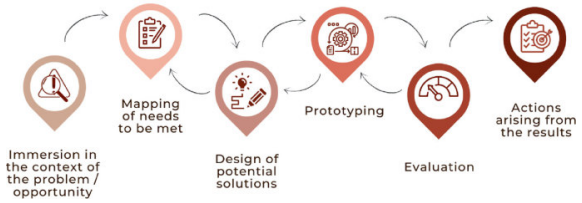

Fig. 1. MIDTS Phases. Adaptaded from [8]

A. Context of the problem

The first stage of the MIDTs consisted of understanding the context of the problem that motivated the development of the proposed solution. To this end, meetings were held between researchers and developers with the goal of identifying recurring difficulties observed during the implementation of mobile applications associated with computer vision models in the healthcare field.

During this stage, it was found that different projects shared similar functionalities, such as image capture and management, user authentication, communication with inference services, result visualization, and dataset management. Despite these similarities, each new model required the development of its own application, resulting in duplication of implementation and maintenance efforts.

The context analysis also took into account experiences gained from the Dr. Bone [7] and Pellis projects: the former focused on the analysis of radiographic exams using artificial intelligence, and the latter on the classification of burns using computer vision. The recurrence of common requirements across these projects highlighted the opportunity to define a reusable architecture capable of centralizing shared functionalities and facilitating the integration of new specialized models.

In addition to internal discussions, this phase involved researching concepts related to artificial intelligence applied to healthcare, medical computer vision, architectures for mobile applications, and mHealth solutions, with the aim of providing a theoretical foundation for the identified problem and supporting subsequent development decisions. This activity is aligned with the MIDTs recommendations, which call for an in-depth understanding of the problem and the conduct of a literature review to inform the subsequent stages.

B. Needs and requirements

The second phase aimed to identify the needs of the solution's potential users and establish the requirements necessary for building the proposed architecture.

Based on the information obtained in the previous stage, we analyzed the functional and non-functional requirements present in the projects that served as the motivation for this study. This analysis allowed us to identify elements common to applications based on computer vision models in healthcare, regardless of the specific task performed by the artificial intelligence model.

Among the identified needs, the following stood out: the ability to integrate multiple computer vision models into a single application; the reuse of functionalities shared across different projects; the simplification of the validation process for new models; and the provision of a standardized interface for visualizing the results produced by the inferences.

Based on these needs, requirements were established for the proposed architecture. As a result of this phase, a consolidated vision of the requirements necessary for developing the Vizu architecture was defined, serving as the basis for the ideation, architectural modeling, and implementation activities carried out in the subsequent phases of the method.

C. Design

The ideation and design phase aimed to transform the requirements identified in the previous phases into an architectural proposal capable of meeting the needs observed in computer vision projects in healthcare. In this phase,

different alternatives for organizing the system's components were analyzed, seeking to maximize the reuse of common functionalities and minimize coupling between the mobile application and the artificial intelligence models.

Given that the different use cases shared the same type of input—images submitted for processing—an architecture was designed based on centralizing the application's generic functionalities and decoupling the inference services responsible for processing the models. This approach allowed new models to be incorporated into the platform without the need to develop a new mobile application for each solution.

The proposed architecture was structured to separate responsibilities related to the user interface, image management, communication with external services, and the presentation of results. As a result, the application now acts as a unified interaction layer between users and the various available computer vision models.

During the design process, the application's usage flows, the mechanisms for linking models and image sets, and the communication strategies with the inference services hosted on dedicated infrastructure were also defined. These definitions served as the basis for designing the system's logical architecture and for developing the solution's functional prototypes.

D. Prototyping

The prototyping phase consisted of implementing the architecture designed in the previous phase through the development of the Vizu platform. The goal of this phase was to bring the proposed architectural concepts to life and verify their applicability in real-world usage scenarios.

Initially, the components responsible for the common functionalities identified during the requirements gathering phase were developed, including user management, image selection and storage, communication with inference services, and result visualization. These components were designed to be reusable regardless of the AI model associated with the application.

Next, the necessary mechanisms were implemented to enable the integration of different computer vision models into the platform. This integration was achieved through communication with external services responsible for performing inferences, allowing the application to remain independent of the specific characteristics of each model.

To validate the implementation of the architecture, the models developed in the Dr. Bone and Pellis projects were incorporated into the platform. These use cases made it possible to verify the solution's ability to support different medical image analysis tasks using the same mobile application framework.

At the end of this stage, a functional version of Vizu was obtained, capable of centralizing interaction with multiple computer vision models in healthcare, thereby laying the foundation for the evaluation activities planned for the subsequent stages of the MIDTs method.

IV. System Requirements

To support the full development of the VIZU platform, the requirements definition described in the methodology first sought to decompose the central idea of the project into smaller units that could be mapped more directly to design and development tasks.

The researchers initially defined the obligations related to authentication: a VIZU user must be able to create an account, log in, and modify account data such as username and password. This aligns the platform with the conventions of widely used mobile applications, improving the user experience through familiarity.

Regarding the AI functionalities, the user must also be able to submit images from the device gallery or camera to the microservice, which forwards the file to the AI model for processing. After processing, the AI result is returned to the user, including a description, a probability, a category, and/or any other elements provided by the model's response. Following this step, VIZU must also allow the user to act upon the result, for instance, adding it to a personal history of analyses linked to the profile, or disagreeing with the AI output, thereby contributing to the model-retraining process.

VIZU further defines functional requirements related to user feedback throughout the interaction with the selected model. The platform must provide visual elements that indicate the current state of the connection with the server (e.g., whether it is under maintenance or operational) and the processing state of the result, informing the user about the steps of the analysis (whether the image has been sent to the server and when processing has completed successfully). For the end user, awareness of these stages and of the current interaction state is essential, since inference may take a few seconds and the absence of visual feedback could create uncertainty about whether the system has completed the task.

In turn, the non-functional requirements of VIZU center on ensuring a uniform and secure experience for all users. Compliance with the Brazilian General Data Protection Law (LGPD) is explicitly defined as a requirement and must be maintained throughout the development process. Passwords, user data, requests, and information storage must follow strict encryption rules, particularly in the case of medical images. In addition, compatibility with both Android and iOS,also highlighted in the requirements document,gives the application a universal scope not restricted to specific operating systems. The use of React Native and Expo to prototype the application facilitates this compatibility, since the build processes for Android and iOS are specific to, and documented by, the framework itself.

As a result, the requirements defined for VIZU (Table II) establish a solid foundation for developing a functional, secure, and user-centered platform. By addressing authentication, AI-based image processing, feedback mechanisms during interaction, and compliance with security and privacy requirements, the set of specifications clearly delimits the responsibilities of the system and the criteria for its implementation. The functional and non-functional requirements thus act in a complementary manner, guiding the development stages and ensuring that the final solution meets both user needs and the technical and legal demands of the application context.

TABLE II
SUMMARY OF VIZU SYSTEM REQUIREMENTS

ID	Requirement
Functional Requirements	
FR1	Create a user account.
FR2	Log in and authenticate.
FR3	Edit account data (e.g., username and password).
FR4	Submit images from the device gallery or camera to the microservice.
FR5	Forward the image to the AI model and return the result (description, probability, category, and other model outputs).
FR6	Add a result to the user's personal analysis history, linked to the profile.
FR7	Disagree with an AI result, supporting the model-retraining process.
FR8	Provide visual feedback on the server connection state (operational or under maintenance).
FR9	Provide visual feedback on the processing state (image sent, processing completed).
Non-Functional Requirements	
NFR1	Ensure compliance with the LGPD throughout the development process.
NFR2	Apply strict encryption to passwords, user data, requests, and storage, especially for medical images.
NFR3	Provide cross-platform compatibility with Android and iOS, using React Native and Expo.
NFR4	Guarantee a uniform and secure experience for all users.

V. PROTOTYPE

A. Design

The ideation and design step aimed to turn the requirements identified in the previous phases into a concept that could meet the needs observed in computer vision projects in the healthcare field. To structure this phase, we adopted the Elements of User Experience framework [17], which organizes the design process into five progressive levels (strategy, scope, structure, skeleton, and surface), moving from the most abstract to the most concrete. This framework was chosen because of its suitability for the development of user-centered digital products. Since it operates gradually, with each stage serving as the foundation for the next, it prevents premature decisions about the application's design before its exact function has been established.

As part of the strategy, a qualitative exploratory study was conducted with professionals who worked in artificial intelligence-based image classification applications. As a data collection tool, a semi-structured interview guide was developed; this format allows for maintaining the thematic focus without losing the fluidity of the dialogue, thereby facilitating spontaneous exploration of points not anticipated by the researcher [18]. The guide addressed the functioning of the applications already developed, the features perceived as most frequently used, those considered critical by the professionals, and any features whose absence was noted during implementation. Based on the accounts, proto-personas were constructed, which, as described by Gothelf [19], are developed from hypotheses and partial data, aimed at aligning the team's understanding of the users prior to the conduct of more in-depth primary studies.

The qualitative summary followed a process of progressive data reduction. Relevant transcript excerpts were synthesized into short sentences capturing their essential content [20], then randomized to remove links to interviewee identities and reduce profile-related bias. The synthesized data were grouped by thematic similarity into an Affinity Diagram, based on the KJ Method [21] and adapted to user-centered design by Beyer and Holtzblatt [22]. Finally, each cluster was labeled by its predominant theme, providing a systemic understanding of shared user problems and needs.

As part of the scope planning, a card-sorting activity was conducted with the interviewed professionals, in which they were asked to organize cards representing features into groups that made sense from their perspective. This technique, described by Spencer [23], reveals mental models of how the system should be structured. In this study, the participants were not end users of the platform, but rather domain experts with direct experience in developing similar applications, a profile that, as pointed out by Nielsen [24], offers a privileged source of knowledge about recurring usage patterns and the system's technical and functional requirements. During the activity, participants were instructed to verbalize their reasoning (think aloud) [24], allowing us to capture not only the final result but also the logic that guided the categorization. The analysis of the resulting groupings was conducted using artificial intelligence-assisted analysis tools, with the goal of identifying cross-cutting patterns among the configurations proposed by different users and consolidating a single structure capable of accommodating the diversity of mental models observed. The result served as the basis for consolidating the functional and non-functional requirements presented in Section IV.

Regarding the structural design planning, the platform's core architectural decisions were made. Given that the different use cases shared the same type of input (images submitted for processing), an architecture was designed based on centralizing the application's generic functionalities and decoupling the inference services responsible for processing the models. This approach allowed new models to be incorporated into the platform without the need to develop a new mobile application for each solution. The proposed architecture was structured to separate responsibilities related to the user interface, image management, communication with external services, and the presentation of results. As a result, the application now acts as a unified interaction layer between users and the several computer vision models available.

Also as part of this plan, the user flow was designed to address two complementary usage scenarios: a monitoring scenario, in which the healthcare professional links classifications to persistent profiles or collections to track the progression of a case, and a sporadic prediction scenario, in which the user performs one-off classifications without the need for linking. Modeling these two workflows meets the architecture's scalability requirement: the platform must accommodate both domains requiring structured history and domains in which each classification is self-contained. At the same time, the application's sitemap was defined, hierarchi-

cally organizing the groupings resulting from card sorting. The adopted nomenclature (New Record, Collections, History, Profile) sought to balance two criteria discussed by Rosenfeld, Morville, and Arango [25]: immediate clarity for the user and modular flexibility so that different application domains can reuse the same structure without renaming hierarchical levels. During the design process, the application's usage flows, the mechanisms for linking models and image sets, and the communication strategies with the inference services hosted on dedicated infrastructure were also defined. These definitions served as the basis for designing the system's logical architecture and for developing the solution's functional prototypes.

B. Prototyping

The prototyping step involved implementing the architecture designed in the previous step through the development of the Vizu platform. The goal of this step was to bring the proposed architectural concepts to life and verify their applicability in real-world use cases.

Prototyping was conducted at three levels of increasing fidelity, in accordance with the progressive approach advocated by Buxton [26] and Snyder [27], who argue that each level of fidelity serves a distinct investigative purpose and that moving prematurely to high fidelity makes iteration more costly and shifts the focus of the discussion from structure to aesthetics. At the skeleton level, low-fidelity wireframes were used to validate the rough hierarchy of elements and the sequence of screens, without any visual considerations. Medium-fidelity wireframes detailed components, states, and microinteractions, allowing for discussion of consistency across screens and affordances [28] without yet addressing visual identity decisions.

At the surface level, the development of high-fidelity prototypes was guided by the Atomic Design methodology proposed by Frost [29], which organizes interfaces into a hierarchy of components—atoms, molecules, organisms, templates, and pages—to promote visual consistency and the systematic reuse of elements. The adoption of this approach was consistent with the platform's central objective: since Vizu aims to accommodate different computer vision models under a single interface, a modular component system reduces the cost of adding new screens associated with new models.

The visual refinement followed established best practices in UI design. Spacing was standardized to multiples of 8 pixels, a grid system widely adopted in digital product design because it ensures mathematical consistency among components and adaptability across screen densities. Accessibility was guided by the Web Content Accessibility Guidelines (WCAG) 2.1, published by the W3C [30], with particular attention to minimum contrast ratios, touch area size, and typographic readability. The visual hierarchy and contrast were developed according to principles established in the interface design literature [31], aiming to direct the user's attention to the priority elements on each screen, particularly in the classification results flow, where the clarity of the information produced by the AI is critical to user trust. Microinteractions were designed based on UX motion principles [32], ensuring that transitions and feedback states intuitively communicate causality and progress, in line with the system state visibility heuristic [24].

The interface as a whole was revised in light of Nielsen's ten usability heuristics [24], with special attention paid to the visibility of the system's status (essential while waiting for inference), the correspondence between the system and the real world (nomenclature adaptable to different domains), error prevention (validations at the time of data entry and segmentation), and recognition rather than memorization (use of the Reference Atlas as a visual aid when there is disagreement with the result).

These components were designed to be reusable regardless of the AI model associated with the application. Next, the necessary mechanisms were implemented to enable the integration of different computer vision models into the platform, through communication with external services responsible for performing inferences, allowing the application to remain independent of the specific characteristics of each model. To validate the architectural implementation, models developed in the Dr. Bone and Pellis projects were incorporated into the platform. These use cases demonstrated the solution's ability to support different medical image analysis tasks using the same mobile application framework. By the end of this stage, a functional version of Vizu had been produced, capable of centralizing interaction with multiple healthcare-related computer vision models and laying the groundwork for the evaluation activities planned for the subsequent stages of the MIDTs method.

VI. Discussion

The scientific contribution of VIZU is therefore not limited to the presentation of a mobile application project, but rather lies in the proposal of an architecture that centralizes CV models and handles inference through a single, end-user-friendly interface. Moreover, given the cutting-edge nature of the study, the possibility of adding new models or versioning existing ones is also taken into account. This section accordingly discusses hypothetical scenarios for the use of VIZU in health-oriented applications. Although the architecture has already been validated in two similar use cases, this section focuses on exploring new possibilities of interaction between AI models and VIZU, as well as how a user could employ the models in a simple manner and make use of the generic functionalities of the application (e.g., adding to a collection, segmenting an image) to facilitate their use.

First, VIZU could assist in the analysis of chest X-ray images to identify possible pulmonary alterations. In this scenario, the user would upload files from the gallery and select the inference model that classifies the image. Making such a model available for use on mobile devices would otherwise require a separate application, with functionalities developed from scratch. Using the proposed architecture, the integration of the CV model would occur through the association of its services with the VIZU model hub, reusing

the authentication, image capture, visual feedback, and other elements that compose the user interface.

Analogously, considering different scenarios, such as the classification of skin lesions from clinical photographs, or the identification of signs of diabetic retinopathy in fundus images, adherence to VIZU is likewise feasible. In both cases, the flow would be very similar to the previous one: an image is sent to the server, which loads it into the model to infer the class and, after processing, returns the result to the user. Although these involve different medical specialties, the proposed architecture allows a new model to be incorporated without significant changes to the structure of the mobile application, demonstrating its capacity to accommodate different medical specialties from a common set of functionalities.

From this perspective, the replicability of the architecture represents a relevant contribution to the development of AI solutions in health. Rather than treating each new model as an independent project, the proposal favors the systematic reuse of components, the standardization of the user experience, and the reduction of the effort required to deploy new models in a mobile environment. The architecture can thus act as a common foundation for different research and development initiatives that share the workflow of processing medical images through CV models. This replicability rests on a small set of design choices: centralizing otherwise dispersed models behind a single interface, standardizing the inference flow across specialties, and treating user feedback, including disagreement with a result, as a first-class input to model improvement.

However, some limitations should be acknowledged. The use cases discussed in this section are hypothetical and intended to illustrate the flexibility of the architecture rather than to report clinical validation; the platform itself remains at an early prototype stage. Although the architecture has been exercised in two similar use cases, its behavior under a broader range of models, image modalities, and real-world usage conditions has not yet been systematically evaluated. Furthermore, compliance with data protection requirements, while embedded in the design, requires rigorous validation before any handling of real patient data, and the quality of the resulting analyses ultimately depends on the individual models integrated into the hub. These aspects motivate the evaluation plan outlined in the following section.

VII. Future Work and Evaluation Plan

As a continuation of this work, we intend to complete the prototyping of VIZU, implementing all components in a generic and adaptable manner so as to support any image-based AI inference interaction. In addition, expanding the proposed architecture to encompass new application scenarios in health, with other CV models, is also part of the researchers' plans. Further improvements are foreseen regarding the dynamic configuration of models, user management, and interoperability mechanisms with systems used in clinical and research environments.

In line with these steps, once the prototype development is complete, we plan to assess the quality and consistency of the application through indicators and through usability tests conducted with user-experience (UX) professionals.

A. Evaluation Plan

The evaluation will be structured along complementary dimensions that together substantiate the central claim of this work, that a centralized, user-facing inference interface lowers the barrier to deploying CV models in health: **Usability:** task-based usability testing conducted with UX professionals and representative users, assessing the submission and inference experience across varied technical profiles. **Application quality and consistency:** measurement of indicators such as the reliability of the inference workflow, the consistency of results returned through the interface, and the responsiveness of the visual-feedback mechanisms. **Architecture replicability:** verification that new CV models can be integrated into the model hub with minimal changes to the mobile application, quantifying the effort required to add or version a model. **Privacy and compliance:** validation of the handling of sensitive data, including the de-identification of medical images, prior to any use of real patient data.

B. Functional Roadmap

The planned extensions define a path from the current prototype toward a validated platform. Beyond completing a fully generic component set, these include dynamic model configuration, allowing models to be added or versioned without modifying the application; richer user-management capabilities; and interoperability with clinical and research infrastructures. Ensuring usability, application quality, replicability, and privacy compliance, in that order, would consolidate VIZU as a common foundation for research and development initiatives that share the workflow of processing medical images through CV models.

VIII. Conclusion

The growing use of AI models in healthcare has driven the development of specialized applications for different CV tasks. However, the need to implement similar functionalities across multiple projects reveals opportunities for adopting reusable and standardized approaches.

This work presented VIZU, a mobile architecture proposal designed for the integration, validation, and visualization of CV models applied to health. It was developed from the observation of recurrent requirements across distinct projects, seeking to centralize shared functionalities and reduce the need to develop independent applications for each new model. Unlike approaches focused exclusively on the management or distribution of AI models, the architecture proposes a unified mobile layer capable of accommodating different solutions under a single, user-centered interaction structure. Within this structure, post-result actions such as archiving an analysis or disagreeing with a model output are treated as integral parts of the workflow, allowing user feedback to support

TABLE III

the subsequent retraining and improvement of the integrated models.

Table III positions VIZU against the reviewed works using the same dimensions. Unlike approaches centered on publishing, serving, or managing the lifecycle of models (generally from a developer or clinical-IT integration perspective), VIZU intends to unify a mobile, end-user-facing layer for testing, validating, and visualizing computer-vision models in healthcare, while allowing user feedback to support subsequent retraining. The comparison highlights that the contribution of this architecture lies not in any single dimension in isolation, but in their integration into a replicable architecture that lowers the barrier to making new models available through a common, user-centered interface.

As a prototype, aspects related to the quantitative evaluation of the architecture, the quality of the datasets produced, and the impact of the platform on the development and evolution cycles of models remain as future research. Nevertheless, the results obtained during development indicate that the proposed approach represents a promising alternative to support research and development initiatives in computer vision applied to health, contributing to the construction of more reusable, consistent, and scalable solutions.

***Abstract*—Vascular neck restraint (VNR) is a submission and control technique used in combat sports and law enforcement defensive tactics to temporarily incapacitate a resistant individual through cerebral hypoperfusion while minimizing airway compression. Despite its widespread application, the evaluation of VNR execution remains predominantly subjective, relying on visual assessment by instructors. This study developed and evaluated a prototype monitoring system, termed the Cervical Constriction Sensor, designed to objectively quantify pressure distribution across the right carotid, left carotid, and tracheal regions using an anthropomorphic training simulator. Twenty-two military police officers performed the technique before and after receiving specific biomechanical instruction based on the official defensive tactics manual. The results demonstrated a significant redistribution of pressure following technical guidance: mean peak pressure increased by 24.6 percent on the left carotid and 225.3 percent on the right carotid, while decreasing by 43 percent over the tracheal region. These findings support the hypothesis that objective monitoring provides valuable quantitative feedback for training quality and consistency, by characterizing whether force is directed toward the intended anatomical targets on the simulator rather than the tracheal region. As this study was conducted exclusively on an instrumented mannequin, no claims regarding operational safety in human subjects can be derived from these results.**

***Index Terms*—Law Enforcement Officers, Monitoring System for Vascular Neck Restraint, Rear Naked Choke, Vascular Neck Restraint.**

I. Introduction

Within the context of Fighting, Martial Arts, and Combat Sports (LAMEC, the Brazilian acronym for Lutas, Artes Marciais e Esportes de Combate), cervical restraint techniques have been employed for centuries as methods of controlling or incapacitating an opponent. Among these techniques, the Rear Naked Choke (RNC), known as hadaka-jime in Japanese martial arts [1] and mata-leão in Brazilian Jiu-Jitsu, is one of the most widely recognized submission maneuvers. When properly executed, the technique aims to compress the lateral structures of the neck while minimizing direct pressure on the airway, producing temporary incapacitation through vascular mechanisms.

Due to its effectiveness as a control technique, adaptations of vascular neck restraint (VNR) have also been incorporated into the defensive tactics programs of several law enforcement agencies. According to the Paraná Military Police Defense Manual [2], VNR is classified as a submission and control technique intended to neutralize aggressive or resistant behavior while reducing the need for higher levels of force. Consequently, proper technical execution is essential to maximize effectiveness and minimize the risk of adverse outcomes.

When applying this technique, the neck is positioned at the apex of the ”V” formed by the arm and forearm (Fig. 1). The operational priority is bilateral compression of the cervical region to promote carotid constriction, while respiratory compression is intended to remain a secondary effect.

Despite its widespread use in both combat sports and law enforcement environments, assessment of VNR execution remains predominantly subjective. Instructors typically rely on visual observation and practical experience to evaluate performance, making it difficult to objectively determine whether pressure is being applied to the intended anatomical targets. As a result, trainees often receive limited quantitative feedback regarding the quality, effectiveness, and safety of their technique. Therefore, the aim of this study was to develop and evaluate a prototype monitoring system capable of measuring pressure distribution during the execution of a vascular neck restraint technique. The proposed device was designed to simultaneously monitor pressure applied to the right carotid region, left carotid region, and anterior cervical region corresponding to the trachea. In the context of VNR instruction, such systems may provide valuable information

This work had the support from Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) and PMPR

regarding pressure distribution across cervical structures and support evidence-based training methodologies.

It was hypothesized that, following specific instruction regarding the biomechanical principles of VNR execution, participants would demonstrate a pressure distribution pattern on the simulator characterized by increased pressure over the carotid regions and reduced pressure over the anterior cervical region. Such findings, if observed, would support the use of objective monitoring as an instrument to characterize technique execution on a surrogate device, without implying validation of the technique's safety when applied to human subjects — a question that lies outside the scope of the present study and would require independent ethical and physiological evaluation.

II. Theoretical Framework

A. Vascular Neck Restraint and Mechanisms of Incapacitation

Vascular Neck Restraint (VNR) is designed to temporarily incapacitate an individual through compression of the lateral cervical structures, particularly the carotid arteries. Unlike airway-based choking mechanisms, properly executed VNR seeks to reduce cerebral perfusion while minimizing direct compression of the trachea and laryngeal structures. Consequently, the resulting loss of consciousness is primarily associated with cerebral hypoperfusion rather than respiratory obstruction. Mitchell et al. [3] investigated the physiological mechanisms associated with blood choke techniques and reported that effective carotid compression may induce loss of consciousness within approximately 5 to 11 s. The authors concluded that reduced cerebral blood flow resulting from carotid artery compression represents the principal mechanism responsible for transient incapacitation. Furthermore, recovery was generally rapid and complete when the restraint was promptly released. Additional evidence was provided by Stellpflug et al. [4], who analyzed validated choking events involving highly trained combat athletes. The authors observed a mean time to loss of consciousness of approximately 9 s following establishment of an effective chokehold. The similarity between these findings and previous physiological investigations reinforces the role of cerebral hypoperfusion as the primary mechanism underlying vascular restraint techniques. The effectiveness of VNR has been investigated in operational law enforcement environments. Bozeman et al. [5] analyzed 944 field applications performed by trained police officers over an 11-year period and reported a success rate of 92.6% in controlling resistant individuals. Importantly, the authors found no fatalities or severe injuries directly attributable to the technique during the study period. Comparable findings were reported by Hickman et al. [6] in an evaluation of VNR use by the Spokane Police Department. The authors observed no fatalities associated with the restraint and documented relatively low injury rates among subjects. Together, these findings suggest that VNR may constitute an effective and relatively safe control option when applied by properly trained personnel according to established protocols. Although available evidence supports the effectiveness and safety of VNR, complications may occur when the technique is improperly applied. Excessive force, prolonged compression, inadequate positioning, or inappropriate force distribution may increase the risk of injury to cervical structures. Demartini et al. [7] reported a case of internal carotid artery dissection in a Brazilian Jiu-Jitsu practitioner following application of a Rear Naked Choke. The authors proposed that arterial compression associated with cervical hyperextension and contralateral head rotation contributed to vascular injury. Although such events appear to be rare, they highlight the importance of proper instruction, supervision, and technical execution. Similarly, reports of severe neurological injury following prolonged strangulation demonstrate that inappropriate cervical compression may produce significant adverse consequences. Collectively, these observations emphasize that the effectiveness and safety of VNR are directly related to the practitioner's ability to apply force to appropriate anatomical targets while avoiding excessive compression of non-target structures.

B. Cervical Anatomy

The neck is organized into muscular compartments that define the principal pathways for vascular structures. Among these, the carotid triangle (Fig. 2), a subdivision of the anterior triangle, represents the main region of surgical interest for access to the carotid arteries. Its boundaries are formed by the superior belly of the omohyoid muscle anteriorly, the posterior belly of the digastric muscle superiorly, and the anterior border of the sternocleidomastoid muscle posteriorly. Throughout its cervical course, the common carotid artery (CCA) is enclosed within the carotid sheath, a condensation of the deep cervical fascia. Within this sheath, the artery occupies the medial position, the internal jugular vein lies laterally, and the vagus nerve is located posteromedially to

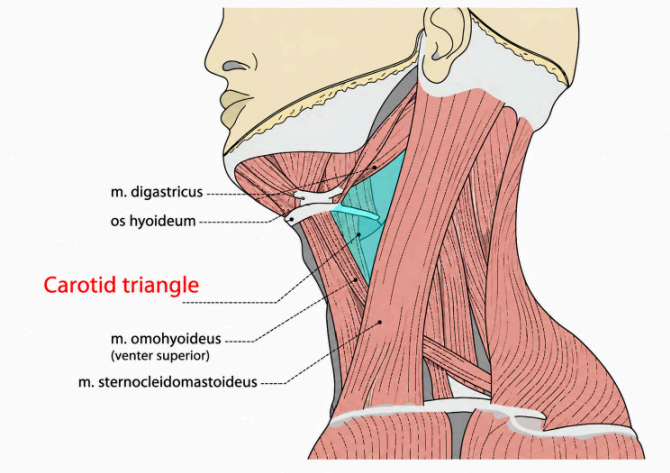

Fig. 2. Illustration of the carotid triangle's location, delimited by the sternocleidomastoid, omohyoid, and digastric muscles, highlighting its spatial relationship with the hyoid bone. Reproduced from [10]

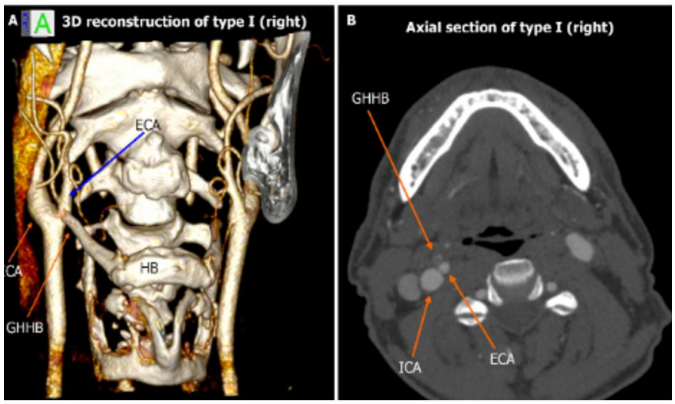

Fig. 3. anatomical relationship between cervical structures. ECA: External carotid artery; GHHB: Greater horn of the hyoid bone; HB: Hyoid bone; ICA: Internal carotid artery. Reproduced from [12]

both vessels. [8] The origin of the common carotid arteries presents a classic anatomical asymmetry. On the right, the common carotid artery (CCA) arises from the bifurcation of the brachiocephalic trunk, whereas on the left it originates directly from the aortic arch, presenting an intrathoracic segment before ascending into the neck. The CCA ascends without giving off collateral branches until reaching the superior border of the thyroid cartilage, where it bifurcates into the internal and external carotid arteries. At this level are located two structures essential for cardiovascular homeostasis: the carotid sinus and the carotid body. The carotid sinus is a dilation at the origin of the internal carotid artery that contains baroreceptors sensitive to changes in blood pressure, whereas the carotid body is a small cluster of chemoreceptor tissue responsible for monitoring blood oxygen and carbon dioxide levels. [9]

C. Physiology And Anatomy Of The Carotid Compression

As illustrated in Fig. 3, the thyroid cartilage (and above it the hyoid bone) forms a rigid structure that protects the larynx and trachea. The literature on VNR biomechanics describes the technique as forming a "V" shape between the arm and forearm, in which pressure is intended to be exerted on the lateral soft tissues (where the carotid and jugular veins are located), while the apex of the "V" remains aligned with this rigid structure. This description is presented here strictly as theoretical background to contextualize the anatomical regions monitored by the proposed sensor system, and should not be interpreted as operational guidance for technique application.

Loss of consciousness following the proper application of a carotid constriction technique does not result from asphyxia, but rather from a combination of cerebral hypoperfusion and autonomic responses. According to Mitchell et al. [3], the abrupt interruption of carotid blood flow reduces cerebral perfusion pressure. In addition, pressure exerted on the baroreceptors located at the carotid bifurcation triggers a vagal response, resulting in bradycardia and systemic vasodilation, thereby accelerating the onset of loss of consciousness. [3]

The forensic pathology literature establishes that the pressure thresholds for interruption of hemodynamic flow are substantially lower than those required for functional airway collapse. According to DiMaio and DiMaio [11], occlusion of the common carotid arteries requires a load of approximately 11 lb (5 kg), while total occlusion of the trachea requires a compression of about 33 lb (15 kg). Although considered a safe technique when interrupted immediately after withdrawal or syncope, there are risks of indirect vascular trauma. The literature reports rare cases of carotid artery dissection, such as a case where combined neck extension and head rotation (as a defense reaction) elongated the compressed carotid artery at its origin, causing dissection. [7]

III. Materials And Methods

This cross-sectional, comparative quantitative study, following the methodological principles described by Thomas et al. [13]. A non-probabilistic convenience sampling strategy was adopted for participant recruitment.

A. Data Acquisition

The sample consisted of 22 adult military police officers enrolled in the Sergeants' Course of the Paraná Military Police (PMPR), including 20 men and 2 women. All participants were right-handed, a characteristic that occurred randomly within the sample. The inclusion criteria were: (I) being a military police officer; (II) currently attending the Sergeants' Course of the Paraná Military Police (PMPR); and (III) not having injuries to the upper limbs or spine that could interfere with the execution of the technique. Participants were questioned regarding their practice of grappling martial arts, and only four reported previous experience, with three at an advanced level and one at a beginner level. However, all participants had previously attended police self-defense training and were familiar

with the VNR technique. During Trial A, each participant positioned themselves behind the anthropomorphic mannequin and executed the VNR motor gesture upon command, applying maximum force until voluntarily interrupting the maneuver. After completing the first trial, participants received standardized technical instruction regarding the proper positioning of the upper limbs according to the Police Defense Manual, while the researcher also corrected the positioning of the arm vertex on the simulator. The procedure was then repeated under identical conditions (Trial B). As a strategy to ensure internal control and experimental validity, the results obtained were not disclosed to the participants at the time of execution. This partial blinding technique aimed to mitigate the Hawthorne effect, characterized by behavioral alterations that occur when individuals become aware that they are participating in a study or having their behavior assessed. By withholding immediate feedback, the protocol sought to prevent conformity to perceived performance expectations or social desirability responses, which could otherwise introduce profound biases into the data reliability. [14]

B. Proposed Instrument

Performance measurement was carried out using a prototype developed by these researchers, called the ”cervical constriction sensor”. The instrument consists of a type of ”cervical collar” made of resilient material (foam and textile covering), adapted to the cervical circumference of an anthropomorphic combat training simulator, of the ”Bob” type. (Fig. 4).

Three pressure sensors were inserted into the system, positioned in specific locations: a) anterior cervical region, in the midline, simulating the position of the trachea; b) in the carotid triangle, right anterolateral region; c) in the carotid triangle, left anterolateral region.

The prototype utilized remained identical across all data collections, and the height of the anthropomorphic simulator was kept constant, with a height-raising platform being provided to the participants for a better technical fit at their own discretion.

The developed prototype consists of an embedded system driven by an ESP32 microcontroller, designed to quantify the pressure exerted on specific anatomical regions during the execution of the Vascular Neck Restraint (VNR) technique. Data captured by the pressure sensors are transmitted via Bluetooth Low Energy (BLE) protocol to a mobile platform, enabling real-time monitoring and data storage for subsequent statistical analysis. Consequently, the device is capable of mapping the simultaneous force distribution across the three cervical points of interest.

The pressure sensing mechanism was structured by coupling each sensor to a flexible tubing segment, with mechanical properties analogous to those found in standard sphygmomanometer cuffs. To enable signal transduction, this pneumatic circuit remained hermetically sealed at one end. This configuration ensured that any external mechanical compression applied to the tubing surface resulted strictly in a change in the internal pressure of the enclosed air volume, allowing this barometric variation to be isolated, detected, and accurately quantified by its respective transducer.

Fig. 4. Prototype installed on an anthropomorphic simulator for pressure data collection.

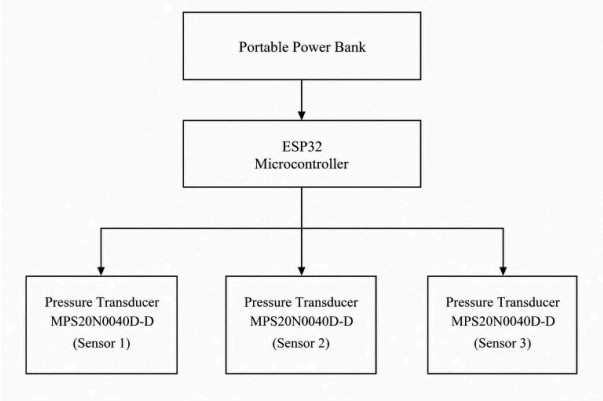

Fig. 5. Block diagram of the proposed embedded system hardware architecture.

C. Hardware

The hardware architecture of the proposed monitoring device is illustrated in (Fig. 5) and comprises three integrated pressure transducers. During the component selection phase, the BMP280 and MPS20N0040D-D transducers were evaluated, with the MPS model being selected due to its superior alignment with the project's efficiency requirements. The MPS20N0040D-D is a gauge/differential piezoresistive pressure sensor (up to 40 kPa) operating on Micro-Electromechanical Systems (MEMS) technology. It incorporates a sensing chip featuring an elastic membrane integrated with a four-piezoresistor array arranged in a Wheatstone Bridge configuration.

D. Software

As illustrated in Fig. 6, the software architecture of the system is divided into two distinct development branches: the embedded firmware within the ESP32 microcontroller and a

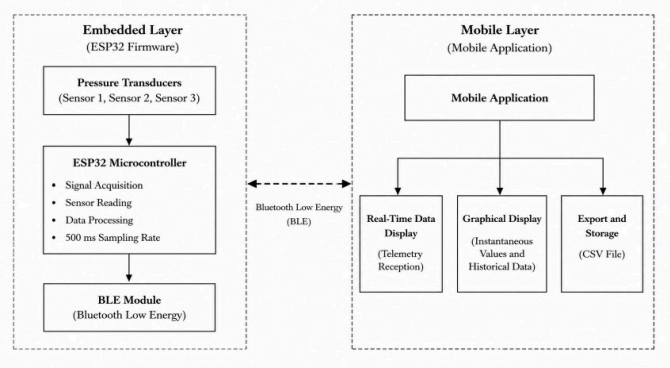

Fig. 6. Software and communication architecture of the proposed monitoring system.

dedicated application tailored for the mobile platform. The embedded software continuously scans and reads the analog signals from the pressure transducers, transmitting these data vectors to the mobile device at a constant sampling interval of 500 ms.

Wireless communication between the microcontroller and the mobile device is established via the Bluetooth Low Energy (BLE) protocol, selected for its energy efficiency, ease of implementation, and widespread standardization in embedded systems. On the receiving end, the mobile application features three core functionalities: (i) real-time reception of telemetry pressure data from the ESP32; (ii) simultaneous graphical display of instantaneous values and temporal measurement history for continuous trial monitoring; and (iii) exporting and storing these time-series datasets as .CSV files.

The 500 ms sampling rate was strategically selected as a design trade-off to optimize power consumption in the portable ESP32 microcontroller and to ensure reliable BLE packet transmission without data loss. Given that the vascular neck restraint (VNR) is characterized by sustained, quasi-static isometric compression rather than high-frequency dynamic impacts, this 2 Hz acquisition rate is mathematically sufficient to accurately capture the pressure plateaus and stable force distributions exerted during the hold phase of the maneuver.

IV. Results And Discussion

A. Results

The peak pressure values recorded by the proposed monitoring system were analyzed for the left carotid, tracheal, and right carotid regions during the two experimental conditions: Trial A (before technical instruction) and Trial B (after technical instruction). Descriptive statistics, including minimum, first quartile (Q_1), median, mean, third quartile (Q_3), and maximum values, are presented in Table II, while the mean peak pressures and overall variations are summarized in Table I. The pressure distribution across the monitored anatomical regions is illustrated in (Fig. 7), and the statistical distribution of individual pressure differences between trials is presented in (Fig. 8) and detailed in Table III.

Technical instruction produced a clear, systematic redistribution of pressure across the cervical region. Mean peak pressure applied to the left carotid increased from 1088.1 ± 538.9 to 1356.1 ± 459.6 sensor units, corresponding to an increase of approximately $+24.6\%$. A far more pronounced change was observed in the right carotid region, where the mean pressure escalated from 364.0 ± 436.8 to 1184.1 ± 732.9 sensor units, representing a substantial increase of approximately $+225.3\%$. Conversely, the mean peak pressure recorded in the tracheal region decreased significantly from 2002.0 ± 572.2 to 1124.7 ± 493.4 sensor units, corresponding to a targeted reduction of -43.0%.

The descriptive statistics further demonstrate that these observed changes were structurally consistent across the entire sample rather than being driven by isolated or extreme observations. Before instruction, the median pressure recorded in the right carotid region was 201.72 sensor units, which dramatically increased to 967.6 sensor units in Trial B, while its maximum value reached 3130.1 units. Likewise, the median pressure in the left carotid region increased from 1063.8 to 1370.9 sensor units. In stark contrast, the median tracheal pressure was halved, dropping from 2041.0 sensor units in Trial A to 1006.7 sensor units in Trial B, with the minimum recorded tracheal force falling to 341.1 units.

The net pressure differences calculated for each participant ($Trial\ B - Trial\ A$) and summarized in Table III reinforce this pressure redistribution pattern. The median increase in the left carotid pressure reached 456.5 sensor units, while the median increase over the right carotid region reached 701.9 sensor units, with a maximum individual increase of 2241.9 units. Simultaneously, the median reduction in tracheal loading reached -914.3 sensor units, with maximum decompressions reaching -1735.9 units. As illustrated by the boxplots in Fig. 8, this redistribution pattern was consistently observed among participants, indicating an association between the instructional intervention and a shift of mechanical force away from the tracheal region and toward the carotid regions monitored by the sensor system. The system was evaluated for hysteresis with increasing loads of 10, 20, 30, 40, 50, and 60 kg, respectively, distributed over the 3 tubes attached to the sensors, followed by the successive decreasing of load (i.e., 50, 40, 30, 20, and 10 kg), showing that the system has a strong dependency of its past input values. This result is shown in Fig. 9.

To establish these experimental equivalences, a physical calibration setup was developed. A mercury column was directly coupled to the same arterial analog rubber tube (8 mm outer diameter) connected to the pressure sensor, allowing for direct hydrostatic calibration. Concurrently, a mechanical calibration was performed by applying standard dead weights over a controlled compression area of 8 mm $\times$ 8 cm. Through this dual-calibration approach, it was observed that a variation of 100 sensor units is equivalent to 1 mmHg of internal pressure, which under this specific experimental setup also corresponds to approximately 1 kgf of externally applied force over the 8 mm $\times$ 8 cm tube surface area. This equivalence translates

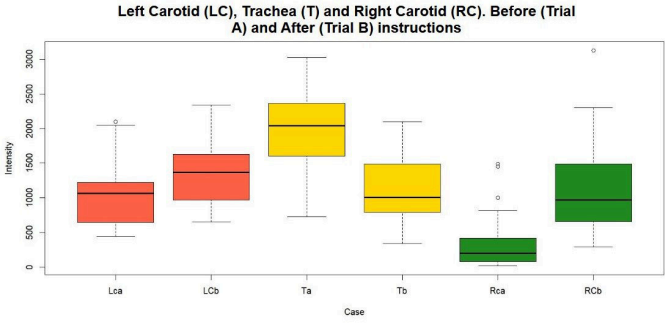

Fig. 7. Effort distribution for the regions of Left Carotid (LC) in red, Trachea (T) in yellow and Right Carotid (RC) in green

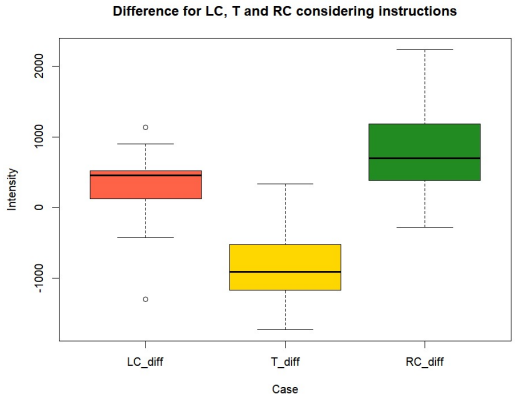

Fig. 8. Distribution of the differences between effort before and after instructions on proper vascular neck restraint protocol

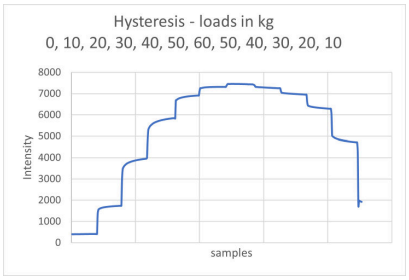

Fig. 9. Intensity measurements for adding loads of 0, 10, 20, 30, 40, 50, 60, 50, 40, 30, 20, and 10 kg, respectively, showing the hysteresis of the system.

the median baseline values (detailed in Table II) to a range spanning from 2.01 mmHg for RC_a (Right Carotid - Trial A) to 20.41 mmHg for T_a (Trachea - Trial A). Furthermore, the highest equivalent pressures recorded during the experiments reached 23.43 mmHg for LC_b (2342.8 units) and 31.30 mmHg for RC_b (3130.1 units).

Nevertheless, it is critical to note that a more refined calibration is necessary in future developments, given the biomechanical differences between the synthetic rubber tube and actual human arteries, as well as the dynamic movements of the human arm during the restraint, which can introduce transient artifacts in the recorded peak pressure values.

TABLE I
MEAN PEAK PRESSURE VALUES AND PERCENTAGE VARIATION BEFORE (TRIAL A) AND AFTER (TRIAL B) TECHNICAL INSTRUCTION.

Region	Trial A ($Mean \pm SD$)	Trial B ($Mean \pm SD$)	Variation
Left Carotid	1088.1 ± 538.9	1356.1 ± 459.6	$+24.6\%$
Trachea	2002.0 ± 572.2	1124.7 ± 493.4	-43.0%
Right Carotid	364.0 ± 436.8	1184.1 ± 732.9	$+225.3\%$

B. Discussion

The present study demonstrated that technical instruction substantially modified the pressure distribution pattern during the execution of the vascular neck restraint (VNR). Following instruction, pressure increased over both carotid regions while decreasing over the anterior cervical region, indicating that participants successfully altered the biomechanical application of force during the restraint. Importantly, this redistribution was consistently reflected across the descriptive statistics—including the mean, median, and quartile values presented in Tables I, II, and III—suggesting that the observed effect was highly representative of the study population rather than the result of isolated or extreme measurements.

The observed pressure redistribution strongly agrees with the physiological mechanisms previously described for vascular neck restraints. Mitchell *et al.* [3] demonstrated that transient loss of consciousness during vascular restraint is primarily associated with a severe reduction in cerebral perfusion resulting from bilateral carotid artery compression rather than airway obstruction. Likewise, DiMaio and DiMaio [11] reported that carotid artery occlusion requires considerably less compressive force than complete tracheal occlusion, emphasizing that an effective vascular restraint must preferentially direct pressure toward the lateral cervical structures instead of the anterior airway. In the present study, the robust reduction in tracheal pressure accompanied by increased pressure over both carotid regions indicates that, after instruction, participants executed the technique in a manner more closely aligned with these physiological principles.

The changes observed after instruction also reinforce the vital importance of structured technical training. Before instruction, the descriptive statistics demonstrated substantial variability in pressure distribution, particularly in the right carotid region, where the median pressure remained considerably lower than the values observed after technical guidance. Following instruction, both the median and mean values increased markedly, indicating that a greater proportion of participants applied pressure to the intended anatomical targets. These findings suggest that the instructional protocol contributed to increasing carotid loading and to improving the overall consistency of pressure application observed on the simulator, without implying a validated safety outcome for human application.

These observations are consistent with previous investigations involving vascular restraint techniques in law enforcement and combat sports. Bozeman *et al.* [5] reported that VNR can be performed safely when applied by properly trained officers according to established operational protocols. Similarly, Stellpflug *et al.* [4] demonstrated that effective sportive chokeholds produce rapid, transient loss of consciousness through vascular compression in highly trained athletes. Although the present study did not directly evaluate physiological outcomes such as cerebral blood velocity or loss of consciousness, the pressure redistribution observed on the simulator after instruction is consistent with the mechanical pattern described in the literature as associated with carotid-directed compression. This mechanical consistency should not be interpreted as evidence that the technique becomes safe when applied to a human being; such a claim would require dedicated physiological and safety studies, which fall outside the scope of the present surrogate-device study.

An important contribution of the present study lies in the objective assessment of technique execution. Conventional defensive tactics training is generally based on instructor observation and subjective evaluation of body positioning and movement. In contrast, the proposed monitoring system successfully quantified surface pressure simultaneously over the left carotid, right carotid, and anterior cervical regions, allowing direct visualization of force distribution throughout the maneuver. This objective feedback provides instructors with quantitative telemetry that complements traditional training methods and facilitates the identification of technical deficiencies that would otherwise remain undetected via visual assessment alone. It should be emphasized that this objective assessment characterizes force application on an instrumented mannequin and does not, by itself, establish that a given execution pattern is safe when applied to a person; VNR remains a high-risk technique whose use should continue to be governed by strict institutional protocols, training oversight, and independent ethical review, regardless of the mechanical results reported here.

From an engineering perspective, the developed embedded system successfully integrated pressure sensors, wireless communication, and mobile data acquisition into a single monitoring platform capable of recording multi-regional pressure distribution in real time. The prototype demonstrated sufficient sensitivity and resolution to distinguish contrasting execution patterns before and after technical instruction, supporting its feasibility as a practical tool for biomechanical assessment and tactical training. Furthermore, the proposed methodology establishes a rigorous experimental framework that can support future investigations involving the objective evaluation and optimization of vascular neck restraint techniques.

V. Limitations and Future Work

Several methodological and structural limitations must be considered when interpreting these results. First, pressure data were gathered using an anthropomorphic simulator rather than human subjects. Although this approach established a controlled and safe setup for initial hardware evaluation, the mechanical compliance of the synthetic rubber tubing differs substantially from the complex viscoelastic behavior of living human cervical tissues. The isotropic properties of the rubber fail to replicate the force dissipation mechanisms inherent to the skin, superficial fascia, muscle layers, and carotid sheath in vivo. Consequently, while the prototype reliably recorded relative force distribution patterns, the absolute pressures required to compress the pneumatic tubing cannot be linearly extrapolated to biological tissues.

Second, the data evaluation was restricted to peak pressure values recorded during each trial. Dynamic biomechanical parameters—such as pressure–time integrals, hold duration, and cumulative mechanical loading—were not quantified. These temporal variables are crucial for a comprehensive characterization of restraint mechanics.

Third, the study population was limited to military police officers enrolled in a single training program. This homogeneous cohort limits the direct generalization of the observed mechanics to other groups, such as combat sports practitioners or personnel from different law enforcement agencies.

Fourth, the experimental setup did not isolate the effects of technical instruction from confounding factors, including task repetition, trial order, and observer effects, as Trial A consistently preceded Trial B without a counterbalanced control group. Accordingly, the observed pressure shifts should be interpreted as correlated with, rather than strictly caused by, the instructional intervention.

Fifth, while the calibration protocol relied on traceable reference standards (a mercury column and calibrated weights), it characterized the sensor–tubing assembly under static bench-top conditions. The system was not cross-validated against an independent pressure-measurement system under dynamic loading, which remains a prerequisite for establishing absolute measurement accuracy.

Sixth, the study did not evaluate inter-instructor variability in the delivery of technical guidance, long-term skill retention among participants, or the reproducibility of the measurements across repeated sessions over time—factors that directly influence the practical implementation of the platform within continuous training curricula.

Finally, vascular neck restraint remains a high-risk physical intervention associated with severe and unpredictable injuries, as documented in medical literature. The findings presented herein strictly characterize the mechanical response of an instrumented simulator and must not be interpreted as a validation, endorsement, or operational guideline for applying such maneuvers to human subjects. Any future studies involving human participants would require independent ethical review, institutional oversight, and specialized protocols powered to assess physiological safety outcomes—none of which are proposed or implied by this work.

Future research should focus on: (i) cross-validating the sensor array against independent, traceable pressure-measurement devices; (ii) analyzing dynamic pressure–time profiles, contact duration, and cumulative mechanical loading; (iii) expanding testing to larger and more diverse simulator-based cohorts; (iv) evaluating inter-instructor consistency and long-term skill retention; and (v) improving sensor design, spatial resolution, and signal processing methods to enhance the platform's utility as a biomechanical research and feedback tool, strictly within the scope of surrogate-device testing.

VI. Conclusion

This study presented the development and evaluation of an instrumented monitoring system designed to quantify surface pressure distribution during the execution of vascular neck restraint (VNR) techniques. The proposed system successfully measured and mapped the mechanical forces applied to the right carotid, left carotid, and anterior cervical regions, providing high-resolution, objective data regarding force distribution during execution.

The experimental results demonstrated that structured technical instruction produced highly significant, systematic changes in pressure distribution patterns across the cohort. Following instruction, the pressure applied to both carotid regions increased markedly, whereas pressure over the tracheal region decreased substantially. These quantified shifts indicate that participants altered their hand-and-arm positioning on the simulator in a manner consistent with the biomechanical principles described in the literature as favoring carotid-directed over tracheal compression. This finding characterizes technique execution on an instrumented mannequin and does not constitute evidence of safety when the technique is applied to a human being.

The capacity of the embedded system to objectively distinguish the distinct profiles between pre-instruction (Trial A) and post-instruction (Trial B) executions on the simulator supports the proposed approach as a candidate tool for tactical training feedback and objective performance assessment, pending the cross-validation and human-subject ethical evaluation. By delivering multi-regional quantitative telemetry, this technology effectively complements traditional, subjective instructor-based evaluations, contributing to the standardization and mechanical characterization of simulator-based training.

Ultimately, these findings confirm the feasibility of utilizing dedicated embedded pressure-sensing platforms to monitor high-risk physical interventions. This methodology establishes a rigorous foundation for future investigations involving real-time hemodynamic cross-validation and evidence-based training protocols in law enforcement and combat sports.

Ethical Considerations

This study involved measurements performed exclusively on an instrumented anthropomorphic mannequin; no human subjects were exposed to the vascular neck restraint technique for data collection purposes. Participants executed the technique against the simulator only, under standard conditions of their regular military training program.

Acknowledgment

The authors express their gratitude for making the infrastructure of the sports practice facilities of the Paraná Military Police (PMPR) available for this research.

***Abstract*— Epileptic seizures are inherently unpredictable events that pose significant challenges for continuous monitoring outside clinical settings. This study presents the development of a wearable, non-invasive, multimodal prototype designed for the acquisition of physiological and contextual variables potentially associated with epileptic events. The system integrates hemodynamic monitoring via functional near-infrared spectroscopy (fNIRS), digital pupillometry, inertial sensors, and psychometric evaluation of perceived stress. An ESP32-based acquisition unit synchronizes and wirelessly transmits measurements to a mobile application for visualization, storage, and processing. The prototype enables the extraction of quantitative features across heterogeneous physiological modalities, providing complementary insights for individualized and longitudinal physiological monitoring. While the system currently lacks clinical validation as a dedicated seizure detector or biomarker platform, it establishes a robust technological foundation for future clinical trials and the development of artificial intelligence models for risk assessment and alert generation in ambulatory environments.**

Keywords—Multimodal monitoring; Functional near-infrared spectroscopy (fNIRS); Digital pupillometry; Wearable technology.

I. INTRODUCTION

Epilepsy is one of the most prevalent chronic neurological disorders worldwide, affecting over 50 million people and imposing a substantial clinical, social, and economic burden on healthcare systems. In Latin America—and specifically in Mexico, where approximately two million individuals live with the condition—epilepsy remains associated with a high burden of morbidity, disability, and premature mortality. Among seizure classifications, focal-onset seizures account for a significant proportion of cases and are characterized by their unpredictable nature, which heightens the risk of physical injury, functional impairment, and loss of patient autonomy. Consequently, identifying physiological alterations accompanying the preictal state and the preictal-to-ictal transition has emerged as a vital research avenue, particularly for developing continuous monitoring strategies aimed at early seizure detection and characterizing candidate neurophysiological precursor signatures [1, 2, 3].

Electroencephalography (EEG) remains the clinical gold standard for evaluating cerebral electrical dynamics in epilepsy due to its high temporal resolution and capacity to capture neuroelectric alterations. Nevertheless, complex instrumentation requirements, multi-electrode configurations, and high susceptibility to motion and physiological artifacts severely restrict its utility for long-term, ambulatory monitoring outside clinical environments. These constraints have catalyzed the exploration of complementary, multi-sensor modalities (Figure 1) To address this gap, integrating functional near-infrared spectroscopy (fNIRS), digital pupillometry, psychometric stress assessment, and inertial measurement units (IMUs) yields synergistic, multi-system data—capturing cortical hemodynamic responses, pupillary autonomic dynamics, psychological stress states, and body kinematic/orientational shifts, respectively. The convergence of these heterogeneous modalities provides quantitative metrics to characterize individual physiological variations tied to seizure phenomena, establishing a foundation for candidate feature extraction and digital biomarker discovery. Ultimately, this approach underpins the design of wearable, user-centric systems tailored for continuous out-of-clinic monitoring and real-time alert generation during daily living activities [4].

Functional near-infrared spectroscopy (fNIRS) is a non-invasive, wearable, and cost-effective neuroimaging modality that enables continuous monitoring of cerebral hemodynamic responses by quantifying concentration changes in oxygenated (Δ[HbO]) and deoxygenated (Δ[HbR]) hemoglobin via neurovascular coupling [5]. However, standard long-separation channels (~30mm) are inherently confounded by systemic extracerebral contamination originating from scalp and skull microvasculature, as well as autonomic physiological fluctuations (e.g., cardiac pulsation and respiration). To isolate true cortical signals, short-separation fNIRS (ss-fNIRS) channels (≤8–10mm) capture superficial hemodynamic dynamics to serve as regressors within a General Linear Model (GLM) framework, effectively removing systemic interference and optimizing the signal-to-noise ratio of reconstructed cortical responses.

A. Pathophysiology

Epilepsy is a chronic neurological disorder characterized by recurrent seizures arising from excessive, hypersynchronous, and transient neuronal activity within cortical or subcortical

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

brain networks (Figure 2) [6]. These alterations can manifest as motor, sensory, cognitive, autonomic, or behavioral symptoms, depending on the specific neural circuits involved. Various precipitating factors, such as sleep deprivation and physical or emotional stress, can lower the seizure threshold and trigger events in susceptible individuals [7, 8].

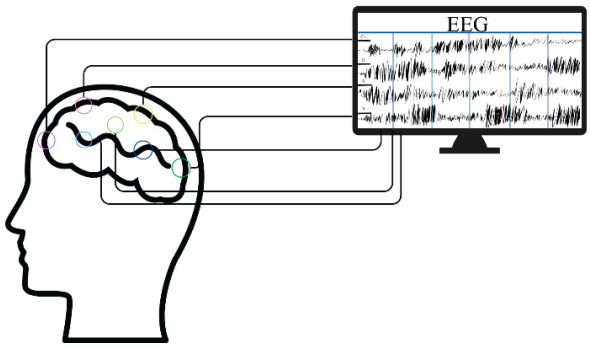

Figure 1 Schematic representation of epilepsy pathophysiology, spanning from excitation–inhibition (E/I) imbalance and neuronal hyperexcitability to pathological hypersynchrony, and the generation and network propagation of epileptiform discharges with their corresponding clinical manifestations. Concurrently, electroencephalographic (EEG) recordings remain inherently susceptible to diverse physiological and non-physiological artifacts that compromise signal fidelity

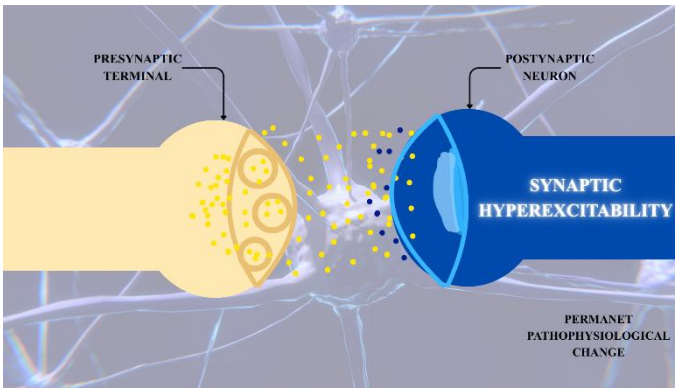

Figure 2 Schematic representation of epilepsy pathophysiology. Seizure onset involves complex network dynamics beyond simple depolarization-repolarization cycles; although rhythmic discharges occur, they exhibit intricate, non-linear spatiotemporal patterns across neural ensembles

At the cellular and network levels, epilepsy pathophysiology stems from an imbalance between excitatory and inhibitory mechanisms, facilitating the generation and propagation of epileptiform discharges through dynamic shifts in neuronal excitability and cerebral metabolism. Seizure recurrence fuels epileptogenic processes that induce structural, functional, and molecular alterations in neural circuits, progressively increasing their susceptibility to subsequent events [9, 10]. Elucidating these dynamic processes is essential for identifying physiological alterations that precede or accompany seizure onset, providing the theoretical rationale for multimodal architectures capable of acquiring and synchronizing neuroelectric, hemodynamic, autonomic, and kinematic data streams.

B. Classification

Contemporary epilepsy classification relies on the International League Against Epilepsy (ILAE) criteria, which establish a standardized framework for clinical characterization and diagnosis [11]. This framework operates across three levels: seizure type, epilepsy type, and epileptic syndrome. Seizures are categorized by onset into focal, generalized, unknown onset, or unclassified [12, 13], whereas epilepsy type and syndrome are determined by integrating clinical features, electroencephalographic (EEG) patterns, age of onset, clinical trajectory, and etiology. In this context, EEG remains crucial for characterizing the spatiotemporal distribution and propagation patterns of epileptiform activity (Figure 3) [14].

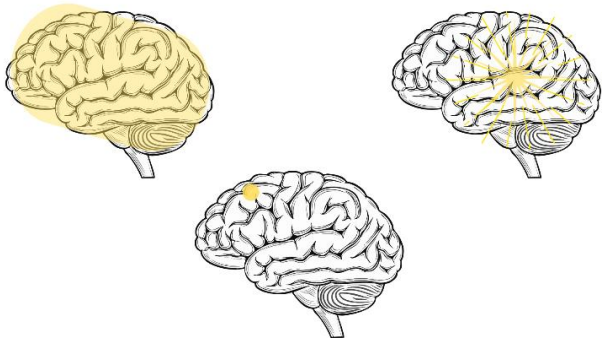

Figure 3 Classification of epileptic seizures based on the spatial distribution of epileptiform activity. Focal seizures originate within networks limited to one cerebral hemisphere, whereas generalized seizures rapidly engage bilaterally distributed networks at onset.

Concurrently, the advent of continuous monitoring technologies has driven multimodal approaches that synthesize neuroelectric, hemodynamic, autonomic, and behavioral indicators. The bidirectional relationship between epilepsy, stress, and neuropsychiatric comorbidities justifies incorporating psychometric scales as a complementary measure of patient status [15]. Furthermore, digital pupillometry objectively quantifies pupillary dynamics, offering valuable insights into autonomic nervous system function and central neurological states [16, 17]. These non-invasive measures complement conventional EEG, particularly within wearable, ambulatory monitoring frameworks.

In this setting, functional near-infrared spectroscopy (fNIRS) captures cortical hemodynamic fluctuations tied to neurovascular coupling by quantifying changes in oxygenated (Δ[HbO]) and deoxygenated (Δ[HbR]) hemoglobin concentrations [18, 19]. However, because fNIRS signals are susceptible to extracerebral hemodynamic contamination, short-separation fNIRS (ss-fNIRS) channels are integrated to estimate superficial interference and enhance cortical specificity. Integrating fNIRS, digital pupillometry, and inertial measurement units (IMUs) into low-power wearable platforms harmonizes hemodynamic, autonomic, and kinematic data streams with neuroelectric activity. This multimodal convergence provides rich, quantitative metrics to characterize individual seizure patterns and lays the groundwork for identifying digital biomarker candidates for early seizure detection and ambulatory alert generation [20].

II. Methodology

To overcome the clinical dependence and artifact vulnerability of ambulatory scalp EEG, a low-power wearable biomedical platform was engineered for continuous, non-invasive acquisition of physiological and contextual parameters associated with seizure dynamics. The system integrates dual-wavelength functional near-infrared spectroscopy (fNIRS), digital pupillometry, a 6-degree-of-freedom (6-DoF) inertial measurement unit (IMU), and an app-integrated psychometric stress assessment module. Central data acquisition, hardware clock timestamping, and Bluetooth Low Energy (BLE) wireless transmission are coordinated by an ESP32 microcontroller streaming to a mobile application for real-time visualization and feature extraction.

A. Cortical Hemodynamics (fNIRS)

Regional prefrontal hemodynamics were monitored bilaterally using dual-wavelength optical front-ends (660nm/ 880nm MAX30102) positioned with an inter-channel spacing of 17cm [21] (Figure 4). Optical attenuation was modeled via the Modified Beer–Lambert Law (MBLL) [22]. to quantify relative concentration changes in oxygenated (Δ[HbO]) and deoxygenated (Δ[HbR]) hemoglobin. An 8mm short-separation channel was incorporated to capture superficial scalp microvasculature dynamics for background noise regression.

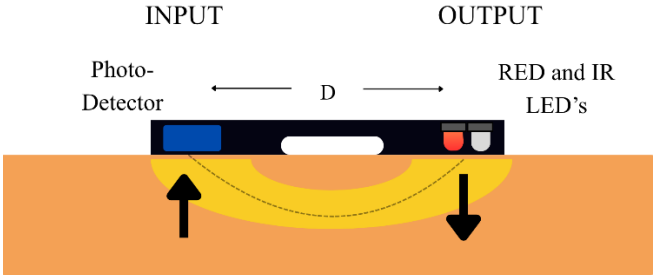

Figure 4 Operation of the fNIR system. It is used as a mapping method in neuroscience, where it measures oxygenation levels in cortical areas.

B. Autonomic Pupillary Dynamics

Pupillary dynamics were evaluated via visible-spectrum digital imagery. Pupil and iris boundaries were segmented using the Circular Hough Transform (CHT) to compute the scale-invariant Pupil-to-Iris Ratio (PIR) at an eye-to-camera distance of 15cm [23].

$$PIR = \frac{\emptyset pupila}{\emptyset iris} = \frac{rpupila}{riris}$$

where r_{pupila} and r_{iris} represent radius estimates in pixel space. Pupillary states were operationalized into miosis (PIR < 0.30), baseline (0.30 ≤ PIR ≤ 0.50) and mydriasis (PIR > 0.50).

C. Psychometric Stress Covariate

Perceived stress was quantified using an 11-item, 5-point Likert survey evaluating sleep deprivation, cognitive load, and environmental triggers [24]. A total score $Stotal = \sum_{i=1}^{11} Item_i$ was calculated, applying an operational cutoff of $Stotal \geq 30$ (>65 of the maximum score) to flag high-stress states as a contextual covariate.

D. Motor Activity (IMU)

Kinematic activity was captured using a 6-DoF IMU (3-axis accelerometer and gyroscope) interfaced via I²C [25]. Roll (∅) and Pitch (θ) orientation angles were derived relative to the gravity vector. Overall movement intensity and kinematic variability were extracted using acceleration magnitude ak, Signal Magnitude Area (SMA), and moving-window acceleration variance (σ^2):

$$Roll\ (\emptyset) = arctan\left(\frac{ay}{\sqrt{a_x^2 + a_z^2}}\right)\left(\frac{180}{\pi}\right)$$

$$Pitch\ (\theta) = arctan\left(\frac{-ax}{\sqrt{a_y^2 + a_z^2}}\right)\left(\frac{180}{\pi}\right)$$

Where ax, ay, and az represent the acceleration components along the three axes. Roll represents the roll angle about the X-axis, and Pitch about the Y-axis.

$$|A| = \sqrt[2]{ax^2 + ax^3 + ax^3}$$

$|A|$ overall intensity of the movement

$$SMA = \frac{1}{T}\left(\sum_{i=1}^{N}|A_x(i)| + \sum_{i=1}^{N}|A_y(i)| + \sum_{i=1}^{N}|A_z(i)|\right)$$

$$\sigma^2 = \frac{1}{N-1}\sum_{i=1}^{N}(|A|_i - \mu)^2$$

where μ is the windowed mean acceleration magnitude.

$$\mu = \frac{1}{N}\sum_{i=1}^{N}|A|_i$$

E. Hardware Control & Data Synchronization

An ESP32 Mini microcontroller unit (MCU) managed I²C sensor communication, assigned independent modality-specific sampling frequencies, and appended microsecond hardware timestamps to maintain inter-channel temporal alignment across all streamed data packets [26]. This architecture enabled the integration of heterogeneous sensors into a portable, low-power platform, while maintaining a modular structure for the future incorporation of new sensors or processing algorithms.

III. Results

The engineered prototype achieved complete functional integration of four complementary sensing modalities for synchronized acquisition of physiological and contextual parameters linked to seizure phenomena: dual-wavelength optical hemodynamics (fNIRS), digital pupillometry, 6-degree-of-freedom (6-DoF) inertial sensing, and psychometric stress profiling. The wearable hardware architecture was implemented as an ergonomic headband that distributed optical

and kinematic sensors across frontal and posterior cranial regions while housing an ESP32 Mini microcontroller unit (MCU), a power management circuit, and an inertial measurement unit (IMU). This configuration enabled continuous multi-channel signal acquisition, microsecond-level temporal synchronization, and wireless telemetric streaming to a custom mobile application (Figures 5 and 6).

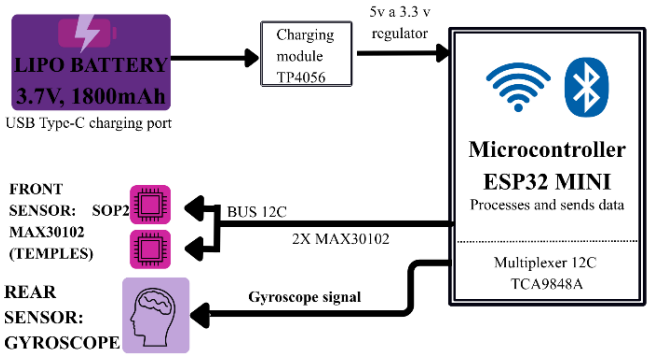

Figure 5 Functional block diagram of the hardware subsystem, detailing power regulation stages, central MCU control logic, and sensor-driver bus interfaces.

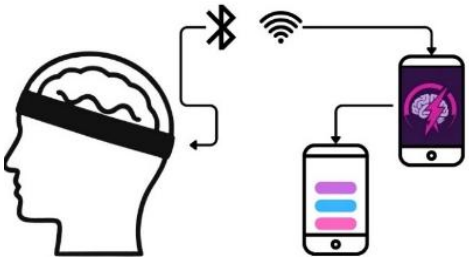

Figure 6 End-to-end architecture of the multimodal platform, illustrating data acquisition via the wearable headband, Bluetooth Low Energy (BLE) wireless transmission, and local/cloud storage, real-time visualization, and processing pipelines within the mobile

The custom mobile application served as the central system node, orchestrating image acquisition, psychometric survey execution, telemetry rendering, and secure data logging (Figures 7–9). The integrated psychometric module administered an 11-item, 5-point Likert scale instrument to assess perceived stress, aggregating a cumulative score Stotal as a real-time contextual covariate alongside streaming physiological signals.

The digital pupillometry pipeline captured visible-spectrum ocular images and executed an automated segmentation workflow based on the Circular Hough Transform (CHT) to extract pupil and iris geometric parameters. The Pupil-to-Iris Ratio was derived as a normalized, scale-invariant index of pupillary aperture dynamics: $PIR = \frac{rpupila}{riris}$. The platform operationalized PIR values into discrete pupillary states, facilitating inter-subject benchmarking and longitudinal tracking of temporal autonomic variability (Figure 10).

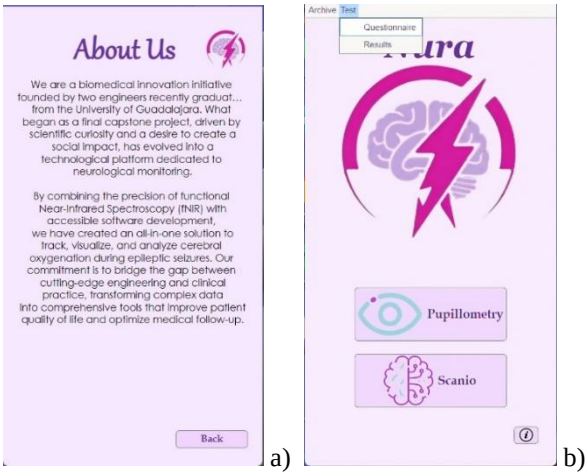

Figure 7 Mobile application user interface: (a) project landing and user authentication screen; (b) main navigation dashboard providing access to live acquisition and query modules.

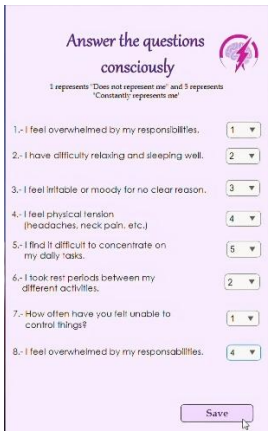

Figure 8 Graphical user interface of the StressTest_Module for psychometric stress profiling via an 11-item 5-point Likert instrument.

Figure 9 Interactive alert-verification interface for real-time event validation. User acknowledgement dismisses false alarms and resumes continuous monitoring, whereas an unacknowledged timeout automatically dispatches emergency notifications to pre-designated

Concurrently, the 6-DoF IMU quantified motor dynamics by capturing raw tri-axial acceleration and angular velocity signals. Derived kinematic features—including spatial orientation angles (Roll (∅) and Pitch (θ)), total acceleration magnitude (ak), Signal Magnitude Area (SMA), and windowed acceleration variance (σ^2) —characterized motor manifestations. When kinematic features exceeded operational threshold criteria, the mobile application initiated an interactive alert dialog with a user-cancellation window to mitigate false positive rates. In the absence of user cancellation during the

allotted interval, the system dispatched automated emergency alerts to pre-assigned contacts.

Overall, these results demonstrate the successful functional integration and operational feasibility of the multimodal wearable platform for synchronized, multi-parametric data acquisition, processing, and visualization. This architecture establishes a scalable technical foundation for individualized, longitudinal physiological profiling, laying the groundwork for future clinical studies to evaluate its diagnostic sensitivity against gold-standard clinical references (e.g., video-EEG).

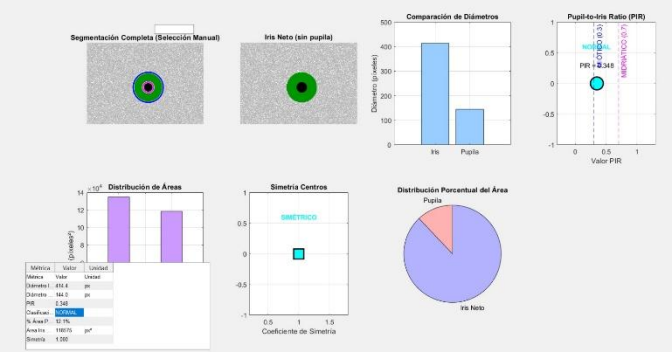

Figure 10 Ocular image processing and pupil-iris segmentation interface: pupil and iris boundaries are segmented via CHT to extract geometric metrics (diameter and surface area), compute the PIR index and centroid offset symmetry, and render static and longitudinal trend visual feedback.

IV. Conclusion

Epileptic seizures remain a major diagnostic and therapeutic challenge due to their paroxysmal nature and the operational constraints of conventional long-term video-electroencephalography (vEEG) in outpatient settings. To address these limitations, this study engineered a wearable, non-invasive, low-power multimodal platform designed for the time-synchronized acquisition of neuro-hemodynamic, autonomic, kinematic, and contextual parameters associated with seizure dynamics. By harmonizing dual-wavelength functional near-infrared spectroscopy (fNIRS), digital pupillometry (PIR), 6-DoF inertial kinematic tracking, and app-integrated psychometric stress assessment, the platform establishes a quantitative, multi-parametric framework for continuous ambulatory physiological profiling and individualized baseline characterization.

In its current stage of development, the system functions as a validated experimental framework for multi-channel signal acquisition, hardware clock synchronization, telemetry streaming, and real-time visualization. It does not yet claim standalone diagnostic autonomy or clinical seizure classification. Future work will focus on validating the extracted feature sets across clinical patient cohorts under standardized observational protocols, benchmarked against continuous long-term vEEG recordings. This translational roadmap will enable the quantitative mapping of multimodal surrogate markers to electrographic seizure onset, facilitate rigorous sensitivity and specificity benchmarking, and ultimately support the integration of edge-compatible machine learning algorithms for predictive seizure risk forecasting and automated early-warning telemetry in continuous ambulatory care.

***Abstract*—Self-monitoring of blood glucose in patients diagnosed with diabetes mellitus is essential for the proper management of the condition. This need has driven the search for electrochemical biosensors that are stable, cost-effective, minimally invasive, and efficient, and that overcome the limitations of conventional lancets. In this work, an integrated platform was developed using a three-electrode system fabricated by laser engraving on a flexible polyimide substrate, producing a conductive three-dimensional graphene network. The working electrode was modified by physical deposition of gold particles, and glucose oxidase was physically entrapped in a polyacrylamide-based hydrogel matrix with a controlled thickness of 2.0 mm. The device and its components were characterized by scanning electron microscopy and energy-dispersive X-ray spectroscopy, which confirmed the porous and rough morphology of the laser-induced graphene and the homogeneous distribution of the gold particles. Fourier-transform infrared spectroscopy demonstrated the structural stability of the hydrogel, evidenced by the preservation of the primary amide band at 1640 cm^{-1}, and revealed catalytic interactions in the fingerprint region (1150–1000 cm^{-1}) after the polymer matrix was subjected to different conditions, including diffusion analysis in glucose solution. Electrochemically, the biosensor exhibited a pseudocapacitive profile, and square-wave voltammetry showed a robust analytical response at -0.55 V, attributed to oxygen consumption during the glucose oxidase-catalyzed oxidation of glucose. These results indicate that the hydrogel synthesis process was efficient, preserved the chemical integrity of the reagents involved, and protected the sensing interface against interferents. It can be concluded that th platform represents a promising technology for minimally invasive glucose monitoring devices.**

***Index Terms*—Electrochemical biosensor, Laser-induced graphene, Glucose oxidase, Polyacrylamide hydrogel**

I. Introduction

Considered a fundamental nutrient in biological systems, glucose is responsible for vital metabolic processes, such as cellular respiration and biosynthesis [1], [2]. However, defects in its cellular uptake lead to its abnormal accumulation in the bloodstream—a condition associated with diabetes, a chronic metabolic disorder with a high global mortality rate that is expected to have a major impact in the coming decades [3]–[6]. Efficient management of this condition requires continuous self-monitoring of interstitial fluid glucose, creating market demand for sensors that offer high performance, cost-effectiveness, and ease of use [7]. Conventional methods for measuring blood glucose levels involve directly collecting blood from the patient using lancets; the discomfort caused by daily skin pricks hinders adherence to self-monitoring routines, leading to inadequate treatment control and, consequently, therapeutic errors, while also creating an entry point for infectious microorganisms. This creates a need to develop devices that improve the patient's quality of life, can be used safely, and provide reliable data [8], [9]. Historically, the concept of the biosensor emerged in 1962 with Clark and Lyons, who used an oxygen electrode to detect the oxidation of glucose by glucose oxidase (GOx). Since then, the system based on disposable reagent strips (commercially established in 1971) has remained conceptually the same: the sample rehydrates the dehydrated enzymes present on the strip, generating a product that is quantified by the detector [10], [11]. In GOx-based electronic systems, the enzyme converts glucose into glucono-

lactone and hydrogen peroxide (H2O2), which reacts with the electrode to generate a current flow [10], [12]. To overcome this, the market is seeking less invasive technologies (optical, transdermal, and thermal), although these face challenges such as sensitivity to perspiration [12] or dependence on skin tone [13]. Impedance-based systems [14] or reverse iontophoresis, also faced limitations due to low accuracy and skin irritation. In this context, electrochemical biosensors stand out as a viable alternative due to their high sensitivity, ease of operation, and excellent characterization of the surface-transducer interface [15]–[17]. However, severe limitations still need to be overcome. Non-enzymatic biosensors suffer from interference due to the adsorption of biomolecules onto their nanostructured surfaces [15], [18]–[21], while enzymatic ones lose activity due to fluctuations in temperature and humidity [19], [20]. Proposals in the literature to improve selectivity—such as increasing catalytic activity, using anti-interference coatings, and employing electron mediators—increase costs and entail high complexity. To overcome these challenges, surface engineering advocates the use of noble metals (Pt, Ag, Au) or micro- and nanostructured metal oxides to directly catalyze glucose [22]. In this context, the use of polyacrylamide gel has emerged as an effective approach. The incorporation of this three-dimensional polymer network enables the homogeneous physicochemical entrapment of biomolecules, establishing a protective hydrophilic microenvironment that preserves the enzymes structural integrity and activity against temperature and pH fluctuations, as well as dehydration. Furthermore, the gel's tunable porosity acts as a steric exclusion barrier against interfering macromolecules, facilitating the selective diffusion of glucose and minimizing leaching, thereby extending the device's lifespan and ensuring signal reproducibility. In parallel, another promising alternative involves the fabrication of electrodes via laser engraving on flexible polyimide substrates [23]. This process locally converts the material into a three-dimensional network of laser-induced graphene (LIG), acting as a highly porous and conductive transducer [24]–[28]. To mitigate interference caused by other biomolecules in complex media, modifying the reference electrode by coating it with gold (Au) particles offers an effective solution; this approach facilitates interfacial charge transfer and ensures the stability required for measurements. In this context, this study develops an electrochemical biosensor—compatible with minimally invasive devices—for quantifying glucose in interstitial fluids. The system integrates a graphene electrode patterned on polyimide, a gold-coated reference electrode, and an enzyme encapsulated within a polyacrylamide network, enabling detection via cyclic voltammetry. This integrated architecture preserves enzymatic activity and protects the interface against electronic interferents, establishing itself as a promising, stable platform for future digital monitoring systems [29]–[31].

II. Materials and Methods

A. Materials

Glucose oxidase (GOx). Glucose. Acrylamide (AAm). N,N-methylenebisacrylamide (BIS). N,N,N,N'-tetramethylethylenediamine (TEMED). and Ammonium persulphate (APS), were purchased from Sigma-Aldrich (Beijing, China). Phosphate-Buffered Saline - PBS (pH 7.4). Hydrogen peroxide PA (Modern chemistry). Glucose – Gluc UP (Newprov). All aqueous solutions were prepared with ultrapure water (Millipore Milli-Q).

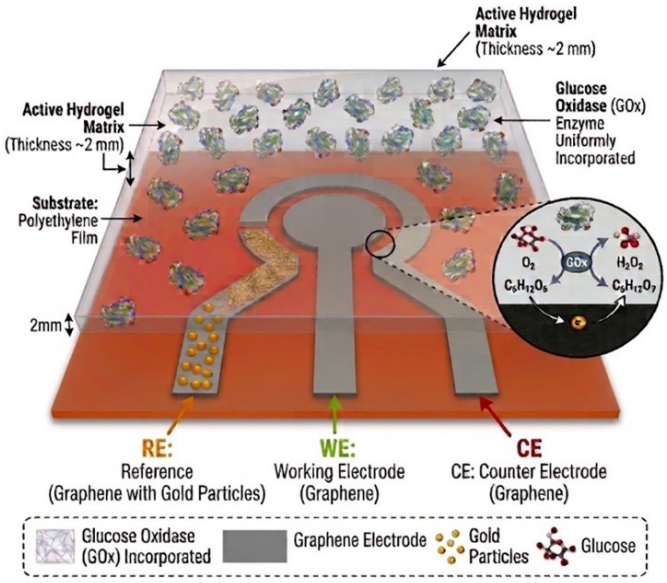

Fig. 1. Schematic diagram of a hydrogel-based biosensor deposited on a polyamide substrate.

B. Methods

1) Preparation of a graphene oxide electrode with a surface functionalized with gold particles: The polyamide film (substrate), with a thickness of 120 µm, was cut into 2.5 x 3.0 cm pieces and processed using a Creality CR-Laser Falcon to engrave the electrodes via surface burning. Operating parameters included a wavelength of 455 ± 5 nm and a power of 10 W, resulting in carbonization and the formation of a graphene surface in a tripolar electrode configuration, as illustrated in Figure 1. The surface of the reference electrode was subjected to a sputtering deposition process for 5 minutes using Quorum Q150RS equipment, producing particles ranging in size from 8 to 12 nm.

C. Synthesis of GOx enzyme-functionalized acrylamide gel

The polyacrylamide-based polymeric hydrogel, used as a platform for the GOx enzyme, was synthesized via the polymerization of acrylamide. A precursor solution was prepared by mixing 1,800 µL of ultrapure water (Milli-Q) with 1.600 µL of a 30% (w/v) acrylamide/bis-acrylamide stock solution. Subsequently, 3 mg of the enzyme glucose oxidase (GOx) was uniformly incorporated into the monomer mixture to reach a final enzyme concentration of 0.0037 mM. To start the polymerization process, 400 µL of freshly prepared 2% w/v ammonium persulfate and 250 µL of N,N,N',N'-tetramethylethylenediamine (TEMED) solution were added

sequentially under gentle stirring to avoid oxygen inhibition. The mixture was immediately poured onto a glass plate with a custom spacer to ensure a uniform hydrogel thickness of 2.0 mm. Cross-linking took place at room temperature (25 ± 2°C) for 30 minutes, resulting in an electrochemically active hydrogel matrix, which was cut to the same dimensions as the graphene electrode surface [23], [32].

D. Characterization

1) Scanning Electron Microscopy (SEM): The surface morphology of the graphene electrode was characterized by Scanning Electron Microscopy (SEM). Prior to analysis, the sample was sputter-coated with a thin layer of gold (Au) using a Quorum Q150RS sputter coater to ensure electrical conductivity at the interface. The micrographs were obtained using a Vega3 electron microscope from Tescan (Brno, Czech Republic), operating at an accelerating voltage in the 5–15 kV range. The images were recorded at magnifications ranging from 81x to 3000x to evaluate the porosity and integrity of the three-dimensional graphene network.

2) Energy Dispersive Spectroscopy (EDS): The elemental chemical composition of the graphene electrode surface was determined by Energy-Dispersive Spectroscopy (EDS). The spectra and elemental mapping were obtained using an EDS detector coupled to the electron microscope Vega3 electron microscope from Tescan (Brno, Czech Republic). The analysis enabled the identification and mapping of the distribution of the elements Carbon (C), Oxygen (O), and Gold (Au) constituting the electrode layer interface.

3) Fourier Transform Infrared (FTIR): To identify the functional groups and the polymerization process, and to examine the chemical behavior of the hydrogels under electrochemical techniques, we used Fourier Transform Infrared (FTIR) spectroscopy. The spectra, along with their respective transmittances and wavelengths, were obtained using a Shimadzu spectrometer (Model IR Prestige-21) operating in Attenuated Total Reflectance (ATR) mode. The readings were conducted in the spectral range of 4000 to 400 cm^{-1} with 64 scans.

4) Electrochemistry: The electrochemical characterization was performed using an AUTOLAB PGSTAT302N potentiostat with a three-electrode configuration patterned onto the polyamide surface, consisting of a counter electrode and a working electrode with graphene surfaces, and a reference electrode with a surface modified by gold (Au) particles. The following hydrogels were deposited on the electrode surface: WG (white gel), GE (gel/GOx enzyme 0.0037 mM), GEG (gel/enzyme/555 mM glucose solution), and GEH2O2 (gel/hydrogen peroxide – 52.2 mM and 104.4 mM). To ensure analytical consistency, we used the same electrode system for all analysis cycles at room temperature. During the analyses, the protocol consisted of the consecutive application of two voltammetric techniques - cyclic voltammetry and square-wave voltammetry - while varying the type of gel. For both

analyses, we used a potential sweep between -1.0 and 1.0 V at a rate of 0.1 V/s over three cycles. The following were evaluated: WG (White Gel), GE (Gel/Enzyme – subjected or not to a glucose solution), and GH2O2 (Gel/hydrogen peroxide). All measurements were performed in a phosphate buffer medium and All evaluated samples were subjected to the same analysis time, standardized at 3 minutes of hydrogel/electrode contact. The curves shown represent the average of three measurements for each situation evaluated.

III. Results and Discussions

A. Scanning Electron Microscopy (SEM)

The microstructure of the graphene electrode, obtained by burning polyamide, was evaluated by SEM at different magnifications and scales (Figure 2). The laser-induced heating process promoted direct carbonization and expansion of the polymer, resulting in a highly porous matrix composed basically of three-dimensional carbon atoms [33].

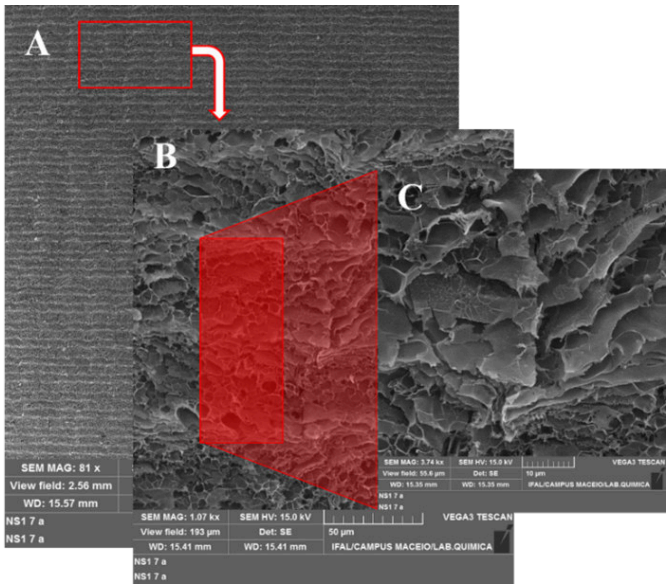

Fig. 2. SEM images of the graphene electrode surface obtained by carbonization of polyamide.

Upon magnifying the image 81x with a 500 µm scale (Figure 2A), an ordered arrangement of parallel, symmetrical lines, resulting from the laser beam scanning is observed. At a magnification of 3700x and a scale of 10 µm (Figure 2B), the transition to a spongy network with cavities becomes evident, likely generated by the rapid release of volatile gases during the formation of the graphene tracks, which consequently significantly increases the active surface area of the electrode [34]. The micrograph reveals an appearance of corrugated, interconnected graphene sheets forming an open-channel structure, creating a porous look, which is ideal for application in biosensor systems. The roughness will facilitate the process of stable mechanical anchoring for the polyacrylamide hydrogel, in addition to easing the diffusive transport of glucose and hydrogen peroxide, the product of the reaction catalyzed by the enzyme glucose oxidase (GOx), to the conductive surface, thereby optimizing electrical charge transfer [35].

1) Energy Dispersive Spectroscopy (EDS): The elemental chemical composition and the spatial distri-bution of the constituents present on the electrode surface were confirmed by EDS (Figure 3). The X-ray spectrum confirms the majority presence of the carbon atom (C), with a peak at approximately 0.27 keV (figure 3B), originating from the laser-induced graphene matrix [35]. We can also identify a low percentage of the element oxygen (Figures 3A1 and 3A2). The technique also reveals the successful incorporation of gold (Au), confirmed by emission lines at 2.12 keV (M), characteristic of the presence of trace amounts of the deposited element, and also shows secondary peaks around 9.71 and 11.44 keV in the intensity-versus-energy spectrum (cps/eV) [36].

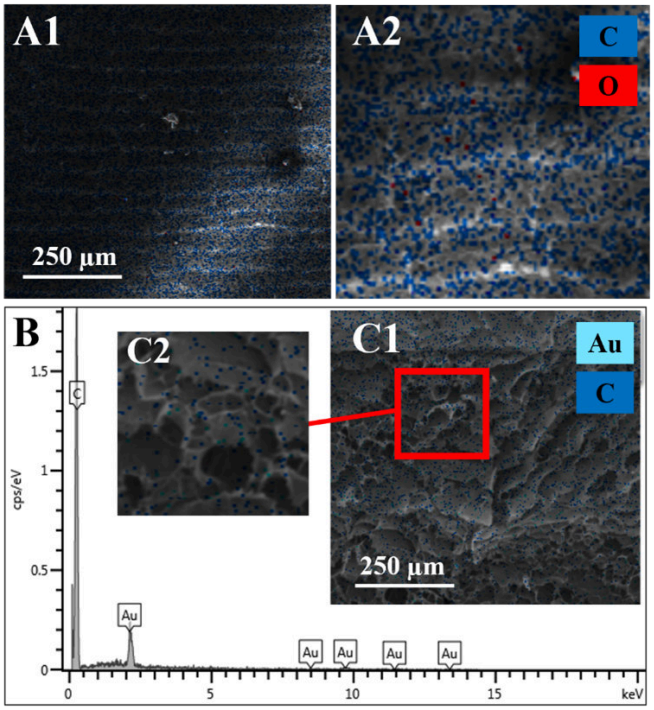

Fig. 3. EDS elemental mapping analysis of the electrode surface. (A1-A2) Non-functionalized surface with gold particles. (B) EDS spectrum showing the peaks of the chemical elements. (C1-C2) Surface functionalized with gold (Au) particles on the carbon (C) matrix

The topographic view of the Au-covered surface shows a homogeneous distribution of particles, with no evidence of severe agglomeration. This surface configuration enables the expansion of the electrode's surface area and optimizes charge transport and reaction kinetics at the electrode/modified-gel interface [37].

B. Fourier Transform Infrared (FTIR)

Overall, the spectra obtained in the infrared region predominantly reveal characteristics of the polyacrylamide polymer matrix (Figure 4). The broad band at 3350 cm¹, observed in all spectra (Figure 4A), can be attributed to the axial stretching vibrations of hydroxyl (O–H) bonds in water molecules, given that the material under evaluation is highly hydrated, but it can also be correlated with the presence of amide (N–H) groups within the hydrogel structure [38]

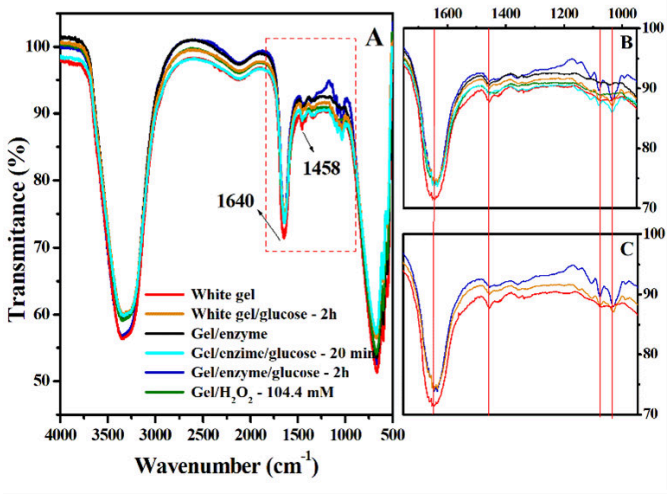

Fig. 4. EFTIR characterization of the biocomposite hydrogel before and after interaction with glucose and H2O2.

In the region between 3000 and 1800 cm¹, peaks of lower intensity are observed, which are attributed to the symmetric and asymmetric stretching of aliphatic groups, such as CH and CH [39]. At a wavenumber of approximately 1640 cm¹, a sharp, intense band stands out this is generally associated with the stretching of the carbonyl (C=O), bond characteristic of the primary amide band present in the hydrogel's polymer chains and may overlap with the angular deformation of interfacial water. The maintenance of these main bands across all curves confirms the structural stability of the biosensor's three-dimensional matrix under different exposure conditions [38], [40], [41]. To assess the permeability of the hydrogel, we evaluated different exposure conditions using a glucose solution (Figures 4B and 4C). Upon obtaining the spectra, we identified a modification in the spectral profile within the so-called "fingerprint" region, likely resulting from molecular interactions involving the enzyme glucose oxidase (GOx) and its catalytic activity in the presence of glucose. We observed no significant changes when comparing the spectra of the white hydrogel not exposed to the glucose solution with those of the same hydrogel after two hours in the glucose solution (Figure 4B, red and orange spectra, respectively); the same applies to the spectrum of the gel containing hydrogen peroxide. The persistence of the band at 1640 cm¹ (primary amide) and the shoulder at 1450 cm¹ (secondary amide)—attributed to C–N stretching combined with N–H bending suggest that in the absence of the enzyme glucose does not chemically alter the primary structure of the gel, instead only physical phenomena involving molecular diffusion within the porous channels may be occurring. Subtle yet significant modifications occur when the enzyme is anchored and active (gel/enzyme/glucose – after 2 hours in solution). A variation in band intensity is observed, as well as a slight shift in wavelength for the bands in the 1150–1000 cm¹ region. This behavior in the infrared region is

characterized by C–O and C–O–C stretching vibrations, which are intrinsic to the chemical structure of glucose, specifically the pyranose ring [42], [43].

C. Cyclic voltammetry

The obtained cyclic voltammograms exhibit an energy storage profile characteristic of a pseudocapacitive system. This behavior is commonly observed in systems comprising hydrogel matrices coupled with carbon-based electrodes operating over a wide potential window of -1.0 V to +1.0 V. The absence of well-defined peaks—also known as Faradaic peaks—suggests that charge transfer processes are occurring in conjunction with the electrical double-layer capacitance at the electrode/hydrogel interface.

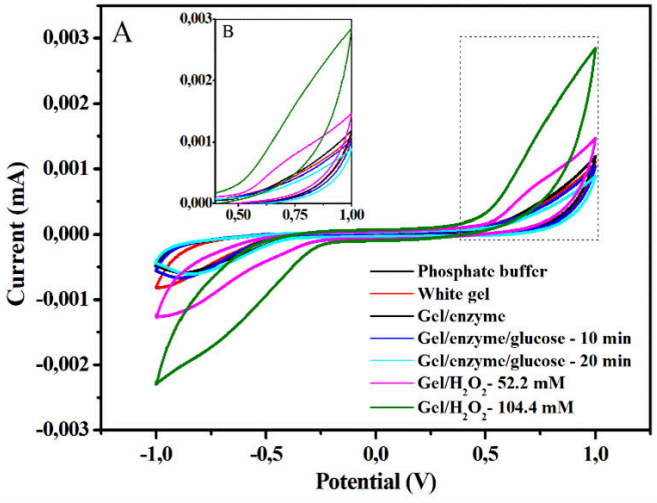

Fig. 5. Cyclic voltammograms of the hydrogels obtained under different experimental conditions. (A) Full voltammetric profile in the potential range of -1.0 V to 1.0 V. (B) Inset showing an enlargement of the anodic region of interest (0.4 V to 1.0 V).

This behavior is observed primarily in the voltammogram of the gel containing only the pure polymer matrix (Whaite gel). Upon the addition of the GOx enzyme to the polyacrylamide matrix, yielding the gel designated as GE, the capacitive profile is maintained, resulting only in a subtle modulation of the background current to -0.9 mA; this suggests that the process of entrapping the macromolecule within the polymer matrix does not block the substrate's electronic percolation pathways [44]. Despite the dominance of the pseudocapac-itive profile, localized deviations in curve symmetry reveal discrete redox events at the electrode interface. In the cathodic region, specifically within the -0.5 V to -1.0 V range, a cooperative reduction process manifests, shifting the limiting current at -1.0 V from -0.51 mA (for the WG) to -0.59 mA and -0.44 mA after 10 and 20 minutes of glucose exposure, respectively. This behavior may be directly linked to these processes. During the reverse scan (anodic phase), the current increase becomes significant above +0.5 V, reaching +1.0 mA at the +1.0 V limit for the glucose-exposed samples. The analytical capability of the electrode is confirmed when evaluating the gel containing the reaction end-product, hydrogen peroxide (H2O2). In the presence of 52.2 mM H2O2, a prominent reduction shoulder begins at -0.35 V and reaches -1.25 mA at -1.0 V, while the oxidation current at +1.0 V is amplified to +1.45 mA. Upon doubling the H2O2 concentration to 104.4 mM, the biosensor exhibits a catalytic response—likely controlled by the diffusion process—in which the cathodic current reaches -2.30 mA at -1.0 V and the anodic current shows a sharper increase starting at +0.5 V, peaking at +2.85 mA at the positive polarization limit.

D. Square Wave Voltammetry (SWV) Analysis

The use of Square Wave Voltammetry (Figure 6) enabled the individual assessment of reduction and oxidation events arising from the interaction between the graphene oxide electrode and the various modifications to the hydrogel's polymer matrix; prominent electrochemical peaks were observed in the cathodic region, highlighting charge transfer processes at the biosensor interface

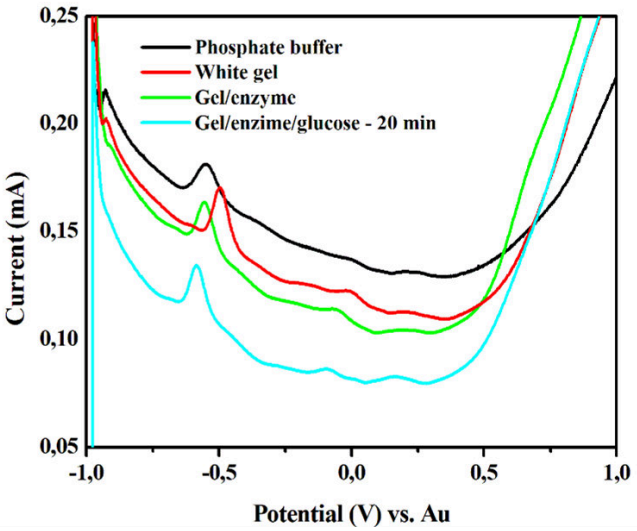

Fig. 6. Square-wave voltammetry (SWV) profiles evaluating the electrochemical behavior of the hydrogel in response to different modifications and interactions

When observing pure PBS, we note a reduction peak centered at approximately -0.55 V, which is associated with the electro-reduction of dissolved oxygen in the electrolytic medium on the carbon surface or with redox processes involving the oxygenated functional groups of the graphene oxide surface itself, corroborating the data obtained via cyclic voltammetry [45]. When the enzyme-free polyacrylamide hydrogel matrix is deposited onto the electrode, a subtle change in the profile occurs: the reduction peak shifts slightly toward lower (more negative) potentials, and the background current undergoes reorganization, demonstrating that the physical presence of the gel modifies mass transport by diffusion to the electrode surface while preserving the system's redox activity. With the incorporation of the GOx enzyme into the hydrogel, the reduction peak shifts back to the -0.55 V region; the change

in shape and the slight decrease in baseline current within the -0.3 V to +0.4 V window, confirmed by FTIR analysis, suggest the successful anchoring of the GOx macromolecule within the matrix, which likely resulted in the partial blocking of capacitive sites without deactivating the system's active redox center. The most important behavior demonstrating the biosensor's operation is its response in the presence of glucose. This curve exhibits a marked decrease in the magnitude of the current, shifting to lower current density levels. This phenomenon arises from a chemical mechanism in which the enzyme entrapped within the hydrogel locally consumes the oxygen available to oxidize the glucose, resulting in less oxygen available at the electrode interface for electrochemical reduction [46]–[48]. The distinct residual peak in the voltammetric curve between -1.0 and approximately -0.6 V serves as the monitored analytical signal, such that the variation in the peak's height or area, or the overall decrease in current relative to the blank hydrogel curve, is directly related to the presence of glucose and its oxidation activity at the biosensor [46].

IV. Conclusion

This study validated the development of a promising electrochemical biosensor obtained through the carbonization of polyamide to synthesize graphene. SEM and EDS analyses confirmed an exfoliated porous mesostructure and the efficient anchoring of gold particles, while infrared spectroscopy (FTIR) verified the chemical integrity of the hydrogel. From an electrochemical standpoint, cyclic voltammetry (CV) and square-wave voltammetry (SWV) demonstrated the system's bioactivity and sensitivity to glucose and H2O2, exhibiting well-defined response profiles. Although this is an experimental device requiring further testing for optimization and measurement standardization, the platform stands as a viable, low-cost alternative for next-generation sensors. The hydrogel/electrode system will undergo future studies for the identification and quantification of other biochemical analytes for calibration purposes.

***Abstract*—Tissue oxygenation monitoring is of great relevance in biomedical applications, particularly in neurological and neonatal contexts. Photoacoustic Imaging (PAI) combines optical excitation and ultrasonic detection to provide functional and morphological information non-invasively. This paper presents a bibliographic review on the integration of embedded systems, such as FPGAs, in the development of compact, efficient, and low-cost platforms for continuous oxygenation monitoring via PAI, with emphasis on neonatal applications.**

***Index Terms*—Photoacoustic Imaging; PAI; Photoacoustic Effect; Embedded Systems; FPGA; Oxygenation Monitoring; Biomedical Signal Processing; Ultrasonic Sensors.**

I. Introduction

Tissue oxygenation monitoring plays a fundamental role in biomedical applications, especially in neurological and neonatal contexts. This parameter reflects the amount of oxygen available in biological tissues, which is essential for proper cellular function and the maintenance of metabolic activity. Hemoglobin is central to this process, as it is responsible for oxygen transport in the bloodstream. Alterations in oxygenation levels may indicate severe clinical conditions, making continuous monitoring an important resource for diagnosis and medical follow-up [1].

Among the main clinical applications are the monitoring of stroke, hypoxia, and neonatal anoxia. In newborns, cerebral oxygenation monitoring is particularly critical due to the vulnerability of the developing nervous system and the risk of irreversible neurological damage [2].

However, many traditional monitoring methods present significant limitations. Systems commonly used in hospital environments tend to be costly, have low portability, and require complex infrastructure, making their use in continuous monitoring and out-of-hospital settings challenging. Furthermore, some equipment demands considerable computational power and robust hardware for biomedical signal processing, reducing accessibility in clinical contexts that require mobility and real-time response. In this regard, recent efforts have sought the development of more compact and accessible systems [3], [4].

In this context, Photoacoustic Imaging (PAI) emerges as a promising alternative: a non-invasive hybrid technique that combines optical excitation and ultrasonic detection to obtain functional and morphological biomedical images.

The basis of PAI-based oxygenation monitoring lies in the distinct optical absorption properties of oxygenated hemoglobin (HbO_2) and deoxygenated hemoglobin (Hb), enabling non-invasive estimation of oxygen saturation in tissues, as further described in Section III-A [5], [6].

PAI offers high spatial resolution and significant functional contrast, enabling the visualization of internal structures and the analysis of optical properties of biological tissues. The technique provides structural and functional information in real time without requiring invasive procedures, positioning itself as a promising tool for advanced biomedical applications [6].

The application of PAI to neonatal cerebral monitoring has shown promising results, particularly through the transfontanelle approach, which exploits the natural acoustic and optical transparency of the fontanelle to acquire transcranial data safely and non-invasively. Recent studies conducted in neonatal animal models have demonstrated the feasibility of the technique for monitoring cerebral oxygenation, suggesting possibilities for early diagnosis and continuous monitoring that remain to be validated in human newborns [2]. Furthermore, advances in skull optical clearing techniques have enabled greater light penetration depth in transcranial applications in rodent models, favoring the acquisition of more detailed neurovascular images [7].

In parallel, the advancement of embedded systems has enabled the development of compact and efficient platforms for real-time acquisition and processing of biomedical signals. In this context, Field-Programmable Gate Arrays (FPGAs) and microcontrollers stand out due to their parallel processing capability, low latency, and high energy efficiency, making them particularly suited for biomedical applications that require continuous monitoring and reduced equipment size and cost [4].

To illustrate the operating principle of a PAI acquisition system, Fig. 1 presents a schematic overview of the technique.

The remainder of this paper is organized as follows: Section II presents the review methodology; Section III presents the fundamentals of photoacoustic imaging and the relation-

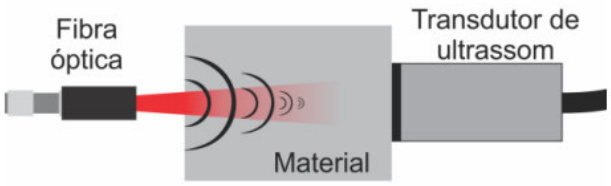

Fig. 1. Illustration of a photoacoustic imaging acquisition system. Source: [8].

ship between hemoglobin and oxygenation; Section IV describes embedded systems applied to PAI; Section V discusses the main applications in oxygenation monitoring; Section VI reviews and compares related works; Section VII identifies current challenges and limitations; Section VIII outlines future research directions; and Section IX presents the conclusion of this review.

II. Review Methodology

This study was conducted as a narrative literature review focused on the use of embedded systems in photoacoustic imaging (PAI), with particular emphasis on oxygenation monitoring and biomedical and neonatal applications. The literature search was conducted using IEEE Xplore, PubMed, Web of Science, and Google Scholar. The search was primarily focused on publications from 2020 onward, while selected earlier studies were included when considered fundamental to the understanding of PAI, photoacoustic oxygenation assessment, or embedded system architectures.

The search strategy was based on combinations of keywords related to the main themes of the review. The principal search strings included: '("photoacoustic imaging" OR photoacoustic) AND ("embedded systems" OR FPGA) AND (oxygenation OR "oxygen saturation")" and '("photoacoustic imaging" OR photoacoustic) AND (oxygenation OR "oxygen saturation") AND (neonatal OR newborn OR cerebral)". Additional combinations of related terms, including 'biomedical applications", 'photoacoustic imaging systems", 'embedded processing", and 'neonatal monitoring", were also considered according to the focus of each database search. The terms were adapted when necessary to account for differences in search syntax and indexing across IEEE Xplore, PubMed, Web of Science, and Google Scholar.

Publications in English and Portuguese were considered. Studies were included when they presented relevant contributions to at least one of the following topics: PAI systems and architectures, embedded or FPGA-based signal acquisition and processing, photoacoustic assessment of oxygenation, biomedical applications of PAI, or neonatal and cerebral monitoring. Classical studies published before 2020 were retained when they provided fundamental concepts or established technical principles relevant to the analysis.

Studies were excluded when they were not directly related to PAI, embedded systems, oxygenation monitoring, or the biomedical applications addressed in this review. Publications whose content did not provide sufficient relevance to the technological or clinical aspects investigated were also excluded from the comparative synthesis.

The final literature search was performed on July 12, 2026. The search across the four databases retrieved a total of 247 records (108 from IEEE Xplore, 60 from Google Scholar, 40 from Web of Science, and 39 from PubMed). Titles and abstracts of the retrieved records were manually screened for relevance to the scope of this review, and full texts were assessed against the inclusion and exclusion criteria described above. After this screening process, 16 studies were selected and retained for the comparative and analytical synthesis presented in this review. The selected studies were analyzed with respect to their imaging architecture, optical excitation source, embedded processing hardware, signal acquisition and reconstruction approaches, biomedical application, validation conditions, and reported limitations. As a narrative review, this study does not aim to provide an exhaustive systematic assessment of all publications in the field, but rather to identify representative technological approaches, current limitations, and research gaps relevant to the development of compact embedded PAI systems for oxygenation monitoring.

III. Fundamentals of Photoacoustic Imaging

Photoacoustic Imaging (PAI) is a hybrid technique that combines optical excitation and ultrasonic detection to obtain functional and morphological biomedical images non-invasively. This approach is based on the photoacoustic effect, in which pulsed light — typically from laser sources — is absorbed by biological tissues, causing a localized temperature increase and consequent thermoelastic expansion. This process generates ultrasonic waves that can be detected by appropriate transducers and subsequently processed to form images [5], [6].

Due to this physical mechanism, PAI enables the simultaneous acquisition of structural and functional tissue information, with particular emphasis on the optical properties of biological chromophores such as hemoglobin. This characteristic makes the technique especially promising for biomedical applications, particularly for monitoring tissue and cerebral oxygenation, since hemoglobin optical absorption is directly related to blood oxygenation levels [1], [5].

Moreover, PAI presents an advantageous combination of high spatial resolution and significant penetration depth in biological tissues. Different studies report values consistent with this potential: Mao et al. [2] demonstrated feasibility of transfontanelle cerebral oxygenation measurement in a neonatal piglet model, while Li et al. [7] reported transcranial neurovascular imaging in the rodent brain assisted by skull optical clearing. Taken together, these studies illustrate the range of depths and resolutions achievable with PAI depending on the specific system architecture and application, rather than a single fixed performance figure. Of particular note is its

use in neonatal contexts, such as transfontanelle evaluation of cerebral oxygenation, enabling non-invasive and continuous monitoring in newborn patients [2].

A. Relationship Between Hemoglobin and Oxygenation

The relationship between hemoglobin and oxygenation is one of the fundamental principles underpinning non-invasive measurement of oxygen saturation in biological tissues. Hemoglobin, the protein responsible for oxygen transport in the blood, exists primarily in two functional forms: oxygenated hemoglobin (HbO_2), when bound to oxygen, and deoxygenated hemoglobin (Hb), when oxygen is released to the tissues. These two forms exhibit distinct optical properties, particularly regarding their absorption spectra, which enables the differentiation and quantification of blood oxygenation through optical methods [5], [6].

The difference between HbO_2 and Hb is directly related to how each form absorbs light at different wavelengths. Oxygenated and deoxygenated hemoglobin present distinct absorption coefficients, generating measurable optical contrasts when exposed to light sources. By analyzing the interaction of light with biological tissues, it is therefore possible to estimate the ratio between HbO_2 and Hb, allowing inference of blood oxygenation levels [1], [6].

This physical principle underlies a range of biomedical technologies, including PAI, in which the absorption contrast between HbO_2 and Hb is converted into measurable acoustic signals. In PAI, the relative photoacoustic responses associated with HbO_2 and Hb can be used to assess local tissue oxygenation and, when appropriate, estimate tissue oxygen saturation (sO_2). This parameter should be distinguished from peripheral oxygen saturation (SpO_2), which is conventionally measured by pulse oximetry and reflects arterial blood oxygenation [2], [5].

The spectral difference between the two hemoglobin forms therefore enables continuous measurement of tissue oxygenation, establishing itself as a central principle in modern biomedical applications. This characteristic is especially relevant in cerebral and neonatal monitoring contexts, where small variations in oxygenation may indicate significant physiological changes and potential clinical risk [1], [2].

IV. Embedded Systems in Photoacoustic Imaging

Embedded systems have played a central role in the development of compact and efficient PAI platforms, enabling real-time acquisition and processing of biomedical signals with low power consumption. In general, an embedded photoacoustic system comprises four main functional blocks: (i) optical excitation source, responsible for generating light pulses; (ii) ultrasonic transducer, responsible for detecting the acoustic waves generated in the tissue; (iii) signal conditioning and acquisition circuit, which amplifies and digitizes the detected signals; and (iv) embedded processing unit, responsible for filtering, image reconstruction, and data analysis.

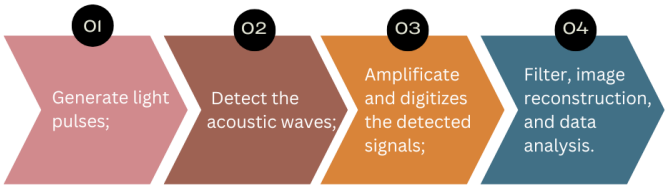

Fig. 2. Functional blocks of an embedded photoacoustic system. Source: elaborated by the authors.

The literature indicates that the choice of each component directly impacts overall system performance, entailing trade-offs between cost, portability, resolution, and processing speed. The following subsections present and compare the main works identified in the literature, followed by an analytical description of each functional block.

A. System Block Description

Based on the reviewed works, the main blocks composing an embedded photoacoustic system are described and analyzed as follows.

Optical excitation source: may be implemented using pulsed lasers or high-power LEDs. As discussed, lasers offer superior performance in depth, while LEDs provide lower cost and greater portability [9]. The choice should be guided by the intended clinical application.

Ultrasonic transducer: detects the acoustic waves generated by the photoacoustic effect and converts them into electrical signals. Transducer selection directly influences the system's spatial resolution and penetration depth [5], making it a critical component for final image quality.

Signal conditioning and acquisition circuit: amplifies, filters, and digitizes the electrical signals from the transducer. Precise synchronization between optical emission and the acquisition window is an essential requirement at this stage, as demonstrated by Alizadeh et al. [4], whose system showed that timing errors directly compromise the quality of reconstructed images.

Embedded processing unit (FPGA): executes filtering, image reconstruction, and system control tasks in parallel. The use of an FPGA significantly reduces latency compared to conventional CPU-based solutions, being essential for real-time operation [4], [10]. Integration with *compressed sensing* techniques represents a promising development toward reducing computational demand without sacrificing image quality.

Fig. 3 illustrates the general architecture of an embedded photoacoustic acquisition system.

B. FPGA versus Microcontrollers

It is observed that FPGA-based systems predominate in photoacoustic implementations requiring real-time processing, owing to their capacity for parallel execution of multiple tasks. Alizadeh et al. [4] demonstrated that a system combining an FPGA with high-power LEDs enables photoacoustic signal acquisition and processing with adequate precision for biomedical applications, with precise control of the timing

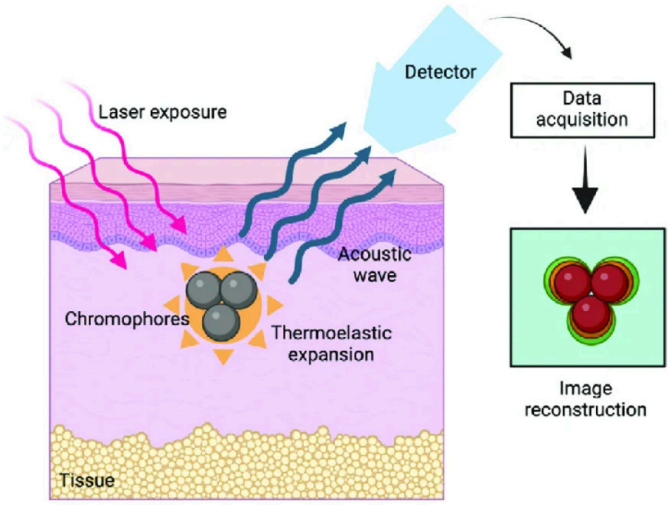

Fig. 3. Photoacoustic imaging system architecture. Source: [11].

between optical excitation and acoustic acquisition — a critical requirement for image quality. In contrast, although microcontrollers offer lower cost and simpler programmability, the literature indicates that their sequential processing architecture limits performance in applications requiring high-speed image reconstruction, making FPGAs the more appropriate choice for high-performance embedded PAI systems [4], [10].

Wang et al. [10] extended this line of work by investigating the use of *compressed sensing* in embedded photoacoustic systems, demonstrating that the number of samples required for image reconstruction can be significantly reduced without relevant quality loss. This approach is particularly relevant for resource-constrained embedded systems, as it alleviates the processing load on the FPGA and reduces energy consumption — a notable advancement over conventional full-sampling architectures.

Hossain et al. [3] developed a compact system for photoacoustic spectral response measurement (PASR), a pump-probe technique that extracts acoustic spectral signatures from biological tissues. Unlike the FPGA-based architecture of Alizadeh et al. [4], which prioritizes parallel processing and temporal precision, Hossain et al. employed a high-speed microcontroller as the embedded processing unit, combined with a 12-bit analog-to-digital converter (ADC) operating at 30 MSPS for real-time signal conditioning and data acquisition. The developed hardware includes a high-frequency preamplifier, a low-pass filter, an electrically isolated trigger circuit, and a high-speed ADC, enabling compact and low-cost implementation. The system was validated in the differentiation of lung and liver tissues, demonstrating the viability of microcontroller-based embedded solutions for biomedical applications outside laboratory settings. Its main limitation, however, lies in the absence of validation for real-time image reconstruction, as the system was designed for point spectral measurements rather than continuous imaging.

C. LED versus Laser as Excitation Source

The choice of optical excitation source is one of the primary factors determining the performance-cost trade-off in PAI systems. The literature indicates that pulsed lasers offer higher optical energy per pulse, resulting in greater penetration depth and better signal-to-noise ratio (SNR), and are therefore preferred in research applications requiring high image quality [5]. On the other hand, there is a growing trend toward replacing lasers with high-power LEDs, driven by significant cost reduction, improved operational safety, and lower implementation complexity [9].

Kuniyil Ajith Singh et al. [9] conducted a comprehensive review demonstrating that LEDs, when driven by appropriate pulsing circuits, are capable of generating detectable photoacoustic signals in biological tissues. The authors note, however, that the lower irradiance of LEDs compared to lasers still limits penetration depth and SNR in thicker tissues — representing the main disadvantage of this approach. It is therefore observed that LEDs are more suitable for superficial applications or anatomically favorable regions, such as transfontanelle neonatal evaluation, while lasers remain more appropriate for deeper imaging.

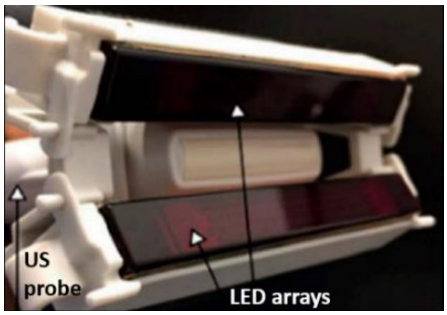

Fig. 4. LED array arrangement around the ultrasound (US) probe. Adapted from [12].

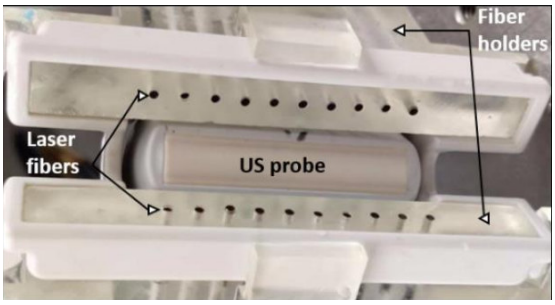

Fig. 5. Laser fiber arrangement around the ultrasound (US) probe. Adapted from [12].

V. Applications in Oxygenation Monitoring

PAI has been extensively investigated for biomedical applications including soft tissue imaging, vascular structure visualization, blood oxygenation monitoring, and functional brain studies. These applications demonstrate the technique's

potential as a non-invasive tool with high sensitivity to physiological variations and strong functional contrast, particularly in scenarios requiring continuous monitoring of biological parameters [5], [6].

In the context of neonatal cerebral monitoring, PAI holds particular clinical relevance. Conditions such as hypoxic-ischemic encephalopathy (HIE) are associated with high mortality and potential neurological sequelae in newborns, making early monitoring of cerebral tissue oxygen saturation (sO_2) essential [13], [14]. PAI stands out in this scenario by enabling continuous, non-invasive assessment of sO_2 — overcoming limitations of conventional methods such as electroencephalography (EEG), which provides electrical brain activity data but does not allow direct mapping of tissue oxygenation, and of peripheral pulse oximetry, which measures SpO_2 and reflects arterial blood oxygenation rather than local tissue status.

Neonatal applications have gained prominence, particularly through the transfontanelle approach, which exploits the natural acoustic and optical window of the newborn skull. Mao et al. [2] demonstrated in animal models that this approach enables safe and non-invasive acquisition of cerebral signals, allowing continuous monitoring of cerebral tissue oxygen saturation (sO_2) and early detection of neurological alterations.

PAI can also be applied to vascular monitoring, enabling real-time analysis of blood flow and local tissue oxygen saturation (sO_2) in peripheral tissues — a functional parameter distinct from the peripheral SpO_2 obtained by conventional pulse oximetry. This capability supports functional assessment of biological systems in clinical environments such as intensive care units (ICUs), where continuous patient monitoring is essential for rapid clinical decision-making [2], [5].

The development of portable PAI-based systems has driven the miniaturization of biomedical equipment. The literature indicates that compact architectures with low power consumption expand the potential for use in bedside monitoring and remote applications, particularly in regions with limited access to specialized hospital infrastructure [2], [6].

Complementarily, the integration of PAI with Artificial Intelligence has improved image reconstruction and the automated classification of physiological patterns, as discussed by Lan et al. [15], while the use of high-power LEDs as excitation sources provides a lower-cost alternative to conventional lasers, enhancing system portability [9].

VI. Related Work

A number of studies have investigated the integration of embedded systems and photoacoustic imaging techniques for biomedical monitoring. The following analysis highlights the contributions, advantages, limitations, and research gaps identified in the reviewed literature. Table I summarizes the technical parameters of the key reviewed works, illustrating the diversity of optical sources, embedded processing architectures, reconstruction methods, and clinical applications covered in this review.

Mao et al. [2] employed a transfontanelle PAI setup using two pulsed Nd:YAG lasers operating across a range of 690–950 nm, combined with a 128-element phased-array ultrasound probe. By exploiting the isobestic wavelength at 798 nm — at which HbO_2 and Hb absorb light equally — the system was able to quantify cerebral hemorrhage independently of tissue oxygen saturation (sO_2), which is particularly relevant in neonates where sO_2 levels fluctuate rapidly. The study experimentally validated the feasibility of the transfontanelle window as a non-invasive acoustic and optical access point for cerebral monitoring in a neonatal piglet model, used as a translational proxy for human newborns; validation in human neonates remains to be performed. Its main limitation remains the use of bulk laser sources, which hinder miniaturization and clinical portability.

Alizadeh et al. [4] proposed an embedded PAI platform featuring an 8-channel analog front-end, ADCs operating at up to 250 MSPS, and a Xilinx Spartan-7 FPGA responsible for real-time image reconstruction via a spatial phase algorithm. The LED excitation source is angularly scanned to acquire data from multiple directions, enabling synthetic aperture reconstruction. This architecture represents one of the most complete low-cost embedded PAI implementations in the reviewed literature, demonstrating that hardware-level integration of excitation control, signal acquisition, and image reconstruction is feasible within a single compact platform. The identified limitation remains penetration depth, constrained by LED irradiance.

Beard [5] presented a photoacoustic scanner based on a Fabry–Perot optical sensor, which scans the acoustic wavefront using a focused 64 μm interrogation beam. This approach eliminates the aperture and bandwidth limitations inherent to conventional piezoelectric transducer arrays, enabling wideband detection across a large sensing area. The system demonstrated 3D reconstruction of palmar vasculature at depths up to 4 mm and was subsequently applied to tumor imaging, murine brain, and embryos. Although the system achieves outstanding resolution and sensitivity, it relies on high-power pulsed lasers and complex optical alignment, limiting its suitability for compact embedded implementations.

Wang and Hu [6] provided a comparative framework covering five PAI architectures — optical-resolution photoacoustic microscopy (OR-PAM), acoustic-resolution photoacoustic microscopy (AR-PAM), linear and circular photoacoustic computed tomography (PACT), and photoacoustic endoscopy (PAE) — and their fundamental trade-offs between spatial resolution, penetration depth, and hardware complexity. This conceptual reference is directly applicable to the selection of embedded system architectures, as it clarifies which configurations are compatible with low-cost, miniaturized implementations and which require expensive or bulky hardware.

Li et al. [7] demonstrated transcranial PAI in neonatal piglets for the localization of photothrombotic stroke lesions, using spectroscopic imaging to map HbO_2 and Hb distributions. Lesions were validated post-mortem by TTC staining 24 h after stroke induction, confirming that ischemic regions

TABLE I
COMPARATIVE SUMMARY OF EMBEDDED PHOTOACOUSTIC IMAGING SYSTEMS REPORTED IN THE REVIEWED LITERATURE.

Parameter	Mao et al. [2]	Alizadeh et al. [4]	Hossain et al. [3]	Beard [5]	Li et al. [7]	Wang et al. [10]	Sari et al. [11]	Agrawal et al. [12]
Optical Source	Nd:YAG laser, 690–950 nm	High-power LED (wavelength n.s.)	Not specified (pump–probe PASR)	Pulsed laser (wavelength n.s.)	Not specified (spectroscopic PAI)	Laser, single-pixel encoding via optical mask	532 nm laser diode, 200 mW	LED array, 850 nm, 200 μJ/pulse, 70 ns, vs. conventional laser
Transducer / Detector	128-element phased-array US probe	8-channel analog front-end	–	Fabry–Pérot optical sensor (64 μm interrogation beam)	–	Single detector element	Condenser microphone	128-element linear US probe
Sampling Rate	–	Up to 250 MSPS	30 MSPS (12-bit ADC)	–	–	–	–	–
Embedded Processing	–	Xilinx Spartan-7 FPGA	High-speed microcontroller	Not embedded (benchtop optical system)	–	–	Not embedded (motorized XY stage)	–
Reconstruction Method	Spectroscopic quantification at isosbestic point (798 nm)	Spatial phase algorithm (synthetic aperture, angular LED scanning)	Point spectral measurement (PASR); not an imaging system	–	Spectroscopic imaging (HbO_2/Hb mapping)	Compressed sensing (single-pixel camera principle)	Point-by-point mechanical scanning	Not specified (comparative benchtop study)
Sample / Validation	Neonatal piglets, transfontanelle	–	Ex vivo lung and liver tissue	Palmar vasculature (human), tumor, murine brain, embryos	Neonatal piglets, transcranial, with optical skull clearing	–	Ex vivo dental tissue (enamel, dentin, cementum, pulp)	–
Depth / Resolution	Up to 5.2 cm	Limited by LED irradiance (value not reported)	–	Up to 4 mm (palmar vasculature)	Sub-100 μm spatial resolution	–	–	Not reported (SNR gap noted for deeper tissue)
Main Limitation	Bulky laser sources	Penetration depth restricted by LED irradiance	No validation for real-time image reconstruction	Requires high-power lasers, complex optical alignment	Clinical applicability of skull clearing needs safety studies	Increased reconstruction processing time	–	Remaining SNR gap for deeper tissue imaging

Note: "–" indicates that the parameter was not reported in the corresponding publication. Explicit terms such as "Not embedded" are used instead of "–" whenever the absence of a feature is a fact stated or clearly implied by the reviewed study, rather than a missing data point.

were clearly identifiable by their characteristic low HbO_2 and high Hb signatures. This work established an important proof of concept for PAI as a tool for real-time, contrast-free functional brain mapping, directly relevant to the neonatal monitoring context addressed in this review.

Agrawal et al. [12] performed a direct experimental comparison between a conventional laser source and LED arrays (850 nm, 200 μJ/pulse per array, 70 ns pulse width) mounted on both sides of a 128-element linear ultrasound probe. The identical probe geometry allowed a controlled substitution of the laser fiber by the LED array, enabling fair performance comparison under equivalent conditions. The study demonstrated that LED arrays operating at high repetition rates (1–4 kHz) provide a viable, lower-cost, and more compact alternative to pulsed lasers, while acknowledging the remaining gap in SNR for deeper tissue imaging.

Wang et al. [10] proposed the application of single-pixel camera principles to PAI: an optical mask spatially encodes the laser illumination pattern before tissue irradiation, and a single detector captures the resulting photoacoustic signal for each mask pattern. Image reconstruction is then performed via compressed sensing algorithms, significantly reducing the number of acquisitions and detector elements required. This approach is especially relevant for embedded systems, as it simplifies the acquisition hardware and reduces computational and data storage demands, at the cost of increased reconstruction processing time.

Sari et al. [11] demonstrated a low-cost photoacoustic microscopy system combining a 532 nm laser diode (200 mW), a condenser microphone as acoustic detector, and a motorized XY scanning stage for ex vivo characterization of dental tissue layers. The system successfully differentiated enamel, dentin, cementum, and pulp based on their distinct photoacoustic signal amplitudes — pulp generating the strongest response and enamel the weakest — and further distinguished carious from healthy teeth based on the enhanced thermoelastic expansion of deteriorated tissue. This work illustrates that low-cost embedded architectures can deliver meaningful diagnostic information even with minimal hardware complexity.

Overall, a common gap is noted across the reviewed works: the absence of systems that simultaneously integrate LED excitation, FPGA processing, real-time operation, and clinical neonatal validation within a single compact platform. This gap constitutes the primary motivation and potential contribution of the present work.

VII. CHALLENGES AND LIMITATIONS

Despite recent advances in photoacoustic imaging and embedded systems, significant technical and clinical challenges remain to be addressed before PAI can be widely deployed for continuous and neonatal monitoring applications.

One of the primary challenges concerns signal quality. Photoacoustic signals are frequently affected by environmental noise, electromagnetic interference, and patient movement. The signal-to-noise ratio (SNR) is a critical factor, particularly in low-cost LED-based systems — such as those proposed by Alizadeh et al. [4] and reviewed by Kuniyil Ajith Singh et al. [9] — which present lower optical energy compared to conventional lasers, resulting in reduced image contrast in thicker tissues.

Penetration depth also represents a relevant limitation, and reported values vary considerably depending on the specific system and tissue target rather than following a single benchmark. Mao et al. [2] evaluated transfontanelle acquisition in a neonatal piglet model, where the natural acoustic and optical window of the skull facilitates signal transmission, whereas Li et al. [7] addressed the more demanding scenario of transcranial imaging through an intact rodent skull, assisted by skull optical clearing to extend penetration. Imaging deeper structures — such as the human neonatal brain outside the fontanelle window — still imposes important technical constraints regardless of the specific approach. The skull optical clearing technique investigated by Li et al. [7] extends

achievable depth in transcranial settings, but its direct clinical applicability still requires additional safety and biocompatibility studies.

In the context of embedded systems, precise synchronization between optical emission and the acoustic acquisition window is an essential requirement, as demonstrated by Alizadeh et al. [4]. Small timing errors introduce distortions that compromise diagnostic accuracy. Furthermore, the miniaturization of platforms integrating acquisition, processing, storage, and communication in a single device requires careful consideration of thermal dissipation, power consumption, and operational reliability — aspects that most reviewed works do not fully address.

The computational cost of image reconstruction algorithms and AI-based analysis poses another challenge for embedded implementations [15]. Compressed sensing techniques, proposed by Wang et al. [10], reduce this demand but still lack validation in real clinical scenarios with low-cost embedded hardware — a gap directly identified in the related work review.

Finally, recent publications such as Park et al. [16] indicate that the clinical translation of PAI is advancing, with growing technological maturity and increasing industry interest. The literature suggests that future developments may converge toward integrated platforms combining LED excitation, FPGA-based embedded processing, and AI-assisted analysis. Such integration represents a promising research direction for the development of compact and potentially lower-cost systems for oxygenation monitoring, particularly in neonatal applications. However, the feasibility, clinical performance, portability, and cost-effectiveness of such a platform remain to be experimentally demonstrated and clinically validated.

VIII. Future Perspectives

The analysis of the reviewed literature indicates that photoacoustic imaging has strong potential to establish itself as a non-invasive biomedical monitoring tool, particularly for neonatal applications. A growing trend of convergence is observed across three development fronts: hardware miniaturization, embedded algorithm optimization, and clinical validation in specific patient populations.

On the hardware side, the gradual replacement of lasers by high-power LEDs, combined with FPGA-based real-time processing, suggests a possible pathway toward more compact and accessible systems [4], [9]; however, this outcome has so far been demonstrated only in isolated components rather than in a single integrated platform. The literature indicates that the main advances expected in this direction involve the development of higher-irradiance LED driver circuits and the integration of multiple acquisition channels on single-chip platforms, which could contribute to reduced size and power consumption if successfully implemented and validated.

Regarding transcranial imaging, advances in optical clearing techniques [7] and in the transfontanelle approach [2] open the possibility of neonatal cerebral monitoring with greater depth and resolution. It is noted, however, that the transition of these techniques to clinical environments depends on safety studies and validation in human clinical trials — representing one of the primary gaps to be addressed in the coming years.

The integration of PAI with Artificial Intelligence represents one of the most promising perspectives for enhancing diagnostic precision and automating the analysis of large volumes of physiological data in real time [15]. There is a growing trend toward the use of neural networks for photoacoustic image reconstruction from undersampled data, which — combined with compressed sensing techniques [10] — may enable high-performance embedded systems with low computational cost.

Finally, recent publications such as Park et al. [16] indicate that the clinical translation of PAI is advancing, with growing technological maturity and increasing industry interest. Taken together, the works reviewed in this paper suggest that an embedded platform combining LED excitation, FPGA-based processing, and AI-assisted analysis for continuous neonatal oxygenation monitoring is a technically plausible research direction. Whether such a platform would in practice achieve portability, low cost, and clinical readiness, however, remains to be experimentally demonstrated and validated; these are properties that the reviewed literature points toward as design goals, not outcomes already established for an integrated system.

IX. Conclusion

This narrative review examined the use of embedded systems, particularly FPGAs, in the development of photoacoustic imaging (PAI) platforms for tissue oxygenation monitoring, with emphasis on neonatal applications. The reviewed literature demonstrates, individually, that FPGA-based embedded processing can achieve real-time image reconstruction with low latency [4], [10], that high-power LEDs constitute a viable lower-cost and safer alternative to pulsed lasers for superficial and anatomically favorable regions [9], [12], and that the transfontanelle approach enables non-invasive acquisition of cerebral oxygenation signals in neonatal models [2].

However, no single work identified in this review integrates LED excitation, FPGA-based processing, and clinical neonatal validation within one compact platform. Consequently, portability, low cost, and clinical readiness should be understood as design goals and research directions suggested by the trends observed across the reviewed literature, rather than as properties already established for an integrated embedded PAI system. Achieving such an integration, and demonstrating its performance under real clinical conditions, remains an open challenge for future research, as discussed in Section VII and Section VIII.

Acknowledgment

The authors thank IFSP – Campus Sertãozinho for the institutional support and infrastructure provided for the development of this research. They also acknowledge the Pro-Rectory of Research of IFSP and the Brazilian National Council for Scientific and Technological Development (CNPq) for funding this work.

***Abstract*—This paper presents a preliminary prototype for the acquisition, processing, and real-time visualization of surface EMG signals from the zygomaticus major muscle, as an initial step toward future applications in consumer neuroscience. The system uses commercial surface electrodes and an ESP32 microcontroller; the acquired signal is conditioned through a high-pass filter, a power-line interference notch filter, rectification, and a moving-average envelope, and streamed in real time to a web-based interface via a WebSocket connection. The reliability of this real-time link was evaluated separately, in six recording sessions with one participant, showing 0% sample loss and an average effective sampling rate of 343 Hz. EMG detection was assessed with three participants under a standardized protocol comprising rest and smiling phases (habitual and maximal), repeated across three sessions per participant at different times of day. The system was able to distinguish muscle contraction from rest periods.**

I. Introdução

A Neurociência do Consumidor é um campo de estudo que visa compreender, de forma objetiva, as respostas neurofisiológicas humanas diante de estímulos de *marketing*, investigando os processos mentais conscientes e não conscientes envolvidos nas decisões de compra. Uma das principais problemáticas da área está relacionada à subjetividade dos métodos tradicionais, que se baseiam em questionários respondidos pelo próprio usuário, sujeitos a vieses interpretativos.

Em contrapartida, tem crescido o uso de métodos capazes de medir respostas implícitas a partir da captação de reações fisiológicas dos consumidores, como reconhecimento facial [1], *eyetracking* e eletromiografia (EMG) [3]. Dentre elas, o EMG tem sido empregado em diversos estudos para o reconhecimento de expressões faciais por apresentar sensibilidade na detecção de movimentos dos músculos faciais, sendo capaz de identificar ativações musculares sutis, de baixa intensidade, que não são perceptíveis visualmente [3].

Apesar dos avanços tecnológicos, estudos que utilizam o EMG facial como meio de detecção ainda apresentam desafios, como interferências externas e ruídos resultantes de movimentos indesejados ou dos eletrodos empregados, além de dificuldades relacionadas à amplificação e ao processamento do sinal eletromiográfico [6].

Diante desse contexto, este trabalho tem como objetivo desenvolver um protótipo de aquisição de EMG facial, como etapa inicial para futuras aplicações em neurociência do consumidor, permitindo o monitoramento da atividade do músculo zigomático maior e a visualização dos dados de maneira simples e intuitiva por meio de uma plataforma *web*.

II. Metodologia

A metodologia empregada neste trabalho foi dividida em quatro etapas principais: (A) estudo teórico sobre eletromiografia e *neuromarketing*; (B) desenvolvimento do protótipo de *hardware*; (C) implementação do *software*; e (D) captação e validação da comunicação;

A. Estudo teórico sobre eletromiografia e neuromarketing

A abordagem adotada baseou-se em um estudo prévio sobre a eletromiografia aplicada à Neurociência do Consumidor, com foco na análise dos tipos de eletrodos, seu posicionamento e das principais interferências que afetam a aquisição do sinal EMG. Foram averiguados alguns trabalhos que utilizam o EMG como ferramenta para detectar expressões faciais associadas à estímulos visuais, evidenciando sua aplicação em estudos de *neuromarketing*.

B. Desenvolvimento do protótipo de hardware

O desenvolvimento do protótipo concentrou-se na implementação do sistema de aquisição e condicionamento do sinal eletromiográfico. Os principais componentes utilizados foram:

- Módulo sensor eletromiográfico *Muscle Sensor v3 (Advancer Technologies)* [5] com eletrodos descartáveis de superfície Ag/AgCl para captação dos sinais EMG na face;
- Baterias de 9V para alimentação do sistema;
- Microcontrolador ESP32 para conversão analógico digital, processamento dos sinais e comunicação com a interface *web*;
- Circuito de proteção composto por um diodo Zener e um resistor de $47\,\Omega$ para limitar a tensão de saída do circuito aos níveis seguros de operação das entradas analógicas do microcontrolador, cuja faixa varia de 0V até 3,3V.

Para a captação do sinal eletromiográfico, foi utilizado o módulo de captação com dois eletrodos para captação bipolar no músculo zigomático e um eletrodo de referência na testa, capaz de detectar as variações de potencial elétrico geradas pela atividade muscular, cuja amplitude típica encontra-se na faixa de microvolts (μV) a 5 milivolts (mV).

A saída da placa de aquisição foi conectada a um circuito de proteção para o ESP32, composto por um resistor de $47\,\Omega$ em série com um diodo Zener modelo 1N4728.

Após a amplificação e limitação da tensão de saída, o sinal condicionado foi conectado ao pino analógico GPIO34 do microcontrolador ESP32 para conversão analógico-digital e processamento posterior.

A alimentação do sistema foi realizada por meio de 2 baterias de 9V, fornecendo tensão simétrica de ±9V. Foi escolhido o uso de baterias para minimizar interferências provenientes da rede elétrica e reduzir ruídos no sinal.

Inicialmente, a montagem foi realizada em protoboard para validação experimental do circuito. Após todos os testes, foi projetada uma placa de circuito impresso (PCI) no sotware EasyEDA, visando maior robustez, organização dos componentes e possibilidade de implementação definitiva do sistema.

C. Implementação do software

A arquitetura de *software* do sistema foi dividida em *frontend* e *backend*, responsáveis, respectivamente, pela interface gráfica de visualização e pelo controle da aquisição e transmissão dos sinais EMG. Desenvolvida no ambiente de desenvolvimento integrado Visual Studio Code, juntamente com a extensão PlatformIO [9] que permite o desenvolvimento de sistemas embarcados, suportando placas como o ESP32.

O *backend* do sistema foi implementado em C++ e executado em um microcontrolador ESP32, responsável pela aquisição do sinal EMG, pelo processamento do sinal e pela comunicação com o *frontend*. O ESP32 foi configurado para operar como um *Access Point Wi-Fi*, hospedando um servidor HTTP, utilizado para o controle de início e parada da aquisição, e um servidor *WebSocket*, utilizado para a transmissão dos dados EMG em tempo real.

A aquisição do sinal foi realizada por meio da leitura de um pino analógico, com frequência de amostragem nominal configurada em 1 kHz. O sinal bruto obtido passa por uma cadeia de processamento composta por: um filtro passa-alta (frequência de corte de aproximadamente 20 Hz), utilizado para atenuar deriva de linha de base e artefatos de movimento; um filtro *notch* centrado em 60 Hz, utilizado para atenuar a interferência da rede elétrica; retificação do sinal; e, por fim, um filtro digital do tipo média móvel, com janela de tamanho fixo de 10 amostras, responsável por suavizar o envelope resultante.

Os dados adquiridos (sinal bruto e sinal filtrado) são transmitidos ao *frontend* em tempo real por meio de uma conexão *WebSocket* persistente, evitando o custo de estabelecer uma nova conexão a cada amostra. O controle da aquisição continua sendo realizado por rotas HTTP específicas para iniciar e interromper a captura, garantindo sincronização entre o *frontend* e o *backend*. A confiabilidade dessa comunicação em tempo real foi avaliada separadamente (Subseção D e Resultados). Todo processamento pode também ser observado no fluxograma apresentado na Fig. 1.

A interface gráfica do usuário foi implementada como uma aplicação *web*, utilizando HTML, CSS e JavaScript, executadas em um navegador padrão, sem a necessidade de instalação de *software* adicional. O JavaScript foi responsável pela comunicação em tempo real com o ESP32 por meio da conexão *WebSocket*, pelo envio dos comandos de início e parada da aquisição por requisições HTTP, e pela atualização da interface em tempo real. O sinal EMG foi representado graficamente utilizando o elemento *canvas*, permitindo a visualização simultânea do sinal bruto e do sinal filtrado.

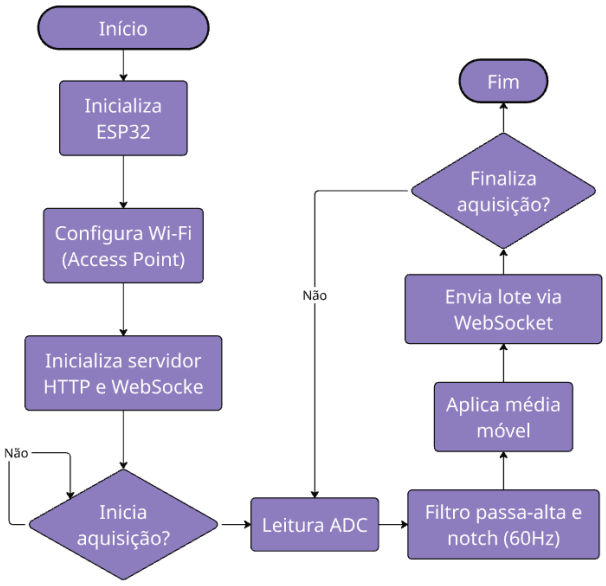

Figura 1. Fluxograma geral do processamento.

No *backend*, foram utilizadas bibliotecas nativas e de terceiros, incluindo:

- WiFi.h, para configuração do ESP32 como ponto de acesso;
- WebServer.h, para implementação do servidor HTTP embarcado;
- WebSockets (Links2004), para implementação do servidor *WebSocket* utilizado na transmissão dos dados em tempo real;
- LittleFS, para armazenamento e disponibilização dos arquivos da interface *web* no sistema de arquivos internos do ESP32.

A interface gráfica desenvolvida apresenta os principais elementos de interação com o sistema. Suas funcionalidades principais incluem:

- Tela de visualização em tempo real do sinal EMG;
- Exibição de métricas instantâneas, como amplitude do sinal, frequência de amostragem e tempo de aquisição;
- Controles para início e parada da captura dos dados;
- Registro e armazenamento das amostras em arquivos no formato CSV;
- Histórico de sessões com opção de *download* dos arquivos gerados.

O código-fonte do firmware e da interface *web* utilizados neste trabalho está disponível publicamente em: https://github.com/emyHorrana/EMG_FACIAL.

D. Captação e validação da comunicação

Os testes experimentais foram conduzidos com os próprios autores do trabalho, totalizando três participantes (duas mulheres e um homem). Por se tratar ainda de uma fase de testes preliminares do protótipo, conduzida apenas com integrantes da equipe de pesquisa, as coletas não passaram por aprovação de comitê de ética; todos os participantes forneceram consentimento informado para a realização dos testes.

As coletas foram realizadas em ambiente com temperatura controlada a 24 °C, em três períodos distintos do dia (manhã, tarde e noite), com cada participante realizando três sessões de aquisição, totalizando nove sessões. O eletrodo de referência foi posicionado na testa. Os eletrodos de sinal foram posicionados na face lateral do osso zigomático, próximo à sutura zigomaticotemporal, com inserção na pele e na fáscia do ângulo da boca (comissura labial), mantendo uma distância de 2 cm entre os eletrodos vermelho e verde, assim como mostra a figura. A Fig. 2 mostra o posicionamento dos eletrodos durante os testes.

Cada sessão seguiu um protocolo padronizado de quatro fases, com duração de 3 segundos cada, conduzidas mediante instruções:

1) *Repouso/neutro*: rosto relaxado, sem falar, cabeça e pescoço imóveis;
2) *Sorriso habitual*: solicitou-se ao participante que sorrisse levemente, buscando mexer o mínimo possível do rosto;
3) *Repouso*;
4) *Sorriso máximo*: solicitou-se ao participante que fizesse o sorriso mais forte possível, sem provocar dor.

Além dos testes de detecção do sinal EMG, foi avaliada a confiabilidade da comunicação em tempo real entre o ESP32 e a interface *web*. Para isso, um participante utilizou o sensor EMG posicionado na face, realizando contrações musculares, em seis sessões de captura. Cada amostra enviada recebe um número sequencial, o que permite identificar no *frontend* se alguma amostra se perdeu no caminho. Nessas sessões, foi medida a taxa de perda de amostras e a frequência real de transmissão, comparada à taxa nominal de 1 kHz configurada no *firmware*.

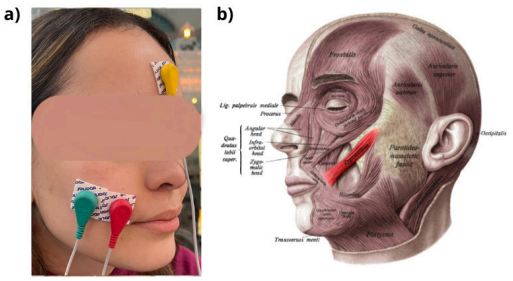

Figura 2. Posicionamento dos eletrodos faciais. a) durante os testes b) anatomia facial destacando o músculo zigomático.

III. Resultados

O estudo teórico sobre eletromiografia mostrou que eletrodos de superfície Ag/AgCl são os mais usados por serem simples de aplicar, não invasivos e produzirem sinal de boa qualidade [6]–[9]. Eletrodos intramusculares, inseridos com agulha, sofrem menos com ruído, mas incomodam mais o usuário, o que os torna menos indicados para estudos com consumidores [8]. Usar muitos eletrodos, como nos esquemas de Fridlund (22 eletrodos) e Kuramoto (8 eletrodos), pode melhorar a qualidade do sinal, mas aumenta o desconforto e a chance de ruído por movimento, impedância da pele e interferência eletromagnética [6]–[8]. Por isso, a literatura destaca a importância de filtrar, amplificar e posicionar bem os eletrodos para reduzir esses problemas [6]–[8]. Hamedi et al. [13] mostraram que é possível classificar gestos faciais por EMG com até 100% de acerto em conjuntos pequenos, o que reforça o potencial da técnica.

O protótipo (Fig. 3) usa um módulo de aquisição EMG, um diodo Zener e um resistor para proteger a entrada do ESP32, além de baterias para alimentar o circuito. O circuito limita a tensão de entrada à faixa de operação do ADC (0 a 3,3V), que só lê valores positivos – por isso, apenas a parte positiva do sinal EMG é captada.

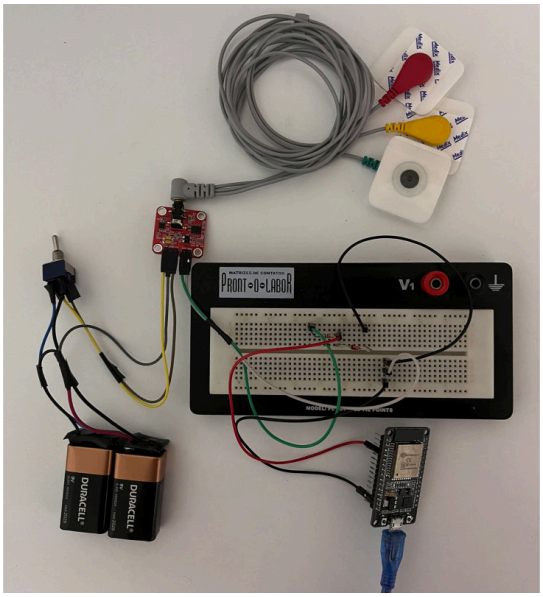

Figura 3. Protótipo físico do sistema.

A Fig. 4 mostra o sinal EMG de quatro sessões de captação, comparando dois participantes (B e C) em dois períodos do dia (manhã e noite), com o sinal bruto em azul e o filtrado em laranja. Os picos indicam contração muscular; os trechos baixos indicam repouso. A Tabela I resume o pico de todas as nove sessões realizadas.

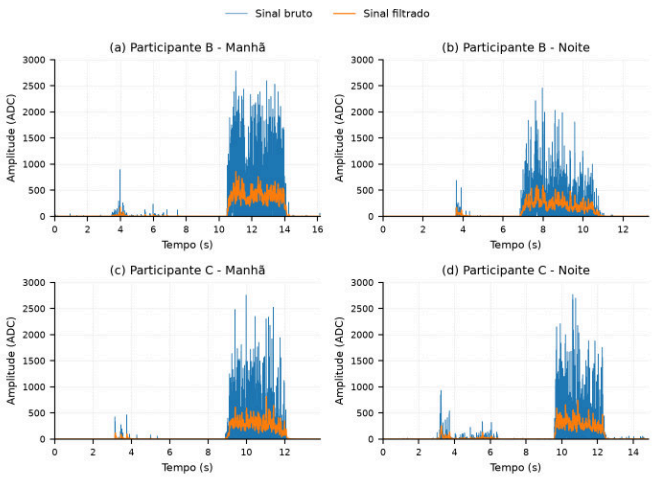

Figura 4. Sinal EMG bruto e filtrado em quatro sessões: participantes B e C, nos períodos da manhã e da noite.

As durações da Tabela I ficaram acima dos 3 segundos previstos no protocolo para cada expressão. O protocolo foi explicado ao participante antes do início da sessão, mas durante a captação não havia nenhum comando externo: cada um contava mentalmente o tempo e alternava a expressão por conta própria, o que naturalmente gera variação em relação ao tempo previsto. Além da duração, os dados também mostram variação entre participantes e entre períodos do dia: o participante B teve picos altos e estáveis (593 a 857), enquanto

Tabela I
RESUMO DAS NOVE SESSÕES DE CAPTAÇÃO. "FAIXA" INDICA O PERCENTUAL DA FAIXA DINÂMICA DO ADC (0–4095) OCUPADO PELO PICO DO SINAL BRUTO.

Sessão	Duração (s)	Pico filt.	Pico bruto	Faixa (%)
A – Manhã	11,89	738	2256	55,1
A – Tarde	14,00	331	1337	32,6
A – Noite	12,06	601	1878	45,9
B – Manhã	16,17	857	2783	68,0
B – Tarde	11,17	824	2846	69,5
B – Noite	13,28	593	2457	60,0
C – Manhã	13,86	811	2757	67,3
C – Tarde	13,25	744	2647	64,6
C – Noite	14,86	747	2768	67,6
Média	13,40	694,0	2414,3	58,9

o participante A teve queda forte à tarde (331) frente à manhã (738) e à noite (601). A manhã, no geral, teve os picos mais altos e mais parecidos entre si (738 a 857); a tarde teve a maior variação (331 a 824). Essa diferença parece estar ligada ao contato do eletrodo em cada sessão ou ao horário em si. O único homem da amostra (B), teve pico médio de 758,0 nas suas três sessões, contra 662,0 das participantes A e C (mulheres); com apenas um homem na amostra, essa diferença não pode ser tratada como uma diferença real de sexo.

O sinal foi lido pelo ADC de 12 bits do ESP32 (0 a 4095), convertido em tensão por [11]:

$$V_{\text{real}} = \frac{\text{ADC obtido}}{4095} \times 3,3 \text{ V}$$

O sinal é sempre positivo, pois o circuito só mede a magnitude da ativação. Nas nove sessões, o pico do sinal bruto variou entre 1337 e 2846 (média 2414,3), entre $1,08$ V e $2,29$ V na entrada do ADC – cerca de 59% da faixa disponível em média, com margem para não saturar. Em repouso, o sinal ficou praticamente em zero. A análise foi feita na escala do sistema ADC.

Antes da adoção do WebSocket, o sistema baseado em requisições HTTP periódicas apresentou latência round-trip média de 5,94 ms (n = 285 requisições), porém com perda de 86,5% das amostras (1820 de 2105) devido ao efeito de *aliasing* do *polling*. Após a migração para comunicação via WebSocket, a perda de amostras caiu para 0% nas seis sessões testadas, com frequência efetiva de amostragem entre 329 Hz e 348 Hz (média de 343 Hz). Como a comunicação via WebSocket ocorre por meio de um fluxo contínuo de dados, sem ciclos individuais de requisição-resposta, a métrica de latência round-trip não se aplica da mesma forma a esse novo modelo. Por isso, a perda de amostras e a frequência efetiva de amostragem passaram a ser os principais indicadores de desempenho em tempo real considerados neste trabalho.

A Fig. 5 mostra a interface web para acompanhar o sinal EMG em tempo real, com opções para iniciar/parar a captura, baixar os dados e limpar a visualização.

Figura 5. Interface web desenvolvida para aquisição e visualização em tempo real dos sinais de EMG facial, permitindo monitoramento da atividade muscular e controle da captura de dados.

IV. Discussão

A Fig. 4 e a Tabela I confirmam que o ADC do ESP32 tem resolução suficiente para separar os momentos de contração muscular dos momentos de repouso. A amplitude variou bastante de uma sessão para outra, o que já era esperado e reforça que calibrar esse ganho deveria ser um dos primeiros passos em uma próxima versão do sistema. Os filtros passa-alta, notch e média móvel, descritos anteriormente, conseguiram limpar o ruído de alta frequência e a interferência de 60 Hz sem apagar as contrações musculares do sinal.

Em relação ao *hardware*, os testes em protoboard cumpriram o papel de validar o circuito de aquisição, mas protoboard é mais suscetível a ruído e a mau contato do que uma placa soldada. Fabricar uma PCI dedicada é, portanto, o próximo passo natural antes de qualquer uso fora de um ambiente controlado.

Na primeira versão, baseada em requisições HTTP periódicas, o sistema chegou a perder 86,5% das amostras em um teste preliminar (Seção V) efeito clássico de *aliasing* de *polling*, em que o navegador simplesmente não consegue pedir dados na mesma velocidade em que o ESP32 os gera. Isso também atrapalhava o desenho do gráfico, já que as amostras nem sempre chegavam na ordem em que foram geradas. A solução foi trocar o HTTP por WebSocket e numerar cada amostra com um número de sequência gerado no próprio ESP32. Essa abordagem permitiu resolver simultaneamente dois problemas: a identificação de perdas de amostras durante a transmissão e a reconstrução correta dos dados na aplicação receptora. Dessa forma, mesmo na presença de atrasos ou variações na rede, tornou-se possível detectar falhas de transmissão e reorganizar as amostras de acordo com sua ordem original de aquisição.

É esperado que haja variabilidade entre indivíduos e entre períodos do dia na amplitude do sinal EMG, o que aparece nos picos da Tabela I. Fatores como a fadiga muscular ao longo do dia podem influenciar essa variação. Ainda assim, com apenas três participantes, esses dados não são suficientes para confirmar um padrão. Seria necessário ampliar o número de pessoas para validar se essa variabilidade se mantém ou segue alguma tendência mais clara relacionada ao horário.

Por fim, vale registrar as limitações deste trabalho. O sistema usa um único canal de EMG no músculo zigomático maior, suficiente para detectar contração muscular, mas não para inferir estados emocionais complexos, isso exigiria vários músculos monitorados ao mesmo tempo. Os testes também foram feitos pelos próprios autores, sem participantes externos, portanto não servem como validação clínica ou comercial, apenas para estudos preliminares. E os filtros aplicados, apesar de terem funcionado bem neste teste, não foram caracterizados formalmente em bancada, não sabe-se, por exemplo, como se comportariam diante de um artefato de movimento mais forte ou de uma rede elétrica mais ruidosa do que a usada nesse trabalho.

V. Conclusão

Este trabalho apresentou o estudo e desenvolvimento preliminar de um protótipo de baixo custo para aquisição de sinais de eletromiografia facial do músculo zigomático maior, usando eletrodos de superfície e uma interface *web* para processamento e visualização em tempo real. Os testes foram conduzidos pelos próprios autores, em nove sessões (três participantes, três períodos do dia), seguindo um protocolo de repouso, sorriso habitual, repouso e sorriso máximo.

Os resultados mostram que o sistema distingue com clareza os períodos de contração muscular e de repouso, mas a ativação isolada do zigomático maior não permite inferir o estado emocional do participante. Nesse estágio, o protótipo deve ser entendido como um sistema de monitoramento de ativação muscular de canal único, e não como um instrumento de mensuração de estados afetivos.

Do lado técnico, a arquitetura baseada no ESP32 e na interface *web* se mostrou viável para aquisição, filtragem e visualização do sinal em tempo real, incluindo o *biofeedback* visual e o download dos dados capturados durante os testes. A migração da comunicação de HTTP para WebSocket eliminou a perda de amostras observada na primeira versão do sistema, e a combinação dos filtros passa-alta, notch e média móvel se mostrou adequada ao sinal captado nos testes realizados.

Como próximos passos, destacam-se a calibração do ganho do estágio analógico, a fabricação de uma placa de circuito impresso e a validação com uma amostra maior e independente dos autores, incluindo comparação com um sistema EMG de referência, sensibilidade a ruído e variações de posicionamento dos eletrodos, além da influência de diferentes condições experimentais e características individuais sobre o sinal registrado. A integração com técnicas complementares, como visão computacional e outros indicadores fisiológicos, também pode contribuir para uma análise mais ampla das respostas dos participantes, desde que acompanhada de protocolos experimentais adequados e validação metodológica, inclusive em aplicações futuras de neurociência do consumidor.

Agradecimentos

Os autores agradecem à FINATEL – Fundação Instituto Nacional de Telecomunicações pelo apoio institucional e infraestrutura disponibilizada, assim como ao Laboratório *eHealth Innovation Center* pelo suporte técnico e ambiente de pesquisa que possibilitaram a realização deste trabalho.

Estendem seus agradecimetos ao Núcleo de Estudos em Neurociência do Consumidor (NENC) pelo incentivo à pesquisa e pelas contribuições científicas que auxiliaram no desenvolvimento do projeto.

***Abstract*—Electrical Impedance Tomography (EIT) is a non-invasive imaging technique based on the estimation of the electrical impedance distribution of a medium from low-amplitude alternating current excitation. However, conventional EIT systems require high-speed signal digitization and extensive digital processing to extract amplitude and phase information, increasing computational complexity, especially in multifrequency applications. This work presents an analog architecture for amplitude and phase acquisition applied to EIT, aiming to reduce the processing burden associated with digital demodulation. Amplitude acquisition was implemented using a precision rectifier based on a super-diode configuration, while phase measurement was performed using zero-crossing detectors and an XOR logic gate. The circuits were evaluated exclusively through LTspice simulations considering frequencies from 1 kHz to 1 MHz and signal amplitudes ranging from 10 mV to 5 V. The amplitude detector achieved residual errors below 1% after calibration for most operating conditions up to 250 kHz and below 3% at 500 kHz. The phase detection circuit provided accurate measurements with errors typically below 1 degree for frequencies up to 125 kHz; however, it exhibited significant phase errors and complete operation failures at 500 kHz and above for low-amplitude signals (10 mV). The simulation results indicate that the proposed architecture is a promising analog front-end capable of reducing digital data processing requirements, though future hardware validation is required to confirm EIT-compatible measurement accuracy under physical conditions.**

***Index Terms*—Analog demodulation, precision rectifier, super diode, comparator circuits, zero-crossing detection, electrical impedance tomography.**

I. Introduction

Electrical Impedance Tomography (EIT) is a non-invasive imaging technique that estimates the electrical impedance distribution of a domain by applying low-amplitude alternating currents and measuring the resulting electrical potentials on the surface of the analyzed medium [1], [2]. Due to the absence of ionizing radiation, low cost, and real-time imaging capability, EIT has found applications in areas such as pulmonary monitoring, brain imaging, and tumor detection [2], [3].

In EIT, an alternating current is injected into the medium through electrodes positioned on its surface. The resulting electrical potentials are measured and used to calculate the electrical impedance of the medium according to (1), which depends on the amplitude and phase information of the measured electrical signals [4], [5].

$$Z = \frac{|V|e^{j\theta_V}}{|I|e^{j\theta_I}} = \frac{|V|}{|I|}e^{j(\theta_V - \theta_I)} \tag{1}$$

where $|V|$ represents the measured voltage amplitude, $|I|$ represents the amplitude of the applied current, θ_V represents the phase of the measured voltage, and θ_I represents the phase of the applied current.

Since impedance is obtained from the amplitude and phase of voltage and current signals, errors in these quantities directly affect tomographic reconstruction [6]–[8]. Therefore, data acquisition systems for EIT must exhibit low measurement error to minimize the influence of instrumentation on impedance estimation and on the quality of the reconstructed images [1], [9].

Most EIT systems determine amplitude and phase by digitizing the acquired signals and estimating these quantities through digital signal processing techniques, including quadrature demodulation and digital lock-in amplification [6], [10]. Although these approaches provide high accuracy and flexibility, they require high-speed analog-to-digital converters and considerable computational resources, especially in multichannel and multifrequency systems.

This work was supported by the Coordination for the Improvement of Higher Education Personnel – Brazil (CAPES) – Finance Code 001.

One strategy to reduce this computational burden is the use of analog demodulation techniques, allowing amplitude and phase information to be extracted before analog-to-digital conversion. In this approach, the system operates with continuous (DC) levels, significantly reducing the amount of processed data and enabling systems with a larger number of acquisition channels and operation at higher frequencies.

Increasing the number of channels enables the use of a larger number of electrodes and, consequently, the acquisition of a greater set of independent measurements, which is directly related to improvements in spatial resolution and reconstructed image quality [11]. Similarly, operation at higher frequencies allows the exploration of tissue dielectric properties through Multifrequency Electrical Impedance Tomography (mfEIT), providing additional information regarding tissue composition and physiological characteristics [12]. Nevertheless, measurements in the megahertz frequency range remain challenging due to the requirements imposed on acquisition and signal-processing circuits [13].

Several acquisition architectures have been proposed to address these challenges. Wu *et al.* reviewed recent EIT instrumentation and showed that digital acquisition combined with synchronous demodulation remains the dominant approach, while emphasizing the growing interest in integrated analog front-ends capable of reducing data throughput and processing complexity. However, the authors also highlighted that trade-offs between bandwidth, accuracy, power consumption, and hardware complexity remain major challenges, particularly for multichannel and multifrequency EIT systems [20]. Likewise, Rezaee-Dehsorkh *et al.* proposed a low-power bioimpedance measurement system employing I/Q demodulation integrated with the analog-to-digital converter to reduce power and silicon area. Although effective, the proposed architecture targets integrated low-power bioimpedance sensing operating at 1 kHz rather than wideband EIT applications [21]. More recently, Nwokoye and Triantis analyzed synchronous demodulation architectures and proposed a digital phase-error correction technique to improve measurement accuracy. Their work demonstrates that synchronous detection remains the preferred architecture for precise bioimpedance measurements but also highlights that phase errors become increasingly significant at higher operating frequencies [9]. These studies indicate that there is still a need for analog acquisition architectures capable of providing accurate amplitude and phase estimation over a broad frequency range while reducing digital processing requirements and maintaining a relatively simple hardware implementation.

In this context, this work presents an analog circuit for amplitude and phase acquisition applied to Electrical Impedance Tomography. The proposed solution performs signal demodulation in the analog domain using precision rectification and zero-crossing detection, providing amplitude and phase information prior to analog-to-digital conversion. The circuit was designed to estimate amplitude and phase for signals from 1 kHz to 1 MHz and was evaluated in terms of amplitude and phase estimation accuracy, which are key parameters for impedance determination and image reconstruction quality. Unlike digital quadrature demodulation, which requires high-speed ADC sampling and continuous digital multiplication and filtering for every acquisition cycle, the proposed analog front-end extracts amplitude and phase as quasi-static DC levels, allowing these values to be digitized with low-speed, low-resolution ADCs and reducing the computational load per channel. Practical implementation also requires careful physical layout to minimize parasitic capacitances and noise coupling, which will be addressed in future experimental validation.

II. Materials and Methods

Amplitude acquisition was performed using a precision rectifier based on the super diode configuration, while phase measurement was implemented using zero-crossing detectors and an XOR logic gate. Both approaches are described in the following subsections.

The proposed circuits were designed and evaluated through simulations performed in LTspice. In both approaches, the AD826 operational amplifier was used and powered by supplied with ± 9 V rails, selected due to their high slew rate, wide bandwidth, and ability to operate with low-amplitude signals [16]. The circuits were simulated without an external load connected to the output terminals, corresponding to an open-circuit condition. The voltage was measured directly at the OUT pin of the XOR gate and at the rectifier output, allowing the intrinsic performance of the proposed architecture to be evaluated prior to considering specific Analog-to-Digital Converter input impedances. Low-amplitude signals were intentionally investigated because voltage measurements in EIT systems often occur in the millivolt range.

To quantitatively assess the measurement accuracy, the differences between the reference and measured values were evaluated using the absolute error (AE) and the relative error (RE), calculated according to (2) and (3):

$$AE = |V_{meas} - V_{ref}| \tag{2}$$

$$RE(\%) = \frac{|V_{meas} - V_{ref}|}{V_{ref}} \times 100 \tag{3}$$

where V_{meas} is the measured value and V_{ref} is the reference value.

A. Analog Amplitude Acquisition

Amplitude acquisition was implemented using a precision rectifier, commonly referred to as a super diode. In this topology, the diode is placed inside the feedback loop of an operational amplifier, as shown in Fig. 1. This configuration allows the operational amplifier to compensate for the diode forward voltage drop, enabling the rectification of low-amplitude signals that would not be properly detected by a conventional diode-based rectifier [14].

The output of the circuit corresponds to a DC voltage level proportional to the peak amplitude of the input signal, since

the holding capacitor charges to the peak of each rectified half-cycle and discharges through the resistor between peaks, with the resulting ripple attenuated by the RC low-pass behavior described below.

Fig. 1 presents both the conventional peak detector and the proposed precision rectifier configuration used to eliminate the error introduced by the diode forward voltage [15]. The conventional circuit consists of a diode responsible for rectification, a capacitor used to store the peak value, and a resistor that provides a controlled discharge path for the capacitor. This configuration performs half-wave rectification and has been widely adopted in signal-conditioning applications [14].

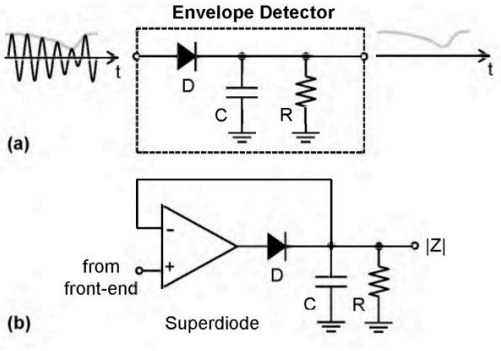

Fig. 1. (a) Conventional amplitude detector and (b) precision rectifier implementation used to eliminate the diode forward voltage drop.

In this work, signal rectification was performed using a BAT54 Schottky diode, chosen for its low forward voltage drop and fast switching characteristics, making it suitable for operation over the frequency range investigated in this work [17]. A 10 kΩ resistor was used as the discharge resistor.

The holding capacitor was dynamically adjusted according to the input frequency. As described by Li and Ferrari [15], the resistor-capacitor network behaves as a low-pass filter, and therefore its cutoff frequency directly affects the ripple and response time of the detected signal. In this work, the capacitor value was calculated such that the cutoff frequency was equal to the input frequency divided by 200. This criterion provided the best trade-off between ripple reduction and response time during simulation.

The capacitor value was calculated according to:

$$C = \frac{1}{2\pi R f_c} \tag{4}$$

where R is the discharge resistor and f_c is the desired cutoff frequency.

For the calculation of the DC output voltage, the average output voltage over the 30th to 40th periods of the waveform was used, excluding the initial cycles to minimize transient effects. The transient simulation step was set to 1 μs.

Fig. 2 presents the complete circuit implemented and simulated in LTspice.

Furthermore, to assess robustness against component tolerances, a Monte Carlo analysis (100 runs, 10% capacitor and

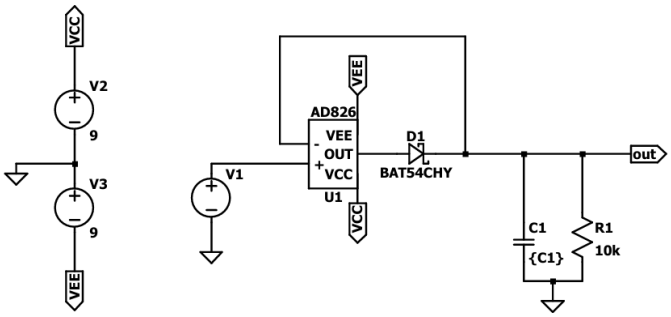

Fig. 2. LTspice schematic of the precision rectifier circuit.

1% resistor tolerance) and a corner (worst-case) analysis were performed.

B. Analog Phase Acquisition

Phase acquisition was performed using zero-crossing detectors combined with an XOR logic gate. Zero-crossing detectors are circuits capable of identifying the instant at which an alternating signal crosses a reference voltage, typically 0 V, causing the output state of the comparator to change at each crossing event [18].

In practice, an operational amplifier configured as a comparator produces a high output level when the input voltage is positive and a low output level when the input voltage is negative [18]. As a result, a square wave synchronized with the zero crossings of the original signal is obtained, as illustrated in Fig. 3.

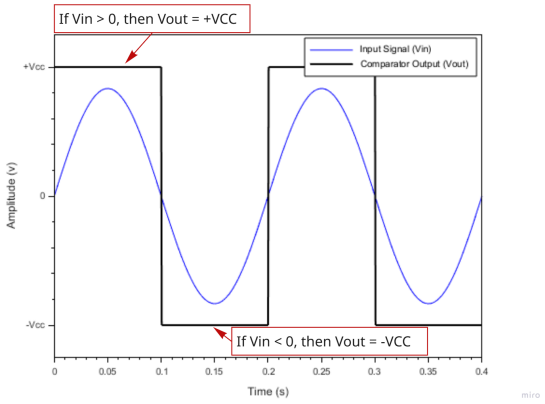

Fig. 3. Behavior of a comparator circuit implemented using an operational amplifier.

In this work, zero-crossing detectors were used to generate square waves synchronized with the sinusoidal signals under analysis. Phase information was then obtained from the time difference between the resulting square waves. To facilitate phase measurement, an XOR logic gate was added to the circuit. Since the XOR output remains at a high logic level whenever its inputs are different, the resulting output is a pulse-width modulated (PWM) signal whose duty cycle is

proportional to the phase difference between the analyzed signals [14], as shown in Fig. 4.

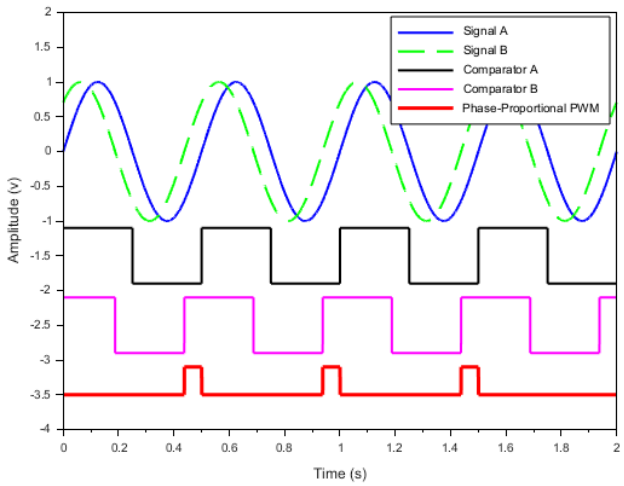

Fig. 4. Operation of the phase detection circuit based on zero-crossing detectors and an XOR gate.

For phase determination, the average output voltage over the interval from the 90th to the 100th period, with transient simulation step set to 1 μs, of the waveform was calculated (V_{avg}). The resulting value was subsequently converted to phase using a proportional relationship, in which the maximum output voltage (V_{max}) corresponds to $180°$. Accordingly, the phase was determined as:

$$\phi = \frac{V_{\text{avg}} \times 180°}{V_{\text{max}}} \tag{5}$$

In EIT applications, the phase shift introduced by biological tissues under low-amplitude alternating excitation is typically limited to a few degrees, remaining far from the 180° range in which the XOR-based detection method becomes ambiguous; therefore, this limitation is not expected to affect the intended clinical application of the proposed circuit.

The block diagram of the proposed phase measurement circuit is presented in Fig. 5.

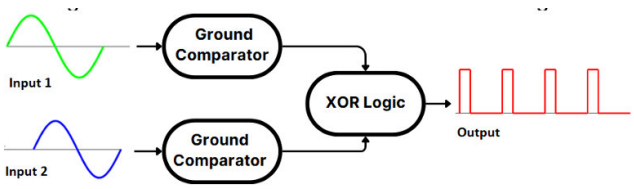

Fig. 5. Block diagram of the phase measurement circuit.

Fig. 6 presents the complete architecture of the phase measurement circuit. The performance of the zero-crossing detectors was evaluated using the AD826 operational amplifier.

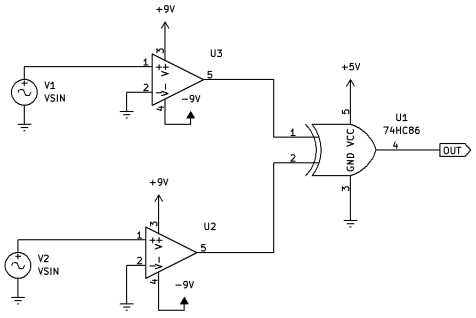

Fig. 6. General schematic of the phase measurement circuit.

III. Results and Discussion

A. Precision Rectifier Results

The precision rectifier circuit was evaluated through simulations considering different excitation amplitudes and frequencies. Table I presents the results obtained for the simulated sinusoidal signals. The gain values presented in the table were calculated according to:

$$Gain = \frac{V_{meas}}{V_{ref}} \tag{6}$$

where V_{meas} is the measured value and V_{ref} is the reference value.

TABLE I
SIMULATION RESULTS FOR DIFFERENT AMPLITUDE AND FREQUENCY CONFIGURATIONS.

Reference Amp. (mV)	Frequency (Hz)	Measured Amp. (mV)	AE (mV)	RE (%)	Gain (%)
10	1k	9.90	0.10	1.00	99.00

100	1M	15.48	84.52	84.52	15.48
1000	1M	841.05	158.95	15.90	84.11
5000	1M	4738.90	261.10	5.22	94.78

These results demonstrate that the super diode configuration successfully compensated for the BAT54 forward voltage drop, enabling the detection of signals with amplitudes in the millivolt range.

Between 50 kHz and 250 kHz, a reduction in measurement accuracy was observed for amplitudes below 1 V. In contrast, the circuit maintained satisfactory performance for 1 V and 5 V signals throughout the entire simulated frequency range, from 1 kHz to 1 MHz.

Although no clear pattern was observed in either the absolute or relative errors, analysis of the simulation results revealed that a subset of the evaluated operating conditions exhibited a nearly constant gain, indicating the presence of a systematic measurement error rather than random deviations. This behavior was observed for all tested amplitudes at 1 kHz and 10 kHz, as well as for amplitudes of 1 V and 5 V at frequencies of 50 kHz, 100 kHz, 250 kHz, and 500 kHz. The average gain obtained from these measurements was

$$G_{avg} = 98.95\% \tag{7}$$

which corresponds to a calibration factor of

$$K = 0.9895 \tag{8}$$

The relatively small variation around this average value suggests that the detector introduces an approximately constant gain error within this operating range. Thus, the corrected amplitude for the main dataset was calculated according to:

$$V_{corr} = \frac{V_{meas}}{K} \tag{9}$$

where V_{meas} is the measured amplitude and K is the average gain factor obtained experimentally.

Table II presents the corrected amplitudes and the residual errors after calibration. The results show an improvement in measurement accuracy. After calibration, the residual error remained below 1% for nearly all operating conditions up to 250 kHz and below 3% at 500 kHz.

To verify the validity of this calibration factor, it was evaluated on a separate set of simulated amplitudes and frequencies not used in its derivation (Table III). For these independent points, the residual error remained below 3%, confirming that a simple linear calibration can be effectively applied to compensate for this systematic deviation.

Finally, a Monte Carlo analysis was performed under three operating conditions. For typical operation (1 V at 100 kHz), the circuit showed stability, with an amplitude error variation below 0.5% standard deviation (SD) and a maximum error of 1.1% under worst-case component variations, indicating that the calibration remains valid under realistic component variation. Under conditions where nominal precision begins to degrade (10 mV at 250 kHz), the circuit became more sensitive to component mismatch, with an error variation of approximately 9% (SD) and a maximum error of 90%, corresponding to an output of 1.0 mV. At the breakdown condition (10 mV at 500 kHz), the output collapsed to 0.088 mV, with a maximum error exceeding 99%, confirming the operational limit of the architecture.

TABLE II
AMPLITUDE MEASUREMENTS AFTER GAIN CALIBRATION FOR OPERATING CONDITIONS EXHIBITING APPROXIMATELY CONSTANT GAIN.

B. Phase Measurement Circuit Results

The comparator-based method enabled the conversion of the angular difference between two signals into a PWM (Pulse-width modulation) signal proportional to the phase shift. Table IV presents the phase shift values obtained through simulation for 10 mV sinusoidal signals at different frequencies, while Table V presents the corresponding absolute errors.

TABLE IV
PHASE SHIFT MEASURED USING THE AD826 FOR DIFFERENT FREQUENCIES AND NOMINAL PHASE SHIFTS WITH A SIGNAL AMPLITUDE OF 10 MV.

Freq.	**1°**	**2°**	**15°**	**30°**	**45°**	**90°**	**180°**
1 kHz	1.07	2.09	15.08	29.95	45.00	90.00	175.65
10 kHz	0.99	1.80	15.13	30.18	44.97	90.21	178.35
50 kHz	0.97	2.18	15.51	30.00	44.16	90.08	178.05
125 kHz	2.17	2.47	14.49	30.82	46.03	90.34	173.43
250 kHz	0.00	0.00	15.06	30.54	44.58	89.58	106.25
500 kHz	0.00	0.00	0.00	0.00	0.00	0.00	0.00

According to the results, the circuit exhibited errors below 1° in most of the evaluated cases for frequencies up to 125 kHz. From 250 kHz onward, a reduction in measurement accuracy was observed for 10 mV signals. At this frequency, phase shifts of 1° and 2° were not detected, and the measurement

TABLE V
ABSOLUTE PHASE MEASUREMENT ERROR FOR DIFFERENT FREQUENCIES WITH A SIGNAL AMPLITUDE OF 10 MV.

Freq.	1°	2°	15°	30°	45°	90°	180°
1 kHz	0.07	0.09	0.08	0.05	0.00	0.00	4.35
10 kHz	0.01	0.20	0.13	0.18	0.03	0.21	1.65
50 kHz	0.03	0.18	0.51	0.00	0.84	0.08	1.95
125 kHz	1.17	0.47	0.51	0.82	1.03	0.34	6.57
250 kHz	1.00	2.00	0.06	0.54	0.42	0.42	73.75
500 kHz	1.00	2.00	15.00	30.00	45.00	90.00	180.00

of 180° presented an error of 73.75°. At 500 kHz, the phase detector failed to operate for all evaluated phase shifts.

To investigate this limitation, additional tests were performed using amplitudes of 100 mV and 5 V at frequencies of 500 kHz and 1 MHz. Table VI presents the measured phase shifts, while Table VII presents the corresponding absolute errors. The results showed that increasing the signal amplitude restored circuit operation at high frequencies. For an amplitude of 100 mV, most phase shifts exhibited errors below 1°, except for the 180° condition, which presented errors greater than 6° at 500 kHz and 11° at 1 MHz. For an amplitude of 5 V, the errors remained below 1.6° for all evaluated phase shifts.

The phase error below 2° obtained in simulation for this analog circuit is within acceptable limits for bioimpedance instrumentation. According to Nwokoye and Triantis [9], keeping the deviation at this level prevents mixing between the real and imaginary components of the signal. This correct analog separation contributes to clean and reliable data before the signal is sent to the image reconstruction algorithm.

TABLE VI
MEASURED PHASE SHIFT AT 500 KHZ AND 1 MHZ FOR AMPLITUDES OF 100 MV AND 5 V.

Phase Shift	100 mV		5 V	
Nominal	500 kHz	1 MHz	500 kHz	1 MHz
1°	0.00	1.43	1.06	0.83
2°	2.08	2.54	2.27	2.13
15°	15.34	15.36	14.91	15.01
30°	30.04	29.65	30.36	29.79
45°	45.05	44.10	44.97	45.04
90°	90.08	89.76	89.99	89.98
180°	173.07	168.28	178.99	178.42

Based on the overall circuit performance, a limitation associated with the combination of high frequencies and low input amplitudes was identified. Tests performed using the AD826 revealed limitations of the operational amplifier when employed as a comparator. Despite its high bandwidth and slew rate of 350 V/μs, switching delays were observed and became more pronounced for high-frequency, low-amplitude signals. As shown in Fig. 7, these delays caused the comparator outputs to deviate from the ideal square-wave shape presented in Fig. 8. This behavior is associated with saturation recovery time and the internal compensation of the operational amplifier, which was designed for closed-loop operation rather than comparator applications.

TABLE VII
ABSOLUTE PHASE MEASUREMENT ERROR AT 500 KHZ AND 1 MHZ FOR AMPLITUDES OF 100 MV AND 5 V.

Phase Shift	100 mV		5 V	
Nominal	500 kHz	1 MHz	500 kHz	1 MHz
1°	1.00	0.43	0.06	0.17
2°	0.08	0.54	0.27	0.13

180°	6.93	11.72	1.01	1.58

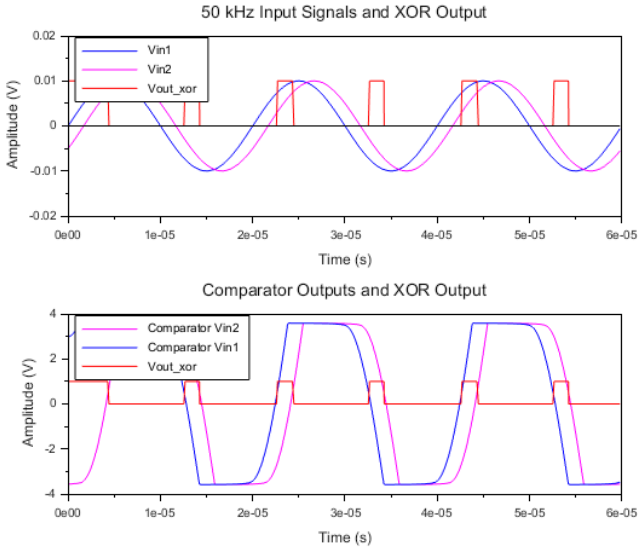

Fig. 7. Comparator output obtained with the AD826 showing switching delay for a 10 mV signal at 50 kHz.

For this application, the presence of switching delay alone would not necessarily prevent phase calculation. Since both signals have the same frequency, the comparators would be expected to introduce similar delays, thereby preserving the time interval between them. The problem arises when the signals have both high frequency and low amplitude. Under these conditions, the comparators can no longer properly follow the transitions of the input signals. Before the comparator output fully reaches one logic level, the input signal has already started transitioning to the opposite state. As a result, the comparator outputs remain at the same logic level, as illustrated in Fig. 9, which shows the simulation results for 500 kHz signals with an amplitude of 10 mV. Consequently, the XOR gate fails to detect the time difference between the signals, and its output remains low, making phase shift determination impossible.

To overcome this limitation, the MAX962ESA was also evaluated [19]. This device is a high-speed comparator specifically designed for applications requiring low propagation delay and fast switching transitions. The component exhibited

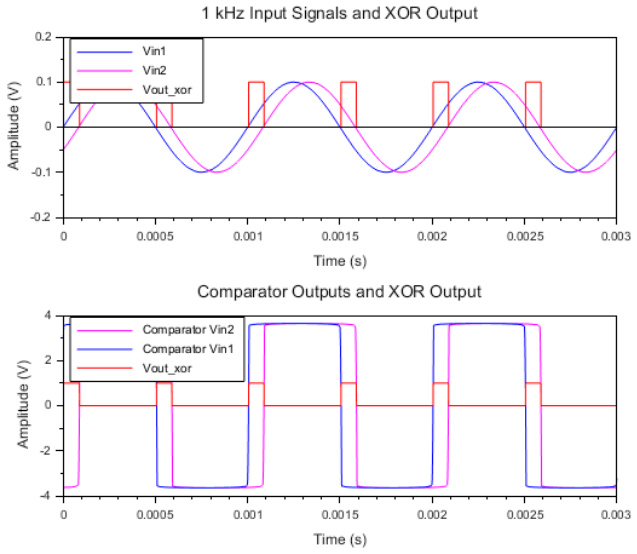

Fig. 8. Ideal comparator response obtained with the AD826 for a 100 mV signal at 1 kHz.

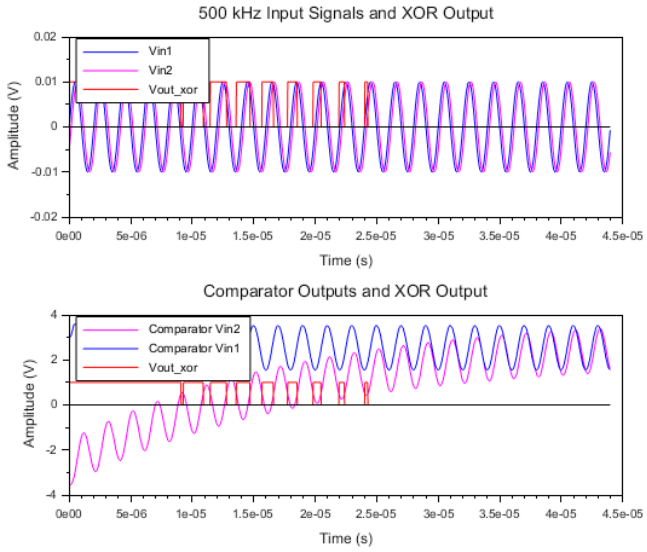

Fig. 9. Comparator output obtained with the AD826, showing that the device is unable to properly track a 10 mV input signal at 500 kHz.

improved dynamic performance during the conducted tests, with reduced distortion at high frequencies and greater stability in zero-crossing detection. However, it did not operate adequately with low-amplitude signals, exhibiting limitations for amplitudes below 300 mV.

IV. Conclusion

This simulation study presented an analog architecture for amplitude and phase acquisition for Electrical Impedance Tomography based on precision rectification and zero-crossing detection. The simulation results demonstrated that the proposed circuits can achieve measurement accuracy compatible with the limits commonly adopted in EIT instrumentation, with amplitude errors below 1% up to 250 kHz after calibration and phase errors typically below 1° for 10 mV signals up to 125 kHz. By extracting amplitude and phase information before analog-to-digital conversion, the proposed approach has the potential to reduce digital processing requirements while maintaining measurement accuracy. These simulated results indicate that the architecture is a promising candidate for implementation in EIT systems.

Future work will focus on the hardware implementation and experimental validation of the proposed architecture under non-ideal conditions. In particular, for low-amplitude signals, a pre-amplification stage at the circuit input will be investigated to mitigate the effects of zero-crossing hysteresis, together with a high-pass filter to eliminate DC offset. The physical circuits are currently under construction, and their experimental performance will be evaluated by comparing the measured amplitude and phase errors with published EIT accuracy limits under matched frequency, load, and signal-level conditions. Following this validation, the architecture will be integrated into a complete EIT system for image reconstruction using experimental phantom measurements.

Artificial intelligence tools were used exclusively to support academic writing, including style revision and improvements in textual fluency. The methodology design, simulation execution, data analysis, and interpretation of the results were carried out entirely by the authors.

Abstract*—Disinformation has reached a global scale driven by generative AI, overcoming the effectiveness of traditional natural language processing (NLP) filters by exploiting vulnerabilities in human cognitive processing. The transition to analyses centered on the message receiver has become imperative. To this end, this work mapped and synthesized the scientific literature on the identification of disinformation through the analysis of Electrodermal Activity (EDA) and eye-tracking. As eligibility criteria, primary articles without temporal restrictions, in English and Portuguese, that address digital deception detection via the aforementioned biosensors were included. The searches were executed in the Scopus, ScienceDirect, IEEE Xplore, PubMed, Web of Science, and SciELO databases. Screening, duplicate removal, and data extraction were performed with the support of the Parsifal platform, correlating biosignals to states of mental load. The unified search resulted in 183 documents, of which 81 were selected for synthesis. The data indicate that the eye-tracking technique identifies patterns of doubt via the rereading of excerpts, while EDA records peaks of sympathetic nervous system activation during exposure to fraudulent information. Detection based on subconscious biosignals presents itself as a viable approach given the limitations of textual methods, highlighting the relevance of investigating multimodal architectures focused on user neurophysiological behavior.

***Keywords*—Disinformation, Electrodermal Activity, Eye-tracking, Scoping review, Biosignals.**

I. Introduction

The way we consume information today has changed drastically, and with that, the spread of fake news on social media has gone from being a technical problem to becoming a crisis of trust. What was once just digital noise now threatens the foundations of institutions. This impact goes beyond the digital realm, directly affecting the basis of decisions made by contemporary society. Disinformation now represents a risk on a global scale, spreading exponentially faster than factual news [1].

In the Brazilian context, informational instability has grown with the popularization of generative Artificial Intelligence (AI). This technology has made the production of misleading content—both in text and image—cheerful and impressively realistic. Recent data shows that the volume of disinformation and *deepfake materials* (videos or images manipulated by AI to simulate reality in an ultra-realistic way) jumped more than 308% in just one year in the country [2], becoming a strategic tool for political manipulation.

Statistical surveys reveal that 93% of the Brazilian population uses some form of social network and approximately 80% of citizens support the creation of legislation to combat the spread of fake news [3]. Despite the high level of concern about the issue, data indicate that 50% of the population declares that they have great difficulty discerning whether digital information is true or fraudulent [4], highlighting a gap in the public's information literacy.

This difficulty, however, is not solely due to deficiencies in digital education, but also to cognitive vulnerabilities inherent in human beings. To understand the root of this scenario, the specialized literature in cognitive psychology categorizes false information into three categories: disinformation, intentionally created to manipulate; misinformation, shared unintentionally, often due to failures in digital literacy; and misinformation, based on real facts but decontextualized to cause harm. In all these scenarios, the user's vulnerability is aggravated by a cognitive limitation of memory known as source monitoring failure.

Due to the high volume and speed of information consumed on social media, the individual's brain often stores the content of a message in long-term memory, but fails to register where, when, or through whom this information was obtained. This results in an inability to later distinguish whether the news was read in a reliable journalistic outlet or in a disseminator of fraud [5].

Faced with fraud that reproduces journalistic language and aesthetics with high fidelity, traditional computational digital security mechanisms based exclusively on Natural Language Processing (NLP) have limitations. As contemporary digital disinformation exploits cognitive biases—such as the Illusory Truth Effect—to increase the perceived credibility of false information, it becomes necessary to broaden the focus of detection. Instead of analyzing only textual content, approaches that also consider the physiological and cognitive responses of individuals during reading can offer complementary information for identifying this type of fraud [6].

The severity of this cognitive vulnerability has been scientifically tested in high-polarity scenarios. Studies focused on skeptical climate claims have revealed that simply repeating misinformation increases the user's belief levels, regardless of their prior knowledge of the subject.

The phenomenon even affects individuals who endorse climate science, demonstrating that processing fluency generated by repetition bypasses analytical judgment [7]. As cognition fails when processing repeated false information, information security should not rely solely on the reader's rationality, which justifies investigating biosignal monitoring (Fig. 1).

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

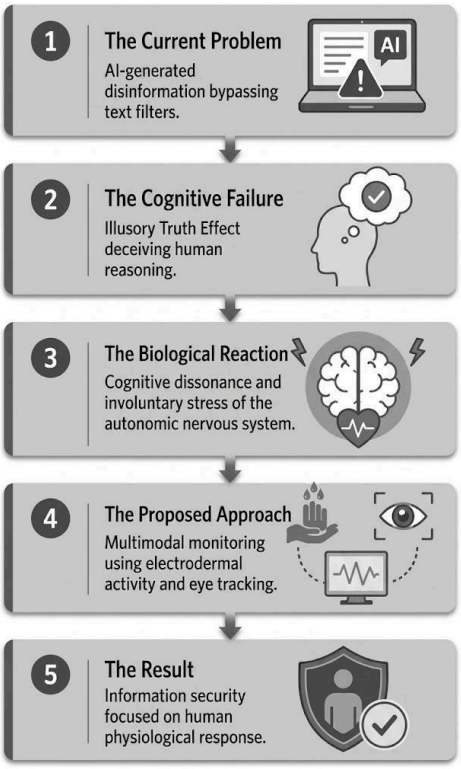

Fig. 1. Conceptual flow of misinformation identification via biosignals.

Electrodermal Activity (EDA) and eye tracking emerge as practical solutions. While EDA monitors skin conductance, eye tracking "reads" mental effort through gaze fixations and pupil dilation. These are new and promising approaches [6, 8]. These biosignals are capable of measuring cognitive dissonance and autonomic stress in the face of fraudulent information involuntarily, operating even before the user makes a conscious decision about the veracity of the content.

Given the above, the objective of this scoping review is to map and synthesize the existing literature on identifying misinformation using physiological and ocular responses. The review seeks to understand the state of the art of these technologies to justify the need for and feasibility of developing new multimodal computational architectures focused on human behavior in the fight against fake news.

To guide the execution of this mapping and achieve the proposed objectives, the protocol in the Parsifal software was structured around five Research Questions: QP1. Which biosignals are most used in the detection of misinformation? QP2. How does eye tracking contribute to identifying cognitive conflict in the face of fake news? QP3. Is there evidence of unconscious truth recognition through biological responses, regardless of the user's belief? QP4. Which elements of the news (text, image, or headline) generate the greatest changes in eye fixation patterns? QP5. How does the time of exposure to information influence the intensity of electrodermal responses (EDA)?

II. Methods

This research was conducted following the guidelines of the PRISMA-ScR extension (*Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews*), ensuring the appropriate methodological rigor for scoping reviews.

A. Protocol

The internal protocol for this review was developed to ensure the transparency of biometric data extraction applied to the context of digital security and deception detection, structured around the search, screening, and qualitative synthesis steps recommended by the PRISMA-ScR checklist. This protocol has not been previously registered.

B. Eligibility criteria

Primary articles published in scientific conferences and journals, in English and Portuguese, were included, with no initial date restriction. The main inclusion criterion required that studies explicitly address the detection of digital deception, misinformation, or cognitive conflict using biosensors focused on receiver analysis, specifically through EDA and eye tracking. Articles focused exclusively on traditional polygraphs for criminal interrogations, or that used only mathematical NLP models without the participation of human volunteers, were excluded from the scope.

C. Sources of information

The searches were initially conducted across three global scientific and technical databases (Scopus, ScienceDirect, and IEEE Xplore Digital Library). Subsequently, the search was expanded to include the reference biomedical database PubMed, the global multidisciplinary database Web of Science, and the regional Latin American database SciELO. The searches were carried out comprehensively, and the final data retrieval was performed on April 15, 2026.

D. Search strategy

To ensure reproducibility and maximum comprehensiveness of the mapping, the complete search strategy was structured in multiple Boolean blocks. The *string* was constructed exclusively with English terms, since international databases standardize metadata indexing in this language, allowing the retrieval of articles regardless of whether the full text is in Portuguese. To facilitate reading, Table I presents the representation of the constructs by groups of terms.

TABLE I
Groups of terms used in the search strategy

Thematic Group	**Search Terms (Synonyms)**
1. Eye Tracking	"eye tracking", "gauze", "pupillometry", "pupil dilation", "fixation"
2. Electrodermal Activity	"EDA", "GSR", "skin conductance", "physiological signals"
3. Misinformation and Deception	"fake news", "disinformation", "misinformation", "deception", "deception detection", "truth recognition"
4. Cognitive Load	"cognitive conflict", "cognitive bias", "arousal", "incongruity"
5. Computational	"classification", "machine learning", "detection"

The groups of terms were combined using the AND operator, while synonyms within each group were combined using OR, resulting in an exact match search strategy applied to the title, abstract, and keywords.

E. Selection of sources of evidence

The Parsifal systematic review management software was used to guide the methodology for study screening and selection. Records retrieved from the unified searches—covering the Scopus, ScienceDirect, IEEE Xplore, PubMed, and Web of Science databases, as well as the regional SciELO database—were imported into the platform, where duplicate identification and removal were performed automatically. In the subsequent phase, the remaining articles were screened against eligibility criteria by reviewing titles and abstracts; studies that passed this stage underwent a detailed full-text evaluation to determine their final inclusion.

While expanding the search to the PubMed and Web of Science databases resulted in the incremental addition of six new unique records to the protocol, the search of the regional SciELO database yielded no results (zero occurrences) that simultaneously met the combined criteria of Electrodermal Activity, Eye Tracking, and Misinformation. To ensure the required transparency and reproducibility, the entire process—from identification and screening to exclusion and final inclusion—was documented using a flowchart structured in accordance with the PRISMA-ScR protocol guidelines (Figure 2).

F. Data extraction process

The data extraction was performed by completing a standardized form within the Parsifal software environment. The questions and fields of this form were structured to extract the methodological variables from each study, which are detailed in the following section (G. Data Items). This process ensured the organized capture of the methodological metrics of each primary article, correlating the type of biosensor equipment used with the results of mental workload and physiological responses reported in the literature.

G. Data items

The variables collected and analyzed from each study included: authorship, year of publication, country or region of origin of the research, biometric modality employed (eye tracking, electrodermal activity, or multisensory), and the main findings related to the neurophysiological behavior of the user during the consumption of misinformation.

H. Critical appraisal of individual sources of evidence

As recommended by the PRISMA-ScR guidelines for scoping reviews, formal risk of bias assessment is an optional criterion. However, to ensure the quality of the basis, the sources were critically evaluated for their "ecological validity." Priority was given to the analysis of studies that emulate real social media or news platform interfaces in the presentation of stimuli, over research that presented decontextualized texts on blank screens, suggesting that the measured stress and visual attention reflected the user's everyday internet behavior.

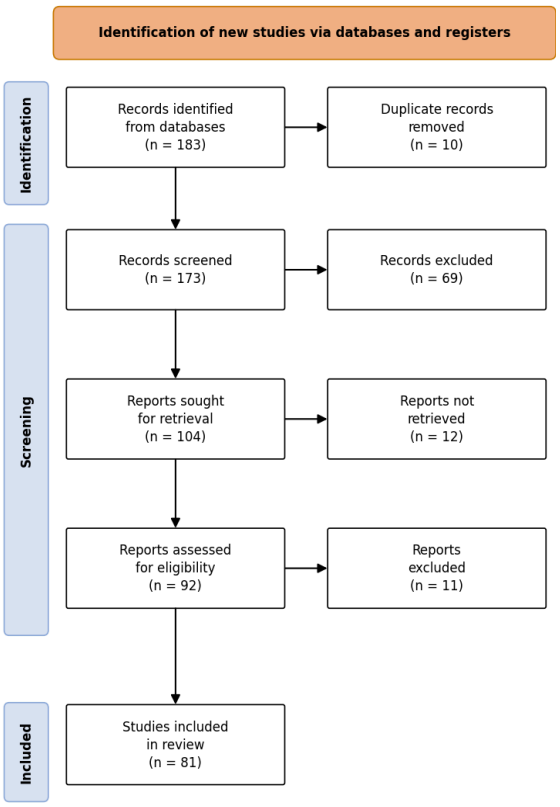

Fig. 2. Flowchart of the process for identifying, screening, determining eligibility, and including studies, developed according to the PRISMA-ScR protocol guidelines.

I. Summary of results

The extracted data were organized chronologically and categorized by type of physiological signal. This structuring allowed for the identification of trends in the temporal evolution of the research, as well as the highlighting of technological gaps, especially regarding the cross-referencing of these biometrics for the Portuguese language and the Brazilian sociocultural context.

III. Results

A. Selection of sources of evidence

The expanded systematic search yielded a total of 183 documents distributed across the selected databases. An analysis of the source distribution revealed that 41% of the articles came from ScienceDirect, 30.6% from Scopus, 24% from the IEEE Xplore digital library, 3.8% from Web of Science, and 0.5% from PubMed, whereas the regional database SciELO yielded no results (0%) based on the established search criteria (the sum of the percentages differs from 100% due to decimal rounding).

After importing the metadata into the Parsifal platform and automatically removing 10 duplicates, the 173 articles underwent screening based on title and abstract, resulting in the exclusion of 69 studies that did not meet the eligibility criteria. Of the 104 publications selected for retrieval, 12 could not be located, leaving 92 articles for full-text analysis. Following a full-text review, 11 studies were excluded due to methodological limitations. At the end of the process, 81 primary articles were accepted and included

in the qualitative synthesis of this review (the list of included studies is available as supplementary material – DOI: 10.5281/zenodo.22719150).

Among the records selected for retrieval, 12 publications could not be located in full-text format. This inability to retrieve the documents stemmed from two main factors: (a) paywall restrictions in highly specialized journals where full-access licenses were not covered by active subscriptions from the CAPES Journal Portal (via the Federated Academic Community – CAFe) or by IFB institutional databases; and (b) inconsistencies in metadata indexing, comprising records that provided only the abstracts from old conference proceedings, without the full text of the corresponding manuscript being available or preserved in the digital repositories of the databases consulted.

The exclusion of 11 studies following a critical analysis of the full text was justified by methodological limitations incompatible with the scope of this review, notably: (a) the absence of primary experimentation (secondary studies), comprising strictly conceptual articles or literature reviews lacking direct empirical collection of biosignals—such as the study by Joey F. George and Sophia Mannina (2025), which focused on a qualitative analysis of secondary health reviews; (b) the exclusive use of Natural Language Processing (NLP), characterized by works applying automated text classification algorithms without the participation of human volunteers or the recording of their physiological responses as receivers; (c) an exclusive focus on the sender (traditional polygraphy), consisting of research aimed at detecting active lying in classic criminal interrogation scenarios, which diverged from the central objective of mapping receiver behavior during the passive consumption of digital misinformation; and (d) biometric hardware inconsistency, identified in studies using abstract biometric simulations without proper specification of electrodermal activity (EDA) sensors or eye-tracker calibration parameters, thereby preventing the technical replicability of the experiments.

B. Main sources of evidence

The analysis of the 81 selected articles reveals a growing trend of integration between Computer Science and fields such as Neuroscience and Cognitive Psychology, aiming to incorporate physiological and cognitive information into traditional misinformation detection methods. Six representative studies stand out among those underpinning this review. In the context of ocular biometrics, studies by Kawano and Severino [9] investigate visual attention patterns in Brazilian individuals, while Wong et al. [8] analyze the monitoring of eye regressions as an indicator of cognitive processing during reading. Regarding autonomic stress, Nguyen et al. [6] and Cheng et al. [10] present evidence on the use of electrodermal activity as a measure of cognitive conflict and physiological arousal. Complementing this perspective, Jiang et al. [7] provide the psychological basis for the Illusory Truth Effect—a phenomenon widely associated with susceptibility to misinformation—while Sun et al. [12] advance this technological frontier by integrating electrodermal activity and ocular metrics to accurately predict a reader's implicit trust in health-related texts generated by Artificial Intelligence.

C. Critical appraisal of sources of evidence

The evaluation of experimental protocols showed that most international studies have high methodological robustness, frequently using clinical gold standard equipment. However, a deficiency was noted in the literature regarding validation in Portuguese-language databases. Few biometric studies cross-reference the use of biosensors with validated and updated ecological stimulus databases from Brazil, such as the FakeRecogna corpus [11].

This repository stands out as a milestone for national research, aggregating tens of thousands of factual and fraudulent news items extracted from partner fact-checking agencies (such as Lupa, Fato or Fake, and E-fakes) and traditional news portals (such as G1 and UOL). By categorizing fraud in a balanced way across areas such as health, politics, and science, including the context of the pandemic, this type of database contributes to the creation of realistic textual stimuli. The absence of standardized *corpora* in international studies suggests a point that is still little explored, which can guide future investigations in the Brazilian context.

Regarding the geographical distribution of the studies, the analysis revealed a strong concentration of experimental research in countries of the Northern Hemisphere and Asia. Publications from China and the United States were prominent, followed by Australia, which are leading the development of neurophysiological architectures for deception detection.

Conversely, a scarcity of applied research in the Brazilian context was observed (Table II). Most of the included national research focuses on the construction of textual databases or the isolated observation of visual attention, highlighting the need to expand multimodal experimentation with biosensors to the Portuguese language.

TABLE II
Geographic concentration and technological focus of the selected publications

Country of origin	**Volume in Literature**	**Predominant Technological/Thematic Focus**
China	High	AI, Eye Tracking and Brain Spectroscopy (fNIRS).
United States	High	Cognitive biases, the Illusory Truth Effect, and EDA.
Australia	Average	Multimodal fusion of biosignals for real-time detection.
Italy	Average	Facial microexpressions and thermal/ocular polygraphy.
Brazil	Low	Isolated visual attention, literature reviews, and textual *corpora* .

Note: The volume of publications in the literature was stratified according to the following occurrence intervals in the sample: High (> 10 articles), Medium (4 to 10 articles), and Low (1 to 3 articles).

To characterize the predominant technological approaches in literature, the frequency of use of physiological modalities in the 81 included studies was extracted. The analysis revealed a historical preference for

the isolated application of sensors, with a strong predominance of eye tracking and EDA, as shown in Fig. 3.

Notably, only a small fraction of studies (approximately 8.9%) adopts real-time multimodal fusion architecture. This metric corroborates the scarcity of systems capable of simultaneously cross-referencing visual attention and autonomic stress during the consumption of misinformation.

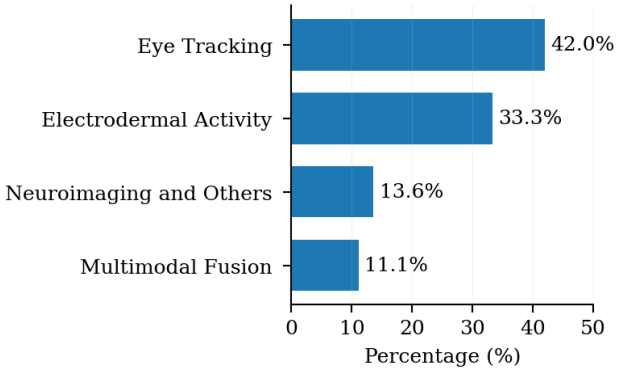

Fig. 3. Proportion of biosignal modalities used in the included studies.

D. Results from individual sources of evidence

The extracted analyses confirmed the viability of biosensors as tools for deception detection. In the ocular spectrum, it was observed that people allocate their visual attention differently when faced with fake news related to COVID-19 [9]. Tracking showed significant differences in areas of interest, with volunteers performing a notable number of regressive saccadic movements and prolonged fixations in the search for sources that attest to the credibility of the material. In addition to these findings, it is observed that ocular metrics, such as time to first fixation (*TTFF*) and dwell time, show significant variations when Brazilian readers are exposed to alarmist headlines [9].

Furthermore, Areas of Interest (AOIs) containing logos of media outlets or images with high emotional appeal tend to capture peripheral visual attention more intensely, inducing the oculomotor system to perform rapid and repetitive scans. This pattern of visual searching for clues that aid in assessing the credibility of information suggests that the design of the social network directly influences the cognitive effort and visual processing involved in interpreting the content.

In another line of research on eye behavior, the processing of misinformation and its respective corrections was mapped [8]. The study monitored the durations of the first and second eye passes in different areas of interest on the screen. The results indicated that the inclusion of explicit reminders about the falsity of a news item drastically altered reading speed and increased eye regressions. Furthermore, it was found that the individual's verbal working memory capacity acts as a significant predictor of the efficiency with which the reader integrates the correction of misinformation, directly reflecting the captured eye effort.

In the physiological field, studies employing EDA have demonstrated that response latency and skin conductance vary autonomously in the face of textual incongruities [6]. The results revealed that, even when participants stated they believed false information, increases in electrodermal activity were observed, indicating greater physiological activation. These findings suggest that the sympathetic nervous system may respond to signals of inconsistency present in the content before a fully consolidated conscious evaluation occurs, evidencing a subconscious component in the processing of misleading information.

Extending the investigation to the cerebral cortex, functional near-infrared spectroscopy (fNIRS) was used to measure how the authority of a fact-checking agency affects mental effort [10]. The data pointed to a neurological pattern associated with cognitive dissonance: when volunteers read fake news corrected by highly authoritative sources, the brain used a "fast track" of heuristic acceptance, reducing the activation of the right prefrontal cortex (RPFC). Conversely, when the verification came from an unofficial source, the perceived low credibility forced the brain to maintain a prolonged and vigilant evaluation, keeping the RPFC highly activated. This indicates that the body reacts measurably not only to the false text, but also to the signals of credibility and authority attached to it.

E. Summary of results

The temporal distribution analysis of the articles revealed a dynamic behavior directly influenced by global crises. Although theoretical studies on biometrics and polygraphs date back to the 1970s, there has been an exponential growth in academic interest focused on the internet since 2018. This leap reflects the shock caused by the use of massive disinformation campaigns in high-impact electoral scenarios, such as the referendum on the United Kingdom's exit from the European Union (Brexit) in 2016, as well as the presidential elections in the United States and Brazil. In the Brazilian context, the phenomenon was strongly characterized by the use of mass dissemination of fake news through messaging applications in 2018, which boosted the global urgency for new detection and literacy tools [5].

The timeline graph extracted from the mapping showed a reduction in the number of publications between 2020 and 2021. This behavior may be related to the impacts of the COVID-19 pandemic on experimental research, a period in which the temporary closure of laboratories and restrictions on conducting in-person studies hampered experiments involving physiological sensors and human participants. With the resumption of in-person activities, a significant increase in publications was observed, culminating in a historical peak in the years 2024 and 2025. This increase may be associated both with the resumption of experimental studies and with the growing scientific interest in developing more effective methods to combat the infodemic and the spread of fake news (Fig. 4).

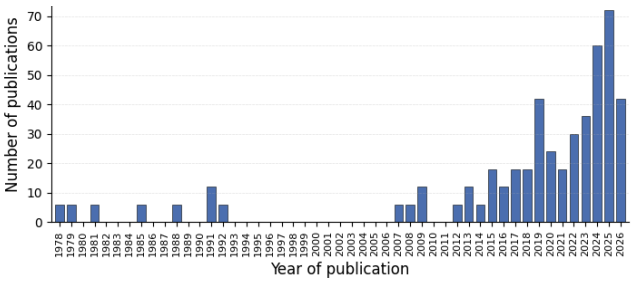

Fig. 4. Temporal evolution of the publications included in the scoping review.

IV. Discussion

A. Summary of the evidence

The gathered evidence supports the proposed objectives of this scoping review and directly answers the questions that motivated this study. Regarding the predominant biosignals (RQ1), the mapping confirmed the literature's historical preference for Eye Tracking (42.0%) and Electrodermal Activity (33.3%), predominantly applied in isolation. As for the contribution of eye tracking (RQ2), the findings indicate that it maps cognitive conflict through increased visual effort and saccadic regressions, revealing exactly where the brain encountered the incongruity. Regarding evidence of the unconscious recognition of truth (RQ3), the literature confirms that autonomic biosignals - particularly Electrodermal Activity (EDA) - register increases in conductance and sympathetic nervous system stress when exposed to fraudulent content; this occurs even when volunteers consciously state they believe the fake news, demonstrating a subconscious and involuntary biometric response to deception [6]. An analysis of news elements (RQ4) revealed that alarmist headlines, emotionally charged images, and media outlet logos (sources) were the factors that triggered the most significant changes in gaze fixation and scanning patterns during the assessment of credibility [9].

The individual efficacy of these technologies already shows promising results for applications in systems engineering. Machine learning models trained exclusively on EDA data achieved 63.46% accuracy (with an F1-score exceeding 62%) in predicting the veracity of information, outperforming other physiological signals evaluated in the same study—such as photoplethysmography (PPG), which achieved 58.79% accuracy in identifying cognitive discrepancies [6]. These results reinforce the potential of biosignals as a source of objective information for developing automated systems to support disinformation detection—a field driven by cutting-edge research demonstrating the feasibility of combining eye-tracking with physiological signals (such as EDA and heart rate variability) to accurately predict users' implicit confidence levels and classify message authorship (human vs. AI-generated) with accuracies exceeding 72% [12].

However, the possibility of incorporating this biosignal-based architecture into everyday applications raises significant bioethical implications. The use of sensors capable of passively inferring cognitive states and detecting physiological stress responses necessitates the establishment of legal and ethical safeguards to protect individuals' cognitive privacy, preventing technologies intended to combat misinformation from being transformed into mechanisms for emotional surveillance. Furthermore, although the mapping indicates that most historical studies have utilized biosignals in isolation, the recent introduction of architectures performing synchronized multimodal fusion of ocular and autonomic data is beginning to bridge this gap, establishing itself as a highly promising direction [12] for future research aimed at developing multimodal systems that are potentially more robust and accurate in detecting misinformation.

B. Physiological and cognitive mapping

Analysis of the literature demonstrated that different types of biosensors are capable of capturing specific dimensions of misinformation processing. While some signals reflect the effort expended to understand the message, others reveal the subconscious stress resulting from cognitive dissonance. To systematize these findings, Table III presents the relational matrix between the main biometric metrics extracted and the psychological phenomena associated with them.

TABLE III
Relational matrix of biosignals and cognitive phenomena in the detection of misinformation

Modality	Extracted Metric	Cognitive Phenomenon
Electrodermal Activity (EDA)	Skin conductance peaks	Cognitive dissonance, involuntary emotional arousal, and autonomic stress in response to deception.
Eye Tracking	Time and Duration of Fixations	Level of visual attention, processing effort, and information extraction from the headline.
Eye Tracking	Regressions	Distrust, reassessment of context, and critical rereading (e.g., source verification)
Eye Tracking	Pupillary dilation	Increased mental load and effort required to decode complex lies.
Neuroimaging (fNIRS / EEG)	Activation of the Prefrontal Cortex	Resolution of conflicts related to credibility, dependence on authority, and decision-making.

C. Research gaps and future opportunities

Despite the exponential growth in publications since 2018, the mapping revealed that the application of biosignals in combating disinformation still has significant methodological and contextual limitations. The predominant focus of the classic literature on polygraphics has always been the analysis of the lie sender (the one who tells the lie), with a lack of models focused on the observer (the one who consumes the fake news). Table IV summarizes the main gaps identified in this work and outlines research opportunities for the advancement of digital security.

TABLE IV
Map of identified gaps and research opportunities

Research Area	Gap Identified in the Literature (Problem)	Research Opportunity (How to fill out)
Focus of Detection	Most studies focus on the "sender" of the lie (criminal analysis/ (polygraphs).	Develop detection systems focused on the receiver/ observer.
Ecological Validity	Laboratory tests using artificial phrases without the real context of a social network.	Use of local ecological databases containing stimuli with Brazilian headlines and logos.
Sensor Architecture	Isolated use of a single sensor	Design multimodal fusion models in a synchronized, real-time manner.
Bioethics and Privacy	Risk of the involuntary use of biometrics for state or corporate	Establishing rigorous ethical frameworks to protect the user's

	surveillance.	"cognitive privacy".

D. Limitations

The limitations of this systematic mapping are restricted to the parameters defined in the initial protocol. The exclusive use of three international academic databases (Scopus, ScienceDirect, and IEEE), while guaranteeing very high quality due to peer review, may have resulted in the omission of preliminary studies, dissertations, and grey literature indexed in regional repositories not integrated into global search platforms.

E. Conclusions

This scoping review revealed that non-invasive biometric technologies, particularly eye tracking and EDA, have the potential to identify neurophysiological responses associated with the consumption of misinformation. The studies analyzed indicate that these biosignals allow the detection of cognitive conflicts and emotional changes triggered during exposure to potentially false content, complementing traditional approaches based exclusively on textual analysis. Given the increasing sophistication of generative AIs in the production of synthetic content, the results suggest that cybersecurity strategies can benefit from incorporating the human factor as an additional layer of detection.

The findings are also relevant from a social point of view. Evidence from the literature indicates that the ability to identify fake news is associated with the level of education and digital literacy, making certain groups more susceptible to misinformation [4]. In this context, biosignal-based systems can reduce the exclusive dependence on the user's conscious cognitive skills, offering complementary mechanisms to support the identification of potentially misleading content and expanding the accessibility of these technologies to different user profiles.

Finally, the mapping identified an important gap in the literature: the predominance of studies that employ eye tracking and EDA independently, to the detriment of synchronized multimodal architectures. This result reinforces the need for experimental research investigating the integration of these biosignals in ecological scenarios, including the Brazilian context. The consolidation of these architectures could contribute to the development of biometric solutions embedded in wearable devices, such as smartwatches, capable of acting as support mechanisms for the detection of disinformation in real time, provided they are accompanied by adequate ethical and privacy safeguards.

Acknowledgments

The authors thank Professor Dr. Carla Simone Castro da Silva for her support and the opportunity to join the team at the School of Business and Social Development (ENEDES). They also thank the Brazilian Agency for Industrial Development (ABDI) and the Federal Institute of Brasília (IFB) for their partnership and support for the research, innovation, and extension activities developed within the scope of projects no. 64/2025 and no. 335/2026. FHMO and RHCS thank the Foundation for Research Support of the Federal District (FAPDF) for granting the Post-Doctoral Fellowships (Processes no. 23098.000311.2026-80 and no. 23098.000264.2026-74), which enabled the development of this research.

Statement on the Use of Generative AI:

The Gemini 1.5 Pro tool (Google) was used exclusively as assistive support in the preparation of this work, limited to aiding in the interpretation of technical terms in English, methodological organization (PRISMA-ScR), spelling review, and the generation of Python scripts for plotting figures.

Resumo*—A espirometria depende da qualidade do sistema de aquisição do fluxo respiratório, e diferentes princípios de sensoriamento podem produzir respostas dinâmicas distintas. Este estudo experimental e comparativo buscou avaliar o comportamento das curvas fluxo-tempo obtidas por um sensor mecânico de turbina e por um sistema piezoresistivo submetidos a padrões respiratórios controlados e reprodutíveis gerados por um ventilador mecânico Servo-s. O sistema piezoresistivo operou com intervalo de amostragem de 50 ms, correspondente à frequência de 20 Hz, totalizando 951 amostras distribuídas em aproximadamente 16 a 20 ciclos respiratórios, contemplando as fases inspiratória e expiratória. Foram analisados morfologicamente o início do fluxo, a formação do pico, a fase de desaceleração, a presença de platô, o retorno à linha de base e a repetibilidade visual dos padrões. As curvas obtidas demonstraram similaridade morfológica na identificação dos principais eventos respiratórios, embora tenham sido observadas diferenças de amplitude e resposta temporal entre os sistemas, especialmente nas regiões de rápida variação do fluxo. Essas diferenças podem estar relacionadas aos distintos princípios físicos de funcionamento, à resposta dinâmica, à calibração e ao processamento dos sinais. Considerando que as aquisições não foram simultâneas e que as séries não foram integralmente padronizadas em uma escala comum de L/s, os resultados desta etapa devem ser interpretados como evidência de similaridade morfológica, não permitindo estabelecer equivalência metrológica ou superioridade entre os sensores. Estudos posteriores com aquisição sincronizada, fluxo de referência comum e análises quantitativas serão necessários para determinar erros, concordância e desempenho metrológico entre os sistemas.

I. Introdução

A respiração é essencial à manutenção da vida e sua avaliação objetiva depende de instrumentos capazes de registrar, com precisão e repetibilidade, as variações de fluxo e volume ao longo do ciclo respiratório [1]. Nesse cenário, a espirometria se consolida como um método de referência para diagnóstico da função pulmonar, de modo que a fidedignidade técnica de seus registros está estritamente vinculada tanto à capacidade operacional do instrumento quanto a processos sistemáticos de calibração, aferição periódica e controle de qualidade [2]–[5]. As recomendações ATS/ERS reforçam a necessidade de padronização dos procedimentos e de controle da exatidão e repetibilidade dos sistemas espirométricos [6] [7]. Estudos de controle de qualidade demonstram que pequenas variações sistemáticas podem não ser identificadas por critérios isolados de calibração, o que justifica a avaliação periódica do comportamento do sistema ao longo do tempo [3] [5]. Dentre as metodologias aplicadas na quantificação do fluxo respiratório, destacam-se os transdutores mecânico-ópticos de turbina e os dispositivos eletrônicos fundamentados no princípio de pressão diferencial. Nos sensores de turbina, o movimento giratório de um rotor interno é traduzido em pulsos proporcionais à taxa de fluxo. Por sua vez, os sistemas piezoresistivos aferem deformações físicas ou gradientes de pressão, demandando uma função matemática de calibração para correlacionar o sinal elétrico de saída com a respectiva vazão respiratória [8]–[11]. Adicionalmente, por viabilizarem a miniaturização e a integração de componentes eletrônicos, os sensores piezoresistivos tornam-se bastante promissores para o desenvolvimento de sistemas vestíveis e embarcados; contudo, sua aplicação com fins quantitativos permanece condicionada a rigorosos processos de calibração, técnicas de compensação e validação metrológica [9]. Sistemas de biofeedback e monitorização respiratória podem ampliar a disponibilidade de informações fisiológicas em tempo real [12]. Além disso, a relevância clínica de medidas respiratórias objetivas é particularmente evidente em doenças como asma e outras condições obstrutivas, nas quais a caracterização funcional auxilia a avaliação do comprometimento respiratório [13]. O interesse pela análise comparativa entre diferentes tecnologias de mensuração do fluxo respiratório surgiu a partir de uma linha de pesquisa desenvolvida pelo grupo voltada à construção de um sistema de feedback respiratório em tempo real, baseado na aquisição do fluxo expiratório por meio de um sensor piezoresistivo. O desenvolvimento desse sistema requer não apenas a aquisição e o processamento do sinal respiratório, mas também a caracterização do comportamento do sensor frente a tecnologias já empregadas na mensuração do fluxo. Nesse contexto, a comparação com o sensor mecânico

de turbina torna-se uma etapa importante do processo de desenvolvimento e avaliação do sistema, permitindo investigar como diferentes princípios de sensoriamento representam os principais eventos das curvas fluxo-tempo, bem como identificar possíveis diferenças relacionadas à resposta dinâmica, amplitude, formação do pico, desaceleração e retorno à linha de base [1]. O objetivo deste estudo foi comparar, a morfologia das curvas fluxo-tempo obtidas por um sensor mecânico de turbina e por um sensor piezoresistivo submetidos a padrões de fluxo gerados por ventilador mecânico Servo-s, descrevendo a capacidade de ambos os sistemas de identificar os principais eventos temporais do ciclo respiratório. O estudo não teve como objetivo, nesta etapa, demonstrar equivalência metrológica entre as tecnologias.

II. Materiais e Métodos

Trata-se de estudo experimental in vitro, metodológico e comparativo, realizado exclusivamente em bancada para calibração e avaliação funcional de sistemas de medida de fluxo. Não foram incluídos sujeitos humanos ou animais, não houve coleta de material biológico e não foram utilizados prontuários ou dados clínicos. Por essa razão, o protocolo correspondeu a ensaio instrumental de bancada, sem participação de seres humanos. O fluxo de referência foi produzido por um ventilador mecânico Servo-s, empregado como fonte controlada e reprodutível de ciclos inspiratórios e expiratórios. Foram avaliados padrões de fluxo contínuo, esforço expiratório e ciclos intermitentes/bifásicos. O conjunto de dados do sistema piezoresistivo compreendeu 951 amostras, correspondendo aproximadamente a 16–20 ciclos respiratórios ao longo dos ensaios. O intervalo entre as amostras foi de 50 ms, equivalente a frequência de amostragem de 20 Hz, contemplando inspiração e expiração. O sensor mecânico de turbina do espirômetro foi empregado como sistema comparativo para registro de fluxo. Seu princípio baseia-se na rotação de um elemento móvel, com conversão da frequência de pulsos ópticos em fluxo e obtenção do volume pela integração temporal [8]–[11]. O sistema piezoresistivo detectou variações de pressão/deformação por alteração resistiva em ponte de Wheatstone; o sinal foi amplificado e digitalizado, sendo sua relação com o fluxo estabelecido durante a calibração em bancada. A comparação desta etapa foi predominantemente morfológica e temporal. Para cada condição, foram examinados o início do fluxo, a ocorrência do pico, a fase de desaceleração, a presença de platô, o retorno à linha de base e a repetição do padrão entre ciclos. As aquisições originais não foram simultâneas, e os dois sistemas não foram registrados em uma escala calibrada comum em L/s. Além disso, o conjunto de dados de origem não fornece a frequência de amostragem do sistema piezoresistivo nem um número predefinido de ciclos repetidos por condição. Portanto, o presente conjunto de dados não permite o cálculo retrospectivo da concordância metrológica quantitativa.

A. Princípio de Funcionamento

Sensor mecânico de turbina: a passagem do ar acelera o rotor e as interrupções de um feixe óptico geram pulsos cuja frequência é relacionada ao fluxo. A tecnologia é utilizada em espirômetros portáteis comerciais e exige procedimentos de verificação e controle de qualidade [9] [11]. Sensor piezoresistivo: a deformação de uma membrana modifica a resistência elétrica dos elementos sensores. A tensão resultante é amplificada e digitalizada; para estimativa de fluxo, o sinal de pressão diferencial deve ser relacionado a uma função de calibração adequada à geometria do sistema [9] [13].

B. Comportamento comparativo das curvas(Fluxo-Tempo)

Em transientes rápidos, diferenças entre as curvas podem decorrer da inércia do rotor, da resposta dinâmica do transdutor, da filtragem e do processamento. Assim, uma subida aparentemente mais íngreme ou um pico mais estreito em um dos sistemas não deve ser interpretado isoladamente como superioridade de desempenho. A confirmação de atraso, erro ou concordância exige aquisição comparável e análise quantitativa.

C. Síntese Comparativa

De forma sintética, o sensor de turbina converte a rotação do rotor em pulsos relacionados ao fluxo e pode sofrer influência de inércia, atrito e rotação residual. O sensor piezoresistivo converte pressão/deformação em sinal elétrico e seu comportamento depende da dinâmica do transdutor, calibração, filtragem, offset e deriva. Em ambos os casos, a comparação de desempenho requer verificação/calibração e controle de qualidade; para o sistema piezoresistivo, a validação quantitativa requer ainda conversão rastreável para L/s frente ao fluxo de referência.

III. Resultados e discussão

Nos 951 pontos amostrados pelo sistema piezoresistivo, distribuídos em aproximadamente 16–20 ciclos, foi possível identificar de forma consistente as fases inspiratórias e expiratórias e os principais eventos temporais dos padrões produzidos em bancada. A frequência de 20 Hz forneceu uma resolução temporal de 50 ms por amostra para a inspeção morfológica realizada nesta etapa. Nos ensaios de esforço expiratório, as curvas de ambos os sistemas exibiram elevação do fluxo, formação de pico e posterior desaceleração. Nos padrões intermitentes/bifásicos, os sistemas permitiram reconhecer picos sucessivos separados por intervalos de menor fluxo. Nos testes de fluxo contínuo, observou-se manutenção de platô e retorno à linha de base. Esses achados sustentam apenas a correspondência morfológica dos eventos, não a equivalência das amplitudes ou do tempo de resposta.

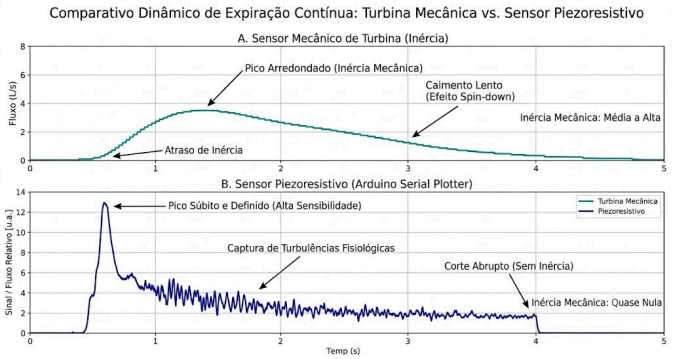

Figura 1. Turbina mecânica vs Sensor piezoresistivo

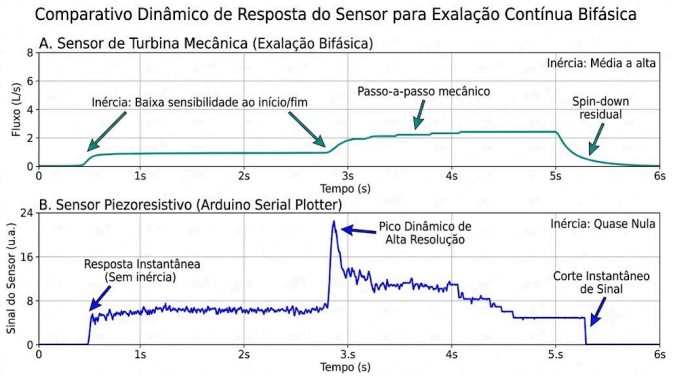

Figura 2. Comparação em Exalação Bifásica

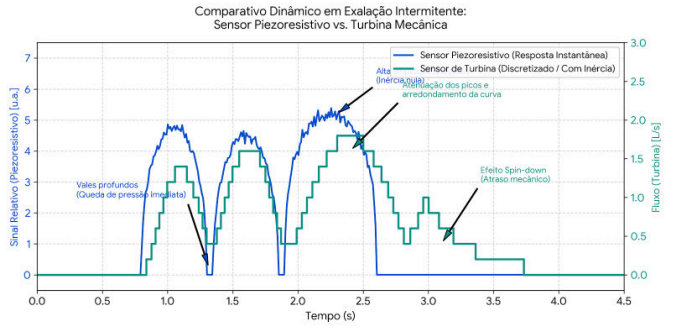

Figura 3. Comparação em Exalação intermitente

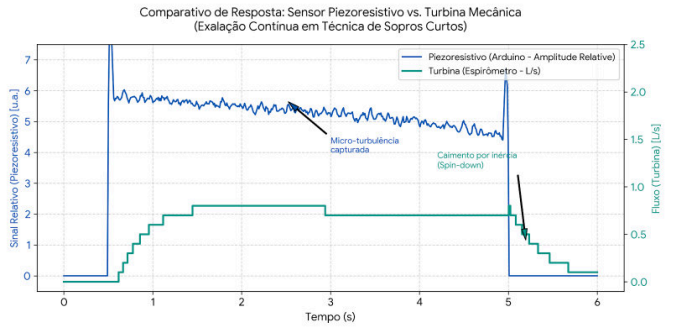

Figura 4. Comparação durante expiração contínua

A interpretação dos gráficos deve considerar que as escalas originais não estão integralmente padronizadas em L/s para os dois sistemas e que não houve aquisição simultânea. Por esse motivo, diferenças visuais de amplitude, inclinação ou posição do pico não foram convertidas em métricas de erro ou atraso. As figuras devem, portanto, ser lidas como descrição dos comportamentos esperados e observados, e não como prova quantitativa de maior sensibilidade, menor inércia ou melhor desempenho de um sensor. Esse cuidado é coerente com os princípios de padronização e controle de qualidade da espirometria, nos quais calibração, repetibilidade e rastreabilidade das medidas são essenciais para comparações instrumentais [2]–[7]. A literatura sobre sistemas portáteis e vestíveis também destaca a necessidade de validação do sinal antes de extrapolar o desempenho para aplicações de monitorização [11] [12]. A inspeção das curvas fluxo-tempo evidenciou diferenças entre os sinais obtidos pelo sensor piezoresistivo e pelo sensor mecânico de turbina, principalmente nas regiões de maior variação temporal do fluxo. Nos eventos de subida e formação do pico, observou-se diferença de amplitude e de posicionamento temporal entre as curvas, enquanto nos segmentos de fluxo mais estável houve maior aproximação do comportamento morfológico dos sistemas. Nos padrões intermitentes e bifásicos, ambos os sensores identificaram adequadamente a sucessão dos ciclos, embora tenham sido observadas diferenças na amplitude dos picos, na inclinação das fases de aceleração e desaceleração e no retorno à linha de base. Essas discrepâncias constituem, nesta etapa, um erro comparativo predominantemente morfológico, potencialmente associado às diferenças entre os princípios físicos de aquisição, à inércia mecânica da turbina, à resposta dinâmica do sistema piezoresistivo, à calibração e ao processamento do sinal. Dessa forma, os resultados atuais demonstram similaridade morfológica entre as curvas fluxo-tempo. Não se afirma que o sensor piezoresistivo tenha desempenho “compatível”, equivalência metrológica ou que já constitua alternativa ao sensor de turbina. Essas conclusões dependerão de nova aquisição quantitativa sob o mesmo fluxo de referência, com sinais em L/s, sincronização temporal e cálculo das métricas recomendadas pelo revisor.

Tabela I
DIFERENÇAS DE FUNCIONAMENTO E COMPORTAMENTO NA CURVA FLUXO-TEMPO

Aspecto	Sensor mecânico de turbina	Sensor piezoresistivo
Princípio de funcionamento	O fluxo de ar gira uma turbina; a rotação é convertida em sinal de fluxo.	A pressão ou deformação modifica a resistência elétrica do sensor, gerando um sinal proporcional.
Resposta ao início do fluxo	Pode apresentar pequeno atraso devido à inércia e ao atrito das pás.	Tende a responder rapidamente às mudanças de pressão, dependendo da calibração e da amostragem.
Pico de fluxo	Pode suavizar ou atrasar o pico quando há variação muito rápida do fluxo.	Pode identificar variações rápidas, mas o pico pode ser influenciado por ruído e filtragem.
Fase de desaceleração	A curva acompanha a redução da rotação da turbina de forma progressiva.	Acompanha a queda do fluxo, podendo apresentar pequenas oscilações eletrônicas.
Retorno à linha de base	Pode ocorrer de forma mais lenta pela rotação residual da turbina.	Pode ser mais rápido, porém sujeito à deriva da linha de base.
Comportamento geral da curva	Curva estável e amplamente utilizada como referência em espirômetros.	Pode reproduzir os principais eventos da curva, com pequenas diferenças morfológicas.
Principal diferença	Depende de componentes mecânicos móveis e sofre influência de inércia, atrito e desgaste.	Não depende de rotação mecânica, mas exige calibração, amplificação e processamento do sinal.

Nota: esta tabela resume o comportamento esperado dos sensores. A confirmação de diferenças de resposta, atraso e concordância depende de aquisição simultânea de dados e validação quantitativa.

IV. CONCLUSÃO

O ensaio de bancada permitiu descrever o comportamento das curvas fluxo-tempo de um sensor mecânico de turbina e de um sistema piezoresistivo submetidos a padrões respiratórios controlados por ventilador Servo-s. O sistema piezoresistivo foi adquirido a 20 Hz (50 ms por amostra), totalizando 951 amostras e aproximadamente 16–20 ciclos, sem participação de seres humanos. Ambos os sistemas permitiram reconhecer morfologicamente início do fluxo, pico, desaceleração, padrões intermitentes, platô e retorno à linha de base. Contudo, a ausência de aquisição simultânea e de padronização integral das séries na mesma unidade impede afirmar concordância, equivalência ou superioridade entre os sensores. Os resultados desta etapa devem ser interpretados exclusivamente como evidência de similaridade morfológica. Como continuidade, recomenda-se validação metrológica com o mesmo fluxo de referência aplicado aos dois sensores, aquisição simultânea ou ciclos rigorosamente reproduzíveis do Servo-s, padronização em L/s e pelo menos 10 ciclos por condição, reportando erro absoluto e percentual do pico, atraso temporal, RMSE, correlação, Bland-Altman, média, desvio-padrão e coeficiente de variação.

***Abstract*—This paper presents a theoretical and experimental study on the use of mmWave sensors for biomedical monitoring. The MR60BHA2 sensor was evaluated for respiratory and heart rate monitoring, while the MR60FDA2 sensor was tested for human presence and fall detection. Experiments were conducted under controlled conditions and in scenarios with possible interference, including humidity, Wi-Fi signals, obstacles, clothing layers, body position, ventilation, metallic objects, and different sensor settings. The results showed that the MR60BHA2 presented better performance in respiratory monitoring than in heart rate measurement, while the MR60FDA2 detected controlled falls but was affected by false positives and fast movements. These findings indicate that mmWave sensors have potential for homecare applications, provided that calibration, installation conditions, and environmental interference are carefully considered.**

***Index Terms*—mmWave, heart rate, respiratory rate, fall detection**

I. Introdução

Os sensores mmWave são dispositivos de sensoriamento que utilizam ondas eletromagnéticas na faixa de ondas milimétricas para detectar presença, movimento e pequenas variações de deslocamento sem a necessidade de contato físico com o alvo. Eles operam, em geral, na faixa de 30 GHz a 300 GHz, que corresponde a comprimentos de onda na ordem de milímetros. Seu funcionamento baseia-se na técnica *Frequency Modulated Continuous Wave* (FMCW), na qual um sinal eletromagnético é transmitido continuamente e refletido ao encontrar um alvo. Ao analisar a diferença de frequência e fase entre o sinal transmitido e o sinal recebido, é possível calcular a distância em relação ao objeto detectado e identificar pequenos movimentos [1].

Os sensores mmWave têm se mostrado promissores em aplicações biomédicas por permitirem a detecção de movimentos corporais sem contato direto com o paciente. Essa característica possibilita seu uso no monitoramento de sinais vitais, como respiração e batimentos cardíacos, na detecção de presença humana em ambientes internos, no reconhecimento de movimentos e atividades corporais e na identificação de eventos de risco, como quedas. Em ambientes hospitalares e de *homecare*, essas aplicações são relevantes para o acompanhamento de pacientes, idosos ou pessoas com mobilidade reduzida, pois permitem um monitoramento mais contínuo, discreto e menos dependente de dispositivos presos ao corpo [2], [3].

No mercado atualmente, existem vários sensores mmWave com diversas aplicações. Entre eles, destacam-se os sensores da linha MR60 da Seeed Studio, como o MR60BHA2, voltado à detecção de sinais vitais, e o MR60FDA2, projetado para a detecção de quedas, com um preço mais acessível [4], [5]. Além destes, fabricantes como Texas Instruments e Infineon oferecem soluções destinadas a aplicações industriais, como o IWR6843ISK, da Texas Instruments, que opera entre 60 e 64 GHz e possui quatro canais de recepção e três de transmissão, com campo de visão de 120° em azimute e 30° em elevação [6].

Apesar da variedade de sensores disponíveis e das aplicações já descritas na literatura, a avaliação prática desses dispositivos em cenários biomédicos ainda exige cuidado, especialmente em condições próximas ao uso real. Em aplicações hospitalares e de *homecare*, fatores como posicionamento do sensor, distância em relação ao usuário, presença de obstáculos, umidade, ventilação, sinais eletromagnéticos e movimentos involuntários podem interferir nos dados coletados e comprometer a confiabilidade das medições. Por isso, estudos experimentais com diferentes condições de interferência são importantes para compreender os limites de uso desses sensores e indicar formas mais adequadas de instalação e operação [7], [8], [9].

Dessa forma, esta pesquisa tem como objetivo realizar um estudo teórico-experimental sobre o funcionamento e as

Fundação de Amparo a Pesquisa de Minas Gerais (Fapemig)

possíveis aplicações dos sensores mmWave na Engenharia Biomédica. Para os testes práticos, foram utilizados os sensores MR60BHA2 [4], aplicado ao monitoramento de sinais vitais, e MR60FDA2 [5], utilizado na detecção de quedas e presença humana.

II. METODOLOGIA

Primeiramente, foram levantados artigos sobre o funcionamento e aplicação dos mmWaves e dos sensores disponíveis no mercado, com base em palavras-chaves como: *milimeter waves*, *60 GHz*, *Radar*, *medical applications*. Também foi pesquisado sobre possíveis interferências que os sensores poderiam sofrer.

Para a escolha dos sensores foram considerados a facilidade de uso, documentação e custo. Assim, foram selecionados os sensores MR60BHA2 [4] e o MR60FDA2 [5] da Seeed Studio. Estes sensores são integrados ao microcontrolador ESP32 e utilizam da técnica FMCW para realizar as medidas dos parâmetros. Para o desenvolvimento foi utilizado a linguagem C e a IDE do Arduino com a biblioteca da Seeed Studio disponibilizada pelo Github [4] [5], juntamente com a linguagem de programação Python responsável por coletar os dados do terminal do Arduino IDE, converte-los em um arquivo .csv e gerar um gráfico para análise. Por fim, testes práticos preliminares foram realizados para explorar o uso dos sensores. Ressalta-se que todos os testes foram realizados apenas para validação técnica preliminar, sem coleta dados sensíveis ou intervenção clínica, e apenas os autores participaram voluntariamente e consentiram com o estudo. As metodologias adotadas para cada sensor são detalhadas a seguir, e um resumo geral encontra-se na Tabela I.

TABELA I
RESUMO DOS TESTES EXPERIMENTAIS.

Teste	**Condição experimental avaliada**
Sensor MR60BHA2	
Ambiente normal	Condição de referência, sem interferências intencionais
Frequência respiratória (RPM)	Comparação com ventilador pulmonar em 16 RPM
Frequência cardíaca (BPM)	Comparação com monitor multiparamétrico
Umidade	Presença de vapor d'água entre o sensor e o voluntário
Interferência de Wi-Fi	Operação na presença de roteador Wi-Fi em diferentes distâncias
Obstáculos	Presença de superfícies de vidro ou acrílico entre o sensor e o voluntário
Camadas de roupa	Aquisição com duas camadas de roupa
Posição e ângulo	Avaliação em diferentes posições e ângulos em relação ao sensor
Sensor MR60FDA2	
Detecção de presença	Entrada e saída do indivíduo no campo de detecção
Detecção de queda	Queda simulada e posterior retorno à posição inicial
Posição corporal	Quedas simuladas em diferentes posições corporais
Movimentos semelhantes à queda	Movimentos bruscos de sentar e ajoelhar
Passagem em alta velocidade	Deslocamento rápido do indivíduo pelo campo de detecção
Sensibilidade e limiar de detecção	Avaliação sob diferentes configurações de sensibilidade e condições de ventilação
Objetos metálicos	Presença de objetos metálicos próximos ao corpo
Interferência entre sensores	Avaliação da influência do MR60FDA2 sobre o MR60BHA2 em diferentes distâncias e ângulos

A. MMwave na avaliação de sinais vitais

O sensor *MR60BHA2* foi empregado para investigar a viabilidade do monitoramento sem contato de sinais vitais, especificamente a frequência respiratória e a frequência cardíaca. O dispositivo fornece duas categorias de dados: a primeira, relacionada à respiração, apresenta o sinal da fase respiratória, correspondente às variações de inspiração e expiração, em formato gráfico, além do valor numérico de respirações por minuto (RPM); a segunda, referente à atividade cardíaca, retorna diretamente os valores de batimentos por minuto (BPM).

Para validar as estimativas fornecidas pelo sensor, foram utilizados equipamentos médicos de referência. A frequência cardíaca foi comparada às medições obtidas por um monitor multiparamétrico *LiFEtouch 10* (Lifemed) [10], enquanto a frequência respiratória foi validada por meio de um ventilador pulmonar *FlexiMag* (Magnamed) [11], configurado para 16 RPM. O ventilador foi acoplado a um pulmão artificial *Maquet TestLung 6006832* [13], instalado em uma incubadora neonatal *Line 4* (Olidef Medical) [12], de modo a simular um ambiente controlado e padronizado.

A.1) *Ambiente Normal*: Com o objetivo de estabelecer valores de referência para leitura da fase respiratória em ambiente sem interferências, o sensor foi posicionado a 0,5m de distância de um dos autores. Em paralelo, realizou-se a mesma medição em um pulmão artificial instalado na incubadora neonatal. Essa configuração permitiu comparar os resultados obtidos em condições reais com aqueles simulados em ambiente padronizado.

A.2) *Teste de RPM*: Para validar a frequência respiratória, utilizou-se a incubadora neonatal *Line 4*, equipada com pulmão artificial *Maquet TestLung*, conectado ao ventilador *FlexiMag*. O sistema foi empregado para simular a respiração de um recém-nascido e avaliar a viabilidade da utilização do sensor no monitoramento respiratório sem contato. O sensor foi fixado no teto da cúpula. O ventilador foi configurado para 16 RPM e foram realizadas cinco medições. Os resultados foram analisados pelo método de Bland–Altman, considerando a diferença entre os valores medidos pelo sensor e o valor de referência de 16 RPM.

A.3) *Teste de BPM*: Este teste buscou validar a medição da frequência cardíaca sem contato físico. A posição ideal foi definida conforme as instruções do manual do dispositivo [5], que recomendam distância entre 0,5 e 1,5 m na altura do tórax (Fig. 1). Para comparação, um dos autores foi conectado simultaneamente ao eletrocardiograma do monitor multiparamétrico

LiFEtouch 10 [10], permitindo a aquisição síncrona dos dados pelos dois equipamentos. Os dois equipamentos realizaram aquisições simultâneas, sendo realizadas cinco medições, cada uma com duração mínima de um minuto, repetidas de três a cinco vezes. Os resultados foram analisados pelo método de Bland–Altman, considerando a diferença entre os valores obtidos pelo sensor e pelo monitor multiparamétrico.

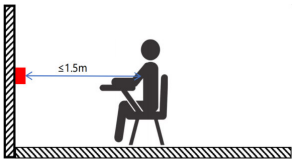

Fig. 1. Posicionamento do sensor MR60BHA2 para medição de sinais vitais.

A.4) *Teste de Umidade*: Uma das aplicações para o mmWave é avaliação dos sinais em cenários de *homecare* onde o uso dispositivos vestíveis de monitoramento nem sempre é possível, como por exemplo, em chuveiros. Para simular esses cenários de *homecare*, um dos autores posicionou-se diante do sensor enquanto uma panela com água em ebulição foi colocada entre ambos, reproduzindo a presença de vapor d'água e permitindo observar seus efeitos sobre a qualidade do sinal da fase respiratória.

A.5) *Teste de sinal Wi-Fi*: Considerando que ambientes domésticos geralmente possuem roteadores em funcionamento, avaliou-se a influência desse tipo de sinal no desempenho do sensor [16]. Foi utilizado um roteador *TP-Link EC220-G5* [14], operando em 2.4 GHz e 5 GHz. O dispositivo foi inicialmente desligado e ligado após 30 segundos de aquisição, e posteriormente foram realizados ensaios em diferentes distâncias (0,1 m, 0,6 m e 1,0 m) para verificar a interferência sobre o sinal de fase respiratória.

A.6) *Teste com vidro e acrílico*: Para avaliar a influência de obstáculos físicos na propagação e leitura dos sinais, foram posicionadas placas de acrílico e vidro entre o sensor e o voluntário durante a captação da frequência respiratória.

A.7) *Teste de camadas de roupa*: Para analisar o impacto de múltiplas camadas de vestimenta, um dos autores utilizou duas blusas sobrepostas. As medições foram realizadas a 0,5 m e 1,0 m de distância, verificando se o aumento da espessura do tecido compromete a precisão das leituras da fase respiratória.

A.8) *Teste de diferentes posições*: Este teste avaliou a influência da orientação corporal em relação ao sensor. Um dos autores foi posicionado a 45°, de perfil e de costas, e os resultados foram comparados à posição frontal, utilizada como referência. A análise permitiu verificar como diferentes ângulos e posturas afetam a qualidade do sinal respiratório detectado pelo *MR60BHA2*.

B. MMWave na detecção de quedas

Além dos testes realizados com o sensor MR60BHA2, foram realizados estudos práticos com o sensor MR60FDA2, utilizado para detecção de quedas e presença estática. Os testes foram conduzidos com o sensor posicionado na vertical, conforme mostra a Fig. 2, e seguiram uma metodologia padronizada, com tempos fixos e altura de instalação predefinida. O campo de detecção considerado foi de 3 m × 3 m × 3 m, conforme recomendado pelo fabricante. Os experimentos foram repetidos três vezes por condição, a fim de aumentar a confiabilidade dos resultados.

A metodologia estabelecida nos testes consistiu na entrada do usuário no campo de visão do sensor aos 5 s, permanência em posição ereta até os 10 s, seguida da simulação de queda, permanência no solo debaixo do sensor até os 40 s e posterior retorno à posição inicial, seguido da saída do campo de detecção aos 60 s. Os tempos predefinidos nessas etapas foram mantidos constantes em todos os experimentos com o sensor MR60FDA2.

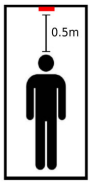

Fig. 2. Posicionamento do sensor MR60FDA2 para detecção de quedas.

As medições para avaliar o desempenho dos testes foram realizadas com auxílio de um cronômetro, ao final foi realizado o cálculo da média dos valores obtidos nos testes. Para a análise desses parâmetros, foram gerados gráficos temporais com o objetivo de representar o comportamento da detecção ao longo de cada experimento. Nesses gráficos, o eixo horizontal corresponde ao tempo em segundos, enquanto as marcações verticais indicam os principais eventos observados durante os testes, como a entrada do indivíduo no campo de detecção, a simulação da queda, o retorno à posição inicial e a saída do campo de visão do sensor.

Foram analisados dois tipos principais de gráfico: o de presença humana, utilizado para verificar o tempo de entrada e saída do indivíduo no campo de detecção, e o de estado humano, utilizado para avaliar a identificação da queda e o retorno ao estado normal. A partir dessas marcações, foram calculados os intervalos entre o evento realizado e a resposta apresentada pelo sensor. Mantida a metodologia padronizada, foram analisados os seguintes parâmetros e condições de teste:

B.1) *Tempo médio de detecção de presença*: Foram analisados os tempos entre a entrada do indivíduo no campo de visão do sensor e o momento em que a presença foi identificada, bem como o tempo necessário para cessar a detecção após a saída do indivíduo do raio de visão do sensor.

B.2) *Tempo médio de detecção de queda e retorno ao estado normal*: foram registrados o tempo para acusar uma queda e o intervalo que o sensor levou para reconhecer que a pessoa havia se levantado após a queda, ou seja, o retorno do indivíduo ao estado normal.

B.3) *Influência da posição corporal na detecção de queda*: foram simuladas quedas reais controladas nos cenários frontal, dorsal e lateral, a fim de verificar a influência da orientação do corpo na detecção. Também foram executados movimentos cotidianos parecidos com uma queda, como sentar-se bruscamente com a coluna de maneira errada e ajoelhar-se no chão de maneira agressiva, com o objetivo de verificar a ocorrência de falsos positivos.

B.4) *Teste passando correndo*: travessia rápida do indivíduo pelo campo de visão do sensor, passando correndo abaixo do dispositivo, a fim de avaliar a detecção de movimentos de curta duração e alta velocidade.

B.5) *Testes com a sensibilidade e threshold*: variação dos parâmetros do próprio sensor, incluindo diferentes graus de sensibilidade e valores de limiar de detecção (threshold), mantendo o ambiente experimental padronizado. Para avaliar a interferência externa do ambiente, foi utilizada ventilação forçada em diferentes intensidades, com o intuito de observar possíveis alterações nos dados coletados pelo sensor. Os dados coletados em formato csv foram organizados em uma tabela comparativa no Excel, permitindo comparar as configurações principalmente em relação à ocorrência de atrasos na detecção, falhas de leitura ou resultados indevidos.

B.6) *Testes com objetos metálicos*: inserção de objetos metálicos, sendo eles uma caixa metálica e uma chave de fenda, sobre o corpo do indivíduo, a fim de avaliar se superfícies reflexivas poderiam interferir no campo de visão do sensor.

B.7) *Interferência entre sensores*: o MR60FDA2 foi posicionado em direção ao MR60BHA2, e os testes foram repetidos variando a distância e o ângulo entre os sensores, com o objetivo de verificar possíveis alterações no desempenho da detecção de dispositivos operando na mesma faixa de frequência.

III. Resultados e Discussão

Os resultados da pesquisa bibliográfica mostram o potencial dos sensores mmWave. O artigo dos autores A. Soumya, C. et al. [1], mostra que os avanços recentes na tecnologia dos mmWaves podem ser aplicados em diversas áreas como: automação, robótica, industrial, saúde, segurança, transporte civil e machine learning. Outra pesquisa de Abdullah K. Alhazmi et al. [3], aborda sobre o uso de mmWaves para detecção humana, com destino para ambientes *homecare*, demonstrando que os sensores são capazes de detectar cinco estados de uma pessoa: deitada, parada, andando, sentando-se e caindo em tempo real. Além de mostrarem modelos de sensores que podem ser aplicados na área biomédica, como os da Texas Instruments. E a publicação de Honglin et al. [2], descreve brevemente as aplicações destes sensores na medicina, destacando a medição de sinais vitais e quedas, e, explica possíveis riscos biológicos para a saúde, como genotoxidade e efeitos biotérmicos de aumento na temperatura das moléculas de água na pele e córnea.

A. Testes do sensor MR60BHA2

A.1) *Ambiente Normal*: Os resultados mostram que a fase da respiração fica entre valores de -10 a +10, conforme mostra a Fig. 3, representando a expiração com valores negativos e inspiração sendo valores positivos, com leves interferências devido à pequenos movimentos da própria pessoa, ou fatores naturais do ambiente (pequenas correntes de ar, pessoas, ondas de sinais telefônicos e Wi-Fi etc.).

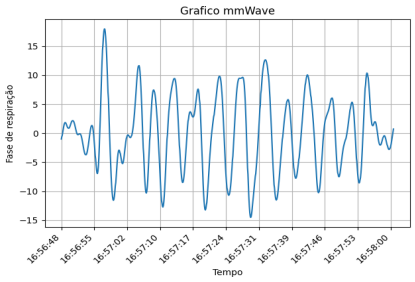

Fig. 3. Sinal da fase respiratória obtido pelo sensor MR60BHA2.

O resultado desse teste, mostrou-se muito próximo dos valores medidos com o pulmão de teste no interior da incubadora, como mostra a Fig. 4, ambiente com menor interferência. Dessa forma, concluiu-se que esses são valores padrões de um processo de respiração.

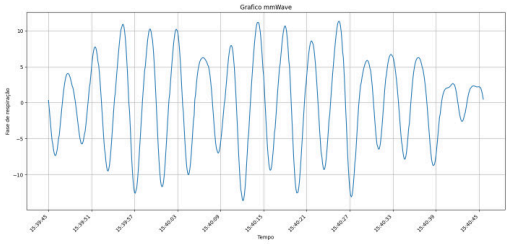

Fig. 4. Sinal da fase respiratória no ensaio com o pulmão artificial TestLung no interior da incubadora neonatal.

A.2) *Teste de RPM*: Para determinar a taxa de respiração por minuto o sensor MR60BHA2 utiliza do príncipio de FMCW, o algoritmo interno do sensor processa os deslocamentos do tórax, a fim de identificar a periodicidade da respiração, e converte a taxa de movimento em RPM. Os resultados obtidos pelo sensor MR60BHA2 foram comparados com a referência de 16 RPM por meio da análise de Bland–Altman. O resultado é apresentado na Figura 5.

O resultado obtido nos testes de respiração apresentou pequena variação em relação ao valor de referência. A análise de Bland–Altman indicou que aproximadamente 95% das diferenças entre as medições do MR60BHA2 e a referência de 16 RPM estiveram entre $-1,13$ RPM e $+2,43$ RPM, com viés médio de $0,65$ RPM. Esse viés positivo indica uma tendência do sensor a superestimar ligeiramente a frequência respiratória em relação ao valor de referência. Apesar dessa diferença, a variação observada foi pequena, indicando boa

concordância entre as medições do sensor e a frequência respiratória configurada no pulmão artificial nas condições avaliadas.

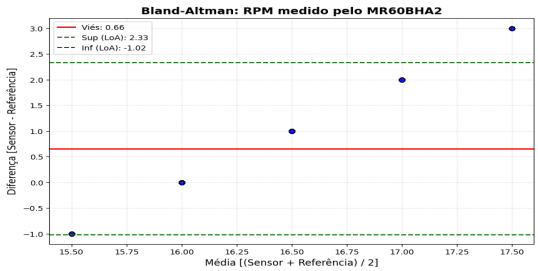

Fig. 5. Gráfico de Bland–Altman comparando a frequência respiratória medida pelo sensor MR60BHA2 com a referência fixa de 16 RPM.

A.3) *Teste de BPM*:

Para a frequência cardíaca, os resultados obtidos pelo sensor MR60BHA2 foram comparados com as medições realizadas pelo monitor multiparamétrico LiFEtouch 10 por meio da análise de Bland–Altman. O resultado é apresentado na Fig. 6.

Observa-se que o sensor MR60BHA2 apresentou uma média com valores superiores aos medidos pelo monitor multiparamétrico em todos os ensaios. Com a média de erro sendo +4,62 BPM, variando entre +23,57 e -14,32 BPM. Esse comportamento está de acordo com a documentação disponibilizada pela Seeed Studio [4], que informa que a estimativa de frequência cardíaca apresenta menor precisão quando o indivíduo não está em repouso ou dormindo.

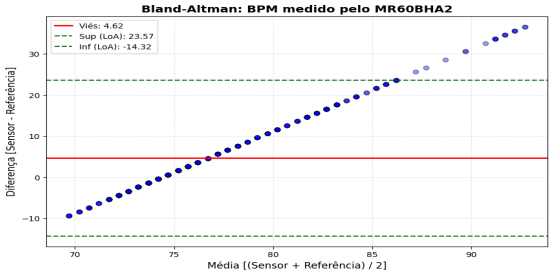

Fig. 6. Gráfico de Bland-Altman comparando a frequência cardíaca (BPM) medida pelo sensor MR60BHA2 com a referência fixa do equipamento (74,3 BPM).

A.4) *Teste de Umidade*:

No experimento realizado, foi demonstrado que o vapor d'água atrapalha consideravelmente na leitura dos dados, evidenciou-se perdas de amplitude, sendo a consequência do sinal percorrido no vapor, conforme mostra a Fig. 7.

Esse resultado é respaldado pela literatura, já que a umidade é um grande exemplo de interferência, como foi citado no artigo [15], o vapor de água absorve a energia das ondas vindas do sensor.

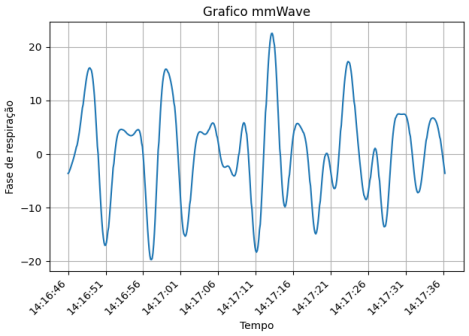

Fig. 7. Sinal da fase respiratória obtido na presença de vapor d'água entre o sensor e o alvo.

A.5) *Teste de sinal Wi-Fi*:

A Fig. 8 apresenta o comportamento do sinal da fase respiratória antes e após o acionamento do roteador Wi-Fi após 30 segundos. Observa-se que, após sua ativação, indicado pela linha vermelha, ocorreram interrupções mais frequentes e perda de amplitude no sinal, indicando a influência da interferência eletromagnética sobre as medições.

Os ensaios realizados com diferentes distâncias mostraram que a interferência foi mais pronunciada quando o sensor estava muito próximo ao roteador. À medida que a distância aumentou, observou-se redução da degradação e perdas do sinal. Nos testes realizados, uma separação mínima de aproximadamente 1 m foi suficiente para minimizar os efeitos da interferência, diminuindo as perdas de amplitude, indicado na Fig. 9, portanto, essa distância é adequada para a operação do sensor em ambientes com redes Wi-Fi.

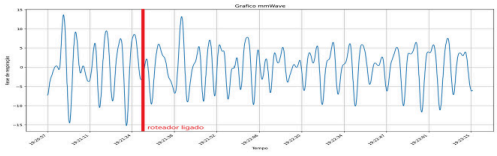

Fig. 8. Sinal da fase respiratória antes e após o acionamento do roteador Wi-Fi.

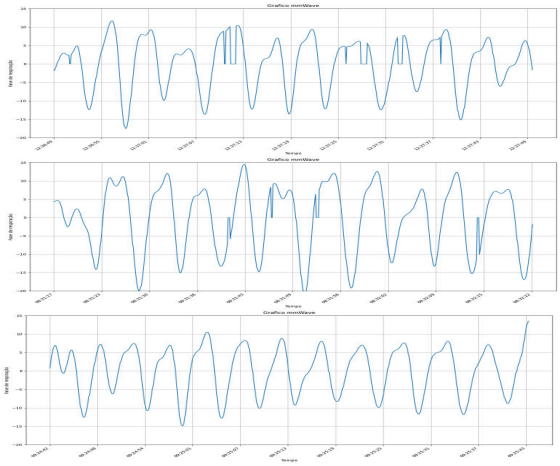

Fig. 9. Sinais da fase respiratória obtidos com o sensor posicionado a 0,1 m, 0,6 m e 1,0 m do roteador Wi-Fi, respectivamente.

A.6) *Teste com vidro e acrílico*: Avaliando a influência de materiais, como acrílico e vidro, evidenciado na Fig. 10 na qualidade do sinal da fase respiratória.

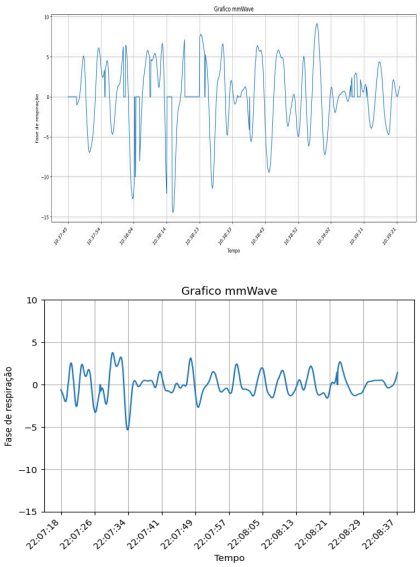

Fig. 10. Sinal da fase respiratória obtido com uma placa de acrílico e vidro (respectivamente) posicionada entre o sensor e o voluntário.

Observa-se que ambos os materiais provocaram atenuação significativa do sinal, reduzindo sua amplitude em relação à condição de referência. Mesmo com espessura de 0,5 cm, as placas interferiram na propagação das ondas, dificultando a detecção das variações associadas à respiração. Esse comportamento está de acordo com o descrito na literatura [17], que demonstra que materiais como vidro, madeira e metais geram interferências nos sensores mmWave.

A.7) *Teste de camadas de roupa*:

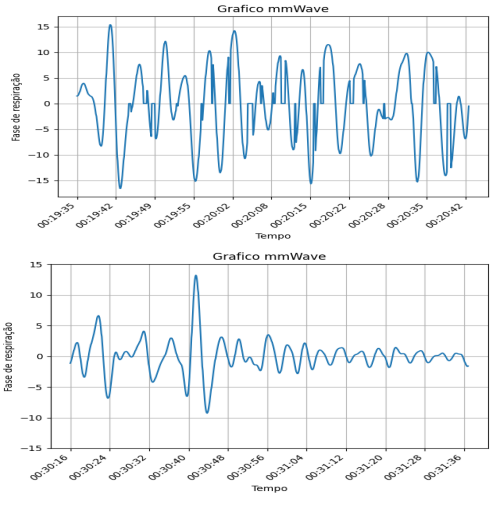

Fig. 11. Sinal da fase respiratória obtido com o voluntário utilizando duas blusas, a uma distância de 0,5 m e 1m do sensor, respectivamente.

Observou-se que a utilização de duas blusas provocou atenuação do sinal da fase respiratória, reduzindo sua amplitude em relação à condição de referência. Esse resultado indica que o aumento da espessura das camadas de tecido entre o sensor e o tórax compromete a qualidade do sinal recebido pelo MR60BHA2. Verificou-se também que a combinação entre o aumento da distância do sensor em relação ao indivíduo e a presença das camadas de roupa, intensifica a atenuação do sinal, resultando na diminuição da amplitude da fase respiratória, como mostra a Fig. 11.

A.8) *Teste de diferentes posições do voluntário*:

Os resultados da Fig. 12 mostraram que a posição a 45° apresentou comportamento semelhante ao da posição frontal, permitindo a identificação do sinal respiratório. Em contrapartida, as posições de perfil e de costas resultaram em maior atenuação do sinal e dificultaram a identificação das variações associadas à respiração, indicando que a orientação do voluntário influencia a qualidade das medições realizadas pelo MR60BHA2.

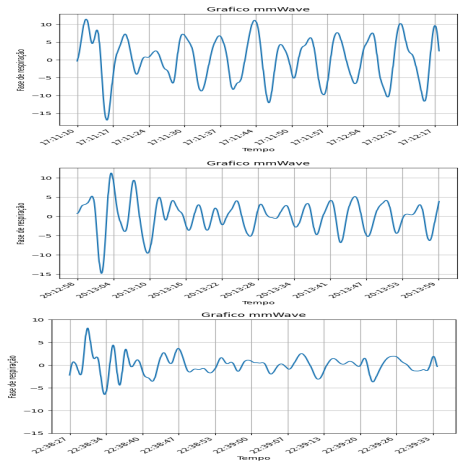

Fig. 12. Sinais da fase respiratória obtidos com o voluntário posicionado a 45°, de perfil e de costas em relação ao sensor, respectivamente.

B. Testes do sensor MR60FDA2

A Fig. 13 apresenta um exemplo dos gráficos temporais utilizados nessa análise.

B.1) *Tempo médio de detecção de presença*: Nos testes realizados, o sensor apresentou resposta rápida para detecção de presença humana, com tempo médio de aproximadamente 1,55 segundos. Já, o tempo necessário para interromper a detecção após a saída do indivíduo do campo de visão foi maior, com média de 18,98 segundos. Ainda assim, esse comportamento deve ser considerado em aplicações domiciliares ou hospitalares que dependem de resposta rápida, principalmente em sistemas de presença em tempo real.

B.2) *Tempo médio de detecção de queda e retorno ao estado normal*: Tempo médio de detecção de queda e retorno ao estado normal: Nos testes realizados, esse processo apresentou tempo médio de 20,48 segundos. Os resultados mostram que o MR60FDA2 conseguiu identificar a queda, mas apresentou maior atraso para reconhecer a mudança de estado após o

usuário voltar à posição inicial. Assim, o ensaio evidenciou que a detecção da queda ocorreu, porém a atualização posterior do estado do usuário não foi imediata.

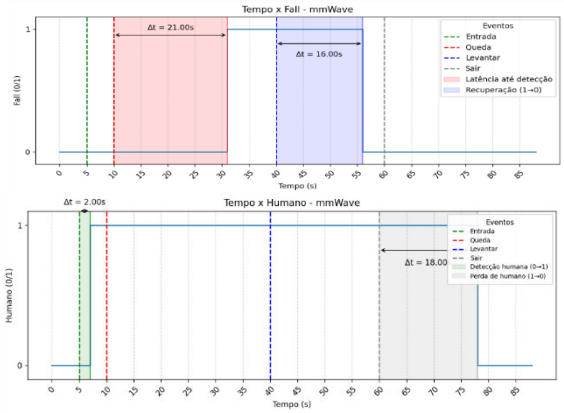

Fig. 13. Gráficos temporais do sensor MR60FDA2 durante teste de queda frontal.

B.3) *Influência da posição corporal na detecção de queda*: Nos testes de quedas reais controladas, o sensor apresentou mesmas detecções nos cenários frontal, dorsal e lateral, com ocorrência de detecção em todos os testes realizados. Esse comportamento está de acordo com os estudos que demonstram a capacidade de sistemas mmWave de reconhecer atividades humanas e detectar queda em tempo real [3] .Os resultados indicam que o MR60FDA2 foi capaz de reconhecer padrões típicos de queda quando há mudança rápida de estado e variações de alturas em relação ao indivíduo e o sensor posicionado na vertical. Dessa maneira conclui-se que a posição não alterou nos resultados coletados.

No entanto, ao realizar movimentos parecidos com uma queda, observou-se que os movimentos cotidianos avaliados podem gerar falsos positivos. Esses casos particulares são importantes para aplicações reais, pois ações comuns no dia a dia podem gerar um alarme falso, assim reduzindo a confiabilidade do sensor se não houver um ajuste preciso nas suas configurações ou uma integração com uma lógica adicional de validação, por exemplo, utilizado inteligência artificial.

B.4) *Teste passando correndo*: No cenário em que o indivíduo atravessava rapidamente o campo de visão do sensor, não houve detecção de presença pelo sensor. Esse comportamento indica uma possível limitação do MR60FDA2 para reconhecer movimentos de curta duração e alta velocidade, especialmente quando o indivíduo permanece pouco tempo dentro da área monitorada. Dessa forma, sua aplicação em ambientes com circulação intensa ou movimentações rápidas deve considerar essa condição como um possível fator de falha na detecção.

B.5) *Testes com a sensibilidade e threshold*: Os parâmetros de threshold e sensibilidade foram variados por serem configurações disponíveis no MR60FDA2 e diretamente relacionados ao processo de detecção de quedas [5]. Conforme apresentado nas Figs. 14 e 15, com ventilação em baixa potência, threshold 0,9 e sensibilidade 20, o sensor apresentou latência de 22,00 s para detecção da queda, 16,00 s para retorno ao estado normal, 2,00 s para detecção de presença e 19,00 s para cessar a detecção após a saída do indivíduo. Na Fig. 14, com ventilação em alta potência, threshold 1,0 e sensibilidade 20, foram observados 16,00 s para detecção da queda, 26,00 s para retorno ao estado normal, 2,00 s para detecção de presença e 6,00 s para cessar a detecção. Esses resultados indicam alteração nos tempos de resposta do MR60FDA2 entre as duas condições, principalmente no retorno ao estado normal, que aumentou de 16,00 s para 26,00 s com a ventilação em alta potência.

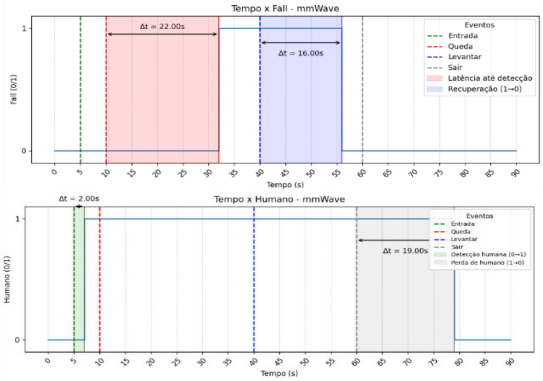

Fig. 14. Gráficos temporais do sensor MR60FDA2 com ventilação em baixa potência, threshold 0,9 e sensibilidade 20.

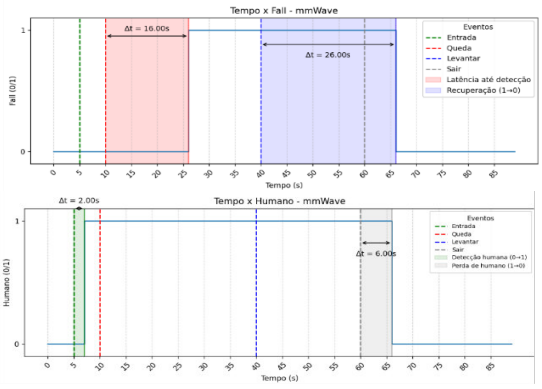

Fig. 15. Gráficos temporais do sensor MR60FDA2 com ventilação em alta potência, threshold 1,0 e sensibilidade 20.

B.6) *Testes com objetos metálicos*: Como o sensor depende da reflexão do sinal, foram observados poucos ruídos durante os testes; no entanto, quando os objetos metálicos estavam muito próximos do sensor, ocorreram alguns falsos positivos. Dessa forma, pode-se concluir que a interferência foi baixa nas condições avaliadas, mas a proximidade direta de objetos metálicos com o sensor deve ser evitada em aplicações reais.

De maneira geral, os testes realizados com o sensor MR60FDA2 indicam que o dispositivo foi capaz de detectar quedas e presença humana em cenários controlados,

compatível com o que foi pesquisado [5]. No entanto, seu desempenho e sua confiabilidade dependeram diretamente do tipo de movimento realizado, das condições do ambiente e da configuração dos parâmetros de sensibilidade e limiar de detecção. Movimentos rápidos ou semelhantes a quedas, como sentar-se bruscamente, ajoelhar-se de forma rápida ou passar correndo abaixo do sensor, podem gerar falsos positivos ou falhas de detecção. Dessa forma, a aplicação do MR60FDA2 em ambientes domiciliares ou hospitalares exige calibração adequada, padronização do local de instalação e cuidado com fatores externos, como ventilação direta e objetos metálicos muito próximos ao sensor.

IV. Conclusão

O objetivo desta pesquisa visou analisar a viabilidade da aplicação dos sensores mmWaves em contextos da Engenharia Biomédica. Uma das principais aplicações avaliadas foi o uso em ambientes *homecare*, por permitir monitoramento sem contato. Foram realizados testes com o sensor MR60BHA2, voltado à medição de sinais vitais, e com o sensor MR60FDA2, aplicado à detecção de presença humana e quedas. Os resultados demonstraram que o desempenho dos sensores pode ser comprometido em ambientes com elevada presença de interferências, como umidade, correntes de ar, sinais Wi-Fi ou obstáculos no campo de visão do sensor, pois essas condições podem aumentar as taxas de erro e a ocorrência de falsos positivos.

Entretanto, em um ambiente limpo e com menos interferências no sinal, é possível coletar dados com resultados mais próximos do real, com pequenos erros, causados por movimentos da própria pessoa sendo medida, principalmente com o MR60BHA2, que mede a respiração e batimentos de forma mais sensível.

Em relação à detecção de quedas, o sensor MR60FDA2 conseguiu identificar quedas frontais, dorsais e laterais nos testes realizados em ambiente controlado. Entretanto, movimentos cotidianos semelhantes a uma queda, como sentar-se ou ajoelhar-se bruscamente, podem provocar falsos positivos, enquanto movimentos muito rápidos podem não ser detectados. Dessa forma, embora o sensor apresente potencial para aplicações de monitoramento, seu uso exige calibração adequada e padronização do ambiente para aumentar a confiabilidade dos resultados.

Os resultados obtidos indicam que a tecnologia mmWave apresenta potencial para aplicações de monitoramento sem contato em engenharia biomédica e ambientes de *homecare*. Como trabalhos futuros, sugere-se o desenvolvimento de estratégias para mitigar as interferências observadas, além do aprimoramento dos algoritmos de processamento, visando aumentar a precisão das medições e a confiabilidade das estimativas dos sinais vitais.

***Abstract*—Sensores indutivos, especialmente os com ausência de núcleo ferromagnético, são mais sensíveis à influência do corpo humano uma vez que as linhas de campo são mais dispersas e os valores concentrados de indutâcia e capacitância são menores. Desta forma, o ensaio e teste de tais sensores práticos depende da presença do corpo humano, o quê dificulta por vezes a execução e a repetibilidade das medidas. O objetivo deste trabalho é apresentar um arranjo utiizando um plano terra e uma bobina com núcleo de ar em autorressonância, de forma que ao impor diferetes condições de contorno no sistema, pode-se medir o módulo da impedância e a fase elétrica da bobina sensora em um analisador de impedâncias, demonstrando assim a viabilidade de se utilizer o arranjo em substituição inicial aos testes com corpo humano. Além disso, o efeito do aumento da capacitância influenciada por efeitos externos é avaliada. As medições confirmam a teoria proposta ao apresentar correlações maiores que 0,8 e erros relativos menores que 3% para os casos de interesse.**

Palavras chave— sensores indutivos, autorressonância, plano terra, biotelemetria

I. INTRODUÇÃO

A biotelemetria consiste na medição e monitoração de parâmetros fisiológicos a distância. De modo a causar a menor interferência possível na rotina e no indivíduo sob observação, dentro do campo da biotelemetria encontram-se técnicas de comunicação com a unidade sensora, como por exemplo, a técnica de comunicação passiva, na qual não necessita-se de fonte própria de alimentação acoplada ao sensor. Isto possibilita uma menor dimensão da unidade sensora, além de aumentar a vida útil do sensor e evitar o risco de danos a um paciente caso ocorra o vazamento do conteúdo químico da bateria. Grandezas como pressão [1], posição, deslocamento linear e angular são comumente medidas com este tipo de sensor, sendo que destes valores podem se extrair parâmetros tais como, elasticidade e deformações de tendões [2] , frequência cardíaca [3], pressões intra-oculares, dentre outras.

Um importante e relativamente novo tipo de sensor utilizado na Biotelemetria passiva é o sensor indutivo autorressonante [4]. O princípio de operação deste sensor é modular a frequência de autorressonância da bobina (f_o) de acordo com o parâmetro medido, e portanto não se faz necessária a adição de um capacitor para que se obtenha a ressonância. Desta maneira, este tipo de sensor pode possuir apenas um componente e possuir pequenas dimensões.

Em [5] foi proposto um sensor de deslocamento autorressonante, que utiliza a modulação da frequência de autorressonância de uma bobina com núcleo de ar, de acordo com a variação do seu comprimento longitudinal (H) ou espaçamento entre espiras. O sensor consiste em uma bobina com núcleo de ar enrolada em torno de um tubo de látex, fixada apenas nas suas extremidades (primeiras e últimas espiras). O tubo sofre a deformação alongando a bobina e variando a sua frequência de autorressonância. Ainda, apresentou-se uma possível aplicação para uso em pletismografia. Entretanto, notou-se que uma vez que o sensor se baseia em autorressonância, isto é, não possui capacitor externo para concentrar as linhas de campo elétrico, e além disso, utiliza núcleo de ar, tornando as linhas de campo magnético mais dispersas, a influência do corpo humano alterou sensivelmente a impedância e a frequência de ressonância do mesmo.

Neste estudo, um ensaio experimental é conduzido de modo a avaliar a possibilidade de se testar o sensor autorressonante por onda estacionária em bancada, sem a presença obrigatória do corpo humano, melhorando assim a repetitividade dos ensaios. Para isto, foi introduzido um plano terra nas proximidades do sensor com o intuito de simular os efeitos do corpo humano. Adicionalmente, outros testes foram feitos de maneira a observar os efeitos da presença de aterramento ligado ou não ao plano terra, e a sua consequente influência nas curvas de impedância, bem como uma avaliação da influência de corpos externos na capacitância concentrada e na frequência de ressonância do sensor.

II. DESENVOLVIMENTO

Bobinas com núcleo de ar e de comprimento longitudinal H relativamente longos, isto é, com uma relação

entre comprimento e diâmetro (D) em geral maior do que 1, podem apresentar frequência de ressonância por onda estacionária. Isto deve-se ao fato de que a bobina quando possui dimensões apreciáveis em relação ao comprimento de onda (λ) suporta a propagação de uma onda com velocidade de fase e comprimento de onda característicos ao longo do seu eixo longitudinal [6]. Neste caso a bobina passa a se comportar como um guia de onda, e quando em ressonância trata-se portanto de um ressonador. No caso de uma bobina com ambas as extremidades abertas ou fechadas (conectada a um gerador por exemplo), esta comporta-se como um ressonador de meia onda. Neste caso existem máximos e mínimos de tensão (V) ou corrente (I), dependendo das condições de contorno do sistema (extremidades abertas ou fechadas) [6]. Desta forma, devido a existência de variações apreciáveis de fase ao longo do próprio comprimento da bobina, um analisador de impedâncias pode registrar ângulos de fase maiores que 90^o, e a frequência de ressonância (fase igual 0^o) ocorre na inversão de fase de $+180^o$ para -180^o [6]. Este fenômeno pode ser observado na Figura1, que mostra o perfil de onda estacionária para uma ressonância de meia onda e a inversão de fase quando observadas as correntes das extremidades.

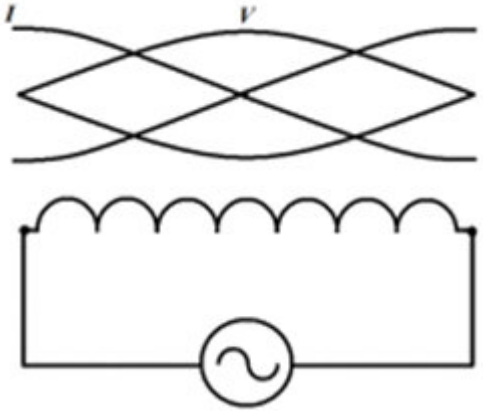

Figura 1. Bobina com ambas as extremidades conectadas a um gerador e os perfis de corrente (I) e tensão (V), para uma onda estacionária de meio comprimento de onda.

A bobina estudada [5] foi enrolada em um tubo de látex, utilizando fio de cobre esmaltado com diâmetro de 0,31 mm, 137 espiras, 55 mm de comprimento e diâmetro da bobina de aproximadamente 7 mm. Apenas as primeiras e últimas espiras são coladas ao tubo que se alongado aumenta o comprimento da bobina, modulando assim a frequência de autorressonância da mesma, conforme equação apresentada em [7].

Para aplicações de biotelemetria passiva e medições de parâmetros fisiológicos de seres vivos, a bobina proposta, por apresentar núcleo de ar, sofre consideráveis influências do corpo, ou parte dele, que pode atuar como um plano terra ao fechar as linhas de campo elétrico, por exemplo. Portanto, para auxiliar na observação controlada, em bancada, que influências externas podem imprimir no comportamento da impedância e fase da bobina sensora, um plano terra foi confeccionado utilizando uma base de madeira revestida com papel alumínio. Deste modo pode-se medir a impedância e fase da bobina ao aplicar diferentes condições de contorno sobre o arranjo bobina-plano. Sendo assim, o objetivo desse estudo é avaliar o arranjo desenvolvido, visando futuras aplicações da bobina como um sensor de deslocamento apresentado em [5] que pode ser testado em bancada simulando o efeito da proximidade do corpo humano, por exemplo. A Figura 2 mostra o plano terra e a bobina sensora sob estudo.

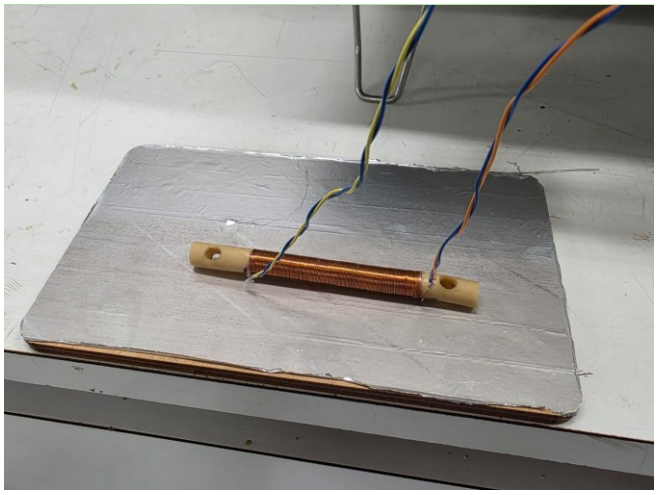

Figura 2. Bobina sensora enrolada em tubo de látex, e plano terra confeccionado.

III. Metodologia e Resultados

Neste estudo, foram conduzidas algumas configurações experimentais distintas do arranjo bobina-plano para medição do módulo da impedância (Z) e fase elétrica (θ) utilizando um analisador de impedância Agilent 4294A configurado para realizar 16 medições e apresentar o valor médio. Em todos os casos, a bobina não apresenta alongamento.

No primeiro caso a bobina foi posicionada sobre o plano de aterramento, sem que este fosse conectado ao condutor de proteção (terra) da tomada de energia, tal como mostrado na Figura 2. A frequência de ressonância medida foi de 55,90 MHz e a impedância de 234,7 Ω na ressonância. Os resultados são mostrados na Figura 3.

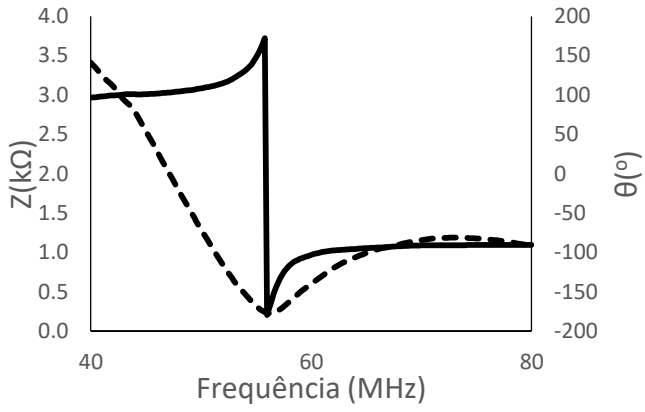

Figura 3. Módulo da impedância (linha sólida) e fase (tracejado) do sensor posicionado sobre o plano.

Na sequência a bobina continua posicionada sobre o plano, com a diferença de que este foi eletricamente conectado ao condutor de proteção, ou terceiro pino (terra), da tomada.de energia. A frequência de ressonância medida foi de 52,70 MHz e a impedância de 372,8 Ω na ressonância.

Resultando em uma diminuição de 3,2 MHz, conforme mostrado na Figura 4.

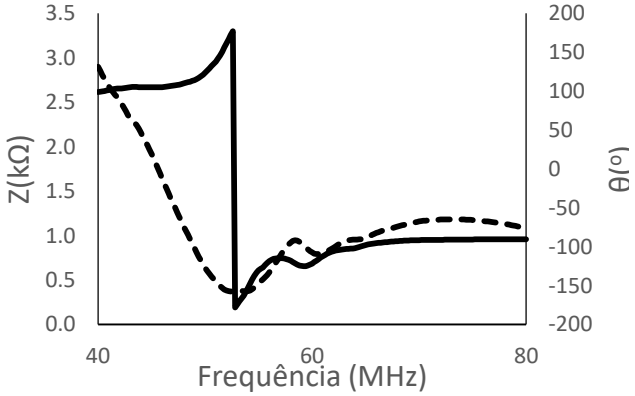

Figura 4. Módulo da impedância (linha sólida) e fase (tracejado) do sensor posicionado sobre o plano aterrado.

Na sequência a bobina foi posicionada diretamente sobre a mão de um dos operadores, sem utilização de plano terra, de modo a avaliar a validade da utilização do plano em substituição ao corpo. A frequência de ressonância medida foi de 54,30 MHz e impedância de 346,5 Ω na ressonância, conforme mostrado na Figura 5. Observa-se uma diferença de mesmo valor (1,6 MHz) para a frequência de ressonância da bobina sobre a mão quando comparada aos outros casos previamente mostrados nas Figuras 3 e 4 (55,9 MHz e 52,7 MHz), o que resulta em um erro relativo de 2,9%. Ainda, as correlações entre as curvas de fase para a bobina sobre a mão (Figura 5), em relação aos casos da bobina sobre o plano sem aterramento (Figura 3), e sobre o plano aterrado (Figura 4), foram de 0,819 e 0,815, respectivamente.

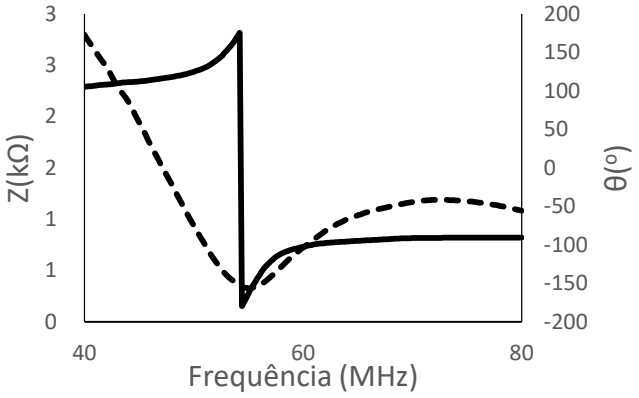

Figura 5. Módulo da impedância (linha sólida) e fase (tracejado) da bobina posicionada sobre a mão da operadora.

Como forma de ampliar o estudo foram ainda propostas outras configurações. A bobina foi posicionada sobre o plano de aterramento, mantendo-se agora a mão de um dos operadores em contato com o plano não aterrado, de modo que o corpo humano atuasse como referência de aterramento. Os resultados são mostrados na Figura 6. A frequência de ressonância medida foi de 24,30 MHz e impedância de 2,112 kΩ na ressonância. Quando comparado ao arranjo da Figura 2 (bobina sobre o plano sem aterramento), com frequência de ressonância de 55,9 MHz, nota-se uma diminuição de 2,3 vezes na frequência de ressonância quando a operadora toca o plano. Esta diferença é esperada, uma vez que, nesta configuração, existe uma diferença evidente de modelo elétrico (o corpo humano passa a ser referência para o plano terra). Adicionalmente, evidencia-se a baixa correlação entre as curvas impedância para este caso, porém este estudo foge ao escopo do presente trabalho.

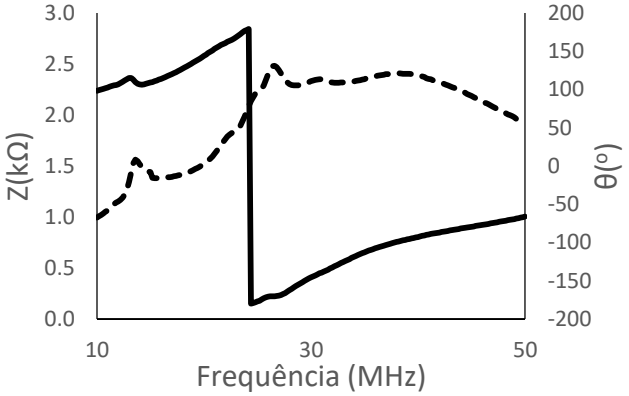

Figura 6. Módulo da impedância (linha sólida) e fase (tracejado) da bobina posicionada sobre a o plano enquanto a operadora toca no mesmo.

Foram propostos dois arranjos adicionais nos quais a bobina é posicionada sobre o plano, a mão da operadora se posiciona sobre a bobina, efetuando contato, sendo que em uma medição o plano não é aterrado (Figura 7) e na outra o plano é aterrado (Figura 8).

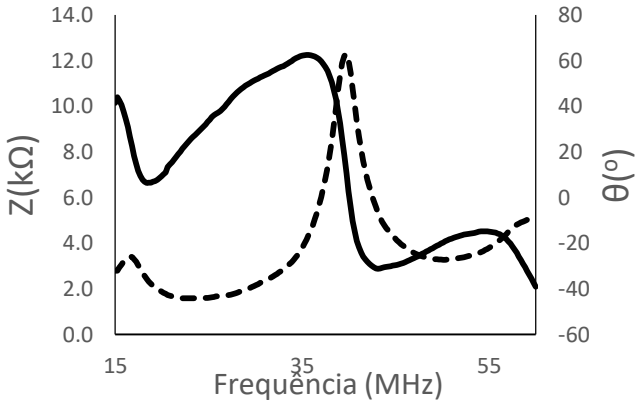

Figura 7. Módulo da impedância (linha sólida) e fase (tracejado) da bobina posicionada sobre o plano não aterrado sendo tocada pela operadora.

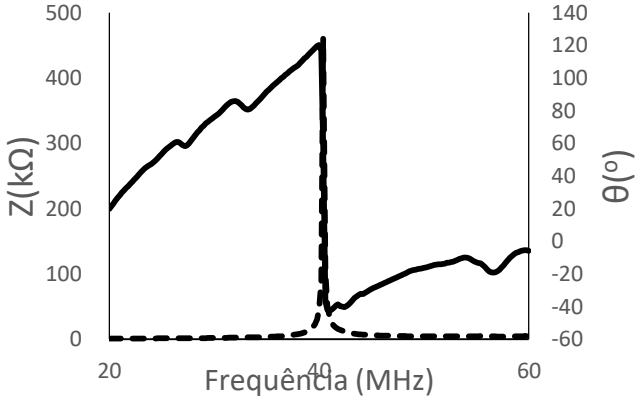

Figura 8. Módulo da impedância (linha sólida) e fase (tracejado) da bobina posicionada sobre o plano aterrado sendo tocada pela operadora.

Para o caso sem aterramento (Figura 7) a frequência de ressonância medida foi de 40,06 MHz e a impedância de 11,80 kΩ na ressonância. Enquanto que para o caso com aterramento (Figura 8) a frequência de ressonância medida foi de 40,52 MHz e impedância de 242,32 kΩ na ressonância. Nota-se portanto a pouca influência da presença ou não de ponto de aterramento no plano, em relação ao valor absoluto da frequência de ressonância (diferença menor que 1,2%). Entretanto, nota-se modificação nas curvas de fase e impedância. Outro ponto que pode ser destacado é a mudança do comportamento da impedância que agora possui máxima impedância na frequência de ressonância, aproximando mais o comportamento ao esperado para uma ressonância de um conjunto LC concentrado, com a diferença principal de que a fase ainda pode passar de noventa graus, ou seja, um caso intermediário. Isto deve-se ao fato de o corpo concentrar as linhas de campo elétrico entre espiras adjacentes e próximas ao mesmo, aumentando a capacitância do conjunto (o que é condizente com a diminuição da frequência de ressonância). De modo a confirmar esta justificativa do aumento da capacitância, outro teste realizado foi o de, para o mesmo arranjo anterior (plano não aterrado), afastar a mão da bobina (e não mais tocá-la como nas Figuras 7 e 8). Neste caso a frequência de ressonância aumentou para 51,46 MHz (encostando a mão, com plano não aterrado, o valor foi de 40,06 MHz conforme Figura 7). Este efeito se deu conforme esperado, uma vez que, ao se afastar a mão ocorre a diminuição da capacitância (alongamento das linhas de campo elétrico) e diminuição da frequência de ressonância. Ainda, o valor da impedância é de 456,8 Ω na ressonância. Os resultados são mostrados na Figura 9.

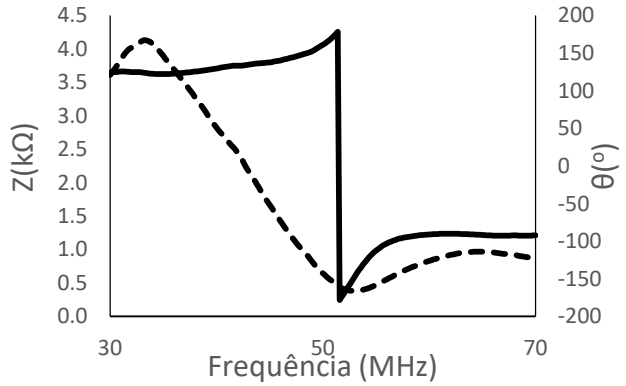

Figura 9. Módulo da impedância (linha sólida) e fase (tracejado) da bobina posicionada sobre o plano não aterrado com a mão da operadora sobre a bobina, sem efetuar contato direto com as espiras.

IV. Conclusões

Os testes e ensaios conduzidos levaram à melhor compreensão dos fenômenos envolvidos ao se utilizar sensores indutivos com núcleo de ar sob influências de corpos externos. Espera-se que este trabalho possa lançar luz sobre alguns efeitos que por vezes são relegados, ou não abordados na prática, por envolver campos eletromagnéticos de relativa complexidade. Especialmente, conforme resultados apresentados na seção anterior julga-se que a utilização de um plano terra pode auxiliar nos ensaios de bancada de sensores indutivos que irão operar próximos ou encostados ao corpo. Destacando que o erro relativo para o valor da frequência de ressonância do sensor no corpo (Figura 5), e do sensor sobre o plano, aterrado ou não (Figuras 3 e 4), foi menor que 3% e a correlação entre as curvas de fase (que é a curva de maior interesse para medição da frequência de ressonância devido ao cruzamento por 0^o) foi maior que 0,8. Adicionalmente, foi possível elucidar experimentalmente o efeito previsto de aumento da capacitância que ocorre ao se aproximar a mão da bobina, o que acarreta na diminuição do valor da frequência de ressonância, e modificação nas curvas de impedância, conforme demonstrado nas medições vistas nas Figuras 7, 8 e 9. Obviamente, as conclusões aqui apresentadas são limitadas à viabilidade preliminar de arranjos iniciais e testes de bancada, necessitando ainda a aplicação de outros métodos estatísticos para análise e avaliação completa dos resultados.

***Abstract*—This paper presents the pre-silicon design and physical verification of BioDiff-CMOS, a CMOS differential block intended for a simulated electrocardiogram (ECG) acquisition chain, implemented in the IHP SG13G2 130 nm BiCMOS process. The reproducible flow, based on Xschem, Ngspice, Magic, and Netgen, covers schematic capture, pre-layout simulation, layout, extraction, post-layout analysis, design rule check (DRC), and layout-versus-schematic (LVS) verification. Under nominal conditions of 1.8 V and 27 °C, the core achieved a differential gain of 0.908 V/V at 100 Hz, a nominal common-mode rejection ratio (CMRR) of 128.3 dB, a positive power-supply rejection ratio (PSRR+) of 48.7 dB, input-referred noise of 29.93 µVrms over 0.5–150 Hz, a cutoff frequency of 120.884 Hz, and power consumption of 36.01 µW. A five-point process-voltage-temperature (PVT) screening showed a gain at 1 kHz between 0.823 and 1.005 V/V, a cutoff frequency between 119.422 and 124.297 Hz, and power between 32.409 and 39.631 µW. DRC reported no violations, and LVS confirmed a unique match. Comparison with representative front-ends highlighted limitations in gain, noise, ideal biasing, and the absence of statistical mismatch analysis. The post-layout extraction contains 18 capacitances and no interconnect parasitic resistances, characterizing a capacitive/hybrid model. The circuit was not fabricated, and no real ECG acquisition was performed. The results establish a solid and reproducible technical basis for further project evolution and future experimental validation.**

***Keywords*—ECG, CMOS differential amplifier, analog front-end, pre-silicon design, open PDK, open-source EDA.**

I. INTRODUCTION

Biopotential signal monitoring is one of the foundations of modern biomedical instrumentation. Among these signals, the electrocardiogram (ECG) remains one of the most widely used tools for assessing cardiac electrical activity, ambulatory monitoring, and digital health applications. However, ECG acquisition poses relevant challenges to analog front-end design because the signals have low amplitude and are subject to power-line interference, electronic noise, motion artifacts, and variations in the electrode–skin interface [1], [2].

In this context, the analog front-end plays a decisive role in preserving useful information before digitization. The signal captured by the electrodes must be amplified, filtered, and conditioned to avoid saturation, resolution loss, and signal-to-noise ratio degradation. Recurring requirements include high input impedance, high common-mode rejection ratio (CMRR), low input-referred noise, low power consumption, bias stability, and robustness to process, voltage, temperature, and device mismatch variations [1]–[5].

The integration of these blocks in CMOS technology has contributed to the evolution of biomedical acquisition systems by enabling amplification, filtering, biasing, and output interfaces within the same technology while reducing area and power consumption. In parallel, the availability of open Process Design Kits (PDKs) and open-source Electronic Design Automation (EDA) tools has broadened access to integrated-circuit development in academic and research environments. A PDK provides electrical models, fabrication rules, device libraries, and technology parameters that establish the interface between electrical design and process constraints [6]. Tools such as Xschem, Ngspice, Magic, and Netgen support schematic

capture, simulation, layout, extraction, and DRC/LVS verification in an open analog-design flow [7]–[10], [12].

BioDiff-CMOS, used as a case study in this work, is a CMOS differential block developed in the IHP SG13G2 130 nm BiCMOS process using this open ecosystem. The process provides electrical models, devices, and geometric rules that enable the design to progress from the schematic level to physical implementation [6]. The focus of this paper is not the validation of a complete biomedical system, but the pre-silicon analysis of an analog block embedded in a simulated ECG acquisition chain.

The contribution of this study is to demonstrate, in a traceable and reproducible manner, the development and verification of this block through a pipeline integrating specification, schematic simulation, layout, extraction, post-layout analysis, and physical verification. Results are presented for gain, CMRR, PSRR, input-referred noise, power, cutoff frequency, area, PVT screening, DRC, and LVS, together with a comparison against representative front-ends from the literature. Thus, the objective is to relate ECG acquisition requirements to analog-design decisions and physical-implementation stages, while highlighting both the possibilities of the open-source flow and the current circuit limitations as a basis for further development and future experimental validation.

II. RELATED WORK

Table I compares BioDiff-CMOS with representative front-ends. Kim and Ko [3] and Zhao, Shang, and Lian [4] reported fabricated and measured circuits, whereas Laababid, El Khadiri, and Tahiri [5] and Wen et al. [2] reported simulation results. Units were standardized where possible, but the scopes remain different: some values refer to instrumentation amplifiers, others to more complete channels, and the reported areas do not always represent the same integration level.

The core presented in this work has sub-unity gain and is approximately 30 to 69 dB below the listed gains. The integrated noise is about 3.5 times the value reported by Wen et al. and more than 29 times the values measured by Kim and Ko and by Zhao et al. The nominal CMRR of 128.3 dB is high, but it was obtained with an ideal tail-current source, deterministic symmetry, and no statistical mismatch, a condition that favors this metric. The 36.01 µW power consumption lies within the range of the compared works, but it includes the simulated CMOS interface and excludes a physical bias circuit. Therefore, the comparison highlights performance gaps and scope differences without establishing a direct ranking among the solutions.

TABLE I — COMPARISON WITH REPRESENTATIVE ANALOG FRONT-ENDS FROM THE LITERATURE.

Work	Status, process, and VDD	Gain	CMRR	Input-referred noise	Power	Bandwidth, area, and notes
BioDiff-CMOS	Hybrid pre/post-layout; IHP 130 nm; 1.8 V	−0.835 dB at 100 Hz	128.3 dB at 100 Hz; nominal, no mismatch	29.93 µVrms, 0.5–150 Hz	36.01 µW, simulated chain	Cutoff = 120.884 Hz; core: 0.00093456 mm²; ideal tail-current source
Kim and Ko [3]	Fabricated and measured; CMOS 130 nm; 1.2 V	44.7 dB at 60 Hz	91.3 dB at 60 Hz	0.92 µVrms, 100 Hz bandwidth	6 µW, IA in PG+CS	100 Hz filter; IA area not reported; die = 6.02 mm²
Zhao et al. [4]	Fabricated and measured; CMOS 350 nm; 1.8 V	56–68 dB	76 dB	1.02 µVrms, 0.4–120 Hz	0.90 µW	0.4–120 Hz; 0.405 mm²
Laababid et al. [5]	Schematic simulation; CMOS 180 nm; 1.8 V	50.75 dB at 20 Hz	102 dB	1.47 µVrms, 0.1 Hz–1 kHz	1.08 µW	0.077–255 Hz in the paper body; area not reported
Wen et al. [2]	TT simulation; CMOS 180 nm; 1.8 V	29.5–47.6 dB	114 dB	8.538 µVrms, 0.5–150 Hz	84.4 µW, inferred	Sampling channel; output and RLD excluded; area not reported

III. ARCHITECTURE AND DEVELOPMENT FLOW

A. Requirements and acquisition chain

BioDiff-CMOS is analyzed within an ECG acquisition chain in which the performance of the first analog stage must be related to the signal characteristics and critical front-end metrics [1], [2]. Fig. 1 summarizes this relationship among requirements, architectural alternatives, performance metrics, and implementation trends. This view positions the differential block as part of a broader biomedical chain without assigning to the standalone circuit functions that were not implemented or validated.

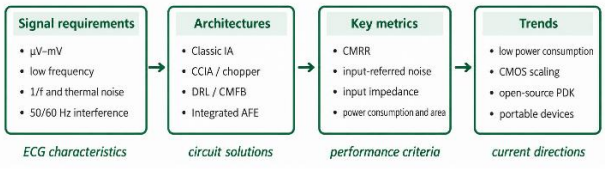

Fig. 1. Summary of requirements, architectural alternatives, critical metrics, and trends associated with analog front-ends for ECG.

Fig. 2 presents the functional chain considered as a reference: electrodes, input protection, the BioDiff-CMOS differential block, low-pass filtering, and the output interface. The first-order filter used in the testbench has a nominal cutoff of approximately 120.9 Hz in the revised version. Electrodes, input protection, and complete analog-to-digital conversion were not implemented in the core layout and therefore remain outside the validation scope of this work.

Fig. 2. Functional reference chain for simulated ECG acquisition with BioDiff-CMOS.

B. Open-source design pipeline

The development of BioDiff-CMOS follows a reproducible pre-silicon pipeline organized into seven stages, as shown in Fig. 3. In Stage 1, the electrical and functional specifications that guide the circuit design are defined. In Stage 2, these specifications are translated into the electrical domain through schematic capture in Xschem, establishing the topology, devices, and bias conditions. Stage 3 corresponds to electrical simulation in Ngspice, where circuit behavior is evaluated before physical implementation, including the analyses required to characterize its main metrics. Once schematic-level behavior has been verified, physical implementation begins. In Stage 4, the layout is developed in Magic according to the IHP SG13G2 process rules, considering geometry, placement, routing, and device symmetry. In Stage 5, parasitic extraction (PEX) is performed, generating an electrical representation derived from the layout and closer to the physical implementation conditions. Next, in Stage 6, DRC (Design Rule Check) and LVS (Layout Versus Schematic) are performed with Magic and Netgen to verify, respectively, geometric compliance with the process rules and connectivity equivalence between the implemented circuit and the reference schematic. In Stage 7, the extracted layout netlist replaces the schematic core in the same testbench used for pre-layout characterization. This approach enables direct comparison of results before and after physical implementation while keeping stimulus and analysis conditions unchanged. The pipeline in Fig. 3 establishes a traceable sequence across specification, electrical design, simulation, physical implementation, extraction, verification, and post-layout analysis, facilitating both experiment reproduction and identification of layout-induced effects. This organization is consistent with open analog-design flows that separate specification, schematic design, simulation, layout, extraction, physical verification, and characterization [12].

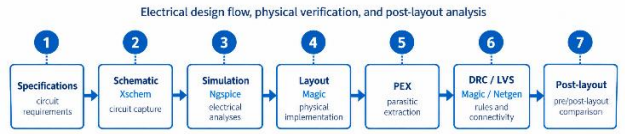

Fig. 3. Reproducible pre-silicon pipeline used in the development of BioDiff-CMOS.

C. BioDiff-CMOS architecture and testbench

Fig. 4 shows the configuration actually used in the revised simulations. The differential core implemented in the layout consists of the NMOS pair and the high-resistance loads; the ideal tail-current source, the RC branch, and the simplified CMOS interface belong to the test environment. This separation is essential for correctly interpreting power, CMRR, frequency response, and the limits of post-layout validation.

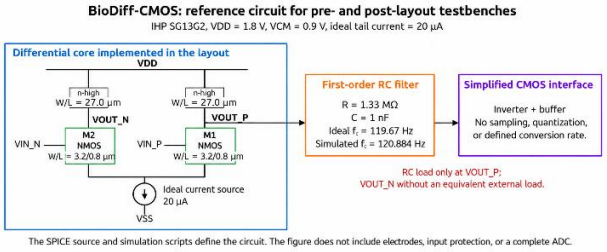

Fig. 4. Circuit and testbench used in the pre- and post-layout analyses; only the indicated core was implemented in the layout.

IV. MATERIALS AND METHODS

A. Circuit and test conditions

The core has two input NMOS devices with width-to-length ratio W/L = 3.2/0.8 µm and two rhigh loads of 2/10 µm. An ideal source provides 20 µA to the tail node. The positive output drives a 1.33 MΩ/1 nF branch and the gates of a CMOS inverter and buffer. The negative output has no equivalent external load. Fig. 4 distinguishes the core implemented in the layout from the testbench load and interface. The interface does not implement sampling, quantization, or conversion rate and is therefore not treated as an analog-to-digital converter.

The pre- and post-layout analyses used the same testbench; only the core netlist was replaced. The nominal condition used the mos_tt, res_typ, and cap_typ models, 27 °C, 1.8 V, and an input common-mode voltage of 0.9 V. The AC analysis applied a 1 V differential signal split into +0.5 and −0.5 V. The transient test applied a 25 mV peak signal per input in opposite phase, equivalent to 100 mVpp differential at 1 kHz. This test is electrical and does not represent an ECG waveform. Input-referred noise was integrated from 0.5 to 150 Hz and, as an additional check, from 0.05 to 150 Hz. CMRR and positive power-supply rejection ratio (PSRR+) were calculated at the differential output.

The nominal offset was obtained from a DC sweep without statistical models. The ideal tail-current source allows nonphysical voltages at low common-mode levels; therefore, the input common-mode range (ICMR) was not reported.

B. Layout, extraction, and reproducibility

The layout in Fig. 5 was created in Magic with symmetry between the input devices. The bounding box of the painted geometry, excluding markers, pads, and die area, measures 26.40 by 35.40 µm, or 934.56 µm². DRC was executed with the IHP SG13G2 deck. LVS compared seven pins and four instances; the sg13_lv_nmos and rhigh classes were treated as equivalent black boxes.

Extraction in Magic used extract do local, extract all, ext2spice lvs, zero capacitive threshold, and resistive extraction enabled. The resulting netlist for this version contains 18 capacitances, no interconnect parasitic resistors, and two rhigh loads reconstructed for testbench

compatibility. Thus, the analysis is capacitive/hybrid post-layout rather than a complete RC PEX.

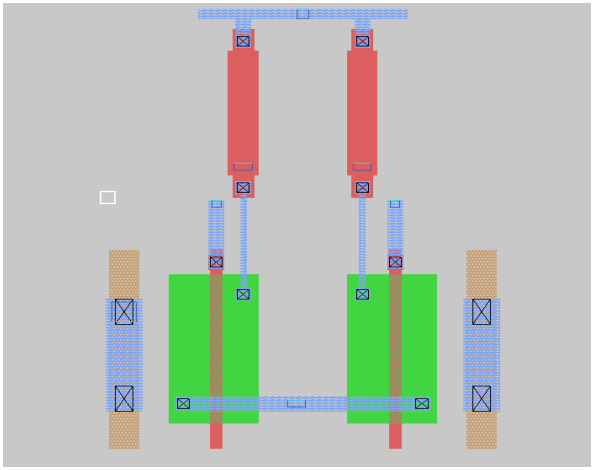

Fig. 5. Layout of the differential core in the IHP SG13G2 process.

The reproducible environment uses the isaiassh/unic-cass-tools:1.1.0 image, IHP Open PDK v0.3.0 at commit 5cccb161f749, Ngspice 44.2, Magic 8.3.613, Netgen 1.5.293, and Xschem at commit 313acc8e2974. The minimum files required for reproduction are the netlists in entrega/sim_pre and entrega/pex_post, the entrega/layout/biodiff_top.mag cell, and the scripts in scripts/entrega. The commands and generated artifacts are described in the project repository [11].

V. RESULTS AND DISCUSSION

A. Nominal pre- and post-layout characterization

Table II consolidates the requested conditions and metrics. The pre- and post-layout results coincide to the reported precision for gain, noise, cutoff frequency, and power. This agreement is due to the small extracted capacitive load and does not demonstrate fabrication robustness.

The frequency response is shown in Fig. 6. The value of 120.884 Hz was measured relative to the low-frequency gain. It is close to the 119.67 Hz calculated from $f_c = 1/(2\pi RC)$ for R = 1.33 MΩ and C = 1 nF. Using 100 Hz as the −3 dB reference would incorrectly shift the crossing because this point is already attenuated.

Wen et al. integrate the input-referred noise over 0.5–150 Hz [2], which is also used here to facilitate comparison. Because the 120.884 Hz cutoff lies below the upper limit of this range, the RC branch progressively attenuates components approaching 150 Hz, and its suitability depends on the intended application. In addition, a first-order filter provides limited rejection, and the design does not define the sampling rate, resolution, or response of a complete converter; therefore, the RC branch alone does not constitute a validated anti-aliasing chain.

TABLE II — BIODIFF-CMOS SPECIFICATIONS AND RESULTS.

Parameter	Condition or definition	Pre-layout	Post-layout	Unit or note
PDK and process	IHP SG13G2 BiCMOS	130	130	nm
Supply	Main supply	1.8	1.8	V
Core devices	Input NMOS; rhigh loads	3.2/0.8; 2/10	3.2/0.8; 2/10	W/L in µm
CMOS interface	PMOS/NMOS inverter; PMOS/NMOS buffer	4/0.35; 2/0.35; 8/0.35; 4/0.35	same	W/L in µm; outside the core layout
Bias current	Ideal tail-current source	20	20	µA; physical bias circuit not implemented
Nominal common mode	Inputs	0.9	0.9	V
Differential gain	10; 100; 1000 Hz	0.909260; 0.908323; 0.906963	0.909260; 0.908323; 0.906963	V/V
Filter cutoff	−3 dB relative to 1 Hz	120.884	120.884	Hz
Input impedance	Not characterized in the testbench	not characterized	not characterized	Biomedical requirement; requires input/electrode model
ICMR	Ideal tail-current source invalidates the lower limit	not characterized	not characterized	Requires physical biasing
Output swing	Extremes of differential DC sweep	0.286523	0.286523	Vpp differential; linear range not qualified
CMRR	Differential output, 100 Hz	128.292	128.291	dB; optimistic, no mismatch
PSRR+	Differential output, 100 Hz	48.683	48.683	dB; ideal biasing
Input-referred noise	Integrated, 0.5–150 Hz	29.9317	29.9317	µVrms
Input-referred noise	Integrated, 0.05–150 Hz	35.4578	35.4578	µVrms
Nominal offset	DC sweep, no mismatch	−25.32	−25.32	µV; not representative of fabrication offset
Power	Average from the 1.8 V supply	36.0116	36.0116	µW; physical biasing excluded
Core area	Geometry bounding box	934.56	934.56	µm²; no pads
Load	Only on VOUT_P	1.33 MΩ/1 nF + CMOS gates	same	VOUT_N has no equivalent external load
Corner and temperature	MOS/R/C models	TT/typical/typical; 27	TT/typical/typical; 27	°C
Extraction	Elements inside the core	none	18 C; 0 parasitic R; 2 reconstructed rhigh	Hybrid post-layout model
DRC/LVS	Executed deck and connectivity	not applicable	0 violations; unique match	Does not constitute electrical validation

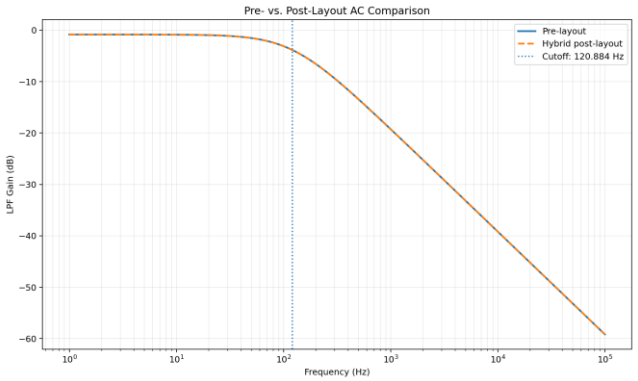

Fig. 6. Pre- and post-layout AC response. The curves overlap at the scale shown.

B. PVT screening and physical verification

The five-point screening combined nominal TT, SS at low voltage and high temperature, FF at high voltage and low temperature, and the crossed SF and FS corners. As shown in Fig. 7, the gain at 1 kHz ranged from 0.823 to 1.005 V/V, the cutoff frequency from 119.422 to 124.297 Hz, and power from 32.409 to 39.631 µW. The pre- and post-layout points remained overlapped. This screening does not replace all PDK-qualified corners or Monte Carlo analysis.

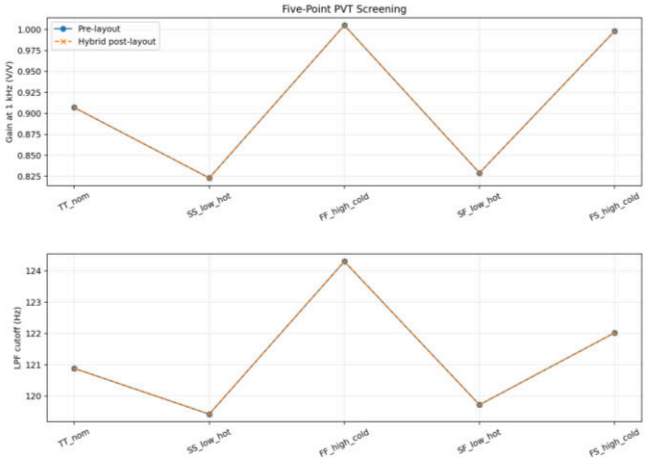

Fig. 7. Five-point PVT screening for gain and filter cutoff frequency.

DRC reported zero violations for the executed rule set. LVS found a unique match between the seven pins and four core instances, confirming connectivity consistency between the extracted layout and the schematic. These results demonstrate geometric compliance with the employed deck and topological equivalence, but they do not verify electrical performance, reliability, packaging, manufacturability beyond the evaluated rules, or behavior in silicon.

Fig. 8 presents enlarged excerpts of the original verification evidence: the Magic report records zero DRC errors, while the Netgen report shows pin and device equivalence and a unique match between the extracted layout and schematic. The detailed presentation preserves flow traceability and improves the readability of the physical-verification results.

VI. LIMITATIONS AND FUTURE VALIDATION

The dominant limitations are the sub-unity gain, the high noise relative to the compared works, the ideal tail-current source, asymmetric loading, post-layout extraction without interconnect parasitic resistances, and the absence of statistical mismatch analysis. Therefore, the nominal CMRR should not be interpreted as a direct prediction of silicon measurements. Electrodes, electrode–skin impedance, electrode offset, 50/60 Hz interference, and input protection were also not modeled.

Future validation should advance along three fronts. First, pre-silicon characterization should be expanded to all PDK-defined corners, Monte Carlo analysis, electrode models, offset, power-line interference, and public ECG signals. Next, physical biasing, input protection, additional gain, and the output interface should be incorporated, followed by renewed RC extraction, DRC, and LVS. Finally, potential fabrication through a multi-project wafer (MPW) run will depend on meeting the specifications and on the availability of a compatible run; in that case, bench characterization should include gain, bandwidth, CMRR, PSRR, noise, offset, ICMR, output swing, and power under a known load, initially using an ECG simulator. Human-subject testing will require an appropriate ethics protocol and safety instrumentation.

VII. CONCLUSION

The development of integrated circuits for biomedical signal acquisition requires the integration of application requirements, analog-circuit fundamentals, and physical implementation. For ECG, key challenges include low signal amplitude, common-mode rejection, noise control, high input

impedance, low power consumption, and robustness to process, voltage, temperature, and device mismatch variations.

As a case study, BioDiff-CMOS demonstrated the feasibility of a reproducible pre-silicon pipeline based on an open PDK and open-source EDA tools, covering schematic capture, simulation, layout, extraction, post-layout analysis, and DRC/LVS verification. Under nominal conditions, the core achieved a gain of 0.908 V/V at 100 Hz, a cutoff frequency of 120.884 Hz, input-referred noise of 29.93 µVrms over 0.5–150 Hz, and power consumption of 36.01 µW. DRC reported no violations, and LVS confirmed a unique match between layout and schematic.

The results must, however, be interpreted within the context of a pre-silicon study. Important limitations remain, including sub-unity gain, the noise level, the ideal tail-current source, asymmetric loading, extraction without interconnect parasitic resistances, and the absence of statistical mismatch analysis. No fabrication, experimental characterization, or real ECG acquisition was performed.

Despite these limitations, the work establishes a solid and reproducible technical basis for further circuit evolution. The next steps include increasing gain, reducing noise, implementing physical biasing, balancing the loads, performing Monte Carlo and mismatch analyses, carrying out more complete RC extraction, and incorporating more representative electrode–skin interface models. Maturing these features may support future fabrication and experimental bench characterization.

More broadly, the use of open PDKs and tools such as Xschem, Ngspice, Magic, and Netgen reinforces the potential of this ecosystem for education, research, and training in biomedical microelectronics, bringing academic training closer to integrated-circuit implementation practices and contributing to the future development of solutions for digital health, wearable devices, and low-power biomedical systems.

***Abstract*—This study noninvasively evaluated gastrointestinal (GI) transit and contractile mechanical activity in rats with diarrhea induced by a high-lactose diet (HLD) using Alternating Current Biosusceptometry (ACB). The same animals were assessed at two different time points: before (CONTROL group) and after the diet (HLD group).**

***Index Terms*—Alternating Current Biosusceptometry (ACB), Lactose, Diarrhea, Gastrointestinal Motility, Colon.**

I. Introduction

Diarrhea is a common gastrointestinal disorder characterized by frequent loose stools and altered intestinal motility, often leading to dehydration and other complications [1], [2]. Experimental models, particularly lactose-induced chronic diarrhea in rats, are widely used to investigate gastrointestinal dysfunction and evaluate new therapies [3]. Conventional techniques for assessing gastrointestinal transit and contractility require euthanasia, preventing repeated measurements in the same animal [4], [5]. Alternating Current Biosusceptometry (ACB) is a non-invasive biomagnetic technique that enables sequential evaluation of gastrointestinal transit and motor activity without ionizing radiation [6]. Owing to its low cost, versatility, and ability to simultaneously assess gastric emptying, orocecal transit, and gastric and colonic contractility, ACB represents a valuable alternative to conventional methods [7]–[9].

This study aimed to establish and validate an ACB-based methodology for the simultaneous assessment of gastrointestinal transit and segmental contractility in a rat model of lactose-induced chronic diarrhea, providing a reliable tool for future preclinical gastrointestinal research [10].

II. Materials and Methods

A. Animals and Experimental Protocol

Fifteen male Wistar rats (Rattus norvegicus albinus), weighing between 250 and 350 g, were used in this study. The animals were maintained under controlled environmental conditions (21 $\pm$ 1°C, 12 h light/dark cycle) with free access to food and water. All experimental procedures were approved by the Institutional Animal Ethics Committee (protocol CEUA 1668051023).

A paired experimental design was adopted, in which each animal was evaluated at two different time points. Initially, measurements were performed under physiological conditions (Control). Subsequently, the same animals underwent induction of chronic diarrhea and were reevaluated (HLD group), allowing direct paired comparisons.

B. Lactose-Induced Chronic Diarrhea Model

Chronic diarrhea was induced by feeding the animals a diet containing 35% lactose for seven consecutive days. Successful

induction was confirmed through daily fecal morphometry. Animals presenting soft, watery, yellowish feces after the dietary intervention were considered successfully induced.

C. Alternating Current Biosusceptometry (ACB)

Gastrointestinal motility was evaluated using a single-channel Alternating Current Biosusceptometry (ACB) system specifically developed for in vivo studies.

The sensor consists of two pairs of coils separated by 15 cm. Each pair contains an excitation coil and a detection coil connected in opposite directions to minimize environmental magnetic noise and maximize the signal-to-noise ratio. The detection principle is based on disturbances produced by magnetic material located near the sensor. The recorded signal is directly proportional to the amount of magnetic material present and inversely proportional to the distance between the sensor and the magnetic marker. The induced electrical signal is processed using a lock-in amplifier, converted into a DC signal, acquired through a BIOPAC MP100 acquisition system at a sampling frequency of 20 Hz, and stored for subsequent processing.

D. Gastrointestinal Transit Measurements

Following a 12-hour fasting period, each animal received a solid magnetic meal (2 g chow, 0.5 g manganese ferrite microparticles, MnFe2O4). Magnetic intensity was recorded every 30 minutes over a 6-hour monitoring period with the sensor positioned over the stomach and cecum. Transit parameters quantified were Mean Gastric Emptying Time (MGET) and Mean Cecal Arrival Time (MCAT).

E. Gastric and Colonic Contractility

Mechanical activity was evaluated by monitoring oscillations in the biomagnetic signal. Animals were anesthetized with isoflurane. Gastric contractions were recorded 15 minutes after meal ingestion, and colonic contractions after six hours. Signals were analyzed using Fast Fourier Transform (FFT). Dispersion parameters obtained via Gaussian fitting were Standard deviation (σ) and Full Width at Half Maximum (FWHM).

F. Statistical Analysis

Statistical analyses were performed using GraphPad Prism 8.0.1. Data are expressed as mean $\pm$ standard deviation. Since the same animals were evaluated before and after diarrhea induction, paired Student's t-tests were used for comparisons between control and HLD conditions. Statistical significance was considered when $p < 0.05$.

III. Results

A. Validation of the Lactose-Induced Diarrhea Model

All animals completed both experimental phases, allowing paired comparisons between physiological conditions (Control) and the high-lactose diet (HLD). Administration of the HLD for seven consecutive days produced the expected diarrheal phenotype. Animals exhibited soft, watery, yellowish feces together with increased stool frequency, confirming successful induction of chronic diarrhea. No significant differences in body weight were observed between control and HLD conditions during the experimental period.

B. Gastrointestinal Transit

The evaluation of temporal parameters demonstrated significant quantitative alterations following diarrhea induction.

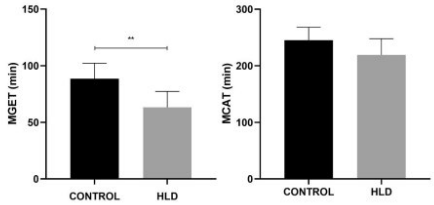

Fig. 1. Mean times of gastric emptying (MGET), cecum arrival (MCAT). ** $p<0.01$.

The Mean Gastric Emptying Time (MGET) was significantly reduced in the HLD group (63.38 ± 13.87 min) compared to the CONTROL group (88.51 ± 13.69 min, $p < 0.01$), indicating accelerated gastric emptying. Regarding the Mean Cecal Arrival Time (MCAT), there was a reduction in the HLD group (219.3 ± 28.56 min) compared to the CONTROL group (245.1 ± 23.17 min); however, this decrease was not statistically significant ($p>0.05$).

C. Gastric Contractility

Representative gastric biomagnetic recordings obtained during control and HLD conditions are shown in Fig. 2.

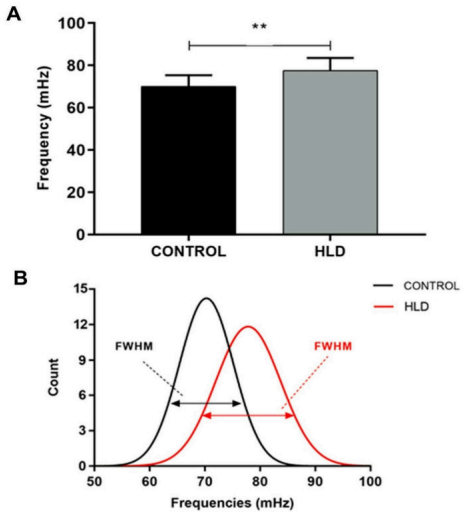

Fig. 2. A. Mean gastric contraction frequency of the CONTROL and HLD groups. ** $p<0.01$. B. Distribution of quantified values of frequency of gastric contraction and the Full Width at Half Maximum (FWHM).

Time-domain recordings revealed periodic oscillations corresponding to gastric contractions in both experimental conditions. However, spectral analysis demonstrated important

differences after diarrhea induction. Fast Fourier Transform (FFT) analysis showed a significant increase in dominant gastric contraction frequency in animals receiving the high-lactose diet. In addition to frequency changes, Gaussian fitting of the frequency spectra demonstrated broader peak distributions in the HLD group, characterized by increased standard deviation (σ) and Full Width at Half Maximum (FWHM). The larger spectral dispersion indicates reduced rhythmic stability and increased variability of gastric contractions, suggesting the presence of gastric dysrhythmia associated with chronic diarrhea.

D. Colonic Mechanical Activity

Colonic signals exhibited complex rhythmic oscillations. Animals subjected to lactose-induced diarrhea showed marked enhancement of colonic mechanical activity.

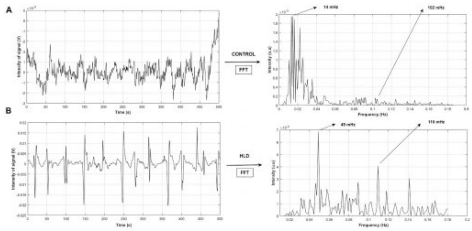

Fig. 3. A. Colonic contraction signal and the respective FFT of the CONTROL group. B. Colonic contraction signal and the respective FFT of the HLD group.

Spectral analysis demonstrated increased power within the frequency bands associated with rhythmic propulsive motor complexes (RPMCs, CONTROL: 38 mHz vs. HLD: 62 mHz, $p< 0.05$) and rhythmic propagation ripples (RPRs, CONTROL: 85 mHz vs. HLD: 95 mHz, $p< 0.05$), indicating increased propulsive activity.

E. Frequency Spectrum Analysis

Power spectral density analysis provided additional evidence of altered gastrointestinal motility following diarrhea induction. Representative spectra are shown in Fig. 4.

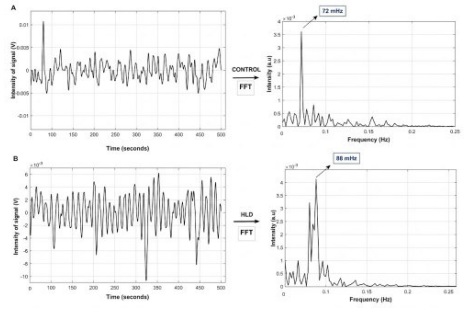

Fig. 4. A. Gastric contraction signal and the respective FFT of the CONTROL group. B. Gastric contraction signal and the respective FFT of the HLD group.

The control group exhibited narrow spectral peaks centered around the physiological gastric contraction frequency. Conversely, spectra obtained after HLD administration presented wider peaks with increased frequency dispersion, demonstrating greater variability in contraction rhythms. Gaussian fitting confirmed statistically significant increases in spectral width parameters (σ and FWHM), indicating disruption of normal gastric rhythmicity.

F. Correlation Between Transit and Contractility

Comparison of transit measurements and contractility parameters demonstrated a close relationship between gastrointestinal transit acceleration and altered motor activity. Animals presenting shorter gastric emptying times also exhibited higher gastric contraction frequencies and increased colonic propulsive activity. These findings suggest that accelerated gastrointestinal transit observed in lactose-induced diarrhea results from coordinated changes involving both gastric and colonic motor functions.

G. Overall Findings

Collectively, the results demonstrate that Alternating Current Biosusceptometry (ACB) enables the simultaneous in vivo evaluation of gastrointestinal transit and regional contractility. The technique successfully detected accelerated gastric emptying, reduced cecal arrival time, increased gastric contraction frequency, a broader distribution of gastric contraction frequencies, enhanced colonic propulsive motor activity, and increased rhythmic propagation ripples. These findings indicate that chronic diarrhea induces profound alterations in gastrointestinal motility involving multiple regions of the digestive tract. Furthermore, they highlight the potential of ACB as a reliable, non-invasive tool for continuously monitoring gastrointestinal motor function, providing valuable insights for preclinical studies of gastrointestinal disorders and the evaluation of novel therapeutic strategies.

IV. Discussion

The present study demonstrated that Alternating Current Biosusceptometry (ACB) provides a non-invasive approach for the simultaneous assessment of gastrointestinal transit and regional contractility. The high-lactose diet successfully induced chronic diarrhea, producing marked alterations in gastrointestinal motility. The quantitative reduction in both Mean Gastric Emptying Time (MGET) and Mean Cecal Arrival Time (MCAT) indicates that diarrhea accelerates gastrointestinal transit.

ACB also detected significant modifications in gastric motor activity. The statistical increase in dominant gastric contraction frequency, together with the broader frequency distribution (higher FWHM and σ) observed after diarrhea induction, suggests disruption of normal gastric rhythmicity. Colonic recordings further demonstrated enhanced mechanical activity, with significant increases in RPMCs and RPRs.

Some limitations of this study must be strongly emphasized. First, the experimental design utilized a relatively small sample size of only 15 rats, which limits the statistical power of broader extrapolations. Second, the evaluation was restricted to a single diarrhea induction protocol (high-lactose diet), which

may not represent the pathophysiological mechanisms of other types of diarrhea. Due to these factors, the impossibility of directly extrapolating these results to human clinical conditions must be acknowledged; any clinical translation should be approached with extreme caution. Future studies with larger cohorts and diverse pathological models are necessary.

V. Conclusion

Alternating Current Biosusceptometry enabled simultaneous, non-invasive evaluation of gastrointestinal transit and regional contractility in a rat model of lactose-induced chronic diarrhea. The biomagnetic methodology detected accelerated gastric emptying, increased gastric contraction frequency, broader frequency distributions indicative of gastric dysrhythmia, and enhanced colonic propulsive activity. These findings demonstrate that ACB provides an assessment of gastrointestinal motor function with the advantage of allowing repeated measurements in the same animals. The technique demonstrates significant potential as an experimental tool for investigating gastrointestinal disorders and evaluating therapeutic interventions specifically within the evaluated experimental model.

***Abstract*—Epsilon iron oxide has emerged as a powerful alternative for expanding the capabilities of magnetic tracking toward multifunctional diagnostics and contactless nanothermometry due to its giant coercive field and strongly temperature-dependent magnetization. In this study, gallium-doped epsilon iron oxide nanoparticles were synthesized via the sol-gel method to tailor the magnetic phase transition window between 5 degrees Celsius and 25 degrees Celsius, aligning with critical intervals required for food preservation, vaccine transportation, and cold-chain logistics. To monitor these phase transitions in real time, Alternating Current Biosusceptometry (ACB)—a versatile inductive technique utilizing a first-order gradiometric coil configuration—was evaluated against a standard Vibrating Sample Magnetometer (VSM). The temperature-dependent magnetic responses of three distinct samples (M-04, M-02, and M-03R) were measured using both systems. The experimental results reveal that both techniques successfully resolve the thermal phase transitions, displaying a consistent trend in the Curie temperature shift as a function of gallium doping. Although the ACB system identified transition peaks at 7.5, 16.4, and 22.0 degrees Celsius, the VSM recorded them at 1.5, 12.0, and 19.0 degrees Celsius. This systematic temperature offset is discussed and attributed to distinct instrumentation profiles, thermal gradients, and signal integration times between the localized dynamic ACB probe and the quasi-static VSM chamber environment. Crucially, despite these instrumentation-specific offsets, ACB demonstrates a promising capability for qualitatively tracking thermal-magnetic variations and distinguishing Tc shifts across doped samples. These findings show that ACB serves as an accessible laboratory tool for preliminary thermal-magnetic phase screening, offering real-time trend monitoring.**

***Index Terms*—AC Biosusceptometry, Magnetic phase transition, Epsilon iron oxide, Nanothermometry, Curie temperature.**

I. Introduction

Superparamagnetic iron oxide nanoparticles (SPIONs) have been widely established as effective contrast agents for magnetic resonance imaging (MRI) [1] and magnetic particle imaging (MPI) [2]. Specifically, commercial solutions such as Sienna+®, which contains dextran-coated SPIONs with an average particle size of $59\,\mathrm{nm}$, have been successfully utilized for the identification of sentinel nodes (SN) in breast cancer surgery [3]. Once injected into the breast, the tracer drains through the lymphatic system and accumulates in the SN. A handheld magnetic probe, known as SentiMag®, is then employed by surgeons to locate these nodes in a manner analogous to conventional radioactive gamma probes. Although this combined Sienna+ / SentiMag system demonstrates non-inferiority compared to standard radiotracer techniques [4], [5] and offers visual identification due to dark brown staining of the nodes, it does present limitations, such as a localized tendency to discolor the skin at the injection site [6]–[10]. More importantly, its functionality is limited strictly to physical tracking and localization.

To expand the capabilities of magnetic tracking for multifunctional diagnostics, epsilon iron oxide (ϵ-Fe_2O_3) emerges as a powerful alternative. ϵ-Fe_2O_3 is a rare Fe_2O_3 polymorph with an orthorhombic crystal structure belonging to the $Pna2_1$ space group [11]. It exhibits a giant coercive field of approximately 2 T at room temperature and an exceptionally large magnetocrystalline anisotropy, making it remarkable among all iron oxide polymorphs. Crucially, ϵ-Fe_2O_3 exhibits a strong variation of magnetization with temperature, undergoing a sharp phase transition from a ferrimagnetic to a paramagnetic state at a specific Curie temperature (T_C). This high coercivity, prominent anisotropy, and distinct thermal transition make ϵ-Fe_2O_3 nanoparticles an ideal candidate for contactless nanothermometry.

The concept of a contactless nanothermometer relies on a system with a highly temperature-dependent, non-linear

magnetic response. Although pure ϵ-Fe_2O_3 has a T_C near $\approx 400\,^{\circ}\mathrm{C}$, this transition temperature can be precisely engineered through gallium doping, tailoring the sensing window to specific industrial or biomedical thermal ranges [12]. The samples used in this study consist of Ga-doped ϵ-Fe_2O_3 nanoparticles whose transition behavior spans between $5\,^{\circ}\mathrm{C}$ and $25\,^{\circ}\mathrm{C}$. This interval aligns well with the temperature windows required for food preservation, vaccine transportation, and perishable goods logistics, making them highly attractive for smart packaging and cold-storage technologies [13].

Integrating these nanoparticles into magnetic sensing systems enables real-time temperature monitoring without direct electrical contact. In this scenario, alternating current biosusceptometry (ACB) emerges as a highly promising, versatile, and low-operational-cost magnetic detection technique. The ACB system utilizes a first-order gradiometric coil configuration to detect the temporal derivative of magnetization under an alternating magnetic field [14], [15]. Furthermore, ACB is a exceptionally cost-effective technique compared to MPI or MRI. It features excellent temporal resolution and has been successfully validated in clinical and pre-clinical applications, including the study of the biodistribution of magnetic nanoparticles (MNPs) [16], gastrointestinal transit time [17], and hepatic uptake investigations [18].

Beyond its conventional uses, ACB serves as an excellent tracking tool for magnetic characterization due to its ability to operate at low primary field excitation frequencies, where thermal fluctuations do not directly compromise the measurements. Furthermore, tailored ACB sensors can detect these non-linear magnetic signals, opening new frontiers for simultaneous non-contact material tracking and precise thermal sensing based on the engineered T_C of ϵ-Fe_2O_3.

II. MATERIALS AND METHODS

A. Chemicals and synthesis

The Ga-doped ϵ-Fe_2O_3 ferrofluids were synthesized using the sol-gel method. Gallium was selected as the dopant to produce ϵ-$Ga_xFe_{2-x}O_3$ NPs, where $x \approx 0.97, 0.99$ and 1.0 for the samples M-03R, M-02 and M-04, respectively. In this procedure, a water-in-oil microemulsion system was employed, where the precursors were formed within the aqueous internal phase. To initiate the synthesis, two separate microemulsions were prepared as the oil phase; for each, 17.87 mL of n-octane, 3.57 mL of 1-butanol, and 3.535 mg of cetyltrimethylammonium bromide (CTAB) as a surfactant were mixed at $18\,^{\circ}\mathrm{C}$.

Subsequently, the aqueous phases were added to the microemulsions. The first aqueous phase was composed of 5.41 mL of water containing $Fe(NO_3)_3$ and $Ga(NO_3)_3$ salts added in stoichiometric ratios corresponding to the target x value, while the second aqueous phase consisted of 5.41 mL of water and 1.18 mL of an aqueous NH_4OH (ammonia) solution. Once both microemulsions reached stability, they were combined under rapid stirring. Following the fusion of the micelles, 0.91 mL of tetraethoxysilane (TEOS) was added as a silica precursor. After a 24-hour reaction period, the NPs were isolated by centrifugation, washed with chloroform and methanol, and dried.

The next step in the synthesis was to calcinate the NPs at $1050\,^{\circ}\mathrm{C}$ for 4 hours. Because this process results in an ϵ-phase embedded within a silica oxide matrix, a final chemical etching step using a 3 M NaOH solution was required to dissolve the matrix and isolate the nanoparticles [12].

B. Alternating current biosusceptometry

Alternating Current Biosusceptometry (ACB) is a cost-effective inductive technique for measuring magnetic materials. The system uses a first-order gradiometric configuration consisting of two pairs of coaxial excitation with a diameter of 2.8 cm (200 wire turns of AWG 24) and pick-up coils with a diameter of 2.1 cm (500 wire turns of AWG 32), as shown in Figure 1. The excitation coils generate an AC field (6.5 mT, 10 kHz), inducing a constant-rate current in the pickup coils. The setup comprises two units: a measurement unit, placed near the sample to detect NPs, and a reference unit, which cancels background noise and residual excitation fields to enhance the signal-to-noise ratio.

In the absence of a sample, the net magnetic flux is balanced, resulting in a null signal. The proximity of NPs alters this balance, inducing a voltage proportional to the parameters of the system (coil geometry, applied current) and the properties of the sample (volume, mass, susceptibility, and distance). The signal is generated and recorded using a low-noise Zurich Instruments MFLI lock-in amplifier (Zurich, Switzerland).

In the linear regime, magnetization is given by $M = \chi H$, where the magnetic susceptibility is $\chi = \chi' - i\chi''$, with χ' and χ'' representing the real and imaginary components, respectively. The ACB signal is proportional to the time derivative of magnetization, $\Delta V \propto \frac{dM}{dt}$. The voltage signal detected by the ACB system can be expressed as:

$$\Delta V = \mu_0 N A \alpha \omega H_0 (\chi'' + i\chi') \tag{1}$$

where ΔV is the induced voltage variation in the detection coil; μ_0 is the vacuum permeability ($4\pi \times 10^{-7}$ H/m); N is the number of turns in the detection coil; α is the geometric coupling factor, which depends on the experimental configuration and the position of the sample relative to the coil; ω is the angular frequency of the applied magnetic field ($\omega = 2\pi f$); H_0 is the amplitude of the applied alternating magnetic field.

The sensor allows the detection of different signal components. The real component is given by:

$$\Delta V_x = \mu_0 N A \alpha \omega H_0 \chi'' \tag{2}$$

and the imaginary component by:

$$\Delta V_y = \mu_0 N A \alpha \omega H_0 \chi' \tag{3}$$

The amplitude in polar coordinates is:

$$\Delta V_R = \sqrt{\Delta V_x^2 + \Delta V_y^2} \tag{4}$$

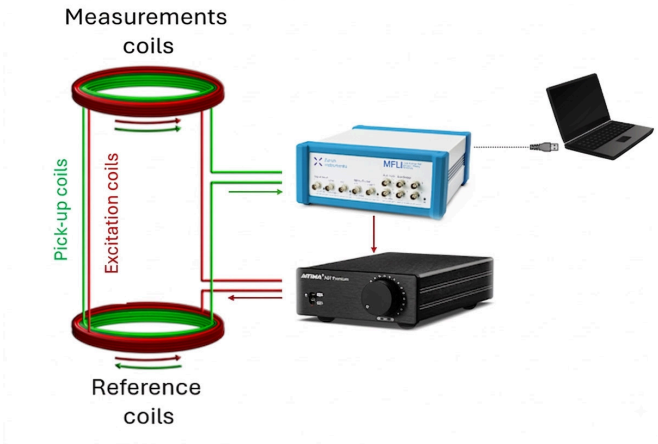

Fig. 1. Schematic diagram of the first-order gradiometric coil system used in the ACB setup, illustrating the arrangement of measurement, reference, excitation, and pick-up coils.

and the phase is given by:

$$\theta = \arctan(\Delta V_y / \Delta V_x) \tag{5}$$

C. Vibrating sample magnetometer

The Vibrating Sample Magnetometer (VSM) quantifies magnetic moments by vibrating a sample at a constant frequency within a uniform magnetic field (H), as illustrated in Fig. 2b. According to Faraday's Law of Induction, this periodic motion induces a voltage in the nearby pickup coils that is directly proportional to the magnetization of the sample. By integrating a temperature controller, the VSM enables precise monitoring of the magnetic moment as a function of temperature (M vs. T). Due to its high sensitivity and accuracy in temperature-dependent measurements, the VSM is widely utilized for studying magnetic nanoparticles, thin films, ferrites, and magnetic phase transitions.

D. Magnetic phase transition measurements

The magnetic phase transition study was conducted by cooling the nanoparticles to temperatures below their Curie temperature (T_C) in the absence of an external magnetic field, ensuring that the magnetic domains remained randomly oriented. To achieve these sub-ambient temperatures, the samples were placed in a temperature-controlled cooling system.

Upon reaching the base temperature, the Zero-Field-Cooled (ZFC) magnetization was measured using the VSM. During this procedure, a small external magnetic field ($B = 5$ mT, where $B = \mu_0 H$) was applied, and magnetization $M(T)$ was recorded as the sample was gradually heated. The resulting ZFC curve exhibits a distinct peak corresponding to the magnetic phase transition temperature (T_C), where the thermal energy becomes sufficient to overcome the magnetic ordering of the material, driving the transition from a ferrimagnetic state to a paramagnetic state.

For the ACB measurements, the samples were frozen similarly using liquid nitrogen and then placed inside the ACB

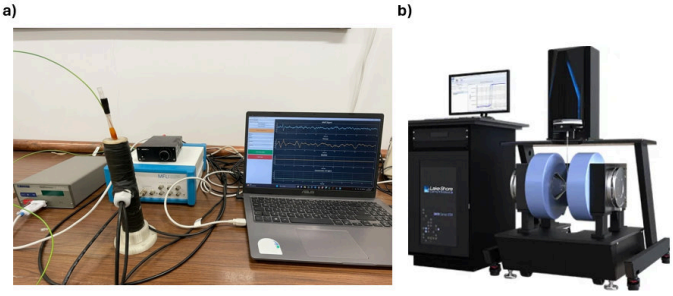

Fig. 2. Experimental setups used for magnetic characterization: a) ACB system integrated with a Neoptix temperature sensor, and a dedicated Python-based interface for real-time data acquisition; b) Commercial Lake Shore Cryotronics VSM system used for M vs. T measurements

system alongside a Neoptix Reflex fiber optic temperature sensor, as shown in Fig. 2a. The ACB signal was digitized using a lock-in amplifier, while the temperature data was captured via a Neoptix Reflex signal conditioner. Both the R component (signal amplitude) and the θ component (phase), along with the temperature, were recorded simultaneously using a custom Python script.

III. RESULTS AND DISCUSSION

Figure 3 presents ACB signals and ZFC curves for Gallium-doped epsilon iron oxide nanoparticles. The VSM measurements (Figs. 3D, 3E, and 3F) provide information on the magnetic ordering and phase transition behavior under a small applied field of $5\,\mathrm{mT}$. All three samples exhibit distinct magnetization maxima corresponding to their Curie temperatures (T_C), where the materials undergo a transition from a ferrimagnetic to a paramagnetic state. The values of T_C were determined to be approximately $1.5\,^\circ\mathrm{C}$ for M-04 (Fig. 3D), $12.0\,^\circ\mathrm{C}$ for M-02 (Fig. 3E), and $19.0\,^\circ\mathrm{C}$ for M-03R (Fig. 3F).

The experimental results reveal that both techniques clearly resolve the ferrimagnetic-to-paramagnetic phase transition. For the ACB measurements, the transition temperatures (T_C) were approximately $7.5\,^\circ\mathrm{C}$ for M-04 (Fig. 3A), $16.4\,^\circ\mathrm{C}$ for M-02 (Fig. 3B) and $22.0\,^\circ\mathrm{C}$ for M-03R (Fig. 3C). In comparison, the VSM profiles yielded T_C values of $1.5\,^\circ\mathrm{C}$, $12.0\,^\circ\mathrm{C}$, and $19.0\,^\circ\mathrm{C}$, respectively. Although a systematic temperature offset of approximately $3.0\,^\circ\mathrm{C}$ to $6.0\,^\circ\mathrm{C}$ is observed between the two methods, the fundamental trend of the T_C shift as a function of gallium doping remains remarkably consistent between both techniques.

To objectively evaluate the degree of agreement between the two methodologies, quantitative comparative metrics were calculated, as summarized in Table I. Across the three distinct nanoparticle formulations, the mean absolute error (MAE) in transition temperature determination between ACB and VSM was $4.47\,^\circ\mathrm{C}$. Despite this systematic absolute offset, the relative sensitivity of T_C shift to gallium content ($\Delta T_C / \Delta x$) shows strong consistency, yielding a Pearson correlation coefficient of $r = 0.998$ ($p < 0.05$) between the transition temperatures estimated by both techniques. This confirms that, while an absolute calibration offset exists, ACB exhibits

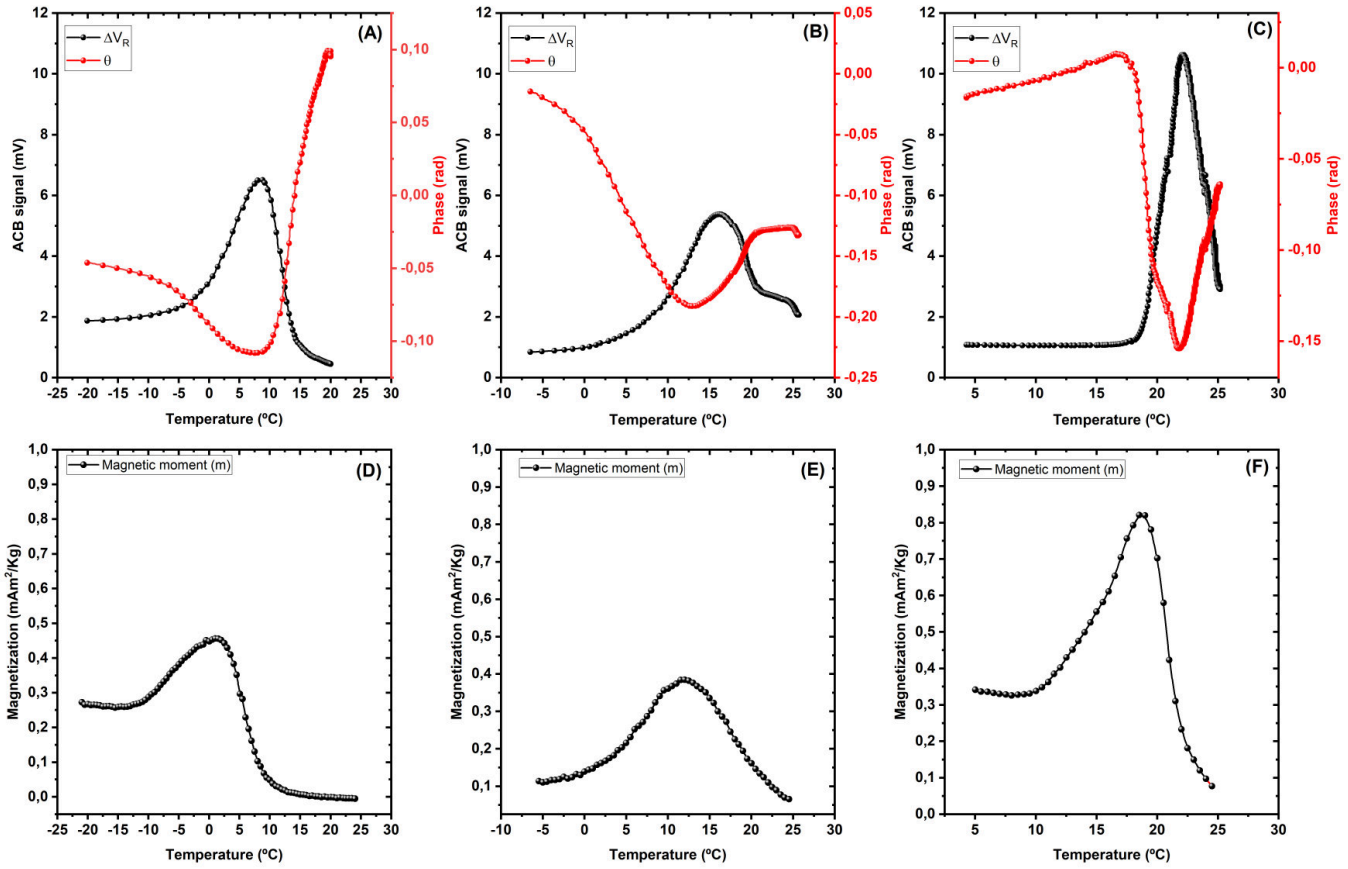

Fig. 3. Temperature dependence of the magnetic properties for the ϵ-$Ga_xFe_{2-x}O_3$ nanoparticle samples M-04, M-02, and M-03R. **(A–C)** AC Biosusceptometry (ACB) signal (ΔV_R) and phase angle (θ) as a function of temperature for samples (A) M-04, (B) M-02, and (C) M-03R. **(D–F)** Zero-Field-Cooled (ZFC) magnetization curves as a function of temperature measured via Vibrating Sample Magnetometry (VSM) under an applied magnetic field of 5 mT for samples (D) M-04, (E) M-02, and (F) M-03R. Both techniques clearly resolve the identical ferrimagnetic-to-paramagnetic phase transition peaks, demonstrating the utility of the ACB method for qualitative thermal-magnetic phase transition tracking compared to static VSM measurements.

exceptional fidelity in tracking the relative thermal-magnetic phase behavior as a function of chemical composition.

TABLE I
QUANTITATIVE COMPARISON AND AGREEMENT METRICS FOR CURIE TRANSITION TEMPERATURES (T_C) DETERMINED VIA VSM AND ACB

Sample	Ga content (x)	VSM T_C (°C)	ACB T_C (°C)	Absolute Offset (°C)	Relative Offset (%)
M-04	1.00	1.5	7.5	6.0	400.0[a]
M-02	0.99	12.0	16.4	4.4	36.7
M-03R	0.97	19.0	22.0	3.0	15.8

[a]High percentage offset for M-04 is due to the small absolute reference denominator near 0 °C.
Summary Metrics: Mean Absolute Error (MAE) = 4.47 °C; Pearson Correlation (r) = 0.998.

This discrepancy in absolute transition temperatures can be attributed to distinct instrumentation profiles, thermal integration times, and physical measurement principles. In the ACB setup, the Neoptix temperature probe is positioned in direct contact with the sample, providing localized real-time thermal readings. In contrast, in the commercial VSM system, the internal temperature sensor is typically located within the sample chamber environment rather than inside the specimen itself, introducing a well-known thermal lag during dynamic temperature sweeps. Furthermore, unlike VSM, which captures quasi-static (DC) equilibrium magnetization (M), ACB measures the dynamic differential susceptibility ($\chi' + i\chi''$) under an alternating excitation field ($f = 10\,\mathrm{kHz}$, $H_0 = 6.5\,\mathrm{mT}$). Near Curie temperature (T_C), as the magnetocrystalline anisotropy barrier decreases, the finite relaxation times of the nanoparticles relative to the 10 kHz excitation period can induce phase shifts and broaden the observed voltage peak (ΔV_R), contributing to apparent shifts in the dynamic transition profile compared to static ZFC curves.

Although the observed temperature shift of 3.0 °C to 6.0 °C is plausibly attributed to thermal lag and dynamic relaxation, this thermal gradient hypothesis was not isolated experimentally in the current study. Future work incorporating systematically controlled heating rates, multi-point temperature sensors, and independent thermal calibration replicates will be required to quantitatively decouple instrumental thermal lag from intrinsic magnetic relaxation effects.

Crucially, despite these instrumentation-specific offsets, the ACB sensor successfully demonstrates its efficacy for monitoring the relative onset and shift of thermal-magnetic phase tran-

sitions. Regarding economic feasibility, although the present laboratory prototype utilizes high-grade instrumentation (such as a Zurich Instruments MFLI lock-in amplifier and a Neoptix optical temperature sensor), the underlying inductive detection technique remains inherently lower in operational complexity compared to commercial VSM systems. VSM units often involve substantial maintenance, specialized power supplies, and, in many configurations, cryogenic cooling infrastructure. In contrast, ACB operates with low-power AC excitation coils at room temperature. Furthermore, the electronic readout components can be streamlined in future iterations using dedicated microcontroller-based lock-in circuits, significantly reducing capital expenditure for point-of-care or field-deployable applications.

In conclusion, ACB demonstrated promising capability for qualitatively tracking thermal-magnetic transitions and resolving relative T_C shifts in ϵ-Fe_2O_3 nanoparticles as a function of gallium doping. While quantitative equivalence with VSM still requires further thermal calibration, systematic offset corrections, and uncertainty analysis, ACB provides an efficient, accessible, and scalable methodology for preliminary phase transition screening.

***Abstract*—Os dispositivos baseados em membranas de nitrocelulose têm sido amplamente utilizados em aplicações de diagnóstico devido ao baixo custo, simplicidade de fabricação e potencial para análises no ponto de atendimento. Neste trabalho, foi empregada a espectroscopia de refletância difusa na região do infravermelho próximo (900–1700 nm), associada à Análise de Componentes Principais (PCA), para caracterizar as alterações ópticas decorrentes das diferentes etapas de funcionalização de membranas de nitrocelulose contendo nanopartículas de ferrita de cobalto ($CoFe_2O_4$), etilenodiamina (EDA), alérgeno AlgH e imunoglobulina G (IgG). Os espectros obtidos foram submetidos à correção de linha de base, normalização por área e análise quimiométrica. Embora os espectros apresentassem perfis semelhantes por inspeção visual, a PCA permitiu discriminar os diferentes grupos experimentais, explicando 98,0% da variabilidade total dos dados nos dois primeiros componentes principais (PC1 = 91,5% e PC2 = 6,5%). A análise dos loadings identificou a região espectral entre 1650 e 1680 nm como a principal responsável pela separação observada entre as etapas de funcionalização. Os resultados demonstram que a combinação da espectroscopia NIR com técnicas quimiométricas constitui uma abordagem sensível para detectar modificações ópticas em membranas de nitrocelulose funcionalizadas, apresentando potencial para aplicação na caracterização de plataformas destinadas ao desenvolvimento de dispositivos analíticos baseados em papel.**

***Index Terms*—Espectroscopia NIR, refletância difusa, análise de componentes principais, quimiometria, nitrocelulose, ferrita de cobalto.**

I. Introdução

Os dispositivos analíticos baseados em papel (microfluidic paper-based analytical devices – μPADs) têm despertado crescente interesse para aplicações em diagnóstico devido ao baixo custo, facilidade de fabricação, reduzido consumo de reagentes e potencial para utilização em análises no ponto de atendimento (Point-of-Care Testing – POCT) [1]. Entre os materiais empregados nesses dispositivos, a membrana de nitrocelulose destaca-se por apresentar elevada capacidade de transporte capilar, alta afinidade para imobilização de biomoléculas e ampla utilização em testes imunocromatográficos, tornando-se uma plataforma promissora para o desenvolvimento de sistemas de detecção [1], [8].

Durante a preparação dessas plataformas, diferentes etapas de funcionalização química são realizadas para promover a imobilização de nanopartículas, agentes funcionalizantes e biomoléculas sobre a superfície da membrana. Essas modificações alteram as propriedades ópticas do material, produzindo variações espectrais geralmente discretas ao longo do processo de funcionalização. Dessa forma, técnicas ópticas não destrutivas capazes de detectar pequenas alterações espectrais tornam-se ferramentas importantes para acompanhar essas modificações superficiais [2].

Entre essas técnicas, a espectroscopia de refletância difusa na região do infravermelho próximo (Near-Infrared Spectroscopy – NIR) destaca-se por permitir a investigação das propriedades ópticas de materiais porosos a partir da interação da radiação incidente com sua estrutura. Alterações nos processos de absorção e espalhamento da luz, decorrentes da deposição de nanopartículas e das modificações superficiais, podem produzir variações espectrais características para cada etapa da funcionalização [2], [4]. Entretanto, essas diferenças são frequentemente discretas e distribuídas ao longo de centenas de comprimentos de onda, dificultando sua interpretação por inspeção direta dos espectros. Nesse contexto, métodos de análise multivariada, como a Análise de Componentes Principais (PCA), tornam-se fundamentais para extrair informações relevantes, reduzir a dimensionalidade dos dados espectrais e identificar padrões associados às modificações da superfície [5], [10], [11].

Neste trabalho, foram utilizadas nanopartículas de ferrita de cobalto ($CoFe_2O_4$) como plataforma de funcionalização devido às suas propriedades magnéticas e ao seu potencial para aplicações em sistemas de biossensoriamento [3], [4], [9]. As nanopartículas foram funcionalizadas com etilenodiamina (EDA), seguida da imobilização do alérgeno AlgH e da imunoglobulina G (IgG), constituindo diferentes etapas de modificação superficial da membrana de nitrocelulose. Os espectros de refletância difusa foram adquiridos na região do infravermelho próximo (900–1700 nm) e analisados por meio da Análise de Componentes Principais (Principal Component Analysis – PCA), com o objetivo de investigar a capacidade da técnica em diferenciar as alterações ópticas produzidas durante as sucessivas etapas de funcionalização da plataforma.

II. Materiais e Métodos

A. Preparação das Amostras

As amostras foram preparadas utilizando membranas de nitrocelulose empregadas como plataforma para funcionalização superficial. Inicialmente, foram utilizadas membranas sem modificação (controle). Em seguida, realizou-se a deposição de nanopartículas de ferrita de cobalto ($CoFe_2O_4$), sintetizadas em laboratório parceiro, seguida da funcionalização com etilenodiamina (EDA), imobilização do alérgeno AlgH e, por fim, incubação com imunoglobulina G (IgG), constituindo diferentes etapas do processo de funcionalização.

A Tabela I apresenta os grupos experimentais correspondentes às diferentes etapas de funcionalização da membrana de nitrocelulose.

As nanopartículas de ferrita de cobalto ($CoFe_2O_4$) foram fornecidas por um grupo de pesquisa parceiro, responsável por sua síntese, sendo posteriormente empregadas nas etapas de funcionalização desenvolvidas no laboratório. A utilização dessas nanopartículas foi motivada por suas propriedades magnéticas e ópticas, que favorecem aplicações em plataformas de biossensoriamento e modificação superficial [3], [4], [9].

Tabela I
Grupos experimentais correspondentes às diferentes etapas de funcionalização da membrana de nitrocelulose.

Grupo	Descrição
Nitrocelulose	Membrana de nitrocelulose sem modificação (controle).
$CoFe_2O_4$	Membrana contendo nanopartículas de ferrita de cobalto.
$CoFe_2O_4$ + EDA	Funcionalização das nanopartículas com etilenodiamina (EDA).
$CoFe_2O_4$ + EDA + AlgH	Imobilização do alérgeno AlgH sobre a superfície funcionalizada.
$CoFe_2O_4$ + EDA + AlgH + IgG	Formação do imunocomplexo após incubação com IgG específica.

Para cada grupo experimental foram analisadas três membranas independentes, sendo realizada uma aquisição espectral em cada membrana, totalizando três espectros por grupo.

B. Aquisição dos espectros de refletância difusa

Os espectros de refletância difusa foram adquiridos utilizando um espectrômetro portátil baseado em fibra óptica (StellarNet, EUA), operando na região do infravermelho próximo (NIR), entre 900 e 1700 nm. A aquisição dos espectros foi realizada por meio de uma sonda de fibra óptica em configuração de refletância difusa, permitindo a iluminação da superfície da amostra e a coleta da radiação retroespalhada pelo mesmo sistema óptico [6], [7].

A sonda foi posicionada perpendicularmente à superfície da membrana de nitrocelulose, mantendo-se uma distância aproximada de 5 mm durante todas as aquisições, a fim de garantir a reprodutibilidade das medições. O tempo de integração foi fixado em 1000 ms para todas as amostras, mantendo constantes as condições experimentais ao longo do estudo.

A Figura 1 apresenta o sistema experimental utilizado para aquisição dos espectros de refletância difusa.

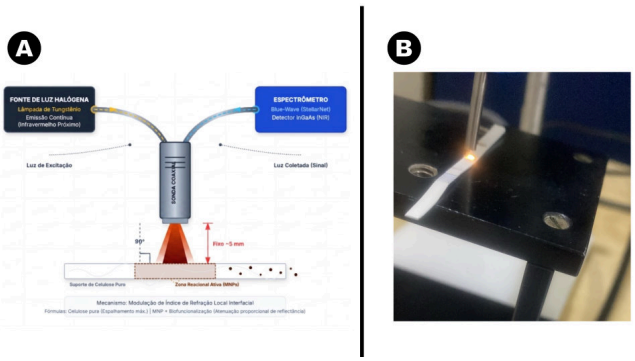

Fig. 1. Setup experimental utilizado para aquisição dos espectros de refletância difusa: (A) esquema da configuração experimental; (B) fotografia do sistema utilizado.

C. Processamento dos Espectros

Os espectros foram processados utilizando um software desenvolvido em Python (PinkApp), desenvolvido especificamente para análise espectral e visualização dos resultados.

Inicialmente, os arquivos espectrais foram importados individualmente e organizados conforme os grupos experimentais. Em seguida, cada espectro foi submetido à correção da linha de base por deslocamento do sinal para o valor mínimo (*baseline offset correction*), seguida de normalização pela soma das intensidades espectrais (*area normalization*), reduzindo diferenças de intensidade absoluta entre as aquisições. Esses procedimentos de pré-processamento são amplamente empregados em análises espectrais para minimizar variações instrumentais e permitir comparações mais consistentes entre as amostras [5], [11].

O software também permitiu selecionar intervalos específicos do espectro para análises localizadas, possibilitando investigar regiões espectrais de maior interesse.

D. Análise de Componentes Principais

A diferenciação entre os grupos experimentais foi realizada por meio da Análise de Componentes Principais (*Principal Component Analysis* – PCA), implementada na biblioteca *scikit-learn* (Python).

A PCA foi aplicada aos espectros normalizados com o objetivo de reduzir a dimensionalidade dos dados e identificar padrões de agrupamento associados às diferentes etapas de funcionalização da membrana de nitrocelulose [5].

Os dois primeiros componentes principais (PC1 e PC2) foram utilizados para construção dos gráficos de dispersão (*scores plots*), sendo apresentada a porcentagem de variância explicada por cada componente.

Além da projeção dos escores, foram analisados os vetores de carregamento (*loadings*), permitindo identificar os comprimentos de onda que mais contribuíram para a separação entre os grupos experimentais [10], [11].

E. Análise dos Loadings da PCA

Os vetores de carregamento (loadings) obtidos pela Análise de Componentes Principais (PCA) foram utilizados para identificar os comprimentos de onda com maior contribuição para a separação entre os grupos experimentais. Os valores absolutos dos loadings foram analisados para determinar as regiões espectrais mais relevantes na discriminação das diferentes etapas de funcionalização da membrana de nitrocelulose [5], [10].

III. Resultados e Discussão

A. Análise Espectral dos Grupos

A Figura 2 apresenta os espectros de refletância difusa adquiridos na região do infravermelho próximo (NIR), entre 900 e 1700 nm, para as diferentes etapas de funcionalização da membrana de nitrocelulose. De maneira geral, os espectros apresentaram perfis semelhantes, indicando que as modificações promovidas pela deposição das nanopartículas de ferrita de cobalto ($CoFe_2O_4$) e pelas etapas subsequentes de funcionalização produziram alterações espectrais discretas, de difícil identificação por inspeção visual. Esse comportamento é esperado em materiais porosos analisados por espectroscopia de refletância, nos quais pequenas modificações superficiais podem resultar em variações sutis nos processos de absorção e espalhamento da radiação incidente [2], [4].

Após o pré-processamento dos sinais, envolvendo correção da linha de base e normalização por área, observou-se melhor definição das diferenças de intensidade entre os grupos experimentais. A distribuição dos valores de pico máximo revelou variações ao longo das etapas de funcionalização, indicando que a incorporação das nanopartículas de $CoFe_2O_4$, seguida da imobilização da EDA, do alérgeno AlgH e da IgG, promove alterações nas propriedades ópticas da membrana de nitrocelulose, modificando sua interação com a radiação NIR. Entretanto, apesar dessas diferenças, ainda existe elevada sobreposição entre os espectros, evidenciando que a análise visual isolada não é suficiente para discriminar de forma confiável todas as etapas do processo, justificando a aplicação de técnicas quimiométricas para extração das informações relevantes [5].

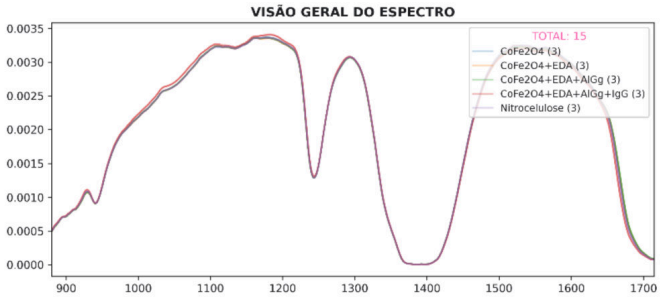

Fig. 2. Espectros de refletância difusa das diferentes etapas de funcionalização da membrana de nitrocelulose obtidos na região do infravermelho próximo (900–1700 nm).

B. Análise de Componentes Principais (PCA)

Com o objetivo de avaliar a capacidade de discriminação entre as diferentes etapas de funcionalização da membrana de nitrocelulose, foi aplicada a Análise de Componentes Principais (*Principal Component Analysis* – PCA). Os dois primeiros componentes principais explicaram 98,0% da variabilidade total dos dados, sendo 91,5% atribuídos à PC1 e 6,5% à PC2, indicando que a maior parte da informação espectral foi representada em um espaço bidimensional [5], [9]. Conforme apresentado na Figura 3, a projeção dos escores (*scores*) evidenciou a formação de agrupamentos distintos para cada grupo experimental. A membrana de nitrocelulose sem modificação apresentou um agrupamento claramente separado das amostras funcionalizadas. A deposição das nanopartículas de ferrita de cobalto ($CoFe_2O_4$) e a posterior funcionalização com etilenodiamina (EDA) promoveram deslocamentos progressivos no espaço multivariado, enquanto as etapas de imobilização do alérgeno (AlgH) e da imunoglobulina G (IgG)

originaram agrupamentos bem definidos, evidenciando que cada etapa do processo produziu alterações ópticas detectáveis pela espectroscopia NIR. Observou-se ainda baixa dispersão entre as três réplicas de cada grupo experimental, indicando consistência dos perfis espectrais obtidos nas condições avaliadas. A baixa sobreposição entre os agrupamentos demonstra que a combinação da espectroscopia de refletância no infravermelho próximo com a PCA foi capaz de diferenciar as sucessivas etapas de funcionalização da membrana de nitrocelulose, mesmo diante de diferenças pouco perceptíveis nos espectros originais [5], [9].

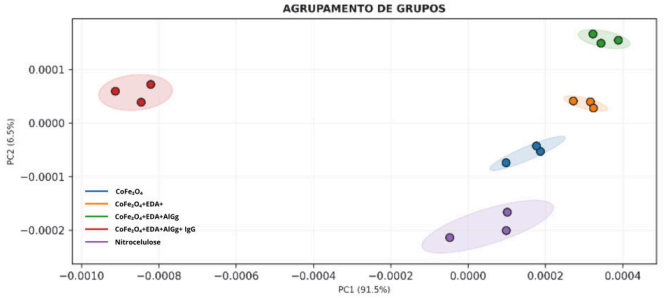

Fig. 3. Projeção dos escores da Análise de Componentes Principais (PCA) obtida a partir dos espectros de refletância difusa das diferentes etapas de funcionalização da membrana de nitrocelulose.

C. Importância dos Comprimentos de Onda (Loadings)

A análise dos *loadings* permitiu identificar os comprimentos de onda que mais contribuíram para a separação observada na Análise de Componentes Principais (PCA). Conforme apresentado na Figura 4, a região compreendida entre aproximadamente 1650 e 1680 nm apresentou maior contribuição para a separação, indicando que essa faixa espectral concentrou as principais diferenças entre as etapas de funcionalização da membrana de nitrocelulose [8].

Os maiores valores de *loading* foram observados em 1665,75 nm para a PC1 (*loading* = 0,235) e em 1669,25 nm para a PC2 (*loading* = 0,174), indicando que esses comprimentos de onda apresentaram maior influência na discriminação entre os grupos experimentais.

Esses resultados indicam que as modificações realizadas ao longo das etapas de funcionalização produziram alterações na resposta espectral da membrana de nitrocelulose, sendo a região entre 1650 e 1680 nm aquela que apresentou maior contribuição para a separação observada entre os grupos. No infravermelho próximo, as respostas espectrais resultam predominantemente de sobretons e bandas de combinação de vibrações moleculares, de modo que alterações na composição e no ambiente químico da superfície podem modificar o perfil espectral registrado. Nesse contexto, a região identificada pelos *loadings* pode refletir mudanças associadas às sucessivas etapas de funcionalização da membrana. Estudos envolvendo sistemas de nitrocelulose e espectroscopia NIR demonstram que essa técnica é capaz de responder a diferenças relacionadas à composição química desses materiais [8]. Entretanto, a atribuição dessa região espectral a um grupo químico ou componente específico não pode ser estabelecida exclusivamente a partir da análise NIR e dos *loadings*, sendo necessárias técnicas complementares, como FTIR-ATR, para uma confirmação estrutural.

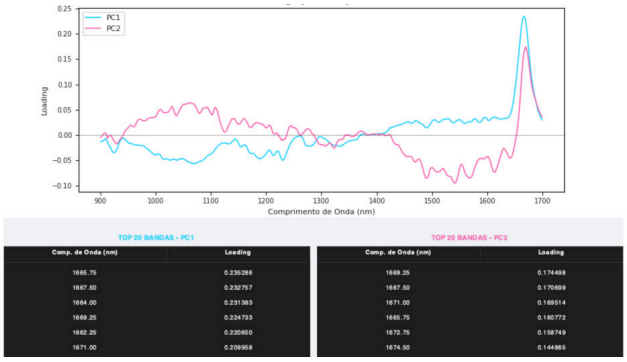

Fig. 4. Perfil dos loadings em função do comprimento de onda e principais regiões espectrais responsáveis pela separação dos grupos experimentais na Análise de Componentes Principais (PCA).

IV. Conclusão

Neste trabalho, a espectroscopia de refletância difusa na região do infravermelho próximo (900–1700 nm), associada à Análise de Componentes Principais (PCA), foi utilizada para avaliar as diferentes etapas de funcionalização de membranas de nitrocelulose contendo nanopartículas de ferrita de cobalto ($CoFe_2O_4$).

Os resultados demonstraram que pequenas alterações espectrais, dificilmente perceptíveis por inspeção visual, puderam ser discriminadas pela PCA, que explicou 98,0% da variabilidade total dos dados utilizando os dois primeiros componentes principais. A análise dos *loadings* identificou a região espectral entre 1650 e 1680 nm como aquela que apresentou maior contribuição para a separação entre os grupos experimentais, indicando que essa faixa pode estar associada às alterações espectrais decorrentes das sucessivas etapas de funcionalização.

Dessa forma, os resultados obtidos fornecem evidências preliminares do potencial da espectroscopia NIR associada à análise quimiométrica como ferramenta para a caracterização de superfícies funcionalizadas em membranas de nitrocelulose. Estudos futuros com um número maior de amostras e técnicas espectroscópicas complementares, como FTIR-ATR, serão importantes para avaliar a robustez dos resultados e aprofundar a atribuição físico-química das alterações espectrais observadas.

Abstract *— This study evaluated the institutional implementation of the American Association of Physicists in Medicine TG-119 protocol for volumetric modulated arc therapy (VMAT) on an Elekta Infinity linear accelerator using 6 MV flattening-filter-free (6FFF) photon beams and the Monaco treatment planning system (TPS). The AP/PA and Bands preliminary tests and the Multi-Target, Prostate, Head-and-Neck, C-Shape Easy, and C-Shape Hard cases were analyzed. Point doses were measured with a PTW31016 PinPoint 3D ionization chamber, and planar dose distributions were verified with an ArcCHECK diode array. Local gamma analysis used the institutional 3%/3 mm criterion with a 10% low-dose threshold. Passing rates ranged from 94.3% to 99.7%, with a mean of 96.89%, a standard deviation of 2.06%, and a confidence limit of 7.15%. Corrected mean point-dose deviations were −1.6% in the high-dose region and −2.5% in the low-dose region; the Head-and-Neck low-dose point was −3.9%. In the C-Shape Hard case, the planned core D5 and D10 objectives were not achieved, while the aggregate gamma passing rate was 94.3%. These results provide an institution-specific dosimetric baseline for the tested Elekta Infinity, Monaco, and 6 MV FFF configuration. Dose-volume histogram objectives, point-dose measurements, and gamma analysis should be interpreted together because they evaluate different aspects of the process.*

Keywords *— radiotherapy; VMAT; TG-119; quality assurance; point dose; gamma index; 6 MV FFF*

I. INTRODUCTION

Volumetric modulated arc therapy (VMAT) delivers radiation during continuous gantry rotation, with simultaneous modulation of multileaf collimator (MLC) aperture, dose rate, and gantry speed. This combination enables conformal dose distributions with shorter delivery times and, in many scenarios, fewer monitor units than static-field intensity-modulated techniques [1]–[3].

Flattening-filter-free (FFF) beams remove the component used to homogenize the beam's transverse profile. As a result, they present a non-flat profile, spectral changes, and higher dose rates [4], [5]. Clinical use of this modality requires that the treatment planning system adequately model the beam, and that the planning, transfer, and delivery chain be tested against situations of known complexity.

The AAPM TG-119 report proposes a standardized set of tests for IMRT commissioning. The protocol includes AP/PA fields, a Bands test, and cases spanning different levels of geometric and dosimetric complexity: Multi-Target, Prostate, Head-and-Neck, C-Shape Easy, and C-Shape Hard [6]. Planning objectives, point-dose measurements, and dose-distribution comparisons allow local reference values to be established and limitations to be identified before routine clinical use of the technique.

Gamma analysis combines dose difference and distance-to-agreement into a single metric [7], [8]. However, the passing rate depends on the detector, normalization, dose threshold, and criteria selected; moreover, an aggregate value does not replace evaluation of the specific objectives of the dose-volume histogram (DVH) [9]–[12]. For this reason, comparison with multi-institutional results must account for differences in equipment and methods.

The objective of this study was to evaluate the implementation of the TG-119 tests for VMAT with a 6 MV FFF beam on an Elekta Infinity accelerator and Monaco treatment planning system, establishing an institutional baseline through plan objectives, point-dose measurements, and ArcCHECK gamma analysis.

II. MATERIALS AND METHODS

A. Linear Accelerator and Treatment Planning System

Plans were generated on an Elekta Infinity linear accelerator equipped with an Agility multileaf collimator, comprising 160 leaves with a 0.5 cm projection at isocenter and a nominal maximum speed of 6.5 cm/s [13]. The 6 MV FFF photon beam was used, with a maximum dose rate of 1400 MU/min.

The Monaco treatment planning system, version 6.1.3, was used for optimization and calculation. Fluence optimization employed the Finite Size Pencil Beam algorithm, followed by final dose calculation using a voxel-based Monte Carlo algorithm. The images and structures provided for the TG-119 cases were imported into the system and registered to the measurement geometries [6], [14], [15].

B. Dosimetry Systems

Dose-distribution verification was performed with ArcCHECK, a Sun Nuclear cylindrical diode array. The device contains 1,386 SunPoint diodes arranged helically, with 1 cm spacing, 21 cm inner diameter, and 27 cm outer diameter. The cylindrical geometry allows entrance and exit signals to be recorded during arc deliveries [16]–[18]. The phantom was CT-scanned on an Aquilion Lightning (Canon) at 120 kV, 170 mA, 0.813 mm pitch, and 2 mm slice thickness. The images were imported into Monaco.

Point doses were measured with a PinPoint 3D ionization chamber (PTW31016), positioned at 10 cm depth in solid-water slabs with total dimensions of 30 × 30 × 20 cm³. Absorbed dose to water was obtained from the corrected chamber reading and the calibration coefficient:

$$D_{w,Q} = M \cdot N_{D,w,Q} \cdot k_{T,P} \quad (1)$$

where M is the corrected chamber reading, ND,w,Q is the absorbed-dose-to-water calibration coefficient, and kT,P is the temperature–pressure correction factor. This factor was calculated as:

$$k_{T,P} = [(273.2 + T) \cdot P0] / [(273.2 + T0) \cdot P] \quad (2)$$

where T and P are the temperature and pressure recorded during measurement, and T0 = 20 °C and P0 = 101.3 kPa are the reference conditions.

C. TG-119 Test Cases

Seven tests were implemented: AP/PA, Bands, Multi-Target, Prostate, Head-and-Neck, C-Shape Easy, and C-Shape Hard. The AP/PA test used opposing 10 × 10 cm² fields with 2 Gy at mid-plane. The Bands test used 3 cm-wide strips with a 0.4–2 Gy gradient. The remaining five cases used the structures, prescriptions, and constraints provided by the AAPM [6].

The point-dose fractional deviation was calculated relative to the prescribed dose and expressed as a percentage:

$$r = (D_{meas} - D_{plan}) / D_{presc} \times 100 \quad (3)$$

Deviations were grouped into high-dose and low-dose regions. The point-dose confidence limit was determined as:

$$CL_{dose} = |mean| + 1.96\sigma \quad (4)$$

D. Gamma Analysis

ArcCHECK measurements were compared to distributions calculated in SNC Patient software (version 6.2). The institutional local gamma criterion of 3%/3 mm was applied, with a 10% low-dose threshold and a minimum passing rate of 90%. The confidence limit was calculated as:

$$CL_{\gamma} = (100 - mean) + 1.96\sigma \quad (5)$$

Accordingly, 95% of results are expected to show a passing rate above (100 − CLγ)%. TG-218 was used only as a contemporary reference for methodological interpretation, since its universal recommendation of 3%/2 mm with global normalization and a 10% threshold is not identical to the local configuration applied in this dataset [9].

III. RESULTS

A. Preliminary Tests

Point-dose and gamma results for the AP/PA and Bands tests are shown in Table I. Deviations were +1.0% and −2.1%, respectively.

TABLE I. AP/PA AND BANDS RESULTS

Test	Meas. (cGy)	Calc. (cGy)	Deviation	Gamma (%)
AP/PA	198.0	196.0	+2.0 cGy (+1.0%)	98.9
Bands	137.1	140.0	−2.9 cGy (−2.1%)	99.7

C. Point-Dose Measurements

Point-dose deviations, correctly converted from fractional ratio to percentage, are presented in Table VII. Means were −1.6% in the high-dose region and −2.5% in the low-dose region. All high-dose results were within ±3%. In the low-dose region, the Head-and-Neck case showed −3.9%, exceeding this criterion.

TABLE VII. POINT-DOSE DEVIATIONS

Plan	High Dose (%)	Low Dose (%)
Multi-Target	−1.8	−1.9
Prostate	−1.2	−1.5
Head-and-Neck	−1.7	−3.9*
C-Shape Easy	−1.8	−2.3
C-Shape Hard	−1.7	−2.8
Mean	**−1.6**	**−2.5**
σ	0.25	0.93
CL	2.1	4.3

** Value above ±3%. Values were originally recorded as fractional ratios and are presented here as percentages. Source: study data.*

D. Planar Dose Measurements

Gamma passing rates ranged from 94.3% to 99.7% (Table VIII). All tests exceeded the institutional minimum criterion of 90%. The mean was 96.89%, the standard deviation was 2.06%, and the confidence limit was 7.15% (Table IX). The value corresponding to 100 − CLγ was 92.85%.

IV. DISCUSSION

The TG-119 protocol let us test planning and delivery across geometries of progressively increasing modulation complexity. PTV objectives were met in every case. Gamma values were lowest for the two C-Shape geometries — the most complex in the set — at 94.9% for C-Shape Easy and 94.3% for C-Shape Hard.

Once corrected to the proper scale, the point-dose results read differently. The high-dose mean was −1.6%; the low-dose mean was −2.5%. Both fall within ±3%, but the low-dose figure sits close to that limit, and the Head-and-Neck case alone reached −3.9%, past the threshold. All point measurements did not, in fact, meet the criterion, and the wider spread at low dose is reflected in the confidence limit as well: 4.3%, against 2.1% for high dose.

At 96.89%, our gamma mean sits 1.01 percentage points below the TG-119 multi-institutional mean of 97.9%; the confidence limit, 7.15%, is 0.15 points above the reported 7.0% [6]. This closeness should be read as descriptive rather than as evidence of equivalence — the treatment planning systems, accelerators, energies, detectors, measurement geometries, and analysis settings behind the two datasets were not the same.

C-Shape Hard met its PTV objectives but not its core limits: D5 reached 1522.3 cGy and D10 reached 1487.0 cGy, both against a ≤1000 cGy target. These figures come from the TPS-calculated DVH and represent an objective the plan simply did not meet. The 94.3% gamma passing rate, by contrast, reflects the aggregate agreement between the calculated and measured distributions across the whole phantom — a different question entirely. One metric passing does not mean the other did too: gamma agreement does not establish that the core objective was satisfied, just as the DVH exceedance on its own does not prove a delivery error [10], [11], [19].

It is tempting to attribute this to the concave geometry of C-Shape Hard, which plausibly adds complexity to optimization and MLC sequencing. This study, however, did not analyze the Agility log files, introduce controlled leaf-position perturbations, repeat the case independently, or compare the 6 MV FFF beam against a flattened beam on the same unit. Absent that work, geometry, MLC behavior, and FFF modality remain hypotheses here, not demonstrated causes.

Reading the gamma passing rate also means reading its configuration. Our 10% low-dose threshold matches the TG-218 recommendation, but our local 3%/3 mm criterion is not the same as the universal 3%/2 mm with global normalization and absolute dose that TG-218 recommends [9], so direct conformity with an identical metric cannot be

claimed. What this dataset does offer is a baseline for this specific local configuration — useful for tracking trends over time, provided the same analysis parameters are kept constant.

A further, detector-level limitation is worth noting: ArcCHECK samples dose on a fixed cylindrical surface, and its response shifts with field size, modulation, and target position relative to the diodes [16]–[18]. This is part of why point dose, gamma, and DVH objectives are best read together rather than relying on the passing rate alone. Three-dimensional reconstruction, independent dose calculation, and log-file analysis are workflows that could sharpen the ability to localize and interpret discrepancies of this kind going forward [12], [19]–[21].

V. CONCLUSION

We implemented the TG-119 tests for VMAT with a 6 MV FFF beam across the Elekta Infinity, Monaco, Agility, PinPoint 3D, and ArcCHECK set, giving this configuration an institutional dosimetric baseline. The mean gamma passing rate came to 96.89%, with a confidence limit of 7.15%. Point-dose deviations averaged −1.6% at high dose and −2.5% at low dose, with the Head-and-Neck low-dose point reaching −3.9%.

C-Shape Hard is the case that warrants the most caution: its core dose objectives went unmet in planning even though the aggregate gamma passing rate reached 94.3%. That gap illustrates, more clearly than any other result here, why delivery agreement and structural-objective evaluation must be read as complementary rather than interchangeable. Nothing in the present design allows the result to be attributed specifically to the FFF beam, MLC sequencing, or the concave geometry; confirming any of these would require repeated measurements and controlled comparisons not yet performed.

***Resumo*—Este artigo apresenta um protótipo de plataforma de Internet das Coisas Médicas (IoMT) destinado ao monitoramento de sinais vitais (frequência cardíaca e saturação de oxigênio) e à detecção de quedas, com foco na arquitetura de software que viabiliza seu funcionamento nesse contexto. Três decisões de software se mostram centrais para garantir a operação confiável e segura da plataforma: o sistema operacional de tempo real FreeRTOS, responsável por garantir a execução concorrente e determinística das tarefas internas do dispositivo; o protocolo de mensageria MQTT (*Message Queuing Telemetry Transport*), responsável por transmitir dados e alertas de forma eficiente mesmo sob recursos limitados; e o protocolo de segurança *Transport Layer Security* (TLS), responsável por proteger a confidencialidade de dados fisiológicos e de localização transmitidos sem fio. O artigo detalha o funcionamento interno de cada uma dessas tecnologias e discute por que cada escolha se torna particularmente relevante quando o sistema opera no contexto de saúde conectada, apresentando ao final evidências de que a integração entre essas camadas operou de forma coerente no protótipo desenvolvido.**

***Index Terms*—FreeRTOS; Internet das Coisas Médicas; Segurança de Dados em Saúde; Sistemas Embarcados de Tempo Real**

I. Introdução

A Internet das Coisas Médicas, ou *Internet of Medical Things* (IoMT), é o conceito associado a sistemas de saúde inteligentes e conectados, capazes de fornecer dados fisiológicos de um sujeito a profissionais de saúde, familiares ou cuidadores de forma automatizada e à distância [1]. Esse conceito ganha relevância particular quando aplicado a populações que necessitam de cuidado contínuo e vivem de forma independente. Como exemplo, estima-se que cerca de 30% dos idosos com 65 anos sofram ao menos uma queda por ano [2], evento que frequentemente exige socorro imediato. Pode-se citar também o caso das pessoas com Alzheimer, com cerca de 60% apresentando tendência à deambulação, processo de vaguear sem rumo, o que aumenta o risco de acidentes e de desorientação em ambientes externos [3]. Ambos os cenários convergem para a mesma necessidade prática: um dispositivo capaz de monitorar parâmetros fisiológicos fundamentais, detectar eventos críticos e de informar a localização da pessoa a um cuidador, de forma automática e em tempo real, para a prestação dos cuidados necessários.

A partir do problema exposto, foi desenvolvido um protótipo de dispositivo vestível capaz de monitorar frequência cardíaca, saturação de oxigênio e eventos de queda, acionando alarmes locais e remetendo alertas incluindo coordenadas de localização a um *broker* MQTT (*Message Queuing Telemetry Transport*), através de uma conexão Wi-Fi local autenticada, com toda a concorrência interna gerenciada pelo sistema operacional de tempo real FreeRTOS e a pilha de rede gerenciada pela biblioteca *Lightweight IP* (lwIP) [4]. A comunicação via MQTT é, ainda, criptografada a partir do protocolo *Transport Layer Security* (TLS), de forma a garantir confidencialidade para o tráfego de informações do usuário.

Desta forma, o presente trabalho tem como objetivo analisar e justificar as principais decisões de arquitetura empregadas no desenvolvimento do dispositivo IoMT. O foco principal é na camada de software, visto que viabilizar esse tipo de plataforma depende diretamente de decisões de software capazes de sustentar a concorrência interna, a comunicação eficiente e a segurança dos dados exigidas em um dispositivo IoMT. Além disso, busca-se discutir se o dispositivo encontra-se em um estágio funcional, com uma operação adequada em tempo real.

II. IoMT e as Restrições de um Sistema Embarcado Crítico

Dispositivos vestíveis voltados ao monitoramento fisiológico tornaram-se amplamente populares na última década [5], [6], sendo aplicados tanto ao desempenho esportivo quanto

ao acompanhamento de saúde em comunidades afastadas de grandes centros. Quando esse mesmo tipo de dispositivo é aplicado ao cuidado de pessoas com condições crônicas ou críticas, contudo, as restrições técnicas comuns a qualquer sistema embarcado (como processamento limitado, energia limitada e conectividade nem sempre estável) deixam de ser apenas problemas de desempenho e passam a ter implicação direta na segurança do usuário.

Diante disso, as necessidades de dispositivos IoMT podem ser, em um primeiro momento, organizadas em três tipos de exigência, cada uma delas mapeada para uma das decisões de software discutidas na Seção IV:

- **Exigência de tempo real e confiabilidade interna.** Um sistema que precisa adquirir dados de múltiplos sensores em taxas distintas, processar um algoritmo de detecção de evento crítico e, ao mesmo tempo, manter uma interface e uma conexão de rede ativas, não pode tratar essas tarefas como uma sequência arbitrária de chamadas de função. Um atraso na resposta a uma queda, por exemplo, compromete diretamente o propósito do dispositivo.
- **Exigência de comunicação eficiente sob recursos restritos.** Um dispositivo vestível tem orçamento de energia e de banda limitado, e frequentemente depende de redes locais (Wi-Fi doméstico) que podem ser instáveis. A transmissão de alertas não pode depender de protocolos pesados ou de múltiplas conexões simultâneas com cada possível interessado.
- **Exigência de confidencialidade de dados sensíveis.** Dados fisiológicos e, principalmente, dados de localização de uma pessoa vulnerável são informações sensíveis. Sua interceptação ou adulteração durante a transmissão sem fio representa um risco que extrapola a esfera técnica, alcançando a privacidade e a segurança física do usuário.

Somado a isso, pode-se pensar em camadas ainda não plenamente exploradas neste protótipo, mas relevantes ao se pensar a evolução de sistemas IoMT. Por exemplo, a possibilidade de identificação de padrões mais sutis de saúde por meio de algoritmos de aprendizado de máquina [7], algo que reforça a tendência dos serviços de saúde em direção a um cuidado contínuo e integral do usuário [8], e não apenas relativo a eventos isolados.

III. Visão Geral do Protótipo Desenvolvido

O hardware é centrado no microcontrolador RP2040, presente na placa BitDogLab [9], ao qual estão conectados: uma Unidade de Processamento de Movimento (MPU) 6050 e um sensor óptico MAX30102 (para medição de frequência cardíaca e saturação de oxigênio), ambos via barramento I2C; um módulo GPS GY-NEO6MV2, conectado por uma porta serial UART; um display OLED, conectado também via I2C; um módulo Wi-Fi, ligado a um barramento SPI; um alarme visual e um sonoro (um LED e um buzzer), acionados por pinos digitais. Vale ressaltar, ainda, que o barramento onde os sensores estão conectados (I2C0) é diferente do barramento onde o display está conectado (I2C1). O protótipo montado e em funcionamento pode ser visualizado na Fig. 1, com a Fig. 2 evidenciando quais informações são mostradas no display OLED: frequência cardíaca, saturação de oxigênio e angulação da MPU6050 (com a última sendo utilizada para a depuração do sistema).

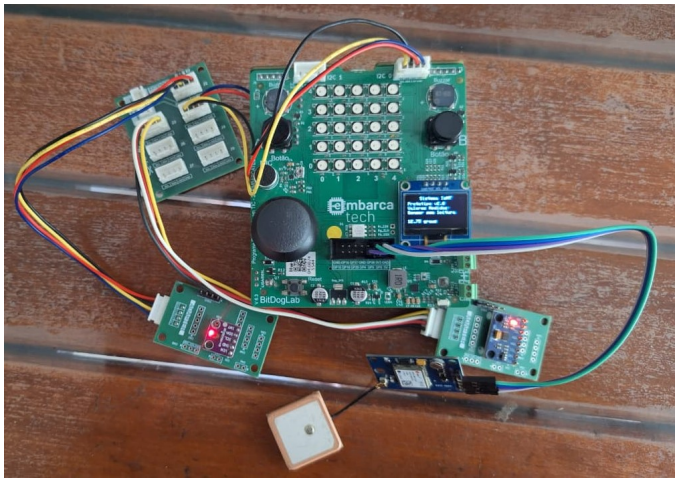

Figura 1. Protótipo do sistema desenvolvido.

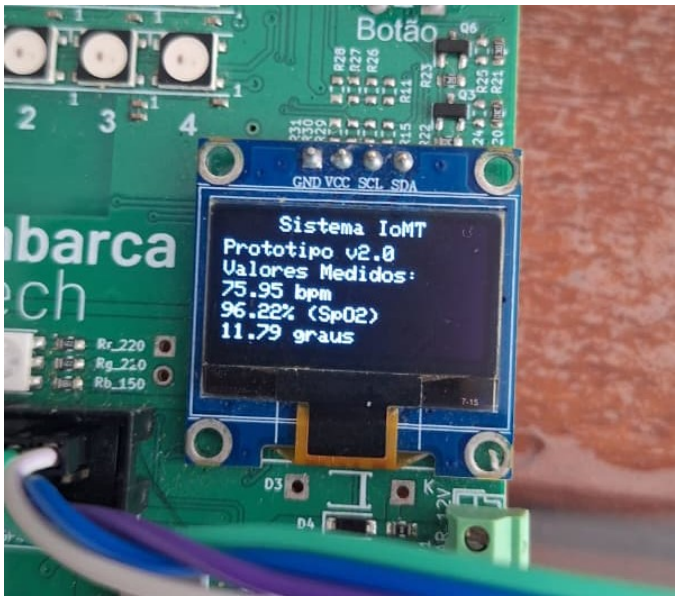

Figura 2. Conteúdo do display OLED com o sistema em funcionamento.

Esses componentes alimentam um conjunto de sete tarefas concorrentes: aquisição de dados do MPU6050, aquisição de dados do GPS, aquisição de dados do MAX30102, processamento de dados (incluindo o algoritmo de detecção de queda), interface com o usuário via display, conectividade MQTT e inicialização do Wi-Fi. A orquestração dessas tarefas é o primeiro ponto central da análise que se segue.

IV. Arquitetura do Sistema

A Fig. 3 apresenta o diagrama de blocos da arquitetura completa do sistema, organizado de baixo para cima em

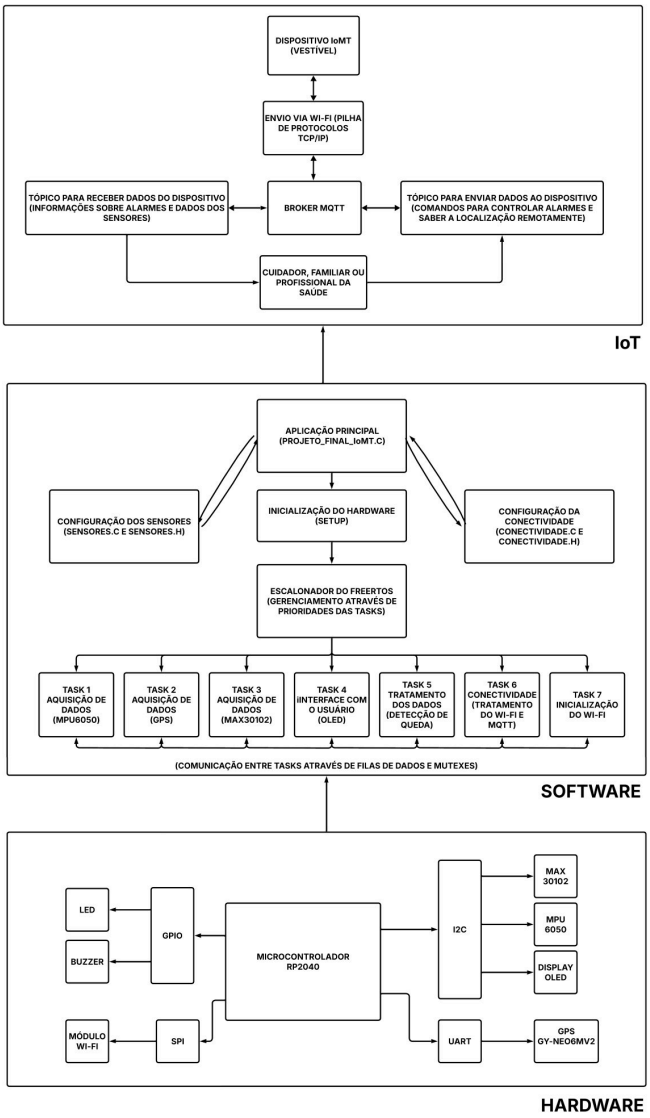

Figura 3. Diagrama da arquitetura completa do sistema.

Hardware, Software e camada IoT, refletindo a dependência hierárquica entre seus elementos: o hardware define os recursos disponíveis; o software os manipula de forma previsível, confiável e com base em prioridades; e a camada IoT expõe os dados ao mundo externo de forma eficiente e segura.

Nas subseções a seguir, são discutidas as três principais decisões de software do sistema: a utilização do FreeRTOS para lidar com a concorrência de eventos, do protocolo MQTT para a comunicação e do TLS como camada de criptografia para proteção dos dados.

A. Gerenciamento de Concorrência com FreeRTOS

O problema central que motiva o uso de um sistema operacional de tempo real é a coexistência, em um único microcontrolador de recursos limitados, de tarefas com requisitos temporais muito diferentes entre si. A aquisição de dados do MPU6050 precisa ocorrer em alta taxa de amostragem, sob risco de perder a janela temporal em que um evento de queda se manifesta nos dados do acelerômetro [10]; a aquisição do MAX30102 também exige prioridade alta para não comprometer a confiabilidade dos valores de frequência cardíaca e saturação de oxigênio; já a atualização do display OLED pode ocorrer em uma taxa muito mais baixa, sem prejuízo perceptível ao usuário. Em um modelo de execução sequencial (*bare-metal*), garantir esse tipo de diferenciação temporal exigiria um controle manual complexo e frágil, sujeito a perda de amostras sempre que uma operação mais lenta (como a leitura via UART do GPS) bloqueasse o fluxo principal.

Tecnicamente, o FreeRTOS organiza a aplicação em um conjunto de tarefas (*tasks*), cada uma implementada como uma função independente, com sua própria pilha de execução e seu próprio contexto de registradores. Diferentemente de um laço principal único, em que apenas uma função está ativa por vez, em um Sistema Operacional de Tempo Real (RTOS), todas as tarefas parecem executar simultaneamente: um componente chamado escalonador (*scheduler*) decide, a cada interrupção periódica do temporizador do sistema (*tick*), qual tarefa pronta para execução deve ocupar o processador naquele instante. No FreeRTOS, esse escalonamento é preemptivo e baseado em prioridades, ou seja, se uma tarefa de prioridade mais alta se torna pronta para executar, o escalonador interrompe imediatamente a tarefa de prioridade mais baixa em execução, salva seu contexto e transfere o processador para a tarefa mais prioritária, sem esperar que ela termine.

É exatamente esse mecanismo que o protótipo explora. A Tabela I lista as sete tarefas do sistema com suas respectivas prioridades e justificativas, tornando explícita a hierarquia temporal que o escalonador impõe: as tarefas de aquisição do MPU6050 e do MAX30102 nunca ficam impedidas de executar por tarefas menos urgentes, enquanto a atualização do display, inofensiva ao usuário em caso de atraso, opera na prioridade mais baixa do conjunto.

Tabela I
TAREFAS DO SISTEMA E SUAS PRIORIDADES NO FREERTOS

Tarefa	**Prior.**	**Justificativa**
`wifi_init_task`	Máx. (trans.)	lwIP; encerra após inicializar
`aquisicao_MPU_task`	Muito alta	Alta amostrag.; janela da queda
`aquisicao_MAX30102_task`	Muito alta	Confiab. do BPM/SpO_2
`processa_dados_task`	Alta	MEF de detecção; latência crítica
`conectividade_MQTT_task`	Alta	Latência do alerta ao *broker*
`aquisicao_GPS_task`	Média	UART; tolera perda de amostra
`interface_usuario_task`	Baixa	Display tolera atraso

A troca de informações entre tarefas não pode ocorrer por simples variáveis globais, sob risco de condições de corrida (*race conditions*). O FreeRTOS resolve esse problema com filas (*queues*): estruturas FIFO que já incorporam a proteção contra acesso concorrente. Já para o barramento I2C0 externo compartilhado pelos sensores MPU6050 e MAX30102, utiliza-se um mutex (*mutual exclusion*), que garante que apenas uma tarefa por vez tenha acesso ao barramento (os barramentos I2C foram configurados com uma frequência de 400 kHz).

Vale notar que o mutex do FreeRTOS implementa herança de prioridade: se uma tarefa de baixa prioridade estiver de posse do mutex e uma tarefa de alta prioridade precisar dele, a primeira temporariamente herda a prioridade da segunda, evitando o problema clássico de inversão de prioridade.

A justificativa específica para o contexto IoMT está no que esse escalonamento garante: a cadeia que liga a leitura do acelerômetro, a execução do algoritmo de detecção de queda e o disparo do alerta MQTT só é confiável se cada elo dessa cadeia tiver prioridade suficiente para não ser indefinidamente postergado por tarefas menos críticas. Nesse sentido, o uso de um sistema operacional de tempo real deixa de ser uma boa prática genérica de engenharia de software embarcado e passa a ser um requisito de segurança do usuário.

B. Algoritmo de Detecção de Queda por Máquina de Estados

O algoritmo de detecção de queda é o consumidor mais crítico da prioridade alta atribuída à `processa_dados_task`: é ele que transforma a sequência de leituras do acelerômetro em uma decisão binária "queda" ou "não queda", da qual dependem o acionamento do alarme local e o disparo do alerta via MQTT. Seu funcionamento baseia-se em álgebra vetorial sobre o vetor aceleração fornecido pelo MPU6050, cujo módulo é expresso em múltiplos de g, e no tempo necessário para que cada estado do processo de queda ocorra.

Segundo a literatura [10], o processo de queda se manifesta nos dados de um acelerômetro de três eixos em quatro fases sucessivas: (1) *ausência de peso*, caracterizada pela queda abrupta do módulo do vetor de aceleração abaixo de um limiar mínimo, correspondendo à fase de queda livre; (2) *impacto*, com o módulo ultrapassando um limiar máximo em um intervalo de tempo curto, indicando a colisão com o solo; (3) *inatividade*, em que o vetor de aceleração permanece com baixa variação por um intervalo prolongado, sugerindo que a pessoa ficou imóvel após a queda; e (4) *mudança de orientação*, verificada pelo ângulo entre o vetor de aceleração atual e o vetor registrado no início do evento, que permanece diferente da orientação de repouso habitual.

Essas quatro fases, precedidas pelo estado de operação normal, definem uma máquina de estados finitos (MEF) com cinco estados: NORMAL, AUSÊNCIA DE PESO, IMPACTO, INATIVIDADE e QUEDA CONFIRMADA. As regras de transição entre estados garantem que apenas a ocorrência *ordenada* dessas fases resulte em confirmação de queda: a transição de AUSÊNCIA DE PESO para IMPACTO, por exemplo, só ocorre se o impacto for detectado dentro de uma janela temporal pequena; do contrário, o sistema retorna ao estado NORMAL, interpretando o evento como um gesto brusco sem queda. A transição final de INATIVIDADE para QUEDA CONFIRMADA exige que o ângulo entre o vetor de aceleração atual e o vetor capturado no início do evento permaneça diferente por um intervalo de tempo mínimo, distinguindo inatividade pós-queda de uma simples pausa no movimento. O diagrama da MEF descrita é ilustrado pela Fig. 4, a qual descreve os limiares adotados para o protótipo desenvolvido.

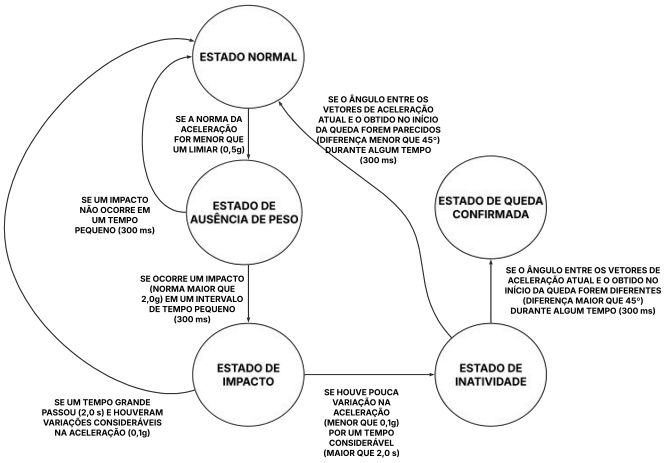

Figura 4. Diagrama de estados do algoritmo de detecção de quedas.

Esta subseção fecha o argumento sobre o FreeRTOS: sem a prioridade alta garantida ao escalonador para a `processa_dados_task`, a MEF poderia não receber amostras em tempo suficiente para detectar a janela de queda livre (um evento que, na literatura, dura tipicamente menos de 500 ms). A prioridade de tarefa, nesse contexto, é diretamente um requisito de desempenho do algoritmo.

C. Comunicação Leve e Assíncrona com MQTT

O MQTT é um protocolo de mensageria que opera sobre a pilha TCP/IP, seguindo um modelo de comunicação *publish/subscribe* mediado por um intermediário central, o *broker*. Nesse modelo, os participantes nunca se conectam diretamente entre si: um cliente que produz dados publica mensagens associadas a um tópico (cujo nome é uma string hierárquica que funciona como um endereço lógico) e qualquer cliente que tenha assinado aquele tópico recebe a mensagem automaticamente, redistribuída pelo *broker*. Essa indireção permite que o número de consumidores de uma informação cresça sem qualquer alteração no lado do dispositivo publicador, que continua enviando uma única mensagem por evento.

O protocolo também define três níveis de qualidade de serviço (QoS): 0, em que a mensagem é entregue sem confirmação; 1, em que a entrega é garantida, ainda que com possível duplicação; e 2, em que a entrega ocorre exatamente uma vez, ao custo de um *handshake* adicional. Soma-se a isso um mecanismo de *keep-alive*, em que o cliente envia periodicamente um sinal mínimo ao broker, permitindo que uma ausência desse sinal seja interpretada como uma desconexão inesperada e perda de informação potencialmente relevante em um cenário de cuidado contínuo. O cabeçalho de cada mensagem é deliberadamente compacto, o que, somado à ausência da sobrecarga textual de protocolos como o HTTP, torna o MQTT consideravelmente mais leve em termos de banda e de processamento exigido do dispositivo.

No protótipo, esse modelo é usado de forma direta: um tópico recebe os dados enviados pelo dispositivo (sinais vitais em condição normal, ou alerta de queda com localização em

condição crítica) e outro tópico recebe comandos remotos (solicitação de localização, ativação ou desativação de alarmes). A leveza do protocolo é explorada ainda na definição de uma ordem de prioridade – mensagens, alertas de queda e respostas de localização têm prioridade sobre o envio rotineiro de sinais vitais. As Figs. 5 e 6 evidenciam o funcionamento do sistema em dois cenários: no primeiro, o sistema está enviando os dados de forma rotineira (frequência cardíaca e saturação de oxigênio); no segundo, o usuário com acesso ao servidor MQTT envia o comando "localizacao" para o dispositivo de forma remota, retornando a latitude e longitude nas quais o dispositivo se encontra.

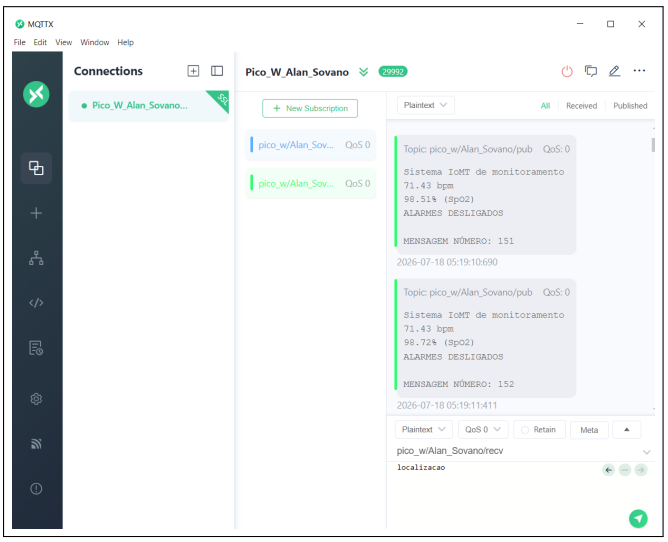

Figura 5. Envio de dados fisiológicos pelo dispositivo embarcado.

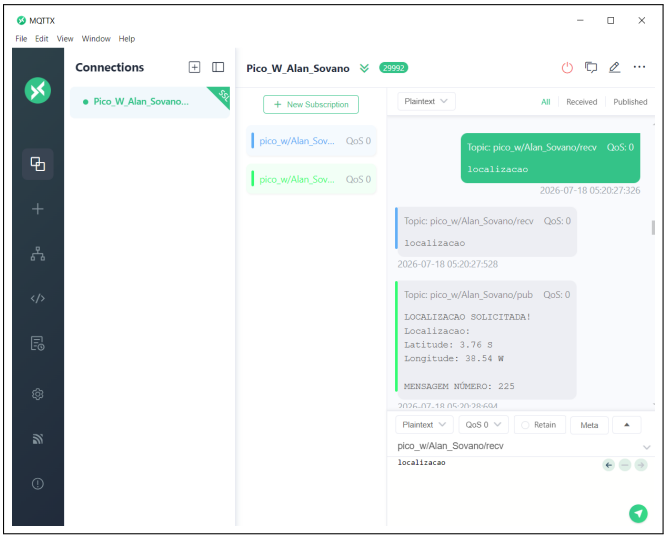

Figura 6. Solicitação da latitude e longitude do dispositivo embarcado.

A justificativa IoMT para essa escolha está na combinação de dois fatores: a necessidade de servir múltiplos interessados simultâneos a partir de um dispositivo com recursos mínimos, e a necessidade de que esse fluxo de comunicação continue funcional mesmo sob condições de rede não ideais, características típicas do ambiente doméstico de cuidado continuado.

D. Segurança de Dados Sensíveis com TLS

O terceiro problema decorre diretamente da resolução do segundo: uma vez que dados fisiológicos e de localização em tempo real passam a transitar por uma rede sem fio até um broker externo, esses dados tornam-se vulneráveis à interceptação. Esse tipo de ataque, conhecido como *Man-in-the-Middle* (MitM), permite que um terceiro não autorizado intercepte ou altere mensagens trocadas entre duas partes [11]. No contexto deste sistema, isso significaria a possibilidade de um terceiro acessar a localização de uma pessoa vulnerável, seus dados de saúde, ou mesmo emitir comandos falsos como desativar um alarme legítimo.

O protocolo TLS (*Transport Layer Security*) opera entre a camada de transporte (TCP) e a aplicação, e seu funcionamento divide-se em duas fases. Na primeira, chamada *handshake*, cliente e servidor negociam os parâmetros criptográficos da sessão: o servidor apresenta um certificado digital assinado por uma autoridade certificadora que permite ao cliente verificar sua identidade antes de prosseguir; em seguida, ambas as partes utilizam criptografia assimétrica para estabelecer, de forma segura e mesmo sobre um canal não confiável, uma chave secreta compartilhada. Na segunda fase, essa chave passa a ser usada com algoritmos de criptografia simétrica, significativamente mais eficientes computacionalmente, para cifrar todo o tráfego de dados da sessão, enquanto mecanismos criptográficos de identidade permitem detectar alterações no conteúdo durante o trânsito.

No protótipo, essa cadeia de garantias é colocada em prática por meio de um certificado de segurança embarcado na memória do dispositivo, que permite ao firmware verificar a validade do *broker* antes de estabelecer a conexão. Essa camada de segurança se soma à autenticação já existente na rede Wi-Fi (login e senha), fornecendo mais segurança na comunicação entre o dispositivo e o destinatário final dos dados.

A Fig. 7 evidencia o efeito da criptografia das informações enviadas pelo sistema. Para realizar essa verificação, o sistema foi conectado, via Wi-Fi, a um computador configurado como ponto de acesso à internet. O tráfego da informação gerado pelo dispositivo foi, então, monitorado pelo Wireshark, aplicativo de código aberto utilizado para a análise de protocolos de rede [12]. Para o teste, o sistema foi configurado sem TLS e com TLS em momentos diferentes, de forma a verificar o envio da mensagem com e sem criptografia.

Vale reconhecer que essa decisão não é isenta de custo: o estabelecimento de uma sessão TLS impõe sobrecarga computacional e energética ao microcontrolador. A escolha de absorver esse custo, em vez de prescindir da criptografia, reflete o julgamento de que, para um dispositivo que transmite dados de saúde e de localização de uma população vulnerável, a confidencialidade não é um refinamento opcional, mas um requisito mínimo de responsabilidade no projeto (mesmo em um protótipo sem caráter diagnóstico).

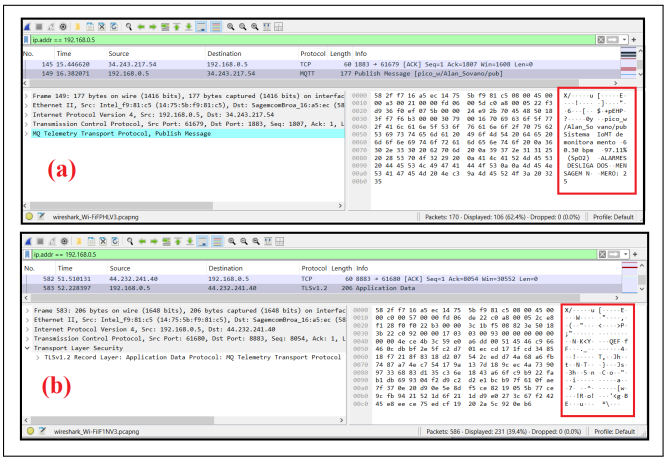

Figura 7. tráfego da informação (a) sem TLS e (b) com TLS.

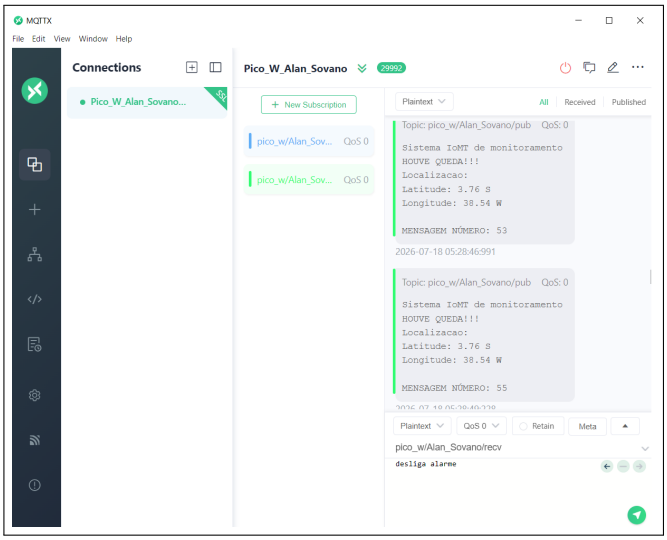

Figura 8. Detecção de queda pelo dispositivo embarcado.

V. Resultados da avaliação experimental do sistema

A validação prática do protótipo mostrou as três camadas operando como um único fluxo coeso. Foi possível observar a conexão Wi-Fi, a resolução de DNS do *broker* utilizado, o estabelecimento da sessão MQTT sobre TLS e a confirmação de inscrição nos tópicos relevantes, sequência que reproduz com exatidão a ordem teórica descrita na Seção IV: primeiro o FreeRTOS inicializa a pilha de rede via `wifi_init_task`; depois o MQTT estabelece a sessão sobre o canal já aberto; por fim, o TLS cifra esse canal antes que qualquer dado dos sensores seja transmitido. A mensagem recebida através do *broker* MQTT, quando ocorre uma queda que é detectada, pode ser visualizada na Fig. 8. Na ocorrência de um evento confirmado de queda, também foi possível verificar o disparo dos alarmes (auditivo e visual). Vale ressaltar que todos os testes de queda foram feitos somente com o dispositivo (sem a presença de nenhum tipo de usuário), visto que o projeto ainda necessita da aprovação de um comitê de ética em pesquisa para essa etapa.

De forma a avaliar se a quantidade de memória de pilha (*stack*) foi alocada adequadamente para cada uma das sete tarefas criadas, uma tarefa adicional (`monitor_task`) foi implementada exclusivamente para a avaliação do desempenho do sistema. Nessa tarefa, foi utilizada a função `uxTaskGetStackHighWaterMark()` do kernel FreeRTOS, que retorna a menor quantidade de memória de pilha que permaneceu livre desde a criação de uma tarefa, permitindo estimar seu consumo máximo de memória de pilha. A Tabela II apresenta a memória de pilha alocada para cada tarefa, bem como o uso máximo estimado durante a execução do sistema ao longo de 10 minutos.

A tarefa de conectividade apresentou o maior consumo de memória de pilha, resultado esperado devido ao uso das bibliotecas responsáveis pela comunicação TCP/IP, pelo gerenciamento do módulo Wi-Fi e pela implementação do protocolo MQTT. Entretanto, todas as tarefas mantiveram uma margem de memória disponível durante os testes, indicando que as

Tabela II
Consumo de memória de pilha das tarefas durante 10 minutos de execução

Tarefa do programa	Pilha de memória alocada (bytes)	Uso máximo estimado (bytes)
`aquisicao_MPU_task`	4096	296
`aquisicao_GPS_task`	4096	504
`aquisicao_MAX30102_task`	8192	616
`interface_usuario_task`	8192	600
`processa_dados_task`	4096	512
`conectividade_MQTT_task`	8192	2920
`wifi_init_task`	8192	656

pilhas foram dimensionadas adequadamente e que o sistema ainda possui capacidade para acomodar futuras expansões ou otimizações. Logo, todas as tarefas tiveram uma margem de segurança suficiente para as respectivas operações, com o FreeRTOS não comprometendo o uso de memória do RP2040.

Além do uso de memória, métricas temporais referentes ao uso do FreeRTOS foram calculadas. Em especial, pode-se destacar o tempo médio entre o início de duas execuções consecutivas de uma mesma tarefa de aquisição de dados, de forma a avaliar a regularidade das mesmas durante a operação normal do sistema (conectado ao *broker* MQTT e enviando mensagens). Além disso, avaliou-se o tempo de atualização do display OLED, de forma a caracterizar também como essas informações seriam repassadas ao usuário. Todas as métricas foram obtidas com o uso da função `get_absolute_time()`, a qual foi colocada em trechos específicos do código principal para captura de marcações de tempo. Após um determinado número de capturas, os dados eram enviados ao usuário por meio da interface serial. A captura das marcações foi feita de modo a minimizar, da melhor forma possível, a interferência no próprio intervalo de tempo que estava sendo medido. Um resumo dos dados é descrito na Tabela III.

A partir dos dados, percebe-se que as tarefas `aquisicao_MPU_task` e `aquisicao_MAX30102_task` possuem boa regularidade,

Tabela III
CARACTERIZAÇÃO TEMPORAL DAS TAREFAS DE AQUISIÇÃO E INTERFACE.

Métrica	MPU	MAX30102	GPS	Interface
Número de testes	500	500	500	500
Média (ms)	51,22	102,77	1235,03	38,06
Desvio-padrão (ms)	0,84	0,44	490,44	1,71
Mínimo (ms)	49,86	102,00	972,06	35,99
1º quartil (ms)	50,96	102,94	976,06	37,00
Mediana (ms)	51,00	103,00	979,06	37,00
3º quartil (ms)	52,00	103,00	982,06	40,00
Máximo (ms)	54,00	104,39	3979,06	43,01

com ambas sendo executadas periodicamente perto do tempo desejado (50 ms e 100 ms, respectivamente). Variações no período de execução dessas tarefas (*jitter*) podem ser explicadas pelo tempo necessário para a troca de tarefas do escalonador e também pelo uso do mutex (uma tarefa só pode ser executada quando outra não estiver sendo executada).

Para a tarefa `aquisicao_GPS_task`, avaliou-se o tempo entre a geração de duas respostas completas do GPS (que é descrita por um conjunto de caracteres vindos da porta UART). A tarefa foi projetada para rodar a cada 1 ms e obter um caracter, o que também foi observado, mas a geração de uma resposta completa (que será enviada via MQTT quando solicitado) é um processo muito mais demorado. Por isso, o sistema foi configurado para manter um mesmo sinal válido de GPS por 5 segundos (na ausência de um outro sinal válido). Como, pelos experimentos realizados, o tempo entre sinais válidos de GPS foi menor do que o estabelecido, percebe-se que há uma consistência no limiar utilizado.

A tarefa `interface_usuario_task`, por sua vez, depende do recebimento de dados de `aquisicao_MPU_task` e `aquisicao_MAX30102_task`, com a comunicação ocorrendo através de filas. Foi possível verificar que, dentro da estrutura do sistema, a taxa de atualização do display OLED ficou em torno de 40 ms, tendo inclusive uma dispersão relativamente baixa. Logo, concluiu-se que essa tarefa também estaria funcionando da forma adequada.

Outro teste realizado consistiu na avaliação da confiabilidade da comunicação MQTT durante 10 minutos de operação contínua. O teste foi realizado utilizando a porta 8883 (com criptografia TLS) do *broker* público EMQX e nível de QoS igual a 0. Cada mensagem publicada continha o valor de uma variável contadora, incrementada a cada transmissão, permitindo identificar mensagens perdidas e mensagens recebidas fora da sequência esperada.

Ao longo do teste, o dispositivo publicou 584 mensagens, das quais 534 foram recebidas na sequência esperada, 47 foram perdidas e 3 foram recebidas com atraso. Dessa forma, obteve-se uma taxa de entrega em sequência de aproximadamente 91,4%. As perdas observadas são compatíveis com a utilização do QoS 0, que não oferece garantia de entrega das mensagens. Logo, observa-se que o sistema consegue realizar o envio de mensagens de forma consistente, com perdas toleráveis. Vale lembrar que, como uma mensagem é enviada a cada segundo pelo dispositivo, há uma redundância no envio da mensagem de alerta (o alerta só para de ser emitido quando o alarme é desligado remotamente ou o sistema é reiniciado).

Durante o experimento, para simular um uso rotineiro do dispositivo, cinco comandos também foram enviados em instantes distintos para acionar e desacionar os alarmes e solicitar sua localização. Não foi observada influência desses comandos na ocorrência de perdas ou atrasos das mensagens publicadas.

Em uma etapa posterior, testes envolvendo a comunicação via MQTT e a detecção de quedas foram realizados, com o intuito de caracterizá-los temporalmente. Os comandos "liga alarme", "desliga alarme" e "localizacao" foram, cada um, enviados 20 vezes (totalizando 60 comandos), com o tempo entre o envio dos comandos e o retorno do dispositivo através do *broker* sendo medido. Dessa forma, procurou-se quantificar o tempo de resposta em um cenário comum de uso. Essa métrica representa o caminho mais crítico do fluxo de informação, visto que o comando passa pelo "*broker*" e é processado pelo dispositivo (com as rotinas incluindo o FreeRTOS e a pilha de protocolos de comunicação) para que, ao final, o sistema retorne uma mensagem confirmando o sucesso do comando (também pelo "*broker*"). Além disso, foram simuladas 50 quedas para verificar qual o tempo de processamento utilizado pela MEF entre a detecção de uma possível queda e a sua confirmação. Por fim, o tempo entre a confirmação de uma queda e o envio da mensagem correspondente para o *broker* foi medido 250 vezes (a partir de uma pequena alteração no código, a qual forçava a MEF a acusar sempre uma queda). A Tabela IV apresenta a média, o desvio-padrão, o primeiro, segundo e terceiros quartis e os valores máximos e mínimos obtidos para tais testes.

Tabela IV
MÉTRICAS TEMPORAIS DO SISTEMA (ENVIO DE COMANDOS E DETECÇÃO DE QUEDA)

Métrica	Tempo de comando–confirmação	Tempo de processamento da MEF	Tempo entre detecção de queda e envio ao broker
Número de testes	60	50	250
Média (s)	1,58	2,48	1,02
Desvio-padrão (s)	1,51	0,06	0,02
Valor mínimo (s)	0,46	2,41	1,00
1º quartil (s)	0,92	2,42	1,01
Mediana (s)	1,13	2,47	1,03
3º quartil (s)	1,56	2,52	1,03
Valor máximo (s)	8,77	2,62	1,05

Analisando a Tabela IV, percebe-se que os tempos de resposta entre um comando e sua confirmação ficaram, em sua maioria, em torno de 1,5 segundos ou menos, um valor compatível com o uso contínuo do dispositivo. Analisando o valor máximo e o desvio-padrão, é possível verificar que houve alguns valores anormais nas medições, cuja causa provavelmente está relacionada aos elos da comunicação que não são controlados (qualidade da comunicação Wi-Fi e disponibilidade do servidor, por exemplo). Dessa forma, considera-se que as oscilações no tempo de resposta do dispositivo estão dentro do esperado para um sistema IoMT. Todos os comandos geraram as respostas desejadas.

Com relação à MEF, o tempo para a detecção de uma queda fica em torno de 2,5 segundos, o que está de acordo com o descrito pela Fig. 4. Esse valor, somado à estimativa de 1 segundo para que a mensagem informando a queda chegue ao *broker*, indica que o sistema leva em torno de 3,5 segundos para detectar a queda, confirmá-la e publicar uma mensagem com o aviso do evento. Esse desempenho foi considerado adequado para o propósito do dispositivo.

É relevante notar que nem toda limitação observada decorre da arquitetura de software discutida aqui. O princípio de medição por fotopletismografia, utilizado pelo sensor de frequência cardíaca e saturação de oxigênio, é intrinsecamente suscetível a artefatos de movimento e a interferência luminosa [13], razão pela qual optou-se por não associar alarmes automáticos a esses parâmetros no estágio atual do protótipo. Essa limitação é de natureza física do sensor, não da arquitetura de concorrência, comunicação ou segurança, o que reforça que as três camadas analisadas neste artigo cumpriram seu papel mesmo onde outras partes do sistema ainda demandam refinamento.

VI. Considerações Finais

Foi possível observar que as decisões de arquitetura do sistema resultaram em um protótipo de dispositivo IoMT funcional, com um tempo de resposta aos comandos, taxa de entrega da informação e uso de memória razoáveis do ponto de vista quantitativo. Além disso, do ponto de vista qualitativo, o dispositivo teve o comportamento esperado ao longo dos testes funcionais, reforçando que as escolhas de arquitetura foram adequadas no estágio atual de desenvolvimento. É possível concluir, ainda, que decisões arquiteturais de software podem ser tão importantes quanto a escolha dos sensores em sistemas IoMT críticos.

A análise apresentada neste artigo buscou argumentar sobre como o FreeRTOS, MQTT e TLS, no contexto do protótipo de plataforma IoMT desenvolvido, não foram escolhidos como peças intercambiáveis de uma caixa de ferramentas genérica de sistemas embarcados conectados. Cada uma dessas três tecnologias resolve um problema que se torna especialmente crítico precisamente porque o sistema lida com a saúde e a segurança física de uma pessoa: o FreeRTOS garante que a cadeia de detecção e resposta a eventos críticos materializada pela MEF de cinco estados descrita na Seção IV-B não seja comprometida por concorrência mal gerenciada; o MQTT permite que esses dados alcancem múltiplos interessados de forma leve e resiliente, compatível com um dispositivo vestível de recursos limitados; e o protocolo TLS garante que esses mesmos dados fisiológicos e de localização permaneçam confidenciais ao longo de todo o trajeto até o destinatário final. Compreender essas três decisões não como escolhas técnicas isoladas, mas como respostas coordenadas às exigências específicas de um sistema IoMT, é o que permite avaliar com mais rigor tanto os méritos quanto os limites do protótipo desenvolvido, e orientar com mais clareza os próximos passos de sua evolução.

Pretende-se, em etapas futuras, realizar mais testes de conexão do dispositivo e implementar mais camadas de segurança. Além disso, tem-se o objetivo de testá-lo com uma diversidade de usuários para avaliar sua eficácia real, avaliando a taxa de acertos do sistema (mediante a aprovação do projeto em um comitê de ética). Conforme o protótipo fique mais elaborado, pretende-se também fazer uma avaliação do consumo energético do dispositivo.

Outra melhoria futura planejada é a adição de mais opções de alarmes e uma maior diferenciação de tipos de queda. Ao se comparar uma queda de frente com uma queda de costas, por exemplo, as lesões podem ser diferentes e o socorro, consequentemente, deve ser mais ou menos imediato. Para a diferenciação de padrões de queda, pretende-se utilizar algum algoritmo de *machine learning* que possa ser embarcado (TinyML) de forma a classificar se o usuário caiu de lado, de frente, de costas, sentado, dentre outros padrões. Por fim, pretende-se colocar no sistema a capacidade de diferenciar situações como bradicardia, taquicardia e hipóxia, a partir dos dados do sensor MAX30102.

***Abstract*— This study reports the development and preliminary bench validation of a low-cost smart system for cognitive-motor assessment in combat sports. The proposed platform integrates a pneumatic-electronic sensing architecture based on an ESP32 microcontroller and a BMP280 barometric pressure sensor, designed to overcome the mechanical noise limitations associated with conventional inertial measurement units (IMUs). By incorporating an air chamber within a polycarbonate enclosure, the system mechanically attenuates impact-induced vibrations before signal acquisition, improving measurement stability and protecting the sensing elements from direct mechanical stress. Bench experiments demonstrated stable operation, high repeatability, and reliable functional performance. Characterization of Bluetooth Low Energy (BLE) communication latency, performed using high-speed video analysis (240 frames per second), revealed transmission delays ranging from 92 to 150 ms, with a mean latency of 121 ms. Repeatability testing showed a baseline noise level below 0.05 hPa and a coefficient of variation (CV) of 1.2% for the pressure-trigger threshold. Temporal accuracy was preserved through a local on-sensor timestamping algorithm, ensuring that wireless communication latency does not influence response-time measurements. These findings demonstrate the technical feasibility of the proposed system as an accessible instrumentation platform for combat sports, establishing a robust technological foundation for future ecological validation and real-world training applications.**

***Keywords*— combat sports, biomechanics, biomedical instrumentation, cognitive-motor assessment, Bluetooth Low Energy, embedded systems.**

I. INTRODUÇÃO

A análise de desempenho em esportes de combate demanda parâmetros quantitativos, em que variáveis como a precisão espacial, a velocidade do gesto motor e o tempo de reação (TR) despontam como determinantes para o sucesso competitivo **[1]**, **[2]**, **[3]**. Contudo, a mensuração fidedigna dessas capacidades em ambiente ecológico apresenta restrições metodológicas **[1]**. Dispositivos baseados em estímulos luminosos carecem de especificidade cinemática para impactos, enquanto sensores inerciais (*Inertial Measurement Unit* - IMU) introduzem artefatos de movimento que comprometem os registros **[1]**. Embora sistemas laboratoriais padrão-ouro (plataformas de força e cinemetria óptica) apresentem elevada acurácia, o alto custo, a baixa portabilidade e a necessidade de infraestrutura especializada limitam sua aplicação na rotina de treino.

Recentemente, sistemas baseados em visão computacional sem marcadores (*markerless*), utilizando modelos como *MediaPipe*, *Blaze Pose* ou *MoveNet*, além de outros dispositivos vestíveis (*wearables*), têm sido propostos para análise de movimento no combate **[4]**, **[5]**. No entanto, essas tecnologias sofrem com limitações de taxa de amostragem, oclusão de segmentos e imprecisão na determinação temporal do instante exato do impacto, especialmente em alta velocidade. Ademais, tais sistemas são direcionados predominantemente à reconstrução cinemática, não sendo concebidos para detectar diretamente o momento da colisão entre o atleta e o alvo.

Fisiologicamente, o tempo decorrido entre o estímulo visual e a detecção física do golpe configura o tempo de resposta, resultante da soma do tempo de reação (processamento cognitivo central eferente) e do tempo de movimento (fase motora periférica). Estudos demonstram variações temporais significativas entre técnicas como *jabs* e diretos (*crosses*), reforçando a importância de monitorar o gesto específico **[6]**. A aplicação de força depende da transferência de momento linear dos membros inferiores e rotação do tronco **[7]**, gerando picos dinâmicos que requerem amortecimento estrutural para proteger o hardware **[8]**. Consequentemente, sistemas destinados a essa avaliação

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

devem apresentar elevada resolução temporal, robustez mecânica e capacidade de operar em condições próximas à rotina esportiva.

Para superar tais limitações, este trabalho propõe o desenvolvimento e a validação em bancada de um sistema baseado em interface pneumática-eletrônica. O dispositivo utiliza uma câmara de ar acoplada a um gabinete de policarbonato para atenuar mecanicamente as vibrações do impacto antes da aquisição pelo sensor de pressão barométrica (BMP280) **[1]**. A interface funciona como um filtro mecânico passivo, reduzindo vibrações espúrias e favorecendo a estabilidade dos sinais. A aquisição local é realizada por um microcontrolador ESP32 (*timestamping on-sensor*), permitindo que a marcação temporal ocorra diretamente no dispositivo, minimizando a influência da latência da comunicação sem fio **[9]**. O objetivo deste estudo é analisar o desempenho técnico do protótipo e calibrar suas latências instrumentais em laboratório **[10]**, estabelecendo a base tecnológica para futuras validações ecológicas com atletas.

II. METODOLOGIA E INSTRUMENTAÇÃO

A. Delineamento Experimental e Planejamento Amostral

Esta pesquisa aplicada, de abordagem quantitativa e delineamento metodológico, validou na Fase I (objeto deste artigo) a consistência metrológica do hardware em ensaios de bancada. Os testes caracterizaram a estabilidade do sensor, repetibilidade, latência e o processamento embarcado. A Fase II compreenderá a validação ecológica do dispositivo por meio de acompanhamento longitudinal com atletas.

Este protótipo, foi desenvolvido para atender as demandas futuras para a realização da Fase II, onde a amostra estimada será selecionada por conveniência e composta por 30 atletas de artes marciais do sexo masculino, distribuídos igualmente por nível de expertise: avançados (profissionais com mais de 5 anos de prática ativa; n = 15) e intermediários (amadores; n = 15). O dimensionamento amostral no software G*Power 3.1.9.7 (tamanho de efeito d = 1,1, $\alpha = 0,05$ e poder estatístico de 0,80) resultou em um poder real de 0,828. Os critérios de inclusão exigirão: idade entre 18 e 55 anos; ausência de lesões osteomioarticulares agudas ou cirurgias que comprometam a performance balística; e experiência consolidada em modalidades de impacto (*striking*). Todos os voluntários assinarão o Termo de Consentimento Livre e Esclarecido (TCLE) após aprovação no Comitê de Ética em Pesquisa (CEP) institucional.

B. Arquitetura do Sistema e Instrumentação Eletrônica

A arquitetura pneumática-eletrônica foi concebida para operar sob impacto repetitivo, preservando a integridade estrutural e a qualidade do sinal. A interface física externa utilizou um manguito de esfigmomanômetro adaptado como cápsula pneumática para capturar a variação transiente de pressão do golpe. Esta bolsa de ar foi acoplada a um gabinete de policarbonato de alta resistência, selecionado por suas propriedades dielétricas e de isolamento elétrico. O conjunto funciona como um filtro mecânico passivo, reduzindo a transmissão de vibrações de alta frequência ao sensor barométrico, aumentando a estabilidade do sinal e minimizando interferências diretas.

A transdução do sinal foi realizada por um sensor barométrico digital BMP280, conectado via I2C a um microcontrolador ESP32, modelo S3 WROOM 1. A escolha do BMP280 (Bosch Sensortec, Alemanha) fundamentou-se nas limitações mecânicas de sensores alternativos em ensaios de impacto repetitivo: sensores de força resistivos (FSR) apresentam elevada histerese e rápida degradação; películas piezoelétricas demandam circuitos complexos para mitigar a deriva estática e rompem-se sob cisalhamento; e células de carga exigem acoplamento rígido a placas pesadas, inviabilizando a portabilidade e a proteção mecânica do usuário.

A interface pneumática baseada na compressão volumétrica atua como filtro passa-baixa. Em regimes de compressão adiabática rápida, a variação de pressão interna (ΔP) é diretamente proporcional à energia de impacto aplicada, sem expor os circuitos a estresse direto. O ESP32 controla os estímulos visuais via matriz de LEDs de alto brilho, executa o processamento local dos dados (*timestamping on-sensor*) e gerencia a comunicação via protocolo Bluetooth Low Energy (BLE) com o aplicativo móvel.

O sistema pode ser incrementado com múltiplos dispositivos microcontrolados, a fim de obter medições de pressão aplicada e tempo de reação em diversas posições. Cada dispositivo adicionado à rede comunica-se com o dispositivo central através do protocolo *wireless* ESP-NOW.

O dispositivo central da solução é composto por dois microcontroladores. Um deles concentra a função de sensor e de servidor BLE, ao passo que o outro atua como comunicador ESP-NOW. Ambos os microcontroladores comunicam entre si via conexão serial UART. Essa separação de tarefas foi necessária pois parte do hardware da ESP-32 é compartilhado para envio e recebimento de ambos os protocolos de comunicação wireless implementados (BLE e ESP-NOW). Dessa forma, quando o dispositivo tem seu módulo BLE atuando, sua capacidade de receber pacotes ESP-NOW é afetada, e vice-versa. Isso resulta em uma considerável perda de pacotes. Por outro lado, ao delegar as comunicações de diferentes protocolos para diferentes dispositivos, não ocorre essa sobrecarga do hardware. Além disso, o dispositivo mestre também atua como um dos sensores da solução, acionando seu LED e aguardando a resposta do usuário sempre que for recebida a devida instrução do aplicativo celular.

C. Rotina de Detecção

O aplicativo móvel atua como interface, enviando comandos ao ESP32 via BLE. O sistema permite a ativação manual dos ensaios ou o acionamento automático, iniciando um novo ciclo pós-impacto sem intervenção do operador. O aplicativo permite envio de requisição de ativação ao dispositivo central, bem como aos dispositivos periféricos. Em caso de ativação do dispositivo mestre, a mensagem BLE parte do celular e é recebida pelo módulo BLE do dispositivo central. Em caso de ativação de um dos dispositivos slaves, a mensagem BLE é enviada pelo celular, recebida pelo módulo

BLE do dispositivo central, replicada via UART ao módulo ESP-NOW e, finalmente, enviada via ESP-NOW do dispositivo central ao dispositivo periférico. Ao receber o comando, o sistema microcontrolado acende um LED e salva o tempo decorrido desde o *boot* via função millis(). O dispositivo lê e armazena o valor de pressão do BMP280 e inicia a rotina de *polling* para monitorar a variação gerada pelo golpe na bolsa de ar.

O loop de amostragem contínua interrompe a rotina assim que a variação de pressão ultrapassa o limiar biomecânico (*threshold*) preestabelecido. Quando o valor medido para de aumentar (após a primeira derivada negativa), o sensor executa novamente a função millis() e computa o tempo de reação pela diferença temporal. Esse método garante o registro do pico máximo de pressão para determinar a intensidade relativa do impacto. Na sequência, o microcontrolador envia o pacote BLE ao aplicativo, que exibe os dados em gráficos em tempo real.

D. Latências e Otimizações de Bancada

Todas as chamadas de depuração serial bloqueantes (exemplo: a rotina Serial.println()) foram removidas do loop principal. O sensor BMP280 foi configurado com resolução de pressão de 0,16 Pa e precisão absoluta de ± 1 hPa. No modo de alta performance (*oversampling* de pressão de 16x e temperatura de 2x), opera com frequência de aquisição efetiva de 157 Hz, garantindo resolução temporal de 6,36 ms. O algoritmo utiliza um limiar de disparo de 15 hPa acima da linha de base atmosférica e encerra a amostragem após detectar a primeira derivada negativa de pressão ($dP/dt < 0$), caracterizando o pico de força. O valor do limiar foi definido a partir de testes com aplicação de golpes de baixa intensidade na câmara com ar conectada ao sensor, de forma que mesmo ações com golpes suaves pudessem ser percebidas.

A latência de transmissão BLE do comando de ativação foi caracterizada filmando o pressionamento do botão no aplicativo e o acendimento do LED a 240 quadros por segundo, com os resultados de conversão matemática registrados na Tabela 1:

Tabela 1: Caracterização experimental da latência de pareamento BLE

Número de quadros	Tempo (s)
25	0,104
36	0,150
22	0,092
33	0,138
29	0,121

(Nota: Média geral de latência de transmissão BLE = 121 ms).

O atraso de transmissão varia de 92 ms a 150 ms, porém não interfere na acurácia da medição psicomotora. O método de *timestamping on-sensor* captura o marcador temporal inicial (millis()) localmente no exato milissegundo de energização do LED. Desse modo, a latência de rede apresentada na Tabela 1, que poderia ser significativa em condições de combate, é completamente isolada do cálculo do tempo de reação, eliminando vieses. Os ensaios de estabilidade revelaram erro instrumental inferior a 0,05 hPa na linha de base e CV de 1,2% para disparos repetitivos controlados.

E. Eficiência da comunicação BLE

A Figura 1 exibe os resultados de RSSI (Received Signal Strength Indicator) da conexão BLE entre um dispositivo celular e um microcontrolador ESP-32 em diferentes distâncias, variando de 1 a 5 metros. Para cada distância, foram realizadas 3 medições e foi calculada a média simples entre os valores coletados. Os testes foram realizados em um local aberto, com poucos obstáculos. Para distâncias de até 5 metros, o RSSI da conexão nunca é mais baixo que -80 dBm.

Fig. 1. Gráfico do RSSI da conexão BLE entre celular e ESP-32 em diferentes distâncias

A tabela 2 mostra os resultados obtidos após o envio e recebimento de 10 mensagens ESP-NOW entre uma ESP-32 slave e o dispositivo mestre. A distância entre os dispositivos era de cerca de 5 metros. Todos os pacotes foram enviados e recebidos corretamente.

Tabela 2: resultado de envio de pacotes ESP-NOW com dispositivos a 5 metros de distância

Pacote	Resultado
Mestre → slave 1	OK
Slave → mestre 1	OK

Slave → mestre 5	OK

A tabela 3 mostra os resultados de um outro experimento seguindo a metodologia das medições anteriores. Contudo, dessa vez, o espaço entre o dispositivo mestre e o dispositivo slave era preenchido por móveis, paredes e portas. Nessa situação, percebe-se que há perda de pacotes. Isso é resultado da grande quantidade de obstáculos entre os dois dispositivos, bem como das limitações de hardware dos microcontroladores. Esses resultados não são preocupantes pois não representam uma situação real, já que a aplicação deste projeto foi idealizada para locais abertos.

F. Comparação com Tecnologias Existentes

Com o objetivo de contextualizar a proposta desenvolvida, o sistema pneumático-eletrônico foi comparado com outras tecnologias frequentemente empregadas para aquisição de sinais mecânicos em aplicações esportivas. Embora sensores inerciais, sensores piezoelétricos e células de carga apresentem vantagens específicas, cada tecnologia possui limitações relacionadas ao custo, à robustez mecânica, à complexidade de integração ou à portabilidade. Nesse contexto, a arquitetura proposta procura equilibrar simplicidade construtiva, baixo custo, elevada resistência mecânica e estabilidade metrológica.

Tabela 2: Vantagens competitivas da tecnologia pneumática proposta frente aos sistemas de medição na literatura

Tecnologia	Custo	Resiliência	Complex.	Portab.
Proposto	Baixo	Alta	Baixa	Exc.
IMUs	Médio	Alta	M. Alta	Exc.
FSR	Baixo	Baixa	Média	Boa
Piezo	Médio	Média	Alta	Boa
Célula	Alto	Alta	Baixa	Lim.
Ópticos	M. Alto	N/A	M. Alta	Nula

(Nota de legenda: M. Alto/M. Alta: Muito Alto / Muito Alta; Exc.: Excelente; Lim.: Limitada; N/A: Não se aplica devido à ausência de impacto mecânico direto).

G. Diagrama de Fluxo da Arquitetura do Sistema

A Figura 2 apresenta o fluxo funcional da arquitetura desenvolvida, desde a emissão do estímulo visual até o processamento local e transmissão das informações ao aplicativo móvel. O diagrama evidencia a integração entre o sistema embarcado, o sensor pneumático, o processamento temporal local e a comunicação Bluetooth Low Energy, sintetizando a lógica de funcionamento proposta para o dispositivo.

III. PROTOCOLOS DE AVALIAÇÃO E ANÁLISE ESTATÍSTICA

A. Especificação do Gesto Motor e Protocolos de Teste

Para garantir a reprodutibilidade da cinemática de impacto e minimizar a variabilidade técnica inerente aos esportes de combate, o soco frontal direto (*cross*) desferido com o membro dominante será adotado como gesto motor padronizado na Fase II. A escolha dessa técnica fundamenta-se em sua elevada reprodutibilidade biomecânica, estabilidade do vetor de impacto e ampla utilização em estudos experimentais envolvendo desempenho de golpes, permitindo comparações consistentes entre atletas e sessões experimentais.

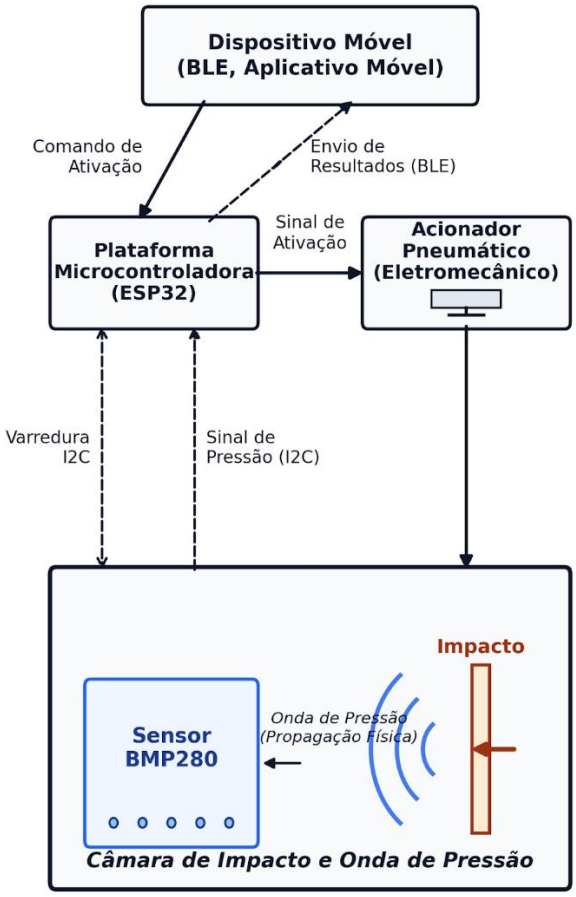

Fig. 2. Diagrama da arquitetura do sistema inteligente de captação e processamento local de dados em ensaios de bancada.

Todos os ensaios serão realizados com o atleta em posição inicial padronizada, respeitando a distância de execução previamente estabelecida e mantendo condições ambientais semelhantes entre as sessões, com o objetivo de reduzir fontes externas de variabilidade experimental.

Os participantes serão submetidos a dois protocolos computadorizados.

Tempo de Resposta Simples (TRS): Avalia a eficiência neuromuscular eferente bruta. O atleta responderá ao acendimento de um único LED central pré-determinado, desferindo o soco direto com o máximo de velocidade e impacto possíveis, registrando o pico de pressão interna.

Tempo de Resposta de Escolha e Coordenação Espacial (TRE): Introduz a carga cognitiva e a leitura tática do ambiente. Múltiplos estímulos luminosos distribuídos no espaço serão acionados aleatoriamente em diferentes coordenadas do gabinete, forçando o atleta a processar a informação visual e selecionar a trajetória espacial correta para atingir o alvo correspondente.

Para mitigar os efeitos da fadiga muscular, cada atleta executará três tentativas válidas por protocolo, com intervalos de 1 minuto de recuperação entre os disparos.

Os ensaios de bancada realizados na Fase I validam a prontidão tecnológica do protótipo para a execução fidedigna desses protocolos. A alta resolução temporal obtida (6,36 ms)

e a imunidade total do cálculo do tempo de reação frente à latência de comunicação Bluetooth (graças ao *timestamping on-sensor* local) asseguram que o dispositivo possui robustez metrológica para discriminar pequenas variações de desempenho tático-motor nas rotinas de alta velocidade exigidas na Fase II.

B. Processamento de Sinais e Validação de Construto

O algoritmo embarcado utiliza um limiar mínimo de ativação para eliminar impactos de baixa intensidade e oscilações decorrentes de ruídos mecânicos. Esse procedimento reduz a ocorrência de falsos positivos e aumenta a robustez da detecção automática dos eventos de impacto.

As janelas temporais de processamento serão configuradas para rejeitar marcações incompatíveis com os limites fisiológicos esperados para o tempo de resposta humano. Valores inferiores a 150 ms ou superiores a 500 ms serão analisados criticamente durante o processamento, uma vez que podem representar erros de aquisição, antecipação da resposta ou falhas operacionais durante o experimento.

Para avaliação da validade concorrente, as medidas obtidas pelo sistema pneumático-eletrônico serão comparadas com um sistema de referência baseado em fotocélulas infravermelhas. A utilização de um equipamento amplamente empregado na literatura como método de referência permitirá verificar a concordância entre as duas metodologias de aquisição temporal. A concordância será avaliada por meio da análise de Bland-Altman e do coeficiente de correlação de Pearson. Entretanto, considerando que elevada correlação não implica necessariamente concordância entre métodos, a interpretação dos resultados será fundamentada prioritariamente nos limites de concordância obtidos pelo método de Bland-Altman. A estabilidade teste-reteste será determinada utilizando o Coeficiente de Correlação Intraclasse ICC(2,1), complementado pelo cálculo do erro padrão da medida (SEM) e da mínima mudança detectável (MDC95). Esses indicadores permitirão quantificar simultaneamente a confiabilidade relativa e absoluta do equipamento, fornecendo uma caracterização metrológica mais abrangente do sistema desenvolvido.

C. Tratamento Estatístico Longitudinal

A distribuição e a normalidade dos dados coletados serão inicialmente testadas por meio do teste de Shapiro-Wilk, enquanto a homogeneidade das variâncias será avaliada pelo teste de Levene. Uma análise estatística descritiva prévia será conduzida para verificar a homogeneidade das características gerais da amostra (idade, massa corporal e estatura), garantindo que os grupos não difiram significativamente além do nível de expertise.

Considerando o caráter longitudinal do desenho de pesquisa com coletas repetidas em sessões semanais ao longo de oito semanas, a comparação dos tempos de resposta entre os grupos será realizada por meio de uma ANOVA fatorial de medidas repetidas [Grupo (2) × Tempo (8)]. O tamanho de efeito mínimo esperado foi fixado em $f = 0,40$ (equivalente a $d = 1,1$ para comparações pareadas). As premissas de esfericidade serão testadas pelo teste de Mauchly, adotando-se a correção de Greenhouse-Geisser caso a esfericidade seja violada. Em cenários com perda amostral controlada, serão aplicados Modelos Lineares Mistos com interceptos aleatórios por sujeito e matriz de covariância estruturada sob o modelo autorregressivo de primeira ordem [AR(1)]. O teste post hoc de Bonferroni será utilizado para identificar as diferenças localizadas entre os tempos e grupos. Todas as análises estatísticas serão executadas adotando-se um nível de significância de $p < 0,05$.

IV. CONCLUSÕES

O presente estudo apresentou o desenvolvimento e a validação preliminar de bancada de um sistema inteligente pneumático-eletrônico destinado à avaliação cognitivo-motora em esportes de combate. Os ensaios experimentais demonstraram estabilidade metrológica, baixa variabilidade instrumental e independência entre a latência da comunicação Bluetooth e o cálculo temporal realizado localmente pelo microcontrolador. Esses resultados evidenciam a viabilidade técnica da arquitetura proposta e estabelecem uma base consistente para futuras validações ecológicas envolvendo atletas em condições reais de treinamento.

***Abstract*—There are multiple applications for brain signal acquisition hardware in a research environment, such as studies involving brain-computer interfaces, characterization of neurological disorders and different kinds of brain activity analysis. This type of research, however, can be limited by the high cost of commercial devices capable of recording neural rhythms. To address this limitation, this research presents the design and characterization of a low-cost single-channel electroencephalography (EEG) acquisition circuit through computational simulation and laboratory measurements. A custom printed circuit board (PCB) was developed for hardware testing. Simulated and experimentally measured Bode plots of each circuit stage were compared. Characterization resulted in an overall measured voltage gain of 79.04 dB, a calculated bandwidth of 36.72 Hz, and a measured CMRR of 115.4 dB. Results indicate that the proposed circuit could be a viable low-cost analog front-end for EEG acquisition. Future work will conduct human subject testing to evaluate the system's performance.**

***Index Terms*—electroencephalogram (EEG), low-cost hardware, biomedical instrumentation, signal acquisition**

I. Introduction

Brain activity has been the subject of scientific research since the 1920s [1] and has become increasingly important in recent years due to advances in fields such as neuroscience, psychiatry, psychology and biomedical engineering, finding applications ranging from the investigation of neurological disorders to brain-computer interfaces [2].

Brain signals can be acquired through invasive and non-invasive methods. Invasive methods use surgery to place sensors inside the skull, examples include electrocorticography (ECoG) and intracortical microelectrode arrays (MEAs), while non-invasive methods aim to record signals from outside the skull without the need for surgery, for example, electroencephalography (EEG), magnetoencephalography (MEG), functional magnetic resonance imaging (fMRI) and functional near-infrared spectroscopy (fNIRS) [3].

EEG is one of the most used methods of brain signal acquisition for academic purposes due to its high temporal resolution, portability and relatively low cost compared with other acquisition techniques [4]. Despite this, many researchers are unable to purchase commercial EEG systems, whose prices can reach thousands of dollars [5].

A number of studies have been conducted to overcome this problem by designing low-cost custom EEG acquisition systems [6]–[12]. However, many of them provide limited experimental characterization of each stage of the developed systems [6]–[12], which can hinder researchers from identifying issues when reproducing the proposed design if the measured circuit behavior diverges from the simulated response.

Under these circumstances, this study proposes the design and characterization of a low-cost single-channel EEG analog front-end (AFE) using computational simulation and experimental measurements, followed by a comparison between simulated results and laboratory measurements. One of the future research goals is to use the developed circuit in brain-computer interface systems.

II. Background and Literature Review

A. Signal Characteristics

EEG signal acquisition is made through the placement of electrodes on a subject's scalp, following one of the standard positioning systems such as the 10-20, 10-10, or 10-5 systems [13], [14]. Examples of electrodes include reusable electrodes, which can be composed of highly conductive materials such as gold or silver/silver chloride, and disposable electrodes, such as gel electrodes [13], [15]. The connection between the electrodes and the EEG acquisition system is done via shielded cables [15].

The electrical signals are measured at the scalp with amplitude ranging from 0.5 to 100 μV [13]. These signals are affected by multiple artifacts such as eye movement artifacts (EOG), cardiac activity (ECG), muscle activity (EMG) and power line interference (PLI), usually having higher amplitudes than the EEG signal itself [16]. For these reasons, EEG

recording requires an acquisition system capable of reducing the artifacts and amplifying the original signal [13].

The brain signals can also be divided into different rhythms based on their frequencies, each one of the rhythms being associated with specific brain states [16], [17]. The neural rhythms and its respective frequency ranges are displayed in Table I [16].

TABLE I
NEURAL RHYTHMS

Rhythm	Frequency range (Hz)
Delta	0.1 - 4
Theta	4 - 8
Alpha	8 - 13
Beta	14 - 30
Gamma	30 - 80

B. Electronic filters and signal amplification

The development of an electronic circuit capable of acquiring EEG signals usually requires the implementation of electronic filters and amplifiers [13].

Electronic filters are classified into two main types, passive filters, which attenuate specific frequency bands using passive components such as resistors and capacitors, and active filters, which in addition to attenuating frequency bands can also amplify the output using operational amplifiers [18].

Filters can also be divided into four categories based on the frequency band they attenuate. High-pass filters attenuate signal components with frequency below their cutoff frequency, low-pass filters attenuate signal components with frequency above their cutoff frequency, band-pass filters attenuate all signal components outside a specific band and notch filters attenuate signal components within a specific narrow band [18].

There are different kinds of topologies for electronic filters. The Sallen-Key topology allows for a simple implementation of higher-order filters, which results in a steeper roll-off in the transition band [18]. The cutoff frequency of a Sallen-Key filter with Butterworth approximation is defined by (1), where fc is the cutoff frequency, R is a resistor, and C is a capacitor [19]. Sallen-Key topology can also be designed to implement different filter approximations, such as the Butterworth, Chebyshev and Bessel [18].

$$fc = \frac{1}{2\pi RC} \tag{1}$$

Active filters have a voltage gain, defined as the amplitude relation between input and output signals. The gain of an active Sallen-Key filter is defined by (2), where G is the gain and R_1 and R_2 are resistors [18].

$$G = 1 + \frac{R_1}{R_2} \tag{2}$$

Common-mode rejection ratio (CMRR) is a relevant feature of EEG acquisition systems. It represents the capacity of a circuit to attenuate noise present in common-mode input and is defined by (3), where A_d is the differential gain and A_c is the common-mode gain [13], [20].

$$CMRR = 20 \times \log_{10}(\frac{A_d}{A_c}) \tag{3}$$

The high importance of CMRR for the development of EEG acquisition systems is due to the fact that major sources of interference, such as PLI, can often appear as common-mode signals [13].

Another important characteristic for EEG acquisition is the input-referred noise (IRN), which can be determined by short-circuiting the system's inputs, measuring the output RMS voltage and dividing it by the differential gain of the circuit [21]. Due to the low amplitude of EEG signals, high IRN can completely mask them, compromising signal integrity [13].

III. MATERIALS AND METHODS

A. System Architecture

To avoid saturation, signal amplification occurs in different circuit stages, as displayed in Fig. 1, consisting of an instrumentation amplifier stage, a high-pass filter, a low-pass filter and a notch filter.

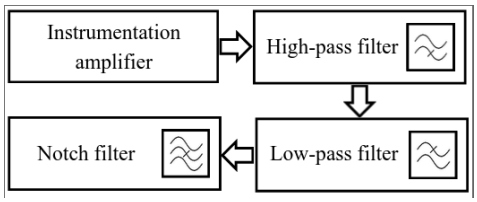

Fig. 1. Circuit stages.

The instrumentation amplifier chosen was INA101HP, mainly because of its CMRR. This stage's gain is defined in (5) derived from (4), where R_G is a resistor and G is the gain [22].

$$G = 1 + \frac{40k}{R_G} \tag{4}$$

$$G = 1 + \frac{40k}{2.2k} \approx 19.18 \tag{5}$$

INA101HP has minimum CMRR ranging from 60 dB (for gain of 1) to 100 dB (for gains of 100 to 1000) at 60 Hz and typical CMRR ranging 85 dB (for gain of 1) to 105 dB (for gains of 100 to 1000) at 60 Hz. Other relevant component characteristics include differential and common-mode input impedance of 10 GΩ $\parallel$ 3 pF, maximum input bias current of 30 nA and typical input bias current of 15 nA, and input voltage noise of 0.8 μV_{p-p} at 0.1-10 Hz [22].

The operational amplifiers implemented in the other circuit stages were of the model TL084CN. To calculate the cutoff frequency and gain of each circuit stage (1) and (2) were respectively used. The high-pass filter stage features a first-order high-pass Sallen-Key filter with Butterworth approximation, having a gain of 101 defined in (6) and cutoff frequency of 0.50 Hz defined in (7). The purpose of the high-pass filter

stage is to attenuate low frequency artifacts, such as baseline drift and EOG.

$$G = 1 + \frac{330k}{3.3k} = 101 \tag{6}$$

$$fc = \frac{1}{2\pi \times 680 \times 10^3 \times 470 \times 10^{-9}} \approx 0.50\,Hz \tag{7}$$

The low-pass filter stage consists of a fourth-order low-pass Sallen-Key filter with Butterworth approximation, having gains of approximately 1.17 and 2.22, as defined in (8) and (9), and cutoff frequency of 37.21 Hz defined in (10). The purpose of the low-pass filter stage is to attenuate high frequency artifacts, such as EMG.

$$G = 1 + \frac{5.6k}{33k} \approx 1.17 \tag{8}$$

$$G = 1 + \frac{2.2k}{1.8k} \approx 2.22 \tag{9}$$

$$fc = \frac{1}{2\pi \times 9,1 \times 10^3 \times 470 \times 10^{-9}} \approx 37,21\,Hz \tag{10}$$

The notch filter stage features a second-order notch Sallen-Key filter with Butterwoth approximation, having a gain of 1.77 and cutoff frequency of 60.28 Hz, as defined in (11) and (12). The purpose of the notch filter stage is to attenuate the PLI artifact.

$$G = 1 + \frac{10k}{13k} \approx 1.77 \tag{11}$$

$$fc = \frac{1}{2\pi \times 22 \times 10^3 \times 120 \times 10^{-9}} \approx 60,28\,Hz \tag{12}$$

The complete circuit has a gain of 78.99 dB and a bandwidth of 36.72 Hz, as defined in (13) and (14). The circuit's diagram is presented in Fig. 2.

$$G_t = 20 \times \log_{10}(19.18 \times 101 \times 1.17 \times 2.22 \times 1.77) \approx 78.99\,dB \tag{13}$$

$$\Delta f = 37,21 - 0.50 = 36.71\,Hz \tag{14}$$

B. Simulation

The circuit was simulated using LTspice, employing generic operational amplifiers in place of the TL084CN and modelling the INA101HP through its discrete circuit. The simulation diagram is presented in Fig. 3.

The simulation results were obtained through AC and transient analysis. The AC analysis was conducted utilizing a frequency sweep from 0.1 Hz to 1 KHz. The transient analysis lasted 5 seconds, in which a waveform was generated to represent the expected characteristics of EEG signals. The waveform was composed of multiple signals, each with the properties of specific signal components present in EEG acquisition, presented in Table II [16], [23].

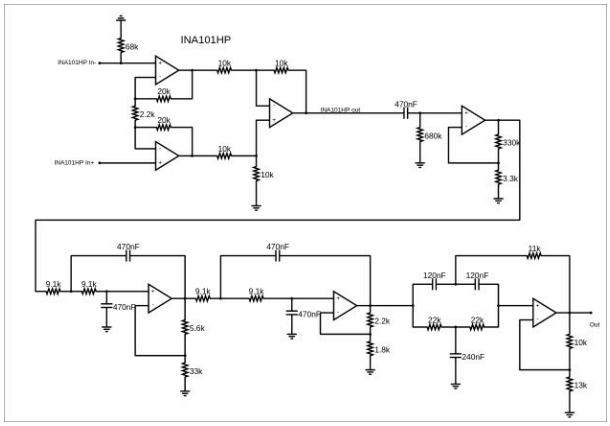

Fig. 2. Circuit diagram.

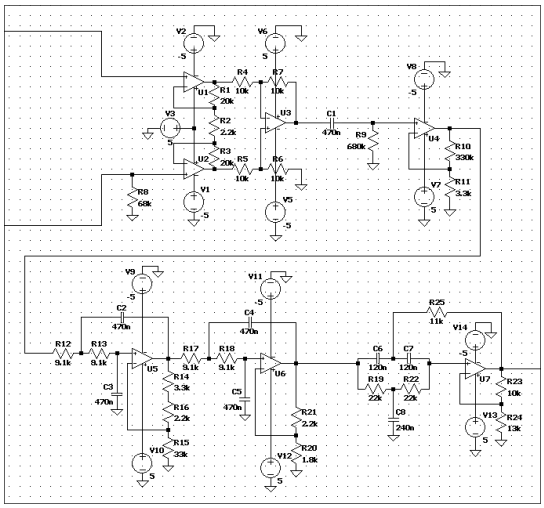

Fig. 3. Circuit simulation in LTspice.

C. Hardware Implementation

The proposed circuit was implemented on a custom printed circuit board (PCB) designed using the EasyEDA software. All passive components used were through-hole and had a tolerance of 5%. After fabrication, the PCB was placed inside a repurposed metallic DC power supply enclosure to provide additional protection against electromagnetic interference. The PCB is presented in Fig. 4. Two 9-V batteries are used as a split power supply for the EEG front-end.

Laboratory measurements were made using a DC power supply (U8031A, Agilent Technologies) to power the circuit,

TABLE II
SIGNAL COMPONENTS.

Waveform	Signal	Frequency	Amplitude
Sinusoidal	Alpha rhythm	10 Hz	10 μV
Sinusoidal	Baseline drift	0.5 Hz	20 μV
Triangular	EOG[a]	0.33 Hz	100 μV
Sinusoidal	PLI	60 Hz	1 mV

[a]Pulse width of 0.3 seconds.

a signal generator (33521A, Agilent Technologies) to produce the input signal, and an oscilloscope (DSO-X 2012A, Agilent Technologies) to measure the output signal.

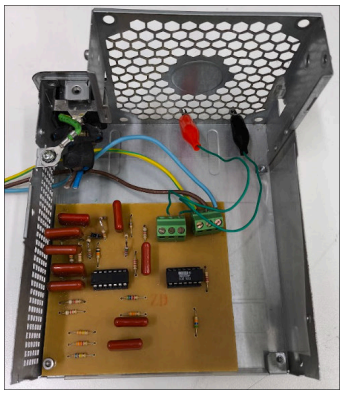

Fig. 4. Printed circuit board.

IV. Results and Discussion

The electronic components used in the PCB manufacturing and their respective prices are presented in Table III. The cost estimation was done based on component prices available from online electronic component distributors in September 2026.

TABLE III
Bill of Materials.

Quantity	Component	Unitary price	Total price
18	Resistor	0.1 USD	1.8 USD
8	Polyester capacitor	0.76 USD	6.08 USD
1	TL084CN	1.07 USD	1.07 USD
1	INA101HP	32.57 USD	32.57 USD
Total:		41.52 USD	

As the instrumentation amplifier accounts for approximately 80% of the hardware cost, the replacement of the INA101HP with modern alternatives, such as the INA333, INA114, or INA828, would reduce the overall cost. The substitution would require circuit changes, such as a power-supply redesign (depending on the selected component), and the adaptation to surface-mount device footprints.

Both the simulated and assembled circuits were characterized. Each figure presents the simulated and measured Bode plots of a circuit stage, with the Figs. 5, 6 and 7 displaying respectively the high-pass filter, the low-pass filter and the notch filter frequency responses. The simulated Bode plot, shown on the left, represents the gain magnitude on the left y-axis with a solid line, the phase on the right y-axis with a dotted line, and the frequency on the x-axis, while the measured bode plot, shown on the right, represents the gain magnitude on the y-axis and the frequency on the x-axis.

The simulated and measured Bode plots show similar responses for the simulated and implemented circuits. However, it is still possible to identify some divergence between the results. The simulated and measured high-pass and low-pass filter responses are nearly identical, but the simulated notch

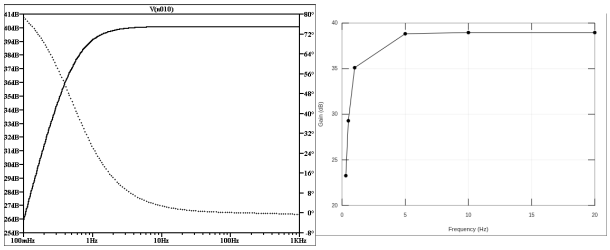

Fig. 5. Bode plots of simulated (left) and measured (right) high-pass filters.

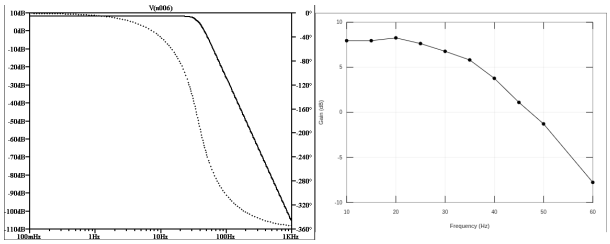

Fig. 6. Bode plots of simulated (left) and measured (right) low-pass filters.

filter plot displays greater attenuation of 60 Hz components compared with the measured plot, with the simulated response reaching a gain magnitude of approximately -50 dB, while the measured response reaches approximately -20 dB.

The Bode plot of the complete circuit is shown in Fig. 8, with the simulated results on the left and the measured on the right. The observed frequency response of both the simulated and measured circuits is consistent with the responses of each of the circuit stages. Lower attenuation at 60 Hz and an earlier low-pass roll-off can be noted on the measured response when compared to the simulated one. The measured response also shows that the previously calculated gain of 78.99 dB remains stable in the range of 1 Hz to 15 Hz, reducing to 75-70 dB between 15 Hz and 37 Hz, and decreasing further at higher frequencies. These response differences between the simulated and physical circuits could be caused by multiple factors such as component tolerances, parasitic capacitances, and limitations in the utilized equipment when generating and recording low-amplitude signals.

The simulated transient response is shown in Fig. 9, with the circuit's input shown on the top, and the circuit's output shown on the bottom. The circuit's transient behavior in simulation shows noticeable attenuation of the PLI component, which was

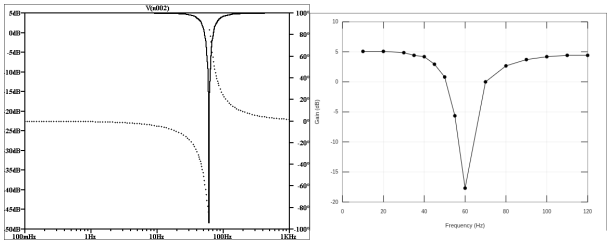

Fig. 7. Bode plots of simulated (left) and measured (right) notch filters.

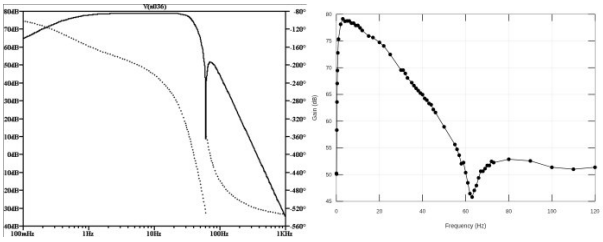

Fig. 8. Bode plots of simulated (left) and measured (right) circuit.

the frequency component with the highest amplitude in the input signal, and significant amplification of the alpha rhythm component, which had an amplitude of 10 μV at the input and approximately 100 mV at the output. The other signal components, representing simulated EOG signals and baseline drift, were still distinguishable in the output signal.

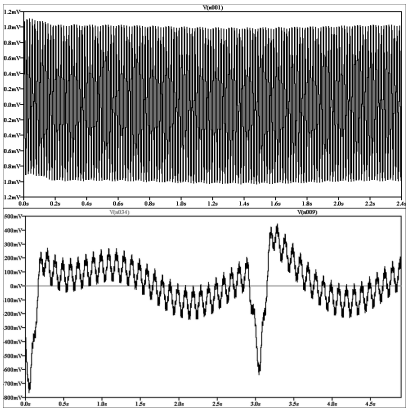

Fig. 9. Simulated circuit's input and output on transient analysis.

The circuit has a measured power consumption of 119.7 mW, which is significantly higher than the power consumption of commercially available EEG AFEs [24], [25]. During the laboratory tests, each of the 9 V batteries used had a capacity of 580 mAh (an energy capacity of 5.22 Wh per battery), resulting in an autonomy of approximately 87.2 hours, as calculated in (15).

$$\frac{5.22\,Wh \times 2}{0.1197\,W} = 87.2\,h \tag{15}$$

At 10 Hz, circuit measurements resulted in a differential voltage gain of 8950 ($\approx$ 79.04 dB), consistent with the calculated gain of 78.99 dB. The measured common-mode voltage gain was 0.0152 at 10 Hz, with a CMRR of 115.4 dB, as calculated in (16). Accurate measurements of the system's input impedance and IRN were not feasible using available equipment. The measurement of input impedance was limited by the loading effect, since the oscilloscope's impedance is 1 MΩ and the INA101HP has a theoretical impedance of 10 GΩ $\|$ 3 pF. The noise floor of the measurement setup masked the circuit's output noise, preventing the determination of the IRN. The system's theoretical IRN is mainly dictated by the INA101HP [21], with a value of 0.8 μV_{p-p} at 0.1-10 Hz [22].

$$G_t = 20 \times \log_{10}(8950/0.0152) \approx 115.4\,dB \tag{16}$$

The measured circuit's CMRR of 115.4 dB meets the recommended CMRR for EEG acquisition systems, which usually have values above 100 dB [13]. It is important to note, however, that in EEG recording the effective CMRR can be reduced by differences between electrode impedances [26]. The datasheet-specified input impedance and input-referred noise values of the INA101HP are also consistent with the criteria for EEG recording equipment [13].

Table IV presents the electrical characteristics of commercial EEG AFE integrated circuits (ICs), low-cost EEG acquisition systems developed in other studies, and the AFE developed and characterized in this research. Studies that provide limited information about the electrical characteristics of the systems were not included in the table as they would add limited value to the comparison. However, the system developed in [6] was included to serve as an example of a system that uses the ADS1298 and to illustrate its price.

The prices of the commercial AFEs were obtained in September 2026 from online electronic component distributors, while their electrical characteristics were sourced from the datasheet of each component [24], [25].

Although the unit costs of the ADS1298 and ADS1299 are similar to the 41.52 USD of the developed circuit, using them in practical EEG acquisition systems would demand a higher implementation of additional hardware. The application of these ICs typically involves additional components, infrastructure, and digital processing hardware, increasing the system's cost [6], [12].

TABLE IV
COMPARISON OF EEG ACQUISITION SYSTEMS AND AFES.

System	CMRR	Gain	IRN	Bandwidth	Channels	Reported Cost/Market Price
This study (Discrete AFE)	115.4 dB	79.04 dB	0.8 μV_{p-p} [a]	0.50-37.21 Hz	1	41.52 USD
[8] (Full System)	>100 dB	90.88-93.97 dB	-	0.5-35.54 Hz	1	25 USD

V. Conclusion

To summarize, the scarcity of low-cost experimentally characterized EEG acquisition systems was addressed in this study through the design and characterization of a low-cost electroencephalography analog front-end. The presented circuit was evaluated using simulation and laboratory measurements.

The system's performance was verified through analysis of the theoretical and experimentally obtained transfer functions. Despite costing less than most commercially available systems, the proposed circuit presents the characteristics recommended for EEG acquisition, such as a CMRR of 115.4 dB, a gain of 79.04 dB, and a bandwidth from 0.50 Hz to 37.21 Hz.

Limitations of the developed system include the power consumption and cost of the INA101HP, which could be replaced with another lower-cost, lower-power instrumentation amplifier, requiring power-supply modifications and applying surface-mount device footprints. The utilization of standard-tolerance passive components, potentially responsible for the discrepancies between simulated and measured results, is another issue that can be addressed.

Future studies will involve human-subject testing to evaluate the system's performance in real EEG acquisition, focusing on brain-computer interface systems. While performing tests with an individual, connecting the circuit to mains-powered equipment will require galvanic isolation to ensure participant safety.

***Abstract*—The use of high-frequency switched-mode converters improves the energy efficiency of the circuit. In the context of functional electrical stimulation, a device using a hybrid switched-mode buck converter was designed to synthesize the stimulation signal. It consists of a proportional-integral (PI) controller, a boost converter, and a hybrid converter (formed by a buck converter and an inverter) that generates the biphasic current signal. The device delivers a stimulation current with an amplitude of 3–100 mA, a resolution of 1 mA, a frequency of 10–250 Hz, and a pulse width of 10–500 μs. The main advantage of this FES system, with switched-mode topology in the output stage, is its simplicity, requiring few components. In the simulation, the design achieves the target parameters of frequency, pulse width, and amplitude, within a maximum deviation of 20% from the reference value of each parameter.**

***Index Terms*—Functional Electrical Stimulation, FES, Buck Converter, Switched-Mode Converter, Inverter, H-bridge, PI Control.**

I. Introduction

Functional electrical stimulation (FES) is a technique used to artificially induce muscle contractions by injecting electrical current into the tissues of the human body, with the intention of producing movement [1]. This technique is widely used in the treatment of people with spinal cord injury (SCI) to improve their motor functions [2]. It is also applied in assisted gait therapy and is associated with improvements in gait, muscle strength, and cardiorespiratory fitness [1].

The output stage of an FES device is the only one that cannot be implemented in software. Its function is to transfer the energy of the low-amplitude pulses generated in the previous stages to the excitable tissues of the body [3].

In the literature, linear converters are commonly used in the output stage, typically voltage-to-current converters and current mirrors [3]. The limitations of this kind of design are related to the transistor mismatch [4], which increases the complexity of the design implementation, and the energy inefficiency [5]. This topology can achieve a stimulation current with low ripple, but the use of semiconductor devices in the linear operating region can waste most of the energy in the process and not deliver it to the final load [5]. The linear topology developed by Blanco et al. [4] is presented in Fig. 1.

By contrast, the use of a switched-mode topology in the output stage of an FES device aims to increase energy efficiency [6] and to reduce volume, seeking portability [7].

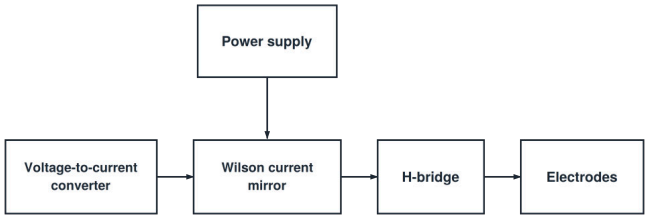

Fig. 1. Block diagram of the output stage with linear topology, adapted from [4].

This topology was chosen due to its simplicity, requiring few components, and to the use of semiconductor devices operating as switches, with only two states: ON or OFF. This switching reduces the energy dissipation involved in this process [5], [8]. As a result, the performance of the device is enhanced, since switched-mode topologies achieve an efficiency of 70–95%, while linear converters reach only 20–60% [5].

This work aims to simulate a surface FES device with a switched-mode topology in the output stage, which generates a biphasic, symmetric, square current, using pulse-width modulation (PWM), with an amplitude of 3–100 mA, a frequency of 10–250 Hz, and a pulse width of 10–500 μs. Fig. 2 shows the blocks that make up the output stage.

II. Materials and Methods

The FES design is divided into a PI controller, a boost converter, and a hybrid converter, formed by a buck converter and an inverter. The block diagram is shown in Fig. 3.

A. Proportional-Integral Control

The first block of the diagram is the PI controller. It is responsible for error correction, allowing an automatic adjustment of the stimulation to the desired value of the current

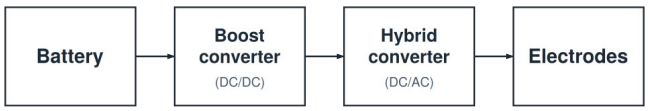

Fig. 2. Block diagram of the output stage with switched-mode topology.

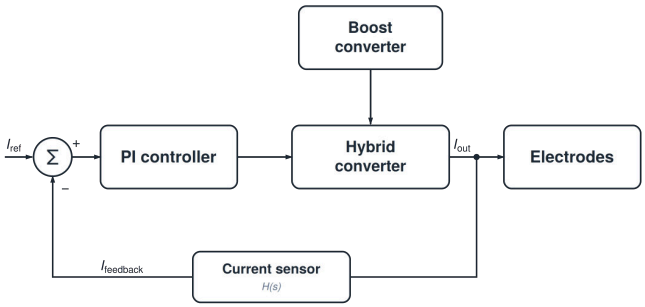

Fig. 3. Block diagram of the functional electrical stimulator design.

[9]. The controller was implemented in continuous time using an available control block in PSIM [10]. The values of K_p and K_i were chosen to obtain a step response with a settling time under 20% of the pulse width. The K_p and K_i values used in the design are shown in Table I.

The use of these parameters in an analog controller circuit would require resistors that implement a gain of 15 and a capacitor on the order of picofarads.

The PI control block is duplicated because the desired waveform is biphasic and symmetric. In the design, each block is adjusted to produce the correct stimulation current.

B. Boost Converter

The boost converter is used to step up the battery voltage to 100 V [8], producing the compliance voltage. This value is necessary for the H-bridge to deliver the desired output current amplitude. The fixed voltage in this stage causes higher energy losses, when compared to an adaptive supply [6]. However, aiming for a simpler implementation, it is the best option.

The battery used in the FES design enables the portability of the device and was one of the main reasons for choosing the switched-mode converter over a linear circuit [11]. This topology aims to provide greater circuit efficiency and, as a consequence, to extend the battery lifetime. This boost converter forms the second block of the design.

C. Hybrid Converter (Buck Converter + Inverter)

The third block of the design is the hybrid converter, formed by a buck converter and an inverter, which represents the output stage of the circuit. The H-bridge is the core of this stage since it enables the biphasic characteristic of the current signal. The waveform is produced by the change of current direction between the H-bridge branches, coordinated by the switching of the devices [8].

TABLE I
PI CONTROLLER PARAMETERS.

Parameter	Value
K_p	15
K_i	1.5×10^{10}

The circuit dedicated to synthesizing the pulse-width modulation (PWM) signal was designed using analog components: operational amplifiers configured as comparators, which produce a high-frequency signal [8]. This signal has two pre-defined frequencies, depending on the desired current amplitude: 250 kHz for low-amplitude currents, with values up to 10 mA, and 50 kHz for high-amplitude currents between 10 mA and 100 mA. This PWM signal is designed to activate two of the H-bridge switches, producing the average current value required for the electrical stimulation.

The output stage of the design is shown in Fig. 4.

Two independent square-wave voltage signals were used to activate switches S_1 and S_3, according to the desired pulse width and current frequency. In addition to activating switches S_1 and S_3, these signals are multiplied by the PWM signal, synthesized in the second block, to activate switches S_2 and S_4. The switch activation signals are shown in Fig. 5.

The S_2 and S_4 switching signals follow the PWM signal, which defines the average output current value. The current conduction path is established by the switching of S_1 and S_3. The parameters of the activation signals were calculated according to the operation of the buck converter. In addition, a phase shift was implemented between the activation signals of S_1/S_4 and S_2/S_3. This phase shift allows an interphase interval between the negative and positive half-cycles of the current, with a duration of 10 μs [4]. The phase shift implemented in the simulation is described by (1), which depends on the duty cycle (D) of the buck converter and the frequency (f) of the stimulation signal.

$$\phi = 360^\circ \times D + 360^\circ \times \left(10 \times 10^{-6}\right) \times f \tag{1}$$

The value of the inductor used in the buck converter (L) depends directly on the stimulation current ripple (Δi_L) and the converter switching frequency (f_{PWM}), as given in (2). The equation also relates these quantities to the output voltage (V_{out}) and duty cycle of the buck converter (D).

$$\Delta i_L = \frac{V_{\text{out}} \times (1 - D)}{L \times f_{\text{PWM}}} \tag{2}$$

The output current ripple of the buck converter is inversely proportional to the chosen inductor value and PWM switching frequency. For the lower current limit, a larger inductor would

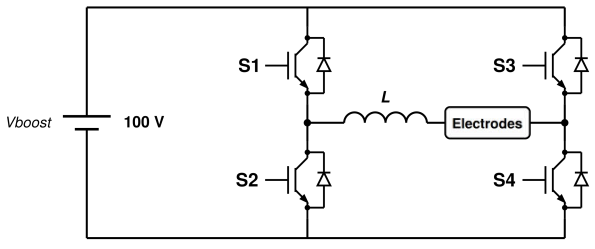

Fig. 4. Output stage of the designed device.

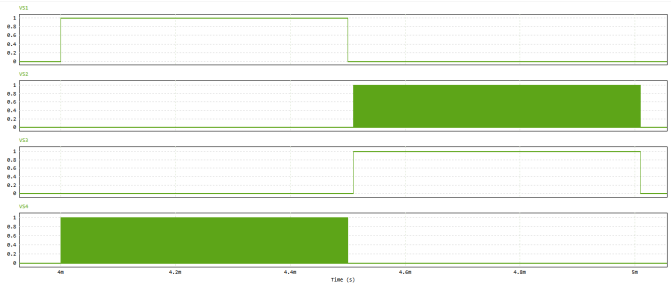

Fig. 5. Switch activation signals of the H-bridge switches.

be necessary to obtain an acceptable current ripple. To overcome this problem, the switching frequency was increased to 250 kHz. For the other current range, between 10 and 100 mA, the current ripple has less influence on the stimulation signal. Therefore, the switching frequency was set to 50 kHz.

In addition, the switching of the output inductors is also necessary, since with a higher inductance value, the current ripple is lower. As a consequence, with a smaller inductor, the current ripple is higher. Furthermore, the inductance value determines the rate of current variation, since with a lower inductance the current varies faster and vice versa [8]. Three inductance values are chosen for switching and combined with each other to select the desired inductance for each current range and for different pulse width and frequency values. The diagram representing the inductor switching is shown in Fig. 6.

The inductor values were chosen to obtain combinations of 1 mH, 2 mH, 4 mH, and 5 mH.

- $L_1 = 1\,\text{mH}$
- $L_2 = 1\,\text{mH}$
- $L_3 = 3\,\text{mH}$

The selection of inductance values depends on the switching of S_5, S_6, S_7, and S_8. This combination is shown in Table II.

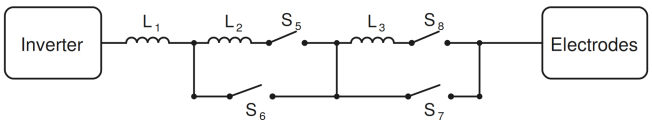

Fig. 6. Diagram of the inductor switching.

TABLE II
SWITCH STATES FOR EACH EFFECTIVE INDUCTANCE OF THE SWITCHING CIRCUIT.

Inductance (mH)	Combination	Switch states			
		S_5	S_6	S_7	S_8
1	L_1	OFF	ON	ON	OFF
2	$L_1 + L_2$	ON	OFF	ON	OFF
4	$L_1 + L_3$	OFF	ON	OFF	ON
5	$L_1 + L_2 + L_3$	ON	OFF	OFF	ON

D. Load Modeling

The simulation was set up with a purely resistive load, in series with the inductor, to verify the correct operation of the stimulation current source and to represent the electrical impedance of the biological tissues, without considering the capacitive component [4], [12]–[14].

III. Results and Discussion

The simulated circuit is capable of synthesizing a biphasic, symmetric, square waveform using a switched-mode output stage.

A. Validation of the Design Limits

Many stimulation current values were analyzed, but only the four scenarios that validate the simulated FES device will be detailed, under the most critical frequency and pulse width conditions.

- Case 1: 10 Hz and 10 μs;
- Case 2: 10 Hz and 500 μs;
- Case 3: 250 Hz and 10 μs;
- Case 4: 250 Hz and 500 μs.

The amplitude values obtained for the stimulation current in the critical scenarios, for reference amplitudes of 100 mA and 3 mA, an interphase interval of 10 μs, and a load of 1 kΩ [4], [12]–[14], are presented in Table III.

The relative percentage error for the worst case, with a reference amplitude of 3 mA, is approximately 9.20%, while for the 100 mA reference it is approximately 10.05%. This behavior occurs at the minimum pulse width chosen for the design, where the settling time has a strong influence on such short signals. The highest current ripple obtained was 9.8 mA, for a stimulation signal with an amplitude of 100 mA, a frequency of 250 Hz, and a pulse width of 500 μs.

The stimulation signal with a frequency of 10 Hz, a current amplitude of 100 mA, and a pulse width of 500 μs is shown in Fig. 7. A load of 1 kΩ was used in this case [4], [12]–[14]. This image was obtained from the simulation in the PSIM software [10], with a time step of 5 ns.

Fig. 8 shows the stimulation signal for a nominal case, with a frequency of 250 Hz, a current amplitude of 40 mA, and a pulse width of 500 μs. A load of 1 kΩ was used in this case [4], [12]–[14]. This image was obtained from the simulation in the PSIM software [10], with a time step of 5 ns.

To verify the maximum current limit, Fig. 9 shows the stimulation current with an amplitude of 100 mA, a frequency of 250 Hz, and a pulse width of 500 μs. The same load and

TABLE III
AVERAGE VALUE OF THE STIMULATION CURRENT FOR THE CRITICAL CASES.

Case	Frequency (Hz)	Pulse width (μs)	Current (mA)	
			3 mA	100 mA
1	10	10	3.2761	90.1182
2	10	500	3.1728	98.6337
3	250	10	3.2741	89.9502
4	250	500	3.1772	98.6312

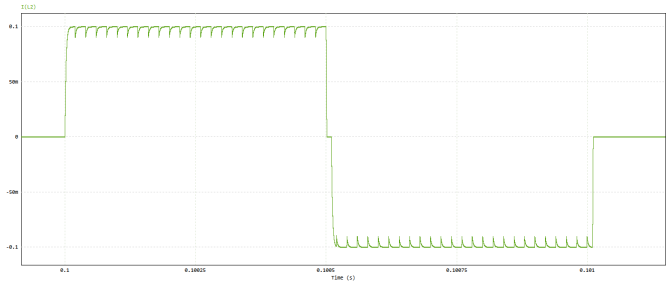

Fig. 7. Biphasic, symmetric stimulation current with an amplitude of 100 mA.

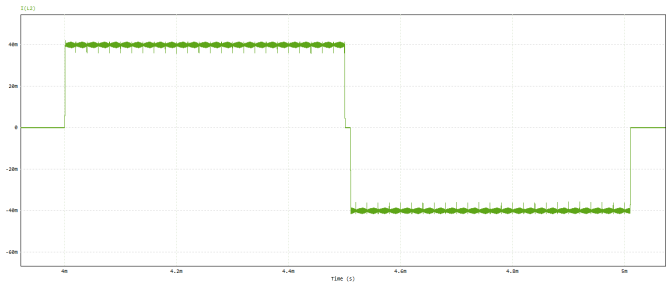

Fig. 8. Biphasic, symmetric stimulation current with an amplitude of 40 mA.

simulation step were used. The reference amplitude used in the test was 1 A, which demonstrates the limitation imposed by the buck converter, according to the values defined in the design.

B. Variation of the Output Inductance

The analysis of the extreme frequency and pulse width values showed that switching the inductance values is necessary for different values of current amplitude and pulse width. Therefore, the possible inductance values were analyzed, according to the inductor combination, for a stimulation signal with a frequency of 10 Hz, a current amplitude of 100 mA, and a pulse width of 500 μs. These results are shown in Table IV, which presents the average value of the positive half-cycle of the stimulation current.

C. Variation of the Circuit Load

Next, a test was performed to verify the correct operation of the current source implemented in the simulation. This test consists of varying the resistive load in series with the output

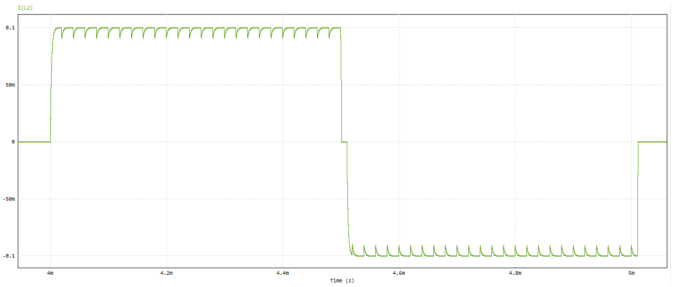

Fig. 9. Stimulation current limitation for a 1 A reference amplitude.

TABLE IV
CURRENT AMPLITUDE WITH A REFERENCE OF 100 MA FOR DIFFERENT INDUCTANCE VALUES.

Inductance (mH)	Average value (mA)
1	98.8270
2	98.6337
4	98.2380
5	98.0393

inductor across 1 kΩ, 800 Ω, and 500 Ω [4], [13], [14]. The goal is to observe the variation of the stimulation current with a reference amplitude of 100 mA, a frequency of 250 Hz, and a pulse width of 500 μs. The results are shown in Table V.

D. ABNT NBR IEC 60601-2-10 Standard

The ABNT NBR IEC 60601-2-10 standard [14] was consulted as a reference for the definition of the design parameters. The current amplitude limit per stimulation frequency and the peak voltage in the circuit were verified. The standard requires an accuracy of 20% for the stimulation parameter limits, limiting the stimulation current amplitude range to 3–100 mA. These values are achievable across the entire available pulse width range.

E. Comparison with Commercial Device

To compare the presented waveform with commercial equipment, a measurement was performed with the FesVif 995 Four device (Quark Medical, Piracicaba, Brazil). This device was chosen for its wide use in the Brazilian clinical market and for being available for testing in the Electrothermotherapy course of the Physical Therapy Department of the Federal University of Minas Gerais (UFMG).

The goal of this comparison is only to present a stimulation current available in the Brazilian market and to propose the developed circuit as a new alternative for this type of application.

The measurement was performed with a stimulation frequency of 50 Hz, a current amplitude of 10 mA, and a pulse width of 150 μs. Fig. 10 shows the voltage waveform obtained across the 1 kΩ load during the test.

The device has a biphasic, asymmetric waveform, with a positive half-cycle similar to that of the proposed FES circuit. The stimulation current is obtained by dividing the voltage by the load resistance used. Analyzing only the positive half-cycle, one observes a significant current ripple, current overshoot, and pulse width and amplitude values close to the desired ones.

TABLE V
COMPARISON FOR DIFFERENT LOAD VALUES (CURRENT OF 100 MA).

Load (Ω)	Average value (mA)
1000	98.6312
800	99.4956
500	99.7030

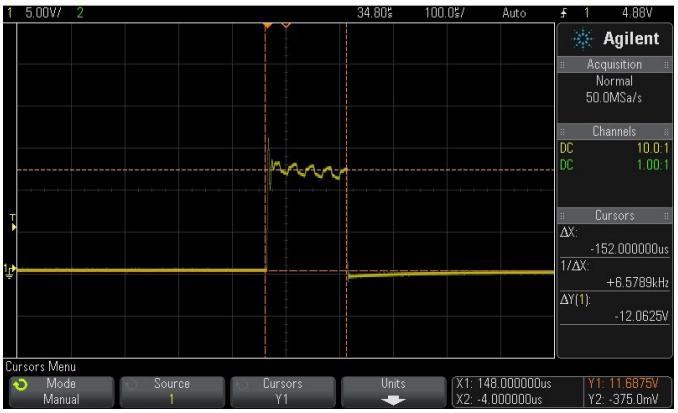

Fig. 10. Measurement of the stimulation signal from the FesVif 995 Four equipment.

IV. Conclusion

The simulated FES circuit can synthesize a biphasic, symmetric, square stimulation current with an amplitude of 3–100 mA, a resolution of 1 mA, a frequency of 10–250 Hz, and a pulse width of 10–500 μs. The maximum error observed for the parameters is within the 20% limit specified by the ABNT NBR IEC 60601-2-10 standard.

The simulated circuit exhibits significant output current errors for shorter pulse widths, related to the settling time required for the stimulation signal. In addition, the efficiency of the circuit is degraded by the fixed compliance voltage of the boost converter [6].

In future work, the FES device will be physically implemented, adding isolation stages for user protection by using high-speed digital optocouplers between the signal-generating circuit and the electrodes [13].

The switch to be used in the physical implementation of the hybrid converter in the prototype will be the GaN power transistor EPC2215 (Efficient Power Conversion Corporation, El Segundo, CA, USA), which allows high-frequency switching. A half-bridge circuit was simulated in LTspice software [15] using the design parameters, with the SPICE model of the switch provided by the manufacturer. The component presented a rise time of 1 ns and a recovery time of 3 μs, confirming its suitability for the design.

In the circuit developed by Blanco et al. [4], the stimulation current flows through the H-bridge and Wilson current mirror circuits, with the three transistors of the current mirror operating in the linear region, which is associated with conduction losses. In the proposed switched-mode topology, the stimulation current also flows through the H-bridge circuit, but it is modulated in the output inductor. The only losses in this model are the switching losses, which are very low in GaN switches and much smaller than the conduction losses of the Wilson current mirror.

With the prototype built, the efficiency study of the device can be carried out, in order to reaffirm the choice of the switched-mode topology for the output stage. In addition, tests with resistive loads will be performed with the goal of demonstrating the correct operation of the developed current source, before applying the stimulation signal to volunteers [4].

***Abstract*— Pain is a subjective experience that varies from individual to individual and has a direct impact on quality of life. This study describes the development of a portable digital algometer to standardize pressure application during the Musculoskeletal Interfiber Counterirritant Stimulation (MICS) technique. Given the subjective nature of pain and the variability in trigger-point sensitivity, the device aims to provide an objective, reliable measurement method. The system integrates a strain gauge into a quarter-Wheatstone bridge, an HX711 amplifier with 24-bit resolution, a PIC16F874A microcontroller and an LCD interface for real-time feedback. Calibration with standard weights showed a strong linear relationship between mass and voltage (R^2 = 0.98734), confirming accurate (mean 89%), repeatable measurements within the elastic region. The device enables precise quantification of applied pressure, supporting treatment consistency and potential home use. Future work will focus on usability validation and miniaturization to improve portability and scalability.**

Keywords— algometer, MICS, pain, strain gauge.

I. INTRODUCTION

Pain is a response to actual or potential tissue damage [1] and is one of the most important clinical symptoms, a subjective experience influenced by physical and psychological factors [2]. Therefore, it is necessary the development of methods to evaluate it, since pain is considered an important clinical symptom [3].

In this context, Myofascial Pain Syndrome (MPS) is the most common form of musculoskeletal pain. This condition can reduce tissue elasticity and decrease an individual's mobility. These symptoms occur due to Trigger Points (TPs), which generate referred pain, that is, pain perceived in a location different from its point of origin [4]. In addition to pain, these TPs may also cause sensations of cold or heat in the affected region [5]. The treatment of MPS focuses on pain control with analgesics and anti-inflammatory drugs, and on deactivating TPs, which can be achieved through invasive and non-invasive methods, such as needling and ischemic compression [6].

In this context, the innovative Musculoskeletal Interfiber Counterirritant Stimulation (MICS) technique emerges as a proposed non-invasive treatment. By using the MICS to apply ischemic pressure to the TP, modulation of the autonomic nervous system is induced, resulting in reduced MPS pain in patients with joint hypermobility [7].

Although several approaches exist for treating MPS, it is essential to establish a standardized pain measurement scale to improve efficiency. In this regard, several methods are available to assess pain, including visual, verbal, and behavioral scales, as well as algometers [2].

Algometers offer an advantage over other measurement methods by providing a more precise scale with less subjectivity in patient pain perception [2]. They are used to measure the pressure applied at the moment pain is perceived, providing an objective measure of pain sensitivity [8]. This is particularly useful for evaluating MPS, since TPs may vary in sensitivity. With algometers, healthcare professionals can quantify pain more precisely, consistently, and in a standardized manner, which is essential for monitoring the progression of the pain condition. This, this study aimed the development of a portable digital algometer to standardize pressure application using the MICS technique.

II. METHODOGOLY

The digital algometer developed was based on the component strain gauge. When subjected to pressure or weight, this sensor deforms, changing its electrical resistance. This effect can potentially allow the innovative quantification of the pressure applied at the tip of the MICS. When bonded to MICS, the strain gauge can stretch or compress, altering its internal resistance, which is measured to determine stress.

To measure the variation in applied mechanical pressure, a Wheatstone bridge configured as a quarter-bridge (1/4) was used. In this configuration, the resistance variation is converted into a voltage variation of about millivolts (mV).

Afterward, the generated signal must be amplified, since the voltage variation is very small. Some microcontrollers (MCUs) operate with supply voltages of 5 V or 3.3 V and include 10-bit or 12-bit ADC converters, resulting in resolutions of approximately 4.88 mV and 0.8 mV, respectively. Therefore, signal amplification was required.

The block diagram in Fig. 1 illustrates the system's overall process, its relationships, and the operating flow.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

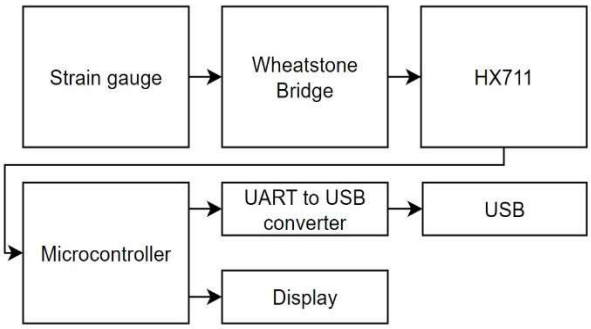

Fig. 1. Block Diagram of the proposed digital algometer.

A. Strain gauge

The precision resistance strain gauge used was a commercial model, BX120-3AA (Ningbo Ane Electric Co., Ltd., Ningbo, China). It was configured in a quarter-bridge (1/4), which, although not completely immune to temperature-related variations, compensates for them using a copper–aluminum alloy.

B. Amplifier/Analog-Digital-Converter

The amplifier used was the HX711 module (Avia Semiconductor, Xiamen, China), which, after signal amplification, performs analog-to-digital (A/D) conversion with 24-bit resolution, however, the effective resolution is lower in practice due to the influence of electronic noise and other non-idealities inherent to the measurement system. Still, it is significantly higher precision than that available in conventional MCUs. The HX711 gain was set to 128, and the clock to 10 Hz.

C. Microcontroller

The selected microcontroller (MCU) was the PIC16F874A, a CMOS flash 8/14-bit family member featuring 14-bit instruction words and a Harvard architecture. It was chosen for its cost-effectiveness (low power and high performance), the adequate number of GPIO (General Purpose Input/Output) pins, and support for UART and I²C communication protocols. This MCU has 192 bytes of SRAM and 128 bytes of EEPROM, which is not a limitation for the chosen display or for reading data from the HX711 module, since each measurement can be stored using 3 bytes.

D. User Interface

A blue 16-character × 2-line Liquid Crystal Display (LCD) module with the HD44780 controller was used. Communication was performed using the 4-bit protocol, reducing the number of required MCU ports. Through this display, the pressure value can be visually presented to the algometer user, allowing the patient undergoing the MICS treatment to use the device to train the standard mechanical pressure application pattern for therapy at home [7].

The digital algometer includes three buttons: one to start and stop the measurement, another to change the pressure scale, and a third to transmit the sampled data via USB at 9600 baud.

E. Power Supply

The power supply is provided by a 9-V Li-Ion battery, with the voltage regulated to 5 V by the LM7805 positive voltage regulator. The choice of a 9 V battery was made due to its practicality and ease of replacement. The 100 µF capacitors filter voltage fluctuations at the output of the voltage regulator.

F. Calibration

To calibrate the strain gauge, a precision digital balance with 1 decimal place resolution was used. The MICS device was positioned on a tiny silicone rubber base to ensure stability. Next, traceable weights (standards) were placed on the device, and their weights were measured using the digital scale. The calibration was performed using three measurements (triplicate), with the mean used to improve accuracy.

With the circuit's resolution and supply voltage, it was possible to relate the A/D converter's output (mV) to reference electrical voltages measured with a digital multimeter, thereby enabling device calibration.

To establish the device's transfer function, a linear regression was applied to the calibration data. The relationship between the applied mass and the resulting electrical voltage is described by the following linear model (Equation 1):

$$V(mV) = S \cdot m(g) + V_0 \quad (1)$$

Where:

- $V(mV)$ is the output voltage measured in millivolts;
- S represents the sensitivity of the system (slope of the calibration curve);
- $m(g)$ is the applied mass in grams;
- V_0 is the intercept, corresponding to the voltage offset at zero load.

The sensitivity (S) was calculated as the ratio of the change in voltage to the change in mass ($\Delta V/\Delta m$). This mathematical model was subsequently implemented in the PIC16F874A firmware to convert the 24-bit digital signal from the HX711 module into real-time mass or pressure measurements, readings displayed on the LCD. The system resolution was determined by correlating the sensitivity with the A/D converter's 24-bit depth.

Pressure values were obtained by converting the reference masses into force using the standard gravitational acceleration (9.81 m/s²). Assuming a contact area of 1 cm² at the device tip, the applied pressure was calculated from the force-to-area relationship. Subsequently, the same calibration and regression procedures previously described were applied to establish the pressure calibration curve. This linear model is described by the following linear model (Equation 2):

$$V(mV) = Sa \cdot P(kPa) + V_1 \quad (2)$$

Where:

- $V(mV)$ is the output voltage measured in millivolts;
- S represents the sensitivity of the system (slope of the calibration curve);
- $P(kPa)$ is the applied pressure in kilopascal;
- V_1 is the intercept, corresponding to the voltage offset at zero load.

G. Softwares

For the development, the electronic schematic design was carried out using KiCad v6.00 (KiCad EDA, GitLab Community, Global), while SimulIDE v1.0.0 (SimulIDE Community, Global) was used for circuit simulation. The source code was written and compiled in MPLAB X IDE

v6.00 (Microchip Technology Inc., Chandler, AZ, USA). Finally, the MCU was programmed using the PICkit 3 v3.01 (Microchip Technology Inc., Chandler, AZ, USA). The data analysis and graphs were created using OriginPro software (v. 8.5, OriginLab, Northampton, MA, USA).

III. RESULTS AND DISCUSSION

The MCU circuit was designed to allow external connections to the LCD and a UART–USB converter, support communication with the HX711, and provide an I²C interface for future use. Fig. 2 shows the MCU circuit.

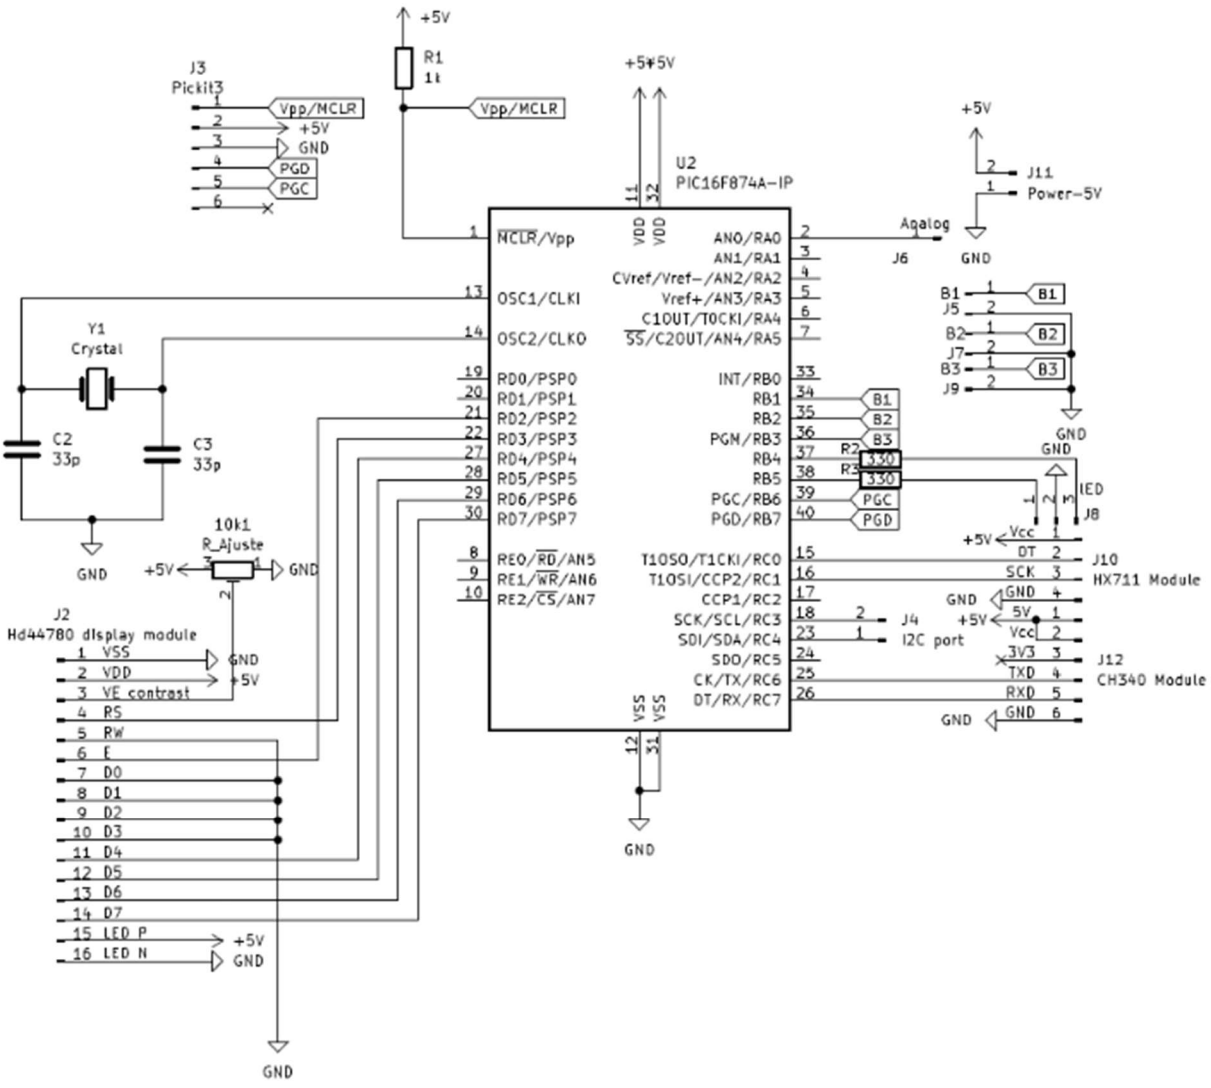

Fig. 2. MCU circuit of the digital algometer.

The pressure measurement circuit schematic was developed separately from the MCU to facilitate a possible strain gauge replacement. Fig. 3 presents this schematic circuit.

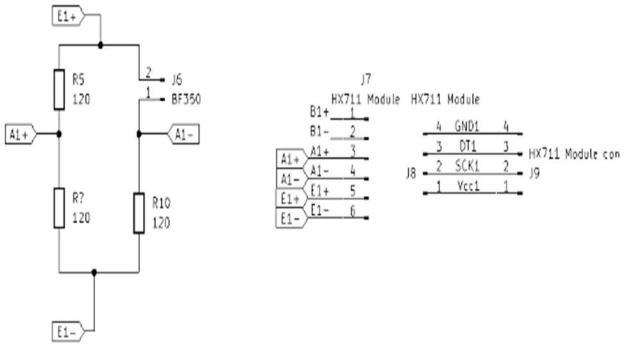

Fig. 3. Circuit HX711 and Wheaston bridge.

Based on the schematics shown in Fig. 2 and using the LM7805 power supply, the Printed Circuit Board (PCB) layouts for the MCU were developed. The jumpers were implemented as traces on the top layer (red lines); however, the PCB was designed to operate as a single-layer board. Fig. 4 shows the MCU PCB layout.

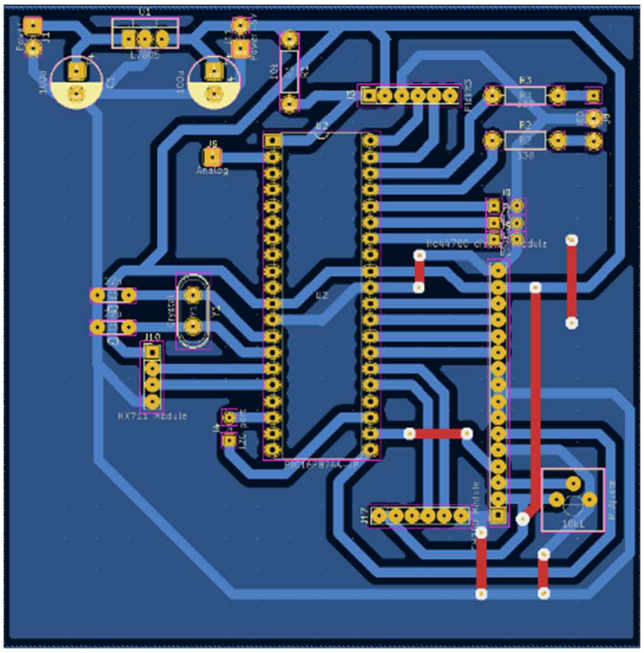

Fig. 4. PCB layout of the MCU.

The PCB layouts for the HX711 and the Wheatstone bridge were developed based on the schematics shown in Fig. 3. The single-layer PCB layout is shown in Fig. 5.

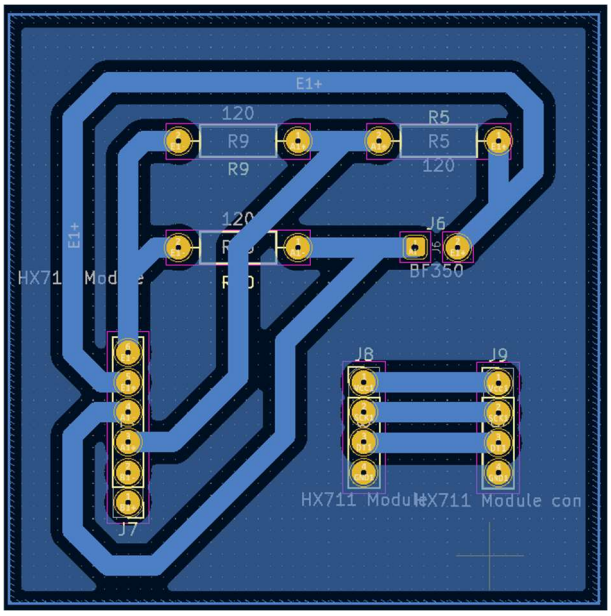

Fig. 5. Circuit HX711 and Wheaston bridge electronic layout.

Figures 6 and 7 show, respectively, the PCB phenolic prototypes developed, which comprise the MCU, and the HX711 and Wheatstone bridge.

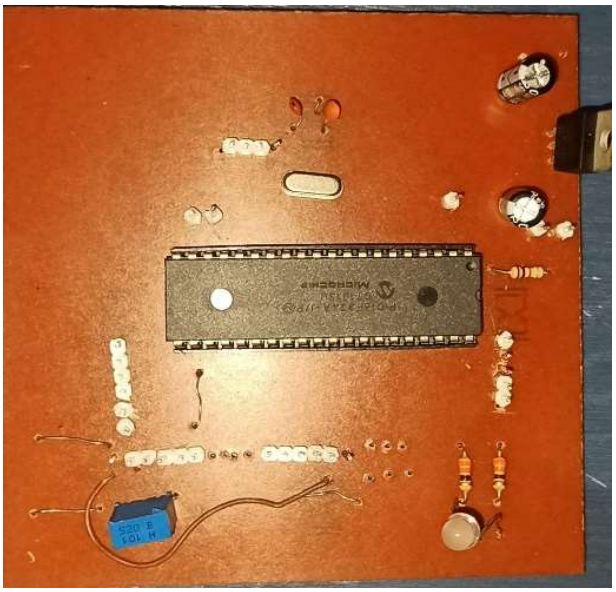

Fig. 6. PCB with a 10 x 10 cm prototype of the MCU.

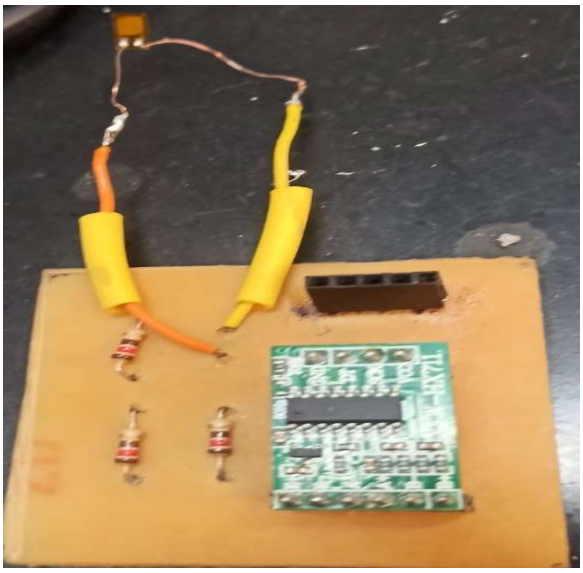

Fig. 7. HX711 and Wheatstone PCB with 5x5 cm prototype connected to the BX120-3AA strain gauge (upper).

The experimental data, f-function and the resulting regression fit are presented in Fig. 8. The calibration curve exhibited high linearity across the clinical range of 100 g to 1000 g, with a coefficient of determination (R^2) of 0.98734. The calculated sensitivity (S) was 0.763 $\mu V/g$. The maximum mass was 1000 g due to the MICS clinical protocol. The low dispersion across triplicates (mean ± standard deviation) indicates high repeatability and confirms that the BX120-3AA strain gauge operated within its elastic region, with no evidence of hysteresis or nonlinearity. This linear response is critical for the MICS protocol, as it ensures that the pressure applied to the trigger point is quantified with precision. The largest absolute error was 61.64 g for a mass of 900 g, and the mean accuracy was 89%.

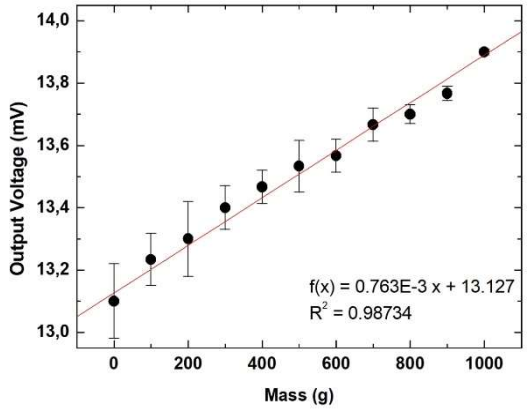

Fig. 8. Experimental data with a regression fit of the strain gauge calibration.

To comply with SI units, the applied loads were converted into pressure values assuming a contact area of 1 cm² at the algometer tip. Consequently, the calibration range corresponded to 0–98.1 kPa, which encompasses the operating range required by the MICS protocol, shown in Fig. 9.

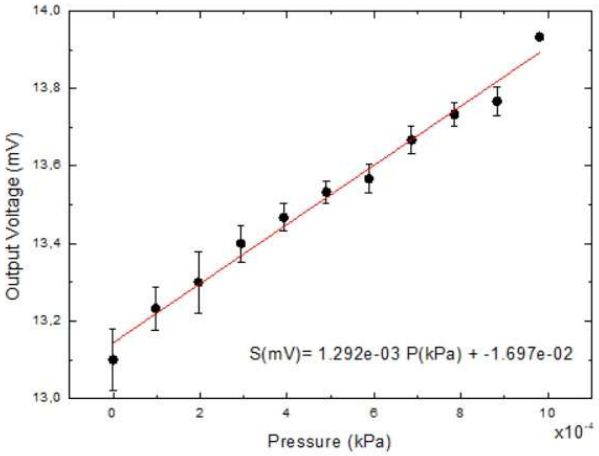

Fig. 9. Strain gauge calibration curve showing the experimental data and the corresponding regression fit of pressure (kPa).

Therefore, the developed digital algometer shown in Fig. 9 was calibrated, and the LCD displays a readout in grams (bottom right). Also, in Fig. 10 a standard weight of 100 g was used (bottom left), and the MICS was positioned in this sample holder. To obtain the signal reading, a linear regression model was applied to the experimental data, relating the output voltage to the applied mass. The average measurement error was 0.015635mV, with a maximum deviation of 0.050600 mV, resulting in a mean relative error of 4.2640%. The system demonstrated a precision of approximately 0.295402 mV.

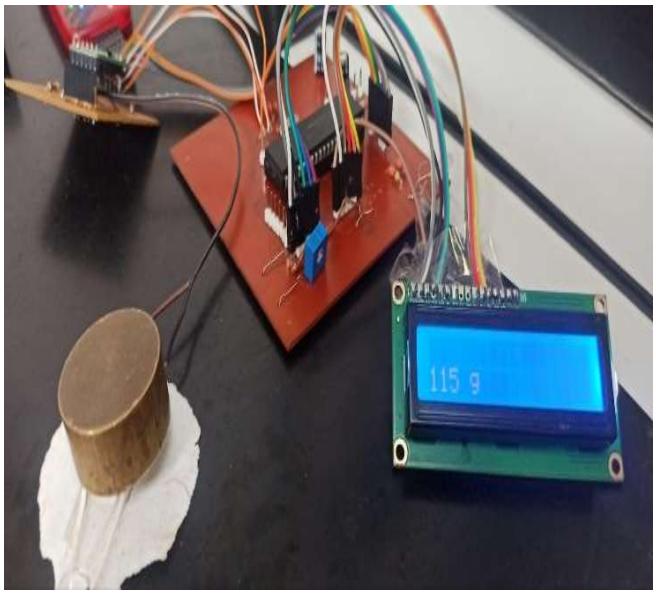

Fig. 10. The digital algometer with the MICS device.

Several studies proposed the development of algometers and used components from this work, such as strain gauges [9] and the HX711 module [9,10], as well as the Wheatstone bridge topology [9].

The differential of this innovative digital algometer compared to other referenced works is its direct focus on the MICS protocol and its use of a MCU from the PIC16 family, rather than the Arduino environment, as in Gimeno (2020)

[9]. An electronic circuit using a more advanced development environment, MPLAB X IDE, provides greater control of the hardware, allowing better optimization and, consequently, the use of a simpler and lower-cost MCU than the ATmega328p (Microchip Technology Inc., Chandler, AZ, USA), as applied in the commercial Arduino Uno R3 and V3.

For the next steps of the project, it will be necessary to conduct intra- and inter-rater analyses to validate the digital algometer's usability. This further analysis also requires ethics & research committee evaluation for tests on humans aiming for usability.

Another important improvement would be a version using SMD (Surface-Mount Device) components, which would significantly reduce its size. This miniaturization using SMD components would offer advantages, such as reduced circuit footprint, improved high-frequency performance, and easier large-scale manufacturing. Other improvements include Bland–Altman agreement assessment, intraclass correlation coefficient (ICC), thermal drift analysis, uncertainty propagation, long-term stability evaluation, and direct comparison with commercially validated algometers.

CONCLUSION

With the development of a portable digital algometer, the possibility arises to standardize the pressure applied to TPs, including in the home care context, which aligns with the MICS treatment approach. This standardization may be a crucial factor in the treatment's effectiveness and in minimizing patient discomfort.

Furthermore, the possibility of self-treatment with the proposed digital algometer may provide patients with greater convenience and autonomy. Future developments will include loading–unloading sensor comparison, redesigning the device using surface-mount technology (SMT/SMD), and enabling a more compact, robust, and user-friendly implementation. However, its clinical applicability, usability, and therapeutic effectiveness still require validation through human-centered studies. In addition, inter-rater and intra-rater reliability assessments must be conducted to evaluate the consistency and reproducibility of the measurements obtained with the device across different evaluators and repeated assessments.

ACKNOWLEDGMENT

The authors would like to thank Federal Technological University of Paraná (UTFPR) for providing all resources for the project development, the National Council for Scientific and Technological Research (CNPq) for a scholarship to A. F. A. A., the Ânima Institute (AI) for the support to L. P. A. and L. H. M., and the Fundação Araucária (FA) & Superintendência de Ciência, Tecnologia e Ensino Superior (SETI) to the conference grants to H. C. C.

***Abstract*—This work presents the development of a novel microcontroller-based dynamic electro-pneumatic actuator for Magnetic Resonance Elastography (MRE) to overcome the frequency and phase limitations of current clinical systems. The proposed actuator integrates a refrigeration compressor, a cylindrical reservoir, and an electroacoustic modulator for high-speed airflow switching. A 3D-printed pneumatic driver with a latex membrane converts air pulses into mechanical waves, reaching up to 500 Hz in water (electroacoustic modulator) and validated in a paraffin gel phantom over 10-200 Hz. Experimental characterization included cylinder loading, duty cycle, static force, pressure-displacement, and wave propagation in a paraffin gel phantom. Results show a linear force-pressure response (R^2 = 0.9998), frequency-dependent viscoelastic dispersion (shear modulus from 3.66 to 22.44 kPa over 10–200 Hz), and modulator sensitivity with a nonlinear frequency-PWM relationship. The system achieved stable operation up to 20 L/min, with a duty-cycle margin and a displacement sensitivity of approximately 0.19 mm/kPa within the recommended 40–50 kPa range. A compact, mobile enclosure with electromagnetic shielding and a touchscreen interface was developed with future MRI integration in mind, though in-scanner compatibility remains unestablished. The actuator generates controlled shear waves in tissue-mimicking media, offering a versatile, low-cost benchtop platform to advance MRE research toward higher-frequency clinical applications.**

***Index Terms*—electro-pneumatic actuator, magnetic resonance elastography (MRE), microcontroller-based control, shear-wave generation, viscoelastic properties.**

I. Introduction

Manual palpation has served as a fundamental diagnostic tool in medical practice for centuries. The ability to distinguish healthy from diseased tissue based on tactile assessment of stiffness reflects significant changes in tissue mechanical properties associated with pathological processes such as inflammation, fibrosis, neoplasms [1] and gel dosimetry [4]. Malignant tumors, for example, are typically stiffer than the surrounding tissue. However, palpation is limited to superficial organs, is inherently subjective, and depends on the examiner's experience. To address these limitations, this work proposes a novel electropneumatic actuator that integrates the advantages of compressed air with the precision of electronic control.

Conventional imaging modalities (CT, ultrasound, MRI) do not directly quantify tissue mechanical properties: their contrast relies on electron density, acoustic impedance, or magnetic relaxation, which vary on much smaller scales than the elastic modulus [2], while CT and MRI parameters vary by factors of two to three, the shear modulus of soft tissues can differ by more than five orders of magnitude [1], [3].

To address this, elastography has emerged over the past three decades as an imaging technique that quantitatively maps tissue elasticity, complementing US, MRI, and CT interpretation [5]. Among these, Magnetic Resonance Elastography (MRE), introduced by Muthupillai et al. in 1995, enables "virtual palpation" of deep-seated organs with high spatial resolution [6] by propagating harmonic shear waves whose wavelength and damping relate directly to viscoelastic parameters such as shear modulus and viscosity [7].

To achieve this quantification, a mechanical actuation system is necessary to generate these waves in a controlled manner, to synchronize them with the gradient pulses of the MRI scanner, and to ensure compatibility with the high-magnetic field environment [8]. Historically, three main actuator families have been explored: electromagnetic, piezoelectric, and pneumatic [9].

Electromagnetic actuators are capable of generating significant forces; however, they are prone to electromagnetic interference with imaging gradients, produce magnetic susceptibility artifacts, and present safety risks due to conductive metallic structures exposed to intense oscillating fields [10].

Piezoelectric actuators are inherently MRI-compatible and offer high temporal precision and a broad frequency range (0-300 Hz). However, they are limited to small displacements, rarely exceeding 1 mm, and often possess a large footprint, complicating their integration and use in clinical applications [11], [12].

Pneumatic systems offer the simplest and safest compatibility, using air displacement to generate vibration, thereby eliminating the need for electronic components near the patient [8]. Nevertheless, these systems face persistent challenges, including phase delay and a frequency range typically limited to less than 100 Hz [12], [13].

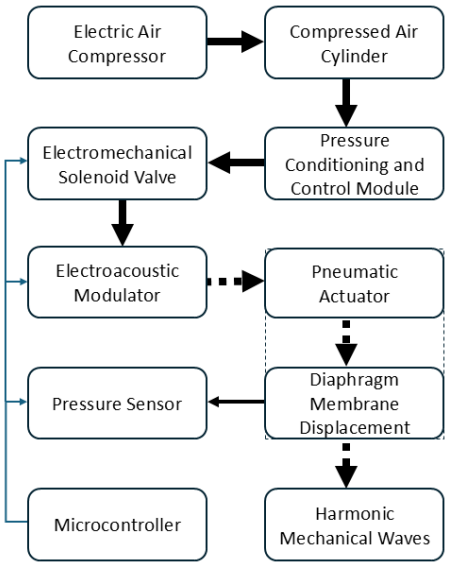
This comparative analysis indicates that the fundamental challenges identified decades ago remain largely unresolved: the only MRE actuator approved for clinical use, the Active Driver^{TM} of the Resoundant system (Rochester, MN, USA), used with GE Healthcare scanners [12], is effective and safe but limited to 40-90 Hz, restricting detailed characterization of stiff tissues or small anatomical structures that require higher frequencies [14].

This scenario reflects both technical and economic barriers, including regulatory approval costs, that keep versatile alternatives such as piezoelectric actuators confined to academic laboratories, while an older, more limited technology remains the only clinically available option — highlighting the need for a solution that directly addresses these unresolved frequency and phase limitations.

This work seeks to combine the safety, compatibility, and flexibility of novel pneumatic systems with the ability to operate in a wide frequency range (10 to 500 Hz), thus directly addressing the phase and frequency limitations of current systems. Our research encompasses the entire process, from mechanical design and 3D component printing, including material selection and flow parameter optimization, to the development of control electronics, microcontroller programming and bench testing measurement.

II. Materials

Here, we describe the materials, components, and methods used to develop the microcontroller-based dynamic electropneumatic system, following a functional hierarchy that details first the pneumatic plant instrumentation and then the control and automation system, to support understanding and reproducibility.



The electropneumatic system consists of an integrated set of devices operating in a cascade to generate, condition, modulate, and apply compressed-air flow as mechanical pressure waves. Figure 1 illustrates the functional block diagram of the system, showing airflow and interconnection between its main modules. Each of these blocks is detailed in the following subsections, with an emphasis on technical characteristics, system function, and selection criteria.

A. Compressed Air Generation and Storage Module

The compressed air generation and storage module captures ambient air, compresses it, and stores it for later use as the system's pneumatic energy source.

1) Electric Air Compressor: The active element of this module is a hermetic reciprocating compressor originally designed for refrigeration by Embraco (Joinville, SC, Brazil), chosen over conventional workshop models for its low noise and vibration — essential in clinical or lab settings. It features a 1/4 HP motor (186 W), operates on 110-220 VAC (50/60 Hz) with a nominal current of 1-4 A, and reduces air volume within a cylinder to increase pressure: the suction (low-pressure) side operates between 0-15 PSI (0-103 kPa), while the discharge (high-pressure) side reaches 100-150 PSI (0.69-1.03 MPa), depending on compression ratio and ambient temperature.

Fig. 1: Functional block diagram of the microcontroller-based dynamic electropneumatic system.

2) Compressed Air Cylinder: The compressed air is stored in a carbon steel cylinder originally designed for refrigerant gas storage (EOS brand, RS, Brazil). The reservoir has a dual purpose: damping pulsations generated by the compressor and providing air volume to meet peak demands without requiring continuous compressor operation. Its internal geometric capacity is 12 liters. The maximum working pressure adopted for the system is 150 PSI (approximately 10.3 bar or 1.03 MPa). When pressurized to 10 bar, the reservoir stores the equivalent of 120 liters of air at standard atmospheric pressure (1 bar), according to Boyle-Mariotte's Law ($P_1V_1 = P_2V_2$), thereby ensuring sufficient capacity for the tests.

B. Pressure Conditioning and Control Module

Before use, the stored air must be reduced to a pressure and stabilized at a safe level suitable for the actuator. This module consists of a pressure regulating valve and a safety and control pressure switch.

1) Pressure Regulator Filter: A diaphragm-type pressure regulating filter (AFR-2000) is installed at the reservoir outlet to reduce the line pressure to a constant working pressure regardless of inlet or downstream flow fluctuations, with a dual-scale (PSI/bar) analog gage for visual monitoring. A rotary knob compresses a spring against the diaphragm to set the valve-opening force, letting the operator select the magnitude of force applied to the actuator.

2) Safety and Control Pressure Switch: To automate reservoir filling and ensure safety, a pressure switch from Evotek Hydraulic Technology Co., Ltd. (Shanghai, China) continuously monitors the cylinder's internal pressure with adjustable hysteresis, typically turning the compressor on at 80 PSI (550 kPa) and off at 120 PSI (830 kPa). Internally, a sensing element (bellow or diaphragm) moves an electrical contact that opens at the upper limit, interrupting the compressor circuit, and closes at the lower limit to restart it.

C. Airflow Modulation Module

This subsystem is responsible for converting the continuous airflow into a high-frequency pulsatile flow. It consists of a solenoid valve and a high-speed airflow switch.

1) Electromechanical Solenoid Valve: A direct-acting, normally closed On/Off solenoid valve (Ar Fusion Brasil Pneumática, Americana, SP, Brazil) serves as the system's master switch, allowing air to flow from the conditioning module to the modulator when activated. It features a 12 VDC, 16 W coil, a brass body, and a 1/4" flow orifice: energizing the coil displaces a ferromagnetic plunger to open the passage, while a spring reseals it on de-energization, with a millisecond-scale response time sufficient for on/off control.

2) Electroacoustic Modulator: We engineered a structure, called an electroacoustic modulator, to manipulate the airflow delivered to the next module, specifically designed to control airflow interruption and featuring high switching speeds between open and closed states. The device operates by discharging high-speed airflow in pulses. It was designed using SolidWorks CAD software (Dassault Systèmes SOLIDWORKS Corp., Waltham, Massachusetts, USA) and fabricated via precisely additive manufacturing (3D printing) with PETG filament. PETG was selected for its high mechanical strength, rigidity, and low moisture absorption.

D. Pneumatic Air Actuator Module

This is the final stage of the pneumatic system, in which the energy of compressed air is converted into periodic mechanical motion for application to biological tissue.

1) Diaphragm Membrane Displacement: The actuator is an electromechanical device designed to transmit air pressure waves to the tissue of interest. The actuator body was designed using CAD (SolidWorks) and fabricated via 3D printing using PETG. Its geometry consists of a cylindrical cavity with a rear inlet for the pulsatile air. The front face of the cavity is sealed by a diaphragm latex membrane (or another low-stiffness, biocompatible elastomer) which acts as a mechanical wave driver. The cyclic increase in internal cavity pressure, caused by the arrival of the air pulses, deforms the membrane outward in a parabolic shape. This deformation (linear motion) constitutes the mechanical wave applied to the tissue in contact with the membrane. The actuator body features a small additional port connected to a flow splitter. This port allows controlled outflow of a fraction of the air and provides a connection to a pressure sensor for monitoring the internal cavity pressure.

2) Pressure Sensor: Real-time pressure acquisition used an MPX2202GP gage pressure sensor (NXP Semiconductors, Eindhoven, The Netherlands; 0-200 kPa range), a low-cost piezoresistive sensor with 0.2 mV/kPa typical sensitivity and a 10-16 VDC supply. A silicon diaphragm with piezoresistors in a Wheatstone bridge deforms under pressure, unbalancing the bridge and generating a differential output voltage, which is amplified and conditioned by a dedicated driver for microcontroller readout. A small-diameter orifice (flow orifice) is connected to the secondary outlet of the flow splitter.

E. User Interface

In this work, a 3.4-inch Nextion TFT LCD touchscreen (Shenzhen, Guangdong, China) interfaces with an ESP32 microcontroller (Espressif Systems, Shanghai, China) for automation and control. This Human-Machine Interface combines a display-integrated processor, 16 MB of flash memory, and Nextion Editor software for GUI development; the display handles graphics (screens, buttons, charts) while the microcontroller updates progress and status via simple ASCII-based text instructions.

F. Power Source

The power supply system for electronic control boards and actuators consists of a 360 W high-performance power supply (SMPS- Switched-Mode Power Supply). This source provides a stabilized 12 VDC voltage and a maximum current of 30 A. It has galvanic isolation between the primary (mains) and secondary (circuits), as well as protection against overcurrent, short circuit, and overvoltage.

The compressor, in turn, is powered directly by the 220 VAC and 60 Hz electrical network, with its own power circuit that includes a protection fuse sized for the starting current and a manual override switch.

G. System Cabinet

All components (pneumatic modules, power supply, motherboard) were integrated inside a metal case, chosen for mechanical shock resistance and Faraday-cage electromagnetic shielding, and mounted on four 360° casters for multidirectional mobility.

III. Methods

A. Cylinder Air Loading Evaluation

The initial test measured the time to pressurize the initially empty reservoir from 0 to 120 PSI in 10-PSI increments, to evaluate the compressor's ability to maintain stable pressure under varying demand. Instantaneous pressure readings were obtained by direct observation of the gauge needle, recorded via smartphone in video-stopwatch mode and tabulated for analysis.

B. Compressor Duty Cycle Evaluation

For compressor duty cycle evaluation, the system was configured with the pressure switch set to a 40 PSI hysteresis, operating within an 80 to 120 PSI range. The system was monitored in various air consumption patterns at constant flow rates of 5, 10, 15, 20, and 25 L/min, with flow rates adjusted using a pressure regulator valve. The compressor's operating times (t_{on}) and rest times (t_{off}) were recorded for each condition.

C. Static Force Calibration

The force generated by the pneumatic actuator's membrane was evaluated with the driver in the horizontal position. Its diaphragm was faced downward, resting on the weighing pan of a precision scale. We then applied increasing static pressures, ranging from 0 to 50 kPa in 10 kPa increments (0.1 bar). The resulting force was displayed on the scale and recorded for subsequent analysis.

D. Pressure-Displacement Relationship

The displacement amplitude of the actuator diaphragm membrane was measured using an FPGA-based development board equipped with two 14-bit, 125 MS/s RF analog channels (ADCs/DACs). Signal processing used a custom algorithm to estimate micrometer-scale vibration motion through coherent phase tracking of ultrasound pulses. A dual-element transducer was used, with a center frequency of 5.8 MHz and a pulse repetition frequency (PRF) of 20 kHz. This transducer incorporates two piezoelectric elements within a single casing, separated by an acoustic barrier: one element transmits the ultrasound signal. The other receives echoes from the medium. During testing, the pneumatic actuator body was partially immersed in a circular container filled with room-temperature water. The transducer was positioned diametrically opposite the actuator at a distance of 50 mm, with its face oriented toward the center of the circular diaphragm. The actuator's excitation frequency was set to 20 Hz to maximize the echo signal-to-noise ratio (SNR). Pressures ranging from 0 to 50 kPa were applied in 2 kPa increments, and the axial displacement of the diaphragm membrane was recorded at each increment.

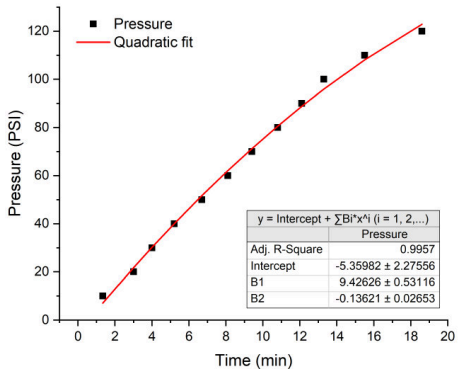
E. Propagation in Gel

To evaluate the system's ability to generate mechanical waves in media that mimic the properties of biological tissues, we prepared a cylindrical paraffin gel block with a diameter of 10 cm and a height of 2 cm. The medium's temperature was kept constant at 25°C throughout the experiment. This controlled thermal condition is crucial because the mechanical and acoustic properties of paraffin, such as the elastic modulus and the speed of sound propagation, are temperature-dependent.

The pneumatic driver actuator vibrating membrane was positioned on the top surface of the block, in its central region. This actuator was programmed to impart small displacements to the material with an amplitude of around 2 mm, operating at frequencies of 10, 20, 30, 40, 50, 100 and 200 Hz.

A dual ultrasound transducer was coupled to the bottom face of the block, diametrically opposite the actuator; this transducer emitted ultrasonic pulses that passed through the material and detected the reflected or transmitted mechanical waves. The measurement principle relies on the fact that the displacement of moving structures induces a phase shift in the transmitted or backscattered ultrasound signals.

To accurately estimate vibration, an algorithm based on coherent phase tracking was employed; this method uses phase correlation between ultrasound signals acquired at different time points to determine the micrometric displacement induced by vibration.



Ultrasound signals were acquired at each excitation frequency. Based on the analysis of phase shift and sound speed in the material (approximately 1448 m/s for paraffin gel at 25 °C). It was possible to determine the material's vibration velocity (m/s) in response to the applied excitation.

IV. Results and Discussion

A. Cylinder Air Loading Evaluation

The air loading of the cylinder was modeled using a quadratic fit, as shown in Fig. 2, with a coefficient of determination (R^2) = 0.997. The concavity, defined by the coefficient B2 = -0.13621, indicates that the curve gradually decelerates. The time required to increase the pressure inside the cylinder increases as the pressure approaches 120 PSI. This deceleration reflects the thermodynamic effects of adiabatic compression, where the air mass inside the reservoir increases, requiring progressively more work to achieve each subsequent pressure increment. As noted by Uffmann and Ladd [8], pneumatic systems face inherent challenges in maintaining stable pressure under varying demand, and our results confirm that the reservoir design effectively dampens compressor pulsations while providing sufficient stored energy for peak demands.

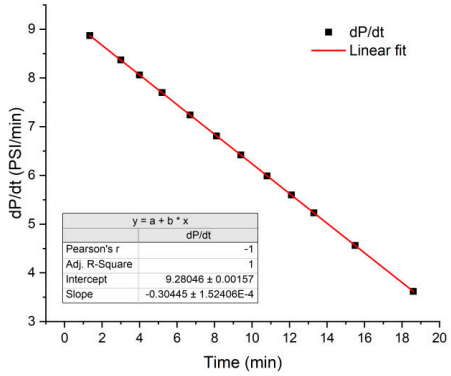


Fig. 2: Air cylinder load curve as a function of the time the compressor remains on, t_{on}

The derivative, representing the average compression rate (dP/dt), is shown in the curve in Fig. 3, fitted by linear regression, with an excellent coefficient of determination (R^2) = 0.9999. We observe that the average compression rate decreases linearly over time, as described by the fitted equation: $dP/dt = 9.2804 - 0.3044\,t$ (with t in minutes

and dP/dt in PSI/min), where the negative slope indicates that the compression rate drops by 0.3044 PSI/min for each additional minute of operation. This means that the medium is "hardening" or compacting, requiring more time for each increment in pressure.

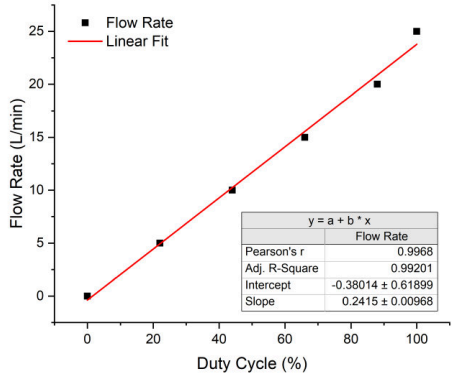

Fig. 3: Air cylinder compression rate curve versus charging time.

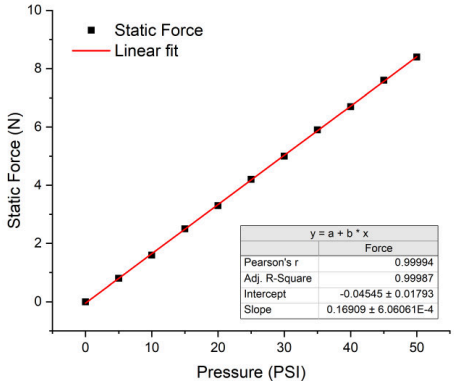
B. Compressor Duty Cycle

The results presented in Fig. 4 show an inverse correlation between the consumption flow rate and the compressor's operating time (t_{on}) and the rest time (t_{off}), with the duty cycle (C) varying linearly with pneumatic demand. The system showed excellent agreement with the theoretical model $C = t_{\text{on}}/(t_{\text{on}} + t_{\text{off}})$, with a maximum deviation of only 0.1% between the measured and calculated values.

Fig. 4: The compressor duty cycle is determined by the compressor's operating times (t_{on}) and rest times (t_{off}) for each condition.

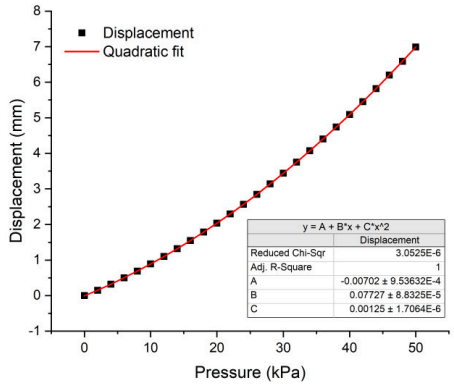


The effective flow rate of the compressor was determined to be 22.7 L/min, which sets the maximum consumption limit for cyclic operation. For demands of 5, 10, 15, and 20 L/min, the operating times were 7.68, 10.71, 17.66, and 50.37 min, respectively, with corresponding duty cycles of 22%, 44%, 66%, and 88%. Operating at a demand of up to 20 L/min is recommended to ensure a safety margin. Demands exceeding 22.7 L/min make cyclic operation unfeasible, causing the compressor to run continuously and leading to a steady drop in pressure. The results underscore the importance of properly sizing the pneumatic system to avoid both undersizing, which can lead to overheating, and oversizing, which can reduce energy efficiency—a trade-off often neglected in laboratory-constructed MRE actuators [9].

C. Static Force Calibration

Fig. 5 shows the static calibration results, showing a linear relationship between applied pressure and the force generated by the pneumatic actuator's membrane, with a coefficient of determination of $R^2 = 0.9998$. The force ranged from 0 N at 0 kPa to 8.4 N at 50 kPa, resulting in an average sensitivity of approximately 0.168 N/kPa.

Fig. 5: Static force calibration: force versus applied pressure.



The observed linearity, with no evidence of hysteresis or saturation, confirms that the membrane operates within the linear-elastic regime described by the generalized Hooke's Law for elastomeric materials, indicating negligible friction or leakage losses. This linear pressure-force response is crucial for MRE, enabling precise, repeatable control of the force — and thus the shear-wave amplitude — applied to the tissue by regulating the supply pressure [1].

D. Pressure-Displacement Relationship in Water

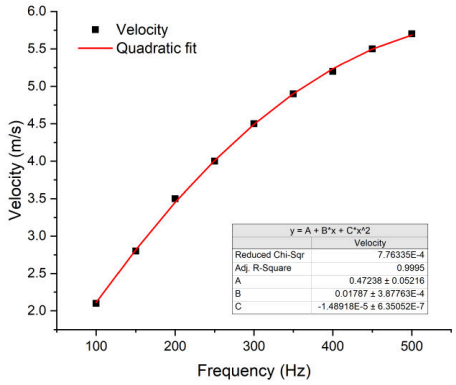
The displacement as a function of pressure is illustrated in Fig. 6. This curve was obtained at a fixed, low excitation frequency (20 Hz, Section III-D) to maximize the ultrasound-tracking SNR, isolating the effect of pressure from frequency-dependent effects; the complementary amplitude-frequency dependence, at fixed pressure, is characterized below (Velocity-Frequency Relationship in Water), where amplitude falls from 3.34 mm at 100 Hz to 1.81 mm at 500 Hz. Pressure and frequency thus act as largely independent control parameters — pressure sets the quasi-static displacement amplitude, while frequency modulates it at higher drive rates — though a full joint characterization was not performed and is left for future work. The system operates predominantly in the linear-elastic regime (R^2 = 0.9997 for the linear fit); however, the increments $\Delta d_\mu/\Delta P$ (0.075-0.200 mm/kPa) reveal a slightly quadratic, upward-concave deviation ($C > 0$).

Although the quadratic fit (R^2 = 0.9999) is slightly superior, the operating range considered strictly linear (deviation $\leqslant$ 5%

Fig. 6: Relationship between the pressure generated by the actuator's diaphragm membrane and its corresponding displacement in water.

relative to the linear model) is limited to 40–50 kPa. This narrowing of the linear range is attributed to the system's progressive compliance, possibly due to an increase in the effective area of the diaphragm or to the settling of elastomeric seals under pressure. For MRE applications that require maximum linearity, it is recommended to operate the transducer within the 40–50 kPa range, where the sensitivity is nearly constant, approximately 0.19 to 0.20 mm/kPa. For the full range of 0 to 50 kPa, the quadratic model best describes the behavior, with an error of less than 0.1% throughout. The ability to generate displacements of several millimeters exceeds the typical requirements of MRE (tens of micrometers) [1], providing ample margin for tissue coupling and ensuring sufficient wave amplitude even with attenuation through tissue.

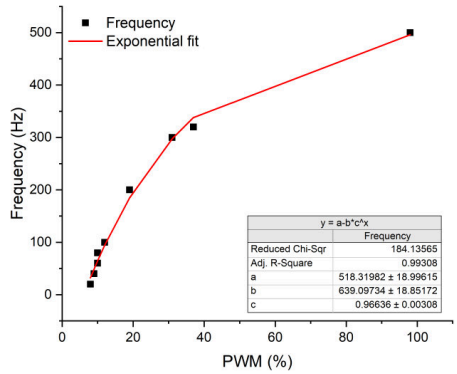
E. Velocity-Frequency Relationship in Water



The velocity as a function of frequency is illustrated in Fig. 7. This test was conducted with the driving pressure held fixed, so that the resulting curve isolates the effect of frequency on wave velocity and amplitude. The results show a sublinear increase in velocity with frequency, with a gain decreasing from 0.014 to 0.004 m/s·Hz and a tendency toward saturation at approximately 6.0 m/s. This behavior is attributed to a reduction in vibration amplitude as frequency increases, from 3.34 mm at 100 Hz to 1.81 mm at 500 Hz.

The 100-300 Hz range shows more linear gain and is recommended for operation, while above 350 Hz the system enters a strongly saturated regime; the estimated natural frequency below 100 Hz suggests further measurements would be needed to fully characterize the system's dynamics in that band. This sublinear response is typical of pneumatic systems, which Triolo et al. [12] report as limited above 100 Hz by phase delays and transmission-line compliance — a range our system significantly extends, particularly relevant for MRE of stiff tissues requiring shorter wavelengths [14].

F. Electroacoustic Modulator Control



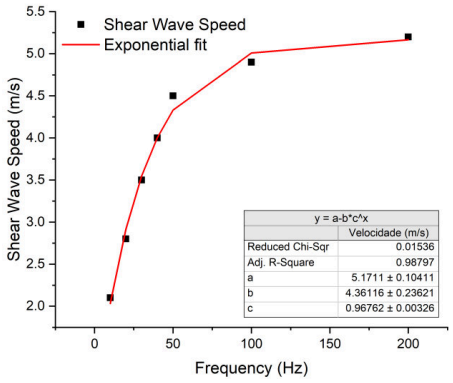
The pulsation-frequency response of the actuator membrane is governed by the duty cycle of the electroacoustic

Fig. 7: Velocity of the mechanical wave propagation in water at different frequencies.

modulator control driver, as shown in Fig. 8. Experimental results demonstrate a non-linear relationship between the duty cycle (PWM) and the pulsation frequency of the pneumatic actuator's membrane. For PWM values between 8% and 12%, the frequency remains in a relatively low range of 20 to 100 Hz. Starting at 19% PWM, an abrupt rise to 200 Hz is observed, followed by a progressive increase to 500 Hz at 98% PWM, with intermediate points at 300 Hz (31%), 320 Hz (37%) and 500 Hz (98%).

Fig. 8: The actuator membrane's pulsation-frequency response as a function of PWM duty cycle.

This behavior highlights the sensitivity of the electroacoustic modulator to pulse width, indicating that the electronic airflow control system directly influences the membrane dynamics. The non-monotonic relationship and observed jumps suggest saturation zones or non-linear response characteristics inherent to the actuator's electromechanical coupling; the 19-37% PWM range exhibits the highest gain and linearity and is the recommended operating region, while above 98% PWM the system approaches saturation, consistent with high-speed pneumatic systems where valve switching times limit the maximum frequency [8].



This PWM-frequency mapping underlies open-loop frequency selection via the user interface; however, its run-to-run stability and the error between programmed and actual pulsation frequency have not yet been systematically quantified, and

are expected to be largest near the non-linear transition regions (e.g., 12-19% PWM) rather than the more linear 19-37% band. A lookup-table-based closed-loop calibration, together with this stability/error assessment, is identified as a priority for future work.

G. Wave Propagation in Paraffin Gel

Fig. 9 shows the relationship between the excitation frequency and the propagation velocity of transverse waves on paraffin gel. This material is considered a linear, isotropic, and homogeneous elastic medium; the transverse wave velocity (v_T) is related to the shear modulus by $G = \rho v_T^2$, where ρ is the density. For paraffin, that value is around 0.82 g/cm^3. The results show that the shear modulus increases with frequency, ranging from 3.66 kPa (at 10 Hz) to 22.44 kPa (at 200 Hz).

Fig. 9: Shear modulus of paraffin gel as a function of excitation frequency.

This behavior is the classic signature of viscoelastic dispersion, in which the material exhibits an increase in apparent stiffness with increasing strain rate [7]. The paraffin gel exhibited linear viscoelastic behavior in the 10-200 Hz range. The shear modulus increases with frequency due to viscoelastic dispersion, reaching saturation above 50 Hz. The values (3.66–22.44 kPa) are consistent with those observed in low-stiffness materials, such as those used in soft-tissue-mimicking ultrasound phantoms [3], [5]. Since the temperature was kept constant (25 °C), the variation in shear modulus is attributed exclusively to frequency dependence, which confirms viscoelastic behavior. The observed behavior is consistent with that described in shear-wave dispersion studies of gel systems [3].

This phantom characterization was limited to 10-200 Hz due to the phase-tracking algorithm's sensitivity to the smaller amplitudes and greater attenuation expected at higher frequencies in this stiffer medium, and is distinct from the modulator's up-to-500 Hz response demonstrated separately in water. Extending gel-phantom measurements to 500 Hz, with amplitude, attenuation, and repeatability reported per frequency, is identified as a priority for future work to confirm the full 10-500 Hz bandwidth in tissue-mimicking media rather than in water alone.

H. Drives and User Interface

The user interface, implemented through the Nextion display, proved to be intuitive and efficient. The screen allowed for navigation between the main menu, the standby screen, and the main control screen. In the latter case, the operator could set the desired frequency and start or stop the system. Real-time feedback, which displays the measured frequency and pressure in kgf, was clearly presented, validating open-loop control under operator supervision.

The control architecture proved satisfactory. A key observation was the need for proper processing of pressure sensor signals; a moving average was implemented in the code to smooth the readings and prevent display fluctuations caused by high-frequency noise from the airflow modulation module and air turbulence itself. This highlights the importance of proper signal conditioning in pneumatic systems, where turbulent airflow and valve switching can introduce significant noise [8].

I. Power Supply System and Enclosure

The power system was designed and built with a focus on safety and resistance to mechanical shock. The 12 V/30 A switching power supply proved capable of powering all low-voltage components and electronic boards, even under maximum load. The dual-pole input fuse protection (rated at 10 A) operated correctly during a test-induced short circuit, cutting power before any components were damaged.

The metal enclosure housed all components in an organized, secure manner. The final dimensions (74 cm high, 38 cm long, and 38 cm deep) and a total weight of 20 kg resulted in a compact, stable, and mobile unit, thanks to the inclusion of wheels, meeting ergonomic and transport requirements for clinical or laboratory use.

The selection of a metal enclosure was a wise decision, providing both mechanical protection and electromagnetic shielding. This is intended to protect sensitive electronics from general external interference and to prevent control signals (PWM, pulses) from radiating and interfering with other equipment [10]. The 30 A power supply's extra current headroom ensures operation within a high-efficiency, low-thermal-stress range, thereby extending the system's service life. The layered safety design (AC fuses, galvanic isolation of the power supply and fuses or PTCs on the control board) adheres to engineering best practices and mitigates the risks of electrical shock and fire.

It should be emphasized that this metallic enclosure was conceived as a Faraday cage for general electromagnetic compatibility (EMC), containing the electronics' own emissions and attenuating ambient interference during benchtop use, which, by itself, does not constitute demonstrated MRI compatibility. Establishing MR compatibility would require dedicated in-scanner testing (gradient synchronization, image-artifact assessment, RF-induced heating, and static/gradient-field behavior), none of which has been performed; the actuator has so far been operated and validated exclusively on

the benchtop and in a tissue-mimicking phantom, outside the scanner environment.

J. Pneumatic Actuator, Flow Splitter, and Pressure Sensor

The pneumatic actuator, the heart of the transduction system, was fabricated according to the design. The cylindrical cavity of the 3D-printed actuator was perfectly sealed when coupled to the latex membrane. The airflow splitter, integrated into the actuator body, directed a portion of the pressurized air to the MPX2202GP pressure sensor, while the remaining air was vented through a small-diameter capillary in the outlet regulator filter. This configuration enabled continuous monitoring of internal pressure without compromising the system's dynamics.

It is important to distinguish two pressure quantities: the internal driving pressure applied to the actuator cavity (0-50 kPa, characterized above) and the pressure actually transmitted to the contact surface, attenuated by the membrane and contact area. This latter, contact-surface pressure was verified with a calibrated pressure analyzer (Handy Press Sphygmomanometer Analyzer, PHPR0004, Protec, Cotia, SP, Brazil), yielding a mean of 2.25 kPa (~16.9 mmHg). Low and consistent with pressures generally tolerable for skin contact, encouraging for eventual *in vivo* use, though this single bench measurement does not by itself establish clinical or biocompatibility suitability. Adjusting the internal driving pressure via the compressor's regulating valve allows the stimulus intensity to be tailored to different tissue types or depths, a feature not available in many commercial systems [12]. The MPX2202GP sensor responded well to pulsatile pressure variations; however, its reading is currently a single-point/linear estimate that requires finer, multi-point calibration against a reference instrument to be accurately converted to kgf and to compensate for non-linearities, planned as future work.

These results demonstrate that the proposed actuator addresses key limitations of current MRE actuators, combining the general safety advantages of pneumatic technology with the control precision and extended frequency range needed for advanced MRE; all results reported here correspond to benchtop/phantom conditions, and in-scanner MRI compatibility remains to be established.

V. Conclusions

This work successfully designed, built, and characterized a novel electro-pneumatic actuator for MRE, addressing key limitations of existing commercial systems. The prototype demonstrated a 10-200 Hz operational range validated in a paraffin gel phantom, while the electroacoustic modulator itself reached up to 500 Hz in water, alongside linear force control and a well-characterized, slightly non-linear pressure-displacement response, all established on the benchtop. The modular, low-cost design (3D-printed components, touch-screen interface, EMC-shielded metal enclosure) confirms the system's potential for MRE research beyond current commercial pneumatic drivers, though these results correspond strictly to benchtop/phantom conditions, and clinical or in-scanner MRI compatibility remains a separate, unaddressed step.

Four directions are prioritized for future work: (i) extending gel-phantom propagation measurements to 500 Hz, reporting amplitude, attenuation, and repeatability per frequency; (ii) quantifying PWM-frequency mapping stability and the programmed-versus-measured frequency error, especially across the non-linear transition regions; (iii) implementing multi-point pressure-sensor calibration against a reference instrument; and (iv) integrating and testing the actuator inside an MRI scanner (gradient synchronization, image artifacts, RF heating, field interaction), alongside closed-loop control and *in vivo* validation.

***Abstract*—The inhalation of cigarette smoke over extended periods exposes the lungs to toxic substances, including carbon monoxide (CO) and particulate matter, thereby contributing to the onset and progression of chronic respiratory diseases. Experimental models involving small rodents and controlled exposure chambers are widely used to investigate the biological effects of this exposure. However, characterization of the CO and particulate matter (PM) generated in these chambers typically relies on expensive instrumentation, limiting access for research groups with limited resources. Consequently, this study describes the development of a cigarette smoke exposure system intended for future trials with small rodents; the goal was to build a low-cost chamber capable of monitoring temperature, humidity, the response signal from the MQ-7 sensor and particulate matter (PM2.5 and PM10) using low-cost sensors (DHT11, MQ-7, and SPS30). Tests conducted with varying rest intervals between puffs (5, 10, and 15 seconds) showed no statistically significant variation for CO (ANOVA, p = 0.214), PM2.5 (ANOVA, p = 0.771), and PM10 (ANOVA, p = 0.684). Despite the need for improvements to the experimental procedure, the electronic architecture appeared to perform adequately regarding signal acquisition.**

***Index Terms*—exposure chamber, cigarette smoke, low-cost sensors, particulate matter, carbon monoxide.**

I. Introduction

Chronic respiratory diseases comprise a group of conditions that persistently affect the respiratory system, impairing lung function and increasing vulnerability to infections [1]. Among these diseases, Chronic Obstructive Pulmonary Disease (COPD) stands out; according to the World Health Organization (WHO), it was associated with approximately 3.5 million deaths in 2021, ranking fourth among the leading causes of death globally [2].

The occurrence of these diseases is linked to the interaction of multiple factors—including genetic, physiological, and environmental aspects—as indicated by epidemiological studies [1]. In the case of COPD, a significant association is observed with continuous exposure to harmful particles and gases, particularly those derived from cigarette smoke [1]. The World Health Organization (WHO) recognizes that exposure to secondhand smoke is associated with substantial health risks and contributes to preventable mortality among non-smokers [3]. In this context, the smoke resulting from cigarette combustion has a complex composition, containing around 7,000 toxic chemical substances, including carbon monoxide (CO) [4] and particulate matter (PM) — which consists of fine particles capable of penetrating deeply into the respiratory tract [5].

A significant portion of research into the toxicological effects of cigarette smoke relies on experimental models using small rodents. Consequently, the use of controlled exposure chambers is common for assessing and understanding how these substances can physiologically alter the human system. Previous studies, such as those by Barbosa et al. (2020) [6] and Junqueira et al. (2020) [7], demonstrate the effects of exposure to conventional cigarette smoke in experimental models using specialized chambers.

However, the equipment required to characterize the smoke generated in these chambers typically consists of high-cost instruments—such as certified gas analyzers (CO) and laser photometers (PM)—whose high price can pose a barrier for certain research groups [8]. Although low-cost experimental setups do exist, cost reductions generally apply only to the structural and mechanical components, while reliance on ex-

pensive commercial devices remains [9].

Thus, this study proposes the development of a conventional cigarette smoke exposure chamber intended for future experiments with small rodents, with the primary objective of using low-cost sensors to monitor carbon monoxide and particulate matter generated by cigarette combustion. This study entails the development and bench testing of the proposed system, involving neither biological exposure nor the use of animals at this stage. The long-term proposal aims to further advance knowledge regarding the toxicological implications of these emissions and their impact on public health by offering a replicable and more accessible alternative.

II. Material and Methods

In order to enable the analysis of particles emitted by conventional cigarettes, this work proposed the development of an exposure system capable of collecting the smoke generated. The system works as a controlled experimental model, allowing standardization of exposure conditions. Furthermore, its physical structure was divided into two compartments, a strategy adopted to favor the accuracy of the readings obtained.

Thus, the primary chamber houses the MQ-7 sensor, which provides a relative response to the gaseous components of cigarette smoke, with CO as its primary target gas, and the DHT11 sensor, used to monitor temperature and humidity. In this same chamber, an electromechanical vacuum system was incorporated, developed to simulate puffing on a cigarette. The analysis of particulate matter (PM) is carried out in a secondary chamber, equipped with the Sensirion SPS30 sensor, which receives sample from the first compartment to be diluted.

The data acquisition architecture was organized with two independent Arduino microcontrollers: the first responsible for the MQ-7 and DHT11 sensors, used to monitor the relative MQ-7 sensor response to gases, temperature and humidity, and the second dedicated exclusively to the particulate matter (PM) sensor - this division allowed the simultaneous processing of information obtained during the tests. Finally, to visualize the measurements in real time, LCD displays incorporated into the system's two electronic circuits were used.

A. Construction of the Primary and Secondary Exposure Chambers

The construction of the primary chamber was inspired by the exposure chamber developed by the LIM 20 team at the *Hospital das Clinicas* of the Faculty of Medicine of the University of Sao Paulo [6] [7]. Therefore, a plastic organizing box with an approximate volume of 30L was used, where four holes were made: two on the sides and two on the lid (Fig. 1.)

In the lower side wall, the first hole was made to allow the mini air compressor to be coupled, with a flow rate of 1.6 L/min. The second hole was positioned on the opposite upper side face and received a hose that was used as an outlet for air to the atmosphere. In this way, the system maintains pressure balance and promotes continuous air renewal, reducing the risk of CO accumulation in concentrations harmful to animals.

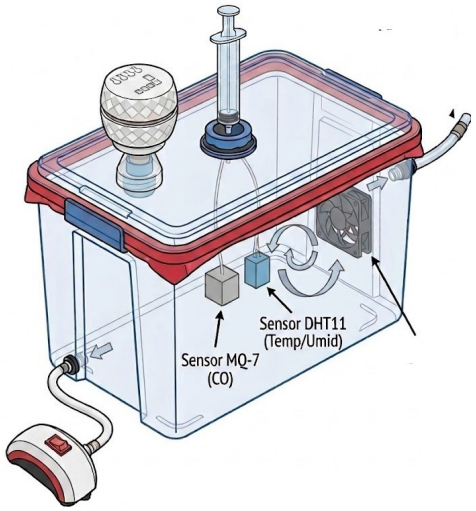

Fig. 1. Arrangement of the Primary Chamber Holes. For more details on the positioning of holes and sensors, see the body of the text.

Finally, in the lid of the box, the other two additional openings were created, one of which was intended for attaching the lung simulator, while the other, located in the central region of the lid, received an elastic rubber seal, used to allow the insertion of the collection syringe.

The MQ-7 and DHT11 sensors were fixed in the central region of the primary chamber to ensure sampling homogeneity, being assisted by an internal microfan that optimizes air circulation and mixing. For the analysis of particulate matter (PM), the implementation of a secondary chamber was essential due to the operational restrictions of the SPS30 sensor, whose reliable measurement range is limited to concentrations of up to 1000 µg/m^3 [10]. Consequently, a 3.1 L glass container was adopted to accommodate the diluted sample (Fig. 2). The lid of this compartment was adapted with two access routes: one dedicated to the controlled injection of the sample using a syringe and the other for the passage of the SPS30 sensor cables.

Fig. 2. Arrangement of the secondary chamber. It is possible to see the SPS30 sensor positioned in the glass jar.

B. Mechanical Cigarette Puff Simulation System

The system responsible for simulating the cigarette puffs was developed with the aim of reproducing the suction and exhaust cycles involved in burning a cigarette. The pneumatic structure of the device was obtained from the adaptation of a breast milk pump, whose silicone membranes and plastic junctions were reused to compose a mechanism similar to a diaphragm associated with an exhaust duct. In this way, the aspirated air is temporarily retained and subsequently conveyed to the main exposure chamber.

The assembly of the cigarette and mechanical components on the box lid was made possible by parts made using 3D printing, allowing better fixation and alignment of the device. Regarding electronic control, the system operates through the alternate activation of a suction motor and a release valve. The drive is coordinated by an Arduino microcontroller connected to a single-channel relay module. During the suction stage, the relay activates the motor, promoting the formation of a vacuum and the aspiration of smoke, while the valve remains closed. In the next step, when the engine is turned off, the valve is opened, allowing the smoke to be released into the chamber.

C. MQ-7 Sensor and Signal Acquisition Circuit

The gaseous response was monitored using the MQ-7 sensor, selected because CO is its primary target gas and due to its widespread use in gas-sensing and environmental monitoring applications [11]. The device's transduction principle is based on modulating the electrical resistance of a tin dioxide film (SnO_2), that is, in environments with clean air, the material presents high resistance, which decreases inversely proportional to the increase in the concentration of the detected gases [12].

Structurally, the component is equipped with heating terminals (H+ and H-) and analog reading (A and B). Prior to the testing phases, the sensor was subjected to a burn-in protocol to volatilize residual manufacturing impurities, applying a continuous voltage of 5 V to the H+ terminal for an uninterrupted period of 48 hours [12].

The MQ-7 presents behavior equivalent to that of a variable resistor sensitive to the presence of gas, with its resistance, called RS, modified according to changes in the conductivity of the sensing material. So that these variations can be interpreted by the microcontroller, the sensor is inserted into a voltage divider, enabling the conversion of the transducer's chemical response into measurable electrical potential differences.

However, it is necessary to respect the thermal cycle indicated in the technical literature. This procedure involves alternating between a high voltage heating phase of 5 V for 60 seconds, aimed at eliminating impurities, and a low voltage phase of 1.4 V for 90 seconds, during which data acquisition occurs. If this cycle was not applied, contaminants could accumulate on the sensitive layer, causing sensor saturation and compromising the accuracy of the results obtained [12].

Each battery of tests was preceded by a stage of conditioning the sensor in clean air, maintained until the reference signal (baseline) stabilized. It was decided not to use the absolute voltage value recorded at the end of each cycle, adopting instead the voltage variation (ΔV) as an analysis parameter. ΔV was obtained by the difference between the maximum voltage value reached at the end of the MQ-7 sensor reading cycle and the initial value, already stabilized in clean air moments before the first puff. This procedure made it possible to disregard the specific reference of each collection and isolate the effect attributable to the entry of cigarette smoke into the primary chamber.

The sensor in question was not calibrated using known CO concentrations; therefore, the presented (ΔV) values are relative measurements of the sensor's response and cannot be interpreted as absolute CO concentrations in ppm. Although the MQ-7 exhibits high selectivity for CO, it also displays cross-sensitivity, albeit to a lesser extent, to other gases (according to the datasheet), which prevents the measured signal from being attributed exclusively to CO.

D. Particulate Matter Detection Circuit

For the detection and quantification of particulate matter (PM) from cigarette smoke, the Sensirion SPS30 optical sensor was used. The selection of this transducer was justified by its metrological reliability and broad validation in the scientific literature for monitoring air quality [13]. The operational principle of the device is based on the scattering of laser light, the process of which begins with the active suction of air into a shielded chamber using an internal microfan. Inside the compartment, the particles interact with a laser beam, generating a light dispersion that is collected by a photodiode. This signal is processed to provide, in real time, the particle mass concentration in µg/m^3 [10].

The measurement of particulate matter (PM) was carried out with the help of a second Arduino microcontroller, powered via a USB connection. This configuration enabled both power supply to the board and direct serial communication with the software used to collect data. The SPS30 sensor was connected according to the manufacturer's specifications, using the I2C bus, while a 16x2 LCD display was added to the circuit to allow viewing of readings in real time, sharing the SCL and SDA pins. The data generated by the SPS30 was recorded in the CoolTerm software, responsible for continuously capturing the information transmitted by the Arduino. The readings were automatically saved in text files (.txt), which they were subsequently used for the statistical treatment of the results.

The SPS30 was kept in a secondary chamber, a strategy adopted to avoid direct exposure to high concentrations of aerosols and, consequently, reduce the risk of sensor saturation and compromise of its optical components. Thus, 40 mL samples of smoke present in the main chamber were collected and injected into the reading chamber, which had an internal volume of 3.1 L.

Due to this procedure, the values initially obtained by the sensor corresponded to the diluted concentration of par-

ticulate matter. To correct this difference and estimate the concentration in the main chamber, a dilution factor (DF) was used, determined by the relationship between the volume of the secondary chamber (3100 ml) and the volume of the introduced sample (40 ml)

$$\mathrm{DF} = \frac{3100\ \mathrm{ml}}{40\ \mathrm{ml}} = 77,5 \tag{1}$$

It should be noted that the dilution factor calculation assumes a homogeneous distribution of the sample introduced into the secondary chamber. Therefore, to approximate this condition, six alternating aspiration and injection cycles were performed using a 60 mL syringe after sample introduction, at a rate of approximately one second per movement. The reported PM2.5 and PM10 values represent concentrations already corrected by the dilution factor.

Suspended particle monitoring and data collection were based on concentration values recorded after the transient phase, aiming to obtain more stable readings following the insertion of the diluted sample. The detection scope focused on particle diameters corresponding to PM2.5 ($\leq$ 2.5 µm) and PM10 ($\leq$ 10 µm).

E. Experimental Procedure and Data Collection Protocol

After the integration of all electronic components, the experimental phase of the work began, involving data acquisition using commercial Marlboro cigarettes ("Red" variant). Prior to testing, the sensors were initially exposed to an environment with clean air and continuous circulation for 30 minutes until they reached thermal and chemical equilibrium, establishing a reliable baseline. After stabilization, the chambers were hermetically closed and the peripheral systems (air compressor and microfan) were activated. Simultaneously, the SPS30 sensor began continuous monitoring, updating values every 1 second.

The sample injection regime was synchronized with the thermal cycle of the MQ-7, that is, during the heating phase (60 seconds under 5 V), the system remained at rest and the activation of the suction simulator occurred exclusively during the sensor measurement phase (90 seconds under 1.4 V). The protocol established cycles of 5 puffs (each puff consisting of a pressure drop developed by a diaphragm of an approximately 30 mL, that forced the smoke in), lasting 2 seconds each, in order to evaluate the dynamics of accumulation of particles and gases. Thus, the cigarettes were reused between trials, with less than one pack being used in total. In this sense, the independent variable stipulated was the rest interval between puffs, adopting periods of 5, 10 and 15 seconds (Fig. 3).

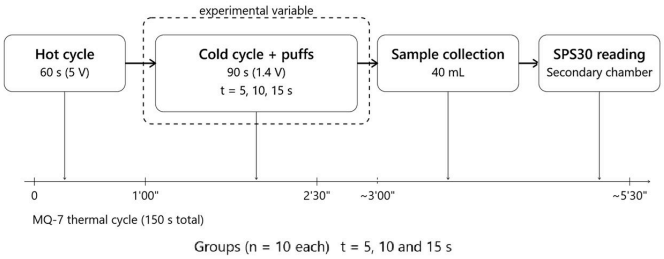

Fig. 3. Temporal protocol of the thermal cycle and synchronization of the cigarette puffs.

At the end of each reading cycle of the MQ-7 sensor, the values corresponding to its relative signal, temperature, and humidity were recorded based on the information displayed on the LCD screen. Next, the particulate material collection stage took place. To do this, a 40 mL sample of the smoke present in the main chamber was extracted with a 60 mL syringe and transferred to the secondary container. After transfer, alternating aspiration and ejection movements were performed with the syringe itself, in order to promote homogenization of the smoke inside the container and ensure better distribution of suspended particles. This procedure allowed the SPS30 sensor to read particulate matter in a more representative way, the data is automatically recorded on the computer using the CoolTerm software.

Then, both boxes were opened, keeping the fan running to remove residual smoke. The cleaning phase was maintained until the sensors returned to values corresponding to clean air, lasting a minimum of approximately 10 minutes per session. The experimental procedure was repeated in blocks by condition, specifically, 10 times for each exposure interval evaluated (5 s, 10 s, and 15 s) in a non-randomized manner, totaling 30 trials. Due to the loss of one experimental record, one observation was excluded from the statistical analyses, resulting in a sample size of 29.

F. Statistical Analysis

Analysis of variance (ANOVA) was performed to evaluate the potential influence of the rest interval between puffs on the mean concentrations of the analyzed pollutants. The normality of the ANOVA model residuals was assessed using the Shapiro-Wilk test to verify adherence to the normality assumption required for ANOVA. Subsequently, the homogeneity of variances across groups was checked using Levene's test; the data were then presented via boxplots showing medians and interquartile ranges, with outliers identified according to Tukey's rule.

III. Results

The cigarette puff simulator presented performance compatible with the expected design during the study. Temperature and humidity were monitored by DHT11 throughout the experiments, resulting in 21.1 °C $\pm$ 0.6 (mean $\pm$ s.d.) and humidity 69.5 % $\pm$ 2.5 (mean $\pm$ s.d.).

Table I presents the medians and standard deviations for the values of particulate matter and (ΔV) obtained under each

evaluated condition, and Table II presents the results of the statistical tests performed for each condition.

TABLE I
MEAN ± STANDARD DEVIATION OF ΔV, PM2.5, AND PM10 FOR DIFFERENT PUFF DURATIONS.

Variable	5 s	10 s	15 s
ΔV (V)	2.601 ± 0.446	2.298 ± 0.560	2.190 ± 0.566
PM2.5 (μg/m^3)	44337.8 ± 15456.7	48096.5 ± 16712.0	49014.4 ± 12452.0[a]
PM10 (μg/m^3)	45880.0 ± 16821.8	50948.5 ± 18631.1	52019.7 ± 13139.0[a]

[a] Nine samples were available for these conditions; all other conditions included 10 samples.

TABLE II
STATISTICAL TESTS FOR ΔV, PM2.5, AND PM10 UNDER DIFFERENT PUFF DURATIONS.

Variable	Shapiro–Wilk[a] p	Levene p	ANOVA p
ΔV (V)	0.336	0.886	0.214
PM2.5 (μg/m^3)	0.676	0.730	0.771
PM10 (μg/m^3)	0.839	0.620	0.684

[a] Shapiro–Wilk test was performed on the model residuals.

Fig. 4 shows the medians and the interquartile range of ΔV obtained for each condition evaluated.

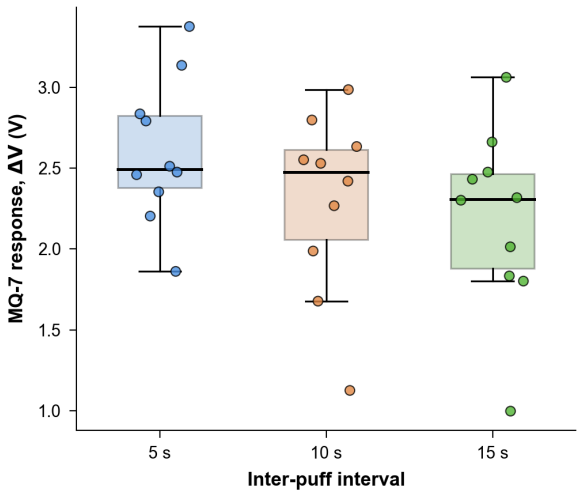

Fig. 4. Boxplot of MQ-7 relative sensor response in relation to the interval between puffs. No statistically significant differences were observed between the intervals (ANOVA, p = 0.214).

The particulate matter values detected after stabilization, expressed as medians and the interquartile range for each time interval studied, are detailed in Figs. 5 and 6.

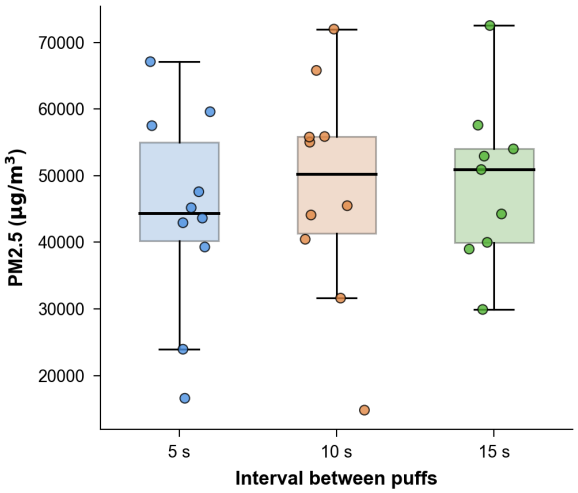

Fig. 5. Boxplot of PM2.5 concentrations in relation to the interval between puffs. No statistically significant differences were observed between the intervals (ANOVA, p = 0.771).

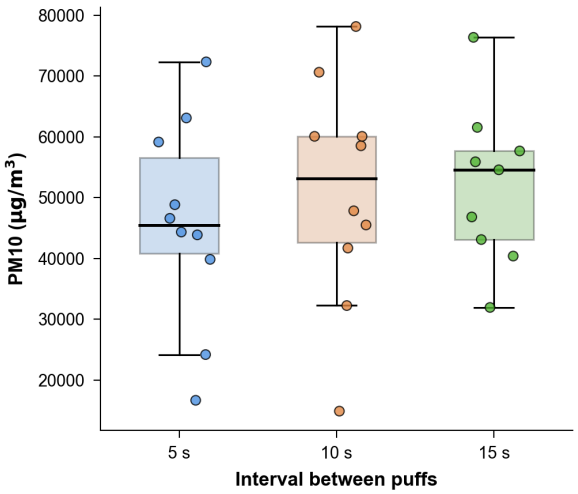

Fig. 6. Boxplot of PM10 concentrations in relation to the interval between puffs. No statistically significant differences were observed between the intervals (ANOVA, p = 0.684).

It is observed that PM10 concentrations are always slightly higher than or equal to PM2.5 in the different experimental groups. This pattern is consistent with the particle size classification of particulate matter, since the PM10 fraction comprises particles with an aerodynamic diameter of up to 10 µm, also covering the fine particles represented by PM2.5. Furthermore, it is important to emphasize that the presented particulate matter values have already been multiplied by the mentioned dilution factor.

IV. DISCUSSION

The purpose of this study was to develop an accessible exposure system, enabling the use of a mechanical structure and low-cost sensors. Data analysis demonstrates the project's

feasibility, as the detected temperature, humidity, MQ-7 sensor signal, and particulate matter (PM) levels confirm the system's viability for monitoring. It was found that, despite being low-cost components, the sensors were capable of capturing data on the experimental conditions.

The MQ-7 sensor selected operates based on changes in the electrical resistance of its chemical layer—composed of tin dioxide—whereby resistance decreases as the ambient CO concentration rises [12]. Consequently, the authors believe that the observed voltage variation values are consistent with the sensor's expected operation, given that these voltages increased upon the entry of cigarette smoke into the primary chamber.

It is worth noting that, although the MQ-7 sensor exhibits a good response to the presence of CO—especially considering its low cost—it also demonstrates documented cross-sensitivity to other substances such as hydrogen, methane, and alcohol compounds [12]. Consequently, since conventional cigarette smoke may contain volatile compounds of this nature [14], the contribution of these gases to the recorded signal cannot be entirely ruled out. Furthermore, MQ-7 relative sensor response was based on the voltage difference read by the microcontroller. Consequently, the values obtained should be interpreted as a relative sensor response rather than an absolute measure of CO concentration.

Regarding particulate matter, the selection of these two ranges—PM2.5 and PM10—aligns with WHO parameters, justified by the high clinical risk associated with the deposition of these fractions directly into the pulmonary alveoli [15]. Furthermore, the PM10 metric encompasses all particles with an aerodynamic diameter of 10 µm or less. Given that the median values for PM2.5 and PM10 were close to one another, it can be inferred that the majority of the particulate matter generated by the cigarette consisted of fine particles capable of penetrating the pulmonary alveoli more easily—a finding that is also consistent with the literature [16].

The sample size used in this study is relatively small, which reduces the statistical power of the tests applied. Therefore, the authors consider that, regarding the relative signal data from the MQ-7 and MP sensors—even though no statistically significant difference was observed for the 5, 10, and 15-second intervals between puffs—it is not possible to assert an absence of equivalence between the groups. It is possible that the air compressor with a flow rate of 1.6 L/min was insufficient to renew and recirculate the air within the chamber within these time intervals. Continuous air renewal is crucial to prevent the asphyxiation of experimental animals caused by CO accumulation; therefore, an airflow rate higher than 1.6 L/min might be more appropriate. Furthermore, it is recommended that future studies increase the sample size and employ intervals between puffs longer than those used in this work, in order to achieve greater control over the relative MQ-7 and PM signals, according to user needs.

V. Conclusion

The present work presented the development of a system that simultaneously integrates a low-cost exposure apparatus and monitoring of temperature, humidity, MQ-7 signal and PM concentrations, using accessible sensors. In this way, it is expected that the model will be replicable and that it will bring together research groups with limited resources, strengthening more accessible science.

***Abstract*—The project aimed to develop a low-cost device for electromyographic signal acquisition and electrical stimulation to evaluate and stimulate muscles. The prototype structure was composed of Ecoflex™ 00-30 silicone, conventional electrode wires with female banana connectors, 3D-printed (PLA) components, and graphite as the conductive material. The pilot model was designed to evaluate the use of graphite combined with a polymeric material as an electrical conductor. The purpose was to assist physical therapists and other healthcare professionals in monitoring patients, with potential future applications in muscle monitoring and rehabilitation.**

***Index Terms*—electrical stimulation, electromyography, graphite, muscle, polymer.**

I. Introduction

Silicone is a highly flexible material that provides improved adaptability and usability to the electrode for the analysis of human bioelectrical signals. As a polymer, it typically exhibits biocompatible properties, causing neither skin irritation nor allergic reactions [1].

Graphite is a mineral that exhibits excellent electrical conductivity. It is essential for providing the electrical properties required for the development of the project proposed in this article. Furthermore, it is a chemically inert material, meaning that it is unlikely to undergo changes when in contact with other substances [2].

In physical therapy, Transcutaneous Electrical Nerve Stimulation (TENS) is performed by delivering low-voltage electrical stimuli through electrodes placed on the patient's skin. It is a safe and non-invasive method [3].

Furthermore, surface electrodes are also used to evaluate muscle electrical activity, that is, the muscle action potential, through electromyography (EMG). This technology has been increasingly explored and applied in a wide range of fields [4].

There is a wide variety of electrodes for different applications, with a specific type required for each use. They can be classified as surface electrodes, which are non-invasive and simply placed on the patient's skin, and implantable electrodes, which are inserted into the region of interest within the body [5].

Furthermore, electrodes can be further classified according to the base material used and their shape. Each type has a specific application. For example, among surface electrodes are metal plate electrodes (ECG, EMG, and EEG), flexible electrodes (wearable devices), suction electrodes (diagnostic ECG), and floating electrodes (biopotential recording). Among implantable electrodes, probe electrodes (body cavities), needle electrodes (intramuscular EMG), fine-wire electrodes (deep muscles), and microelectrodes (neural and cellular recording) are the most prominent [5].

In the book Medical Instrumentation: Application and Design, Chapter 5 – Biopotential Electrodes, Webster and Nimunkar emphasize that biopotential electrodes are responsible not only for conducting electrical current but also for converting the ionic conduction present in biological tissues into the electronic conduction used by measurement equipment [6].

Another important aspect to highlight is the need to reduce the manufacturing costs of these electrodes in order to increase production, simplify their fabrication, and make them more accessible and scalable. This also enables them to be disposable and intended for single use, thereby ensuring more reliable results [7].

Based on this challenge, the objective of this study was to develop a low-cost device intended for future electromyo-

Fundação Instituto Nacional de Telecomunicações (FINATEL).

graphic signal acquisition and electrical stimulation for the evaluation and stimulation of human body muscles, aiming to provide a non-invasive diagnosis and improve accessibility.

II. Methodology

Initially, a survey was conducted on different conductive, flexible materials and their possible combinations, aiming to develop a flexible electrode with reduced dimensions.

This device was required to exhibit sufficient electrical conductivity for the acquisition of muscle action potentials (electromyography) and the delivery of electrical pulses (electrical stimulation) to the muscles. Furthermore, its components needed to possess flexible characteristics to allow coupling and adaptation to different regions of the human body. These characteristics were considered desirable for potential future applications in muscle assessment.

In addition, the objective was to develop a low-cost electrode to improve accessibility for healthcare professionals and their respective patients.

To achieve this objective, research was conducted on the following materials:

- **Hydrogel:** an electrically responsive material; however, due to its consistency, its application would not be feasible;
- **Silver Fiber:** Ag/AgCl electrodes are the most commonly used, providing a more stable interface and relatively lower interference; however, they have a high cost;
- **Disposable conductive defibrillator pad:** used to assist the defibrillator in monitoring cardiac rhythm, enabling the identification of arrhythmias and cardiorespiratory arrest. However, it is a very rigid structure, making it unsuitable for the present application;
- **Disposable conductive return electrode for electrosurgical units:** its function is to provide coagulation and cauterization while ensuring patient safety through electrical current dispersion. However, it cannot be cut or modified in shape;
- **Conductive filament:** a conductive material for 3D printing; however, the specific requirements for proper printing would make the manufacturing process more difficult;
- **Flexible filament:** a flexible material for 3D printing; however, the specific requirements for proper printing would make the manufacturing process more difficult;
- **Silver chloride + silicone:** to make a polymer conductive, a dopant capable of promoting polymer reduction or oxidation is required. However, no specific studies were found involving the addition of silver chloride to silicone to make it conductive;
- **Graphene:** it has lower electrical resistivity than silver (the best electrical conductor among metals) and an electrical conductivity of approximately 2×10^6 S/m (siemens per meter). It also exhibits favorable biocompatibility; however, it requires a high investment;
- **Graphite:** it conducts electricity due to the free electrons present between the layers of carbon atoms and has an electrical conductivity of approximately 10^3 S/m (siemens per meter). Although it is less conductive than some metals (such as silver) and graphene, it is a low-cost material.;
- **Silicone + graphite**: according to the supplier, contaminants that may interfere with silicone curing include sulfur (latex), tin-based catalysts, and epoxy resin hardeners. Therefore, graphite does not interfere with the silicone curing process.

Furthermore, electrical insulation between the healthcare professional's finger and the electrode was required to prevent the electromyograph from acquiring the professional's muscle action potentials. To achieve this insulation, it was necessary to identify a material that was both electrically insulating and flexible, allowing the finger to move as required.

In this regard, suitable materials would include polymers and silicone, allowing the entire finger to be covered. Another alternative would be to coat the side of the sensor that comes into contact with the finger with an electrically insulating material, such as rubber. In this case, material flexibility would not be required, since the entire finger would not be covered by the insulating material.

For the electrode fabrication, molds made of alginate, EVA foam, and 3D-printed PLA were tested to determine which would provide the most uniform and suitable results.

A. Cost Analysis

A cost analysis of the electrodes developed in this study was conducted, considering exclusively the materials used in their fabrication. Costs related to labor, electricity consumption, equipment depreciation, and other indirect manufacturing expenses were not included. In addition, whenever possible, the obtained costs were compared with those of commercially available conductive electrodes.

All prices correspond to values obtained in July 2026.

Mold fabrication, failed batches, labor, electricity consumption, equipment depreciation, and other indirect manufacturing costs were not included.

For the smallest electrode, approximately 0.5 g of graphite was used per unit. Considering an approximate cost of R$40.00 per kilogram of graphite, it was estimated that 2,000 electrodes could be manufactured, resulting in a graphite cost of R$0.02 per unit.

Regarding the silicone, approximately 2/3 g of component A and 2/3 g of component B were used per electrode, totaling 4/3 g of silicone per unit. Considering that 1 kg of silicone (500 g of component A and 500 g of component B) cost R$332.80, it was estimated that approximately 750 electrodes could be manufactured, resulting in a silicone cost of R$0.44 per unit.

The 3D-printed structure cost R$50.98 to manufacture 50 units, corresponding to a unit cost of R$1.02.

In addition, a conventional electrode wire with a female connector was used. Based on the cost of the material employed (conductive carbon fiber heating wire), the estimated cost was approximately R$0.05 per electrode, considering a 100 m

spool priced at R$50.00 and a consumption of approximately 10 cm per unit, allowing the manufacture of 1,000 electrodes.

Thus, the estimated raw-material cost per unit of the smallest electrode was approximately R$1.53 per unit. No commercially available conductive silicone electrodes with equivalent dimensions were identified, making a direct cost comparison impossible.

For the largest electrode, approximately 2.85 g of graphite was used per unit. Considering an approximate cost of R$40.00 per kilogram of graphite, it was estimated that 351 electrodes could be manufactured, resulting in a graphite cost of R$0.16 per unit.

For the fabrication of this electrode, approximately 4.28 g of silicone component A and 4.28 g of silicone component B were used per unit, totaling 8.57 g of silicone. Considering a cost of R$332.80 per kilogram of silicone (500 g of each component), it was estimated that approximately 117 electrodes could be manufactured, corresponding to a silicone cost of R$2.84 per unit.

A conventional electrode wire with a female connector was also used, with the estimated cost remaining at R$0.05 per unit, based on the same criteria described previously.

Thus, the estimated raw-material cost per unit of the largest electrode was approximately R$3.05 per unit. For comparison purposes, a commercially available conductive silicone electrode was found to have a unit cost of R$9.23.

III. Results and Discussion

The feasibility of this project was achieved through the use of the following materials:

- **Graphite powder (Emavi®):** the material responsible for providing the electrical conductivity required for the electrode;
- **Ecoflex™ 00-30:** an extra-soft, platinum-cure, high-performance biocompatible silicone rubber used to provide the flexibility and malleability essential to the device;
- **Electrical conductors:** conventional electrode wires (conductive carbon fiber heating wires) with female banana connectors, enabling the integration of the bioelectrode with the electromyograph or the electrical stimulator;
- **3D-printed (PLA) components:** biocompatible polylactic acid (PLA) polymer structures used to shape and support the wearable device.

After defining the materials required for the device fabrication, the next step consisted of developing the physical structure of the electrode. The geometric characteristics of the prototype were designed considering both the anatomical adaptation and the requirements for incorporating the conductive composite.

The 3D models were designed using the *Autodesk Tinkercad* online platform. For the physical fabrication, a configuration with two walls and 40% infill density was adopted to optimize the mechanical strength of the printed parts.

Different molding approaches were tested to identify the most suitable option for the present project. Therefore, different types of materials were evaluated.

Initially, alginate (a material widely used in dentistry for dental impressions) was employed to produce the mold, using a part manufactured by additive manufacturing (3D printing) to shape it, as shown in Figure 1.

Fig. 1. Alginate mold. Source: Author (2025).

However, it was observed that the alginate dried out very quickly, requiring a new mold to be prepared before each test, which would be impractical for the proposed project.

Therefore, an EVA foam mold was developed, also using a part manufactured by additive manufacturing to cut the material (Figure 2), as well as another 3D-printed part placed inside the electrode to provide structural support.

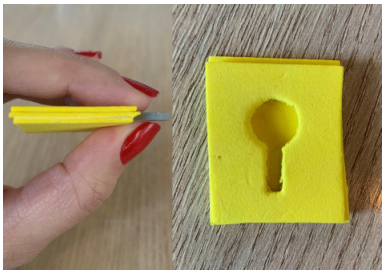

Fig. 2. EVA foam mold. Source: Author (2025).

However, it was evident that, after the silicone had cured in this mold, the resulting electrode did not exhibit the desired appearance (Figure 3). In addition, the 3D-printed PLA part detached easily from the silicone, indicating that PLA was more suitable as a mold material.

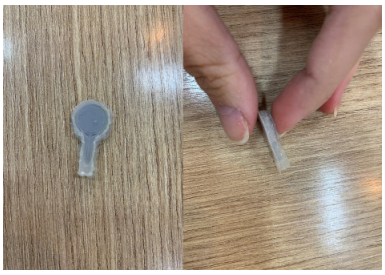

Fig. 3. Pure silicone molded in EVA foam. Source: Author (2025).

Thus, initially, an external mold was designed for the curing of silicone containing graphite, in which the silicone, prior to

hardening, would be deposited, along with an internal support structure with a similar shape but reduced dimensions. This internal structure aims to ensure the mechanical integrity of the electrode and the proper positioning of the conductive components inside the device. These initial test prototypes can be observed in Figures 4 e 5.

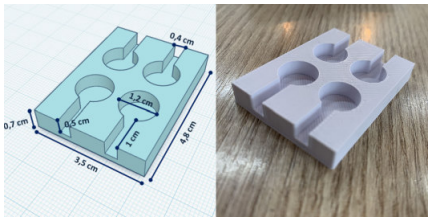

Fig. 4. Initial mold prototype and its dimensions. Source: Author (2025).

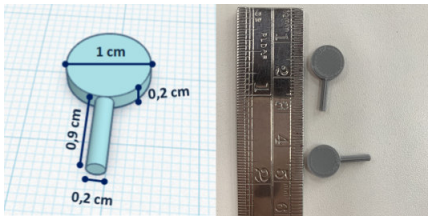

Fig. 5. Initial structure prototype and its dimensions. Source: Author (2025).

In addition to the material tests for modeling, tests regarding the electrode composition were also performed.

Regarding silicone curing and its homogenization with graphite, numerous tests were performed using different percentage concentrations to determine the most suitable ratio. The spreadsheet software *Microsoft Excel* was used to organize and compare the data obtained from each measurement (Table I), in which G represents graphite and S represents silicone.

TABLE I
COMPOSITION OF GRAPHITE SAMPLES. THE FORMULATION IDENTIFIED AS SAMPLE 17 (59.47% GRAPHITE) WAS SELECTED FOR FABRICATION OF THE FINAL PROTOTYPES.

Sample	G (g)	G (%)	S (g)	S (%)	T (g)

17	1.5030	59.47	1.0244	40.53	2.5274

Based on the preliminary electrical evaluation, the formulation containing 59.47% graphite by mass was selected for the fabrication of the final prototypes. This composition was chosen because it provided the most suitable electrical response among the tested formulations under the experimental conditions.

For the preliminary evaluation of the graphite concentration, three small electrode specimens were fabricated for each tested concentration. The formulation was selected based on the highest measured peak voltage and its numerical proximity to the commercial reference under the same bench conditions was selected for subsequent evaluation. Six additional small electrode specimens were then fabricated using the selected concentration for further characterization and statistical analysis. Since the optimal graphite concentration had already been determined from the preliminary tests with the small electrodes, six large electrode specimens were fabricated exclusively using the selected concentration.

From this perspective, it is important to emphasize that the differences in mass for each experiment were justified not only by the tested concentrations but also by the number of electrodes produced in a single process.

In this context, it was observed that the higher the graphite concentration used in the development of the device, the better the achieved result, meaning that the measured peak voltage increased with graphite concentration under the evaluated bench conditions.

Initially, the graphite and silicone mixture was applied throughout the entire electrode surface, as illustrated in Figure 6, resulting in a fully conductive device.

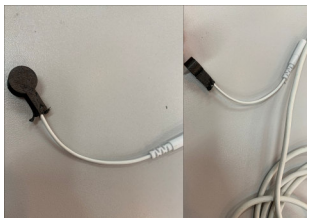

Fig. 6. First graphite-silicone electrode: front and side views, respectively. Source: Author (2025).

However, it was experimentally observed that thinner layers of graphite-doped silicone exhibited a more favorable electrical response under the evaluated bench conditions. This observation cannot be directly attributed to a reduction in electrical resistance based solely on the conductive-layer thickness. According to the resistance relationship, the electrical resistance (R) of a conductor depends on its resistivity (ρ), the effective length of the current path (L), and its cross-sectional area (A):

$$R = \rho \cdot \frac{L}{A} \tag{1}$$

In this equation, ρ represents the electrical resistivity of the material, L is the effective current path length, and A is the corresponding cross-sectional area. Therefore, the effect of reducing the conductive-layer thickness depends on the actual geometry and direction of current flow within the

electrode. Since the current path and the resistivity of the composite were not directly characterized in the present study, the improved electrical response observed for the thinner layer is reported as an experimental observation rather than as a direct consequence of reduced electrical resistance.

Subsequently, a new prototype was fabricated, consisting primarily of pure silicone intended for electrical insulation and structural support, with the addition of only a thin layer of graphite-doped silicone (Figure 7), aiming to optimize contact with the tissue and improve signal conduction efficiency.

Fig. 7. Prototype of the pure silicone mold: front and side views, respectively. Source: Author (2025).

Subsequently, a new mold with larger dimensions and a quadrangular shape was developed to validate the use of graphite-doped silicone in electrodes with different shapes and sizes (Figure 8).

It is noteworthy that the use of the internal support structure manufactured by additive manufacturing became unnecessary for this new mold.

Comparative tests were performed with and without the use of this component. The results did not demonstrate significant improvements when the component was used, making its application unnecessary.

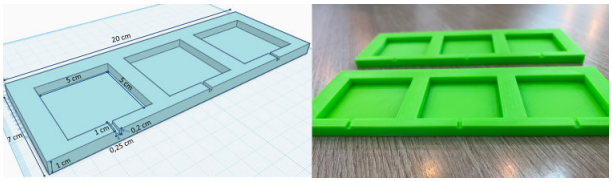

Fig. 8. Square mold prototype and its dimensions. Source: Author (2026).

The final configurations obtained during the prototype development process are summarized in Table II. The table presents the main physical and fabrication parameters of the small and large electrode prototypes, including their dimensions, conductive-layer thickness, graphite concentration, and curing time.

TABLE II
FINAL SPECIFICATIONS OF THE DEVELOPED ELECTRODE PROTOTYPES

Parameter	Small Electrode	Large Electrode
Electrode geometry	⌀12 mm circular region + 10 mm extension	50 × 50 mm
Electrode thickness (mm)	∼5	∼5
Conductive layer thickness (mm)	1	1
Graphite concentration (%)	59.47	59.47
Curing time (h)	12	12

Furthermore, a comparison was performed between the curing of graphite-doped silicone exposed to UV-C light and without UV-C exposure. For four days, measurements were performed by weighing the amount of graphite particles released through the application of a piece of masking tape on the electrodes. The results were recorded in a spreadsheet, and a graph was generated (Figure 9) using the spreadsheet software *Microsoft Excel*.

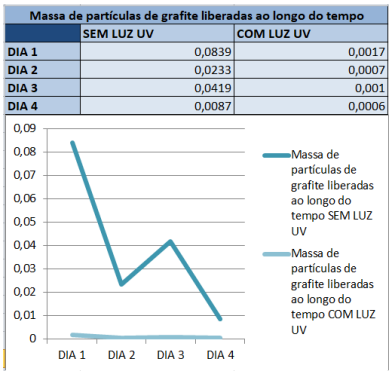

Fig. 9. Comparison graph (UV-C light). Source: Author (2026).

When applied to the electrodes with reduced dimensions, the result was positive, with lower graphite release observed in the electrodes exposed to light.

However, when applied to the larger electrodes, they exhibited similar graphite particle release when exposed and not exposed to UV-C light (slightly lower for the exposed samples). Nevertheless, the electrodes exposed to UV-C light developed surface cracks (Figure 10).

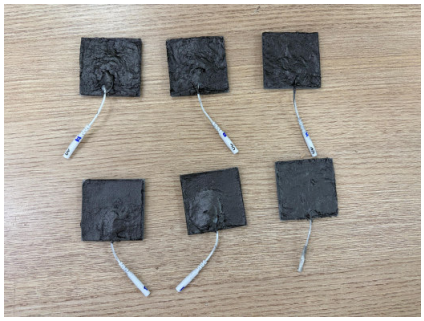

Fig. 10. Quadrangular electrodes: UV-C-exposed electrodes at the top and non-exposed electrodes at the bottom. Source: Author (2026).

Although platinum-cured silicone is not designed to cure under UV-C radiation, UV-C post-curing exposure was associated with reduced graphite particle release in the smaller electrodes under the evaluated conditions. This observation suggests a possible improvement in surface particle retention; however, the underlying mechanism was not directly characterized in the present study.

The samples were exposed to UV-C radiation using the UV-C lamp integrated into a Pachane PCR T2 ECO vertical laminar flow cabinet. The lamp emitted radiation with a wavelength of approximately 254 nm, within the UV-C spectral range. The

irradiance at the sample surface was not measured; therefore, the UV-C dose received by the samples could not be quantified.

The homogenization and curing process of the conductive composite was performed according to the following steps:

1) **Material Preparation:** separation of graphite, silicone rubber (Parts A and B), electrical conductors with female banana connectors, 3D-printed molds and structures, hot glue, beakers, spatulas, and precision balance;
2) **Conductor Preparation:** adjustment of the conductive wire length and stripping of the ends to ensure electrical contact;
3) **Structural Fixation:** positioning of the conductors in the 3D-printed internal structure using hot glue to ensure stability, when applicable (reduced-dimension electrode);
4) **Silicone Preparation:** individual homogenization of Parts A and B. Subsequently, equivalent masses were weighed (1:1 ratio) in a previously tared beaker, followed by mixing for three minutes and subsequent deposition into the external mold;
5) **Assembly of the Set:** positioning of the internal structure (with the wire) over the still slightly liquid pure silicone layer;
6) **New Silicone Preparation:** preparation of a new pure silicone sample (Parts A and B in a 1:1 ratio) for subsequent graphite doping;
7) **Graphite Doping:** addition of graphite (mass calculated according to the desired percentage) to the silicone mixture, followed by homogenization for two minutes to ensure particle dispersion;
8) **Conductive Layer Positioning:** deposition of the silicone/graphite mixture over the internal structure with the wire facing upward;
9) **Curing and Finalization:** resting of the assembly for 12 hours to allow complete polymer crosslinking at room temperature, followed by careful demolding of the electrode (square-shaped);
10) **Post-curing UV-C Light Exposure:** the assembly was exposed to UV-C light for 96 hours to evaluate its effect on graphite particle adhesion and release, followed by careful demolding of the electrode.

After the electrode modeling process was completed and the device was manufactured, preliminary electrical tests were conducted to characterize the prototype under the evaluated bench conditions.

Voltage measurements were performed using an oscilloscope, an electrical stimulator, and a 330 Ω load resistor, allowing a direct comparison with the voltage levels obtained from a commercial conductive rubber electrode.

The peak voltage values generated by each electrode were recorded in the spreadsheet software *Microsoft Excel* for subsequent analysis (Table III).

In the table, the samples correspond to the electrodes developed and tested, Electrode refers to the conventional electrode (commercially available), Voltage represents the peak voltage measurement in volts, and G(%) indicates the graphite concentration used in each sample.

From this perspective, it can be observed that the higher the graphite concentration, the closer the developed electrode becomes, in terms of electrical performance, to the conventional electrode. Except for some cases in which improper positioning during fabrication resulted in undesired conductivity.

TABLE III
VOLTAGE BY GRAPHITE SAMPLE COMPOSITION.

Sample	G (%)	Voltage 1 (V)	Voltage 2 (V)	Voltage 3 (V)
Electrode	-	14.8	14.8	14.8
1	0.95	0.0	0.0	0.0
2	27.30	0.7	0.6	0.6
3	29.87	0.0	0.0	0.0
4	40.07	0.2	0.2	0.3
5	41.32	0.0	0.0	0.0
6	41.32	0.0	0.0	0.0
7	45.89	0.0	0.2	0.0
8	49.37	0.8	1.6	1.4
9	49.90	2.7	2.5	2.9
10	49.91	2.4	2.2	1.8

14	58.83	14.8	14.4	14.4
15	59.08	14.8	14.6	14.6
16	59.26	14.8	14.6	14.8
17	59.47	14.8	14.8	14.8

The experimental setup used for the measurement process is shown in Figure 11.

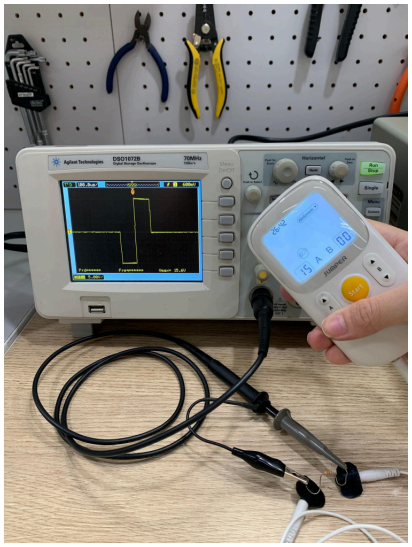

Fig. 11. Oscilloscope measurement. Source: Author (2025).

From this perspective, the prototype — composed of pure silicone with a thin layer of graphite-doped silicone, molded using the additive manufacturing mold (Figures 4 and 8) and supported by the internal structure (Figure 5) — exhibited measurable electrical conduction under the evaluated bench conditions.

The performance surpassed the results obtained in the initial tests with lower graphite concentrations and produced peak

voltage values comparable to those obtained with the commercial reference electrode under the evaluated bench conditions.

It is important to emphasize that the final electrode prototypes were not subjected to experimental biocompatibility tests in the present study. Although Ecoflex™ 00-30 and PLA were selected based on their material properties and suitability for prototype fabrication, the biocompatibility of the complete fabricated electrode, including the graphite-silicone conductive composite and the assembled structure, was not experimentally established. Therefore, no claim regarding the biocompatibility or safety of the final electrode for human use can be made based on the results presented herein.

IV. Conclusion

The development of a low-cost conductive electrode prototype based on graphite and silicone enabled preliminary electrical characterization under controlled bench conditions, using graphite as the conductive material, enabled preliminary electrical characterization under controlled bench conditions. It should be emphasized that the device has not yet been tested in humans, and the current results are limited to preliminary electrical validation.

The silicone rubber provided the necessary flexibility for anatomical positioning, in addition to enabling the electrical insulation of healthcare professionals, optimizing the functionality and application of the bioelectrode.

UV-C post-curing exposure was associated with reduced graphite particle release in the smaller electrodes under the evaluated conditions, whereas the larger electrodes exhibited surface cracking after exposure.

The objective of the project was to develop a low-cost conductive electrode prototype for potential future applications in electromyographic signal acquisition and electrical stimulation.

V. Future Studies

Future work will include real EMG signal acquisition, electrical stimulation tests in biological tissue, biocompatibility assessment, and *in vivo* tests in rats. Subsequently, clinical trials with humans may be conducted to further evaluate the potential application of the device in muscle assessment and rehabilitation.

Additional studies should also investigate the electrode–skin interface impedance, frequency response, temporal stability, signal-to-noise ratio, and repeatability among different fabricated devices. Direct measurements of electrical resistance or resistivity should also be performed to provide a more comprehensive characterization of the conductive composite and its electrical behavior.

Further evaluation should include mechanical-cycle testing, assessment of material durability, irritation and cleaning procedures, as well as tests involving volunteers before considering potential clinical applications. Future studies should also investigate the electrical current delivered to biological tissue during stimulation and evaluate the long-term stability of the electrode under repeated use.

A more comprehensive statistical characterization of the electrical performance and repeatability of the fabricated electrodes will be performed in future work, including the analysis of variability among specimens and additional statistical parameters.

Finally, the fabrication process may be further optimized by evaluating the reproducibility of the selected graphite concentration, conductive-layer geometry and thickness, and the effect of UV-C exposure on graphite particle release and material stability. These additional investigations are necessary to advance the present prototype from preliminary electrical validation toward a more comprehensive evaluation of its performance and potential biomedical application.

Acknowledgment

This work was carried out with the support of the Fundação Instituto Nacional de Telecomunicações - FINATEL, the Instituto Nacional de Telecomunicações - Inatel and the eHealth - Innovation Center Laboratory, which diligently provided the necessary resources for the development of the project.

To Professor Filipe Bueno Vilela, Ph.D., for providing essential research contributions for the development of the artifact.

To Professor Luma Rissati Borges do Prado, for indicating the electrode testing method using the oscilloscope.

To Professor Maysa Costa Alves, Ph.D., for suggesting the use of UV-C light for silicone curing.

To the advisor, Professor Elisa Rennó Carneiro Déster, M.Sc., for all the support, ideas, and knowledge shared.

***Abstract*—This paper presents a low-cost IoMT laboratory prototype based on an ESP32 that displays ECG, SpO_2/heart rate, and non-contact temperature on a local Nextion HMI and a Progressive Web App (PWA). The sensing chain uses an AD8232 (ECG), a MAX30102 (PPG/SpO_2 and heart rate), and an MLX90614 (infrared temperature). Work started with software/simulation checks of the data path and then moved to a physical board. In SoftAP (software-enabled access point) laboratory demonstrations on an iPhone 11, Wi-Fi JSON streaming to the PWA was adequate for teaching; Table III records what passed, what was only partial, and what failed. Datasheet figures such as MLX90614 $\pm$0.5°C are design references, not measured system accuracy. Parts cost 140 dollars (Table I). The platform is intended for teaching and demonstration, not clinical use: no volunteer study, ethics protocol, or gold-standard comparison is reported, and the firmware still shows occasional freezes.**

***Index Terms*—Telemedicine, IoMT, ESP32, SpO2, Vital Signals**

I. Introduction

Chronic diseases remain major causes of death worldwide, and continuous vital-sign monitoring is one tool discussed for preventing complications [1]. Commercial multiparameter monitors work well in hospitals, but their price often keeps them out of teaching labs and other low-budget settings. This paper describes a compact ESP32-based sensing setup intended for laboratory use and clinical-engineering teaching—not for clinical care [2], [3], [4].

Supported by Distrito Federal Research Support Foundation (FAPDF), Process n. 23098.000264.2026-74 and Brazilian Ministry of Science, Technology and Innovation (MCTI), TED 973460, Process 01245.019107/2024-05.

IoMT papers often link home care with wireless vital-sign streams [5]. This literature provides useful context, but it is not validated here. An AD8232 (ECG), a MAX30102 (heart rate and SpO_2), and an MLX90614 (temperature) were connected to an ESP32, and the readings were sent to a Progressive Web App (PWA) and a Nextion panel. Abdullah et al. [6] and Islam et al. [7] discuss filtering and feature extraction on biomedical signals; the present work borrows the general idea of embedded conditioning, without claiming clinical-grade pipelines. Before hardware assembly, the data path was exercised in software simulation [4]—a preliminary software verification, not a metrology exercise.

Overall, the paper documents a low-cost ESP32/PWA teaching prototype and qualitative bench results. Patient benefit, institutional rollout, and clinical accuracy are not claimed.

II. Materials and Methods

A laboratory prototype was assembled to acquire ECG, SpO_2/heart rate, and temperature and to display them on-site and on a phone. The AD8232 (Analog Devices, Wilmington, MA, USA) [8] amplifies electrode ECG for demonstration traces [3]. Temperature comes from the MLX90614 (Melexis, Ieper, Belgium) [9] over I^2C; the $\pm$0.5°C figure is from the datasheet only [4].

Peripheral oxygen saturation (SpO_2) and heart rate use the MAX30102 (Maxim Integrated, San Jose, CA, USA) [10], a common PPG module with red/infrared LEDs [4]. The ESP32 runs acquisition, lightweight filtering, and the Wi-Fi link to the PWA and the Nextion HMI (Itead Studio, Shenzhen, China),

TABLE I
UNIT-COST BREAKDOWN (USD) COMPOSING THE REPORTED TOTAL OF 140 DOLLARS FOR SENSORS, NEXTION 2.4" HMI, AND ASSEMBLY EXTRAS (RETAIL/EDUCATIONAL-MODULE PRICES).

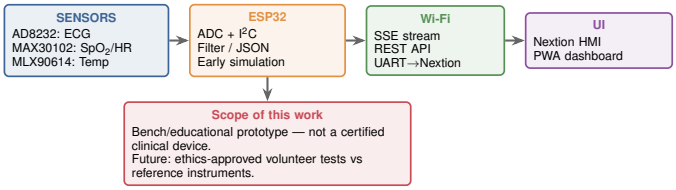

Fig. 1. Simplified system architecture (left-to-right data flow). Sensors feed the ESP32; Wi-Fi serves the PWA; UART drives the Nextion HMI. The bottom box states the intended scope of this paper.

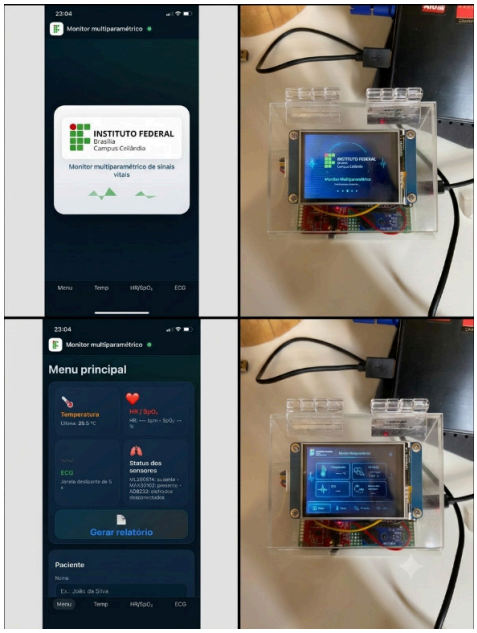

Fig. 2. Laboratory prototype: Nextion 2.4" HMI (right) and PWA dashboard on an iPhone 11 SoftAP demonstration (left). Image documents the setup; it does not imply clinical validation.

whether the source data are software-simulated or from the board.

Bench work focused on noise awareness, shared grounds, and simple checks; IEC 60601 certification or any medical-device clearance was not pursued. Fig. 1 sketches the data flow. The build is intended for teaching and laboratory demonstration, not for delivering a telemedicine service [11], [1]. Parts cost is 140 dollars (Table I).

A. System Overview

The prototype consists of: ESP32 for connectivity and lightweight processing; AD8232 ECG front-end; MAX30102 for SpO_2 and heart rate; and MLX90614 for non-contact temperature; plus a Nextion 2.4" HMI (Itead Studio, Shenzhen, China).

The ESP32 reads analog ECG from the AD8232 (GPIO34), combines SpO_2/heart rate from the MAX30102 (I^2C) and temperature from the MLX90614 (shared I^2C bus), and streams values over Wi-Fi for display. Fig. 2 shows the apparatus used in laboratory demonstrations.

B. Proposed System Architecture

The ESP32 was selected for integrated Wi-Fi/Bluetooth and comparatively larger on-chip resources than simpler microcontroller boards such as the Arduino R4. The architecture is organized into three layers—signal acquisition, processing, and communication:

Signal Acquisition: Sensors use the I^2C bus (MLX90614 and MAX30102) and a dedicated ADC input (Fig. 3 and Table II): GPIO 21 (SDA), GPIO 22 (SCL), AD8232 OUTPUT on GPIO 34, and lead-off on GPIO 32 and GPIO 26.

Processing: Firmware applies basic DSP on ECG sampled at a design rate of 250 Hz, with 5 s windows, simple moving-average or FIR filtering, and JSON serialization. R-peak / beep (prototype concept only): within each ECG window the signal is band-limited; candidate peaks are local maxima above an adaptive amplitude threshold separated by a refractory interval; each accepted peak triggers a short GPIO pulse to the buzzer. Exact thresholds, refractory constants, and firmware version identifiers were not retained for quantitative re-analysis, so the $\leq$100 ms beep-latency target remains an engineering goal rather than a measured result.

Communication: Resource separation on the ESP32 is by peripheral domain, not by sharing the same pins: (i) I^2C + ADC for sensors; (ii) UART0 (GPIO1/3) for the Nextion HMI; (iii) Wi-Fi SoftAP HTTP for SSE (continuous PWA events) and REST (short request/response for demographics and last readings). SSE and REST share the HTTP stack but use distinct routes; UART does not contend for Wi-Fi GPIO. Contention risk is CPU/time-sharing in the cooperative loop that interleaves sensor reads, Nextion updates, and network replies—consistent with intermittent freezes under SSE load (Table III). A forehead-aiming laser module was not included; optical safety classification and clinical necessity were not established.

The PWA provides the remote dashboard and can run as a standalone app on devices such as an iPhone 11 (Apple, Cupertino, CA, USA) in SoftAP laboratory demonstrations.

C. User Protection

High-impedance inputs and common-mode rejection in the ECG front-end are intended to support safer bench handling

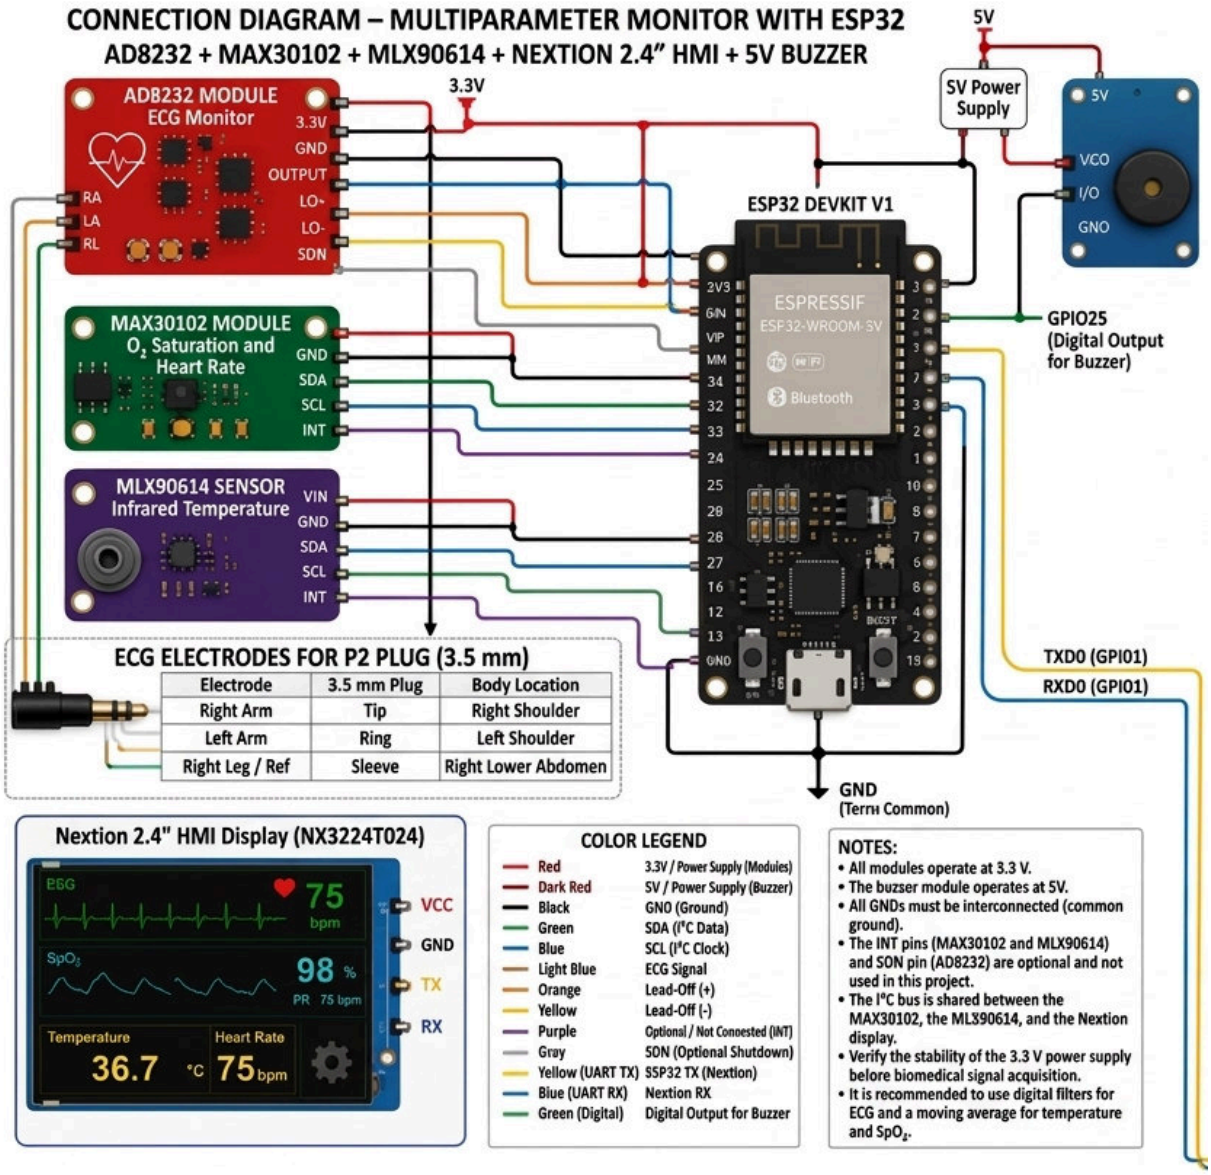

Fig. 3. Connection diagram (enlarged for readability): AD8232 (ECG), MAX30102 (SpO_2/HR), MLX90614 (temperature), Nextion 2.4" HMI, and buzzer on the ESP32 DEVKIT V1. Wire colors match Table II.

and reduce coupling of interference. This design note does not constitute electrical-safety certification (e.g., IEC 60601) or medical-device clearance.

III. Results and Discussion

Three layers of evidence are kept apart:

1) **Software simulation:** early virtual checks of the data path before assembly.
2) **Technical bench tests:** outcomes observed in laboratory demonstrations (Table III).
3) **Human / clinical evaluation:** *not performed*—no ethics protocol, no volunteers, no calibrated clinical reference.

A. Bench outcomes versus acceptance criteria

Table III is a qualitative status summary against the intended targets. "Partial" means the feature worked only sometimes, or missed a numeric goal. Mean±SD error and failure-rate percentages are not reported.

B. Procedures used in development

Heart rate and SpO_2 were checked with a finger on the MAX30102 while Nextion and PWA fields were observed during SoftAP laboratory demonstrations. ECG used three electrodes in a bench demonstration setup (not an ethics-approved study), with a 5 s sliding window on both displays. Temperature used the UI "Measure" action; after disconnecting the MLX90614 and rebooting, the last value retained in NVS

TABLE II

ESP32 PIN MAP (LARGER TYPE). POWER/GND AND SIGNAL LINES PER MODULE; COLORED DASHES FOLLOW THE WIRING LEGEND OF FIG. 3.

(a) AD8232 MODULE – ESP32

Pin	ESP32 Pin	Function
VIN	3.3 V	Power Supply
GND	GND	Ground Reference
OUTPUT	GPIO34	ECG Analog Signal
LO+	GPIO32	Loose Electrode Detection (+)
LO–	GPIO26	Loose Electrode Detection (–)
SDN	Not Connected	Shutdown (Optional)

(b) MAX30102 MODULE – ESP32

Pin	ESP32 Pin	Function
VIN	3.3 V	Power Supply
GND	GND	Ground Reference

(d) NEXTION 2.4" HMI – ESP32 (UART)

Pin	ESP32 Pin	Function
VCC	3.3 V	Power Supply
GND	GND	Ground Reference
RX	TXD0 (GPIO1)	Nextion Reception
TX	RXD0 (GPIO3)	Nextion Transmission

(e) 5 V BUZZER – ESP32

Pin	ESP32 Pin	Function
VCC	5 V	Power Supply
I/O	GPIO25	Digital Output (Buzzer Activation)
GND	GND	Ground Reference

(f) ESP32 GPIO CONNECTIONS SUMMARY

ESP32 GPIO	Function	Type	Connection
GPIO34	ECG Signal Input	Analog	AD8232 OUTPUT
GPIO32	Loose Electrode Detection (+)	Digital	AD8232 LO+
GPIO26	Loose Electrode Detection (–)	Digital	AD8232 LO–
GPIO21	I^2C Data	I^2C	MAX30102 SDA, MLX90614 SDA
GPIO22	I^2C Clock	I^2C	MAX30102 SCL, MLX90614 SCL
GPIO25	Buzzer Output	Digital	5 V Buzzer I/O
GPIO1 (TXD0)	UART Transmission	Digital	Nextion RX
GPIO3 (RXD0)	UART Reception	Digital	Nextion TX

was verified. The intended latency method (timing logs not available for this report) would use 240 fps video or a dual-channel oscilloscope,

$$Delay\ (ms) = \left(\frac{\Delta frames}{240}\right) \times 1000 \qquad (1)$$

C. Limitations

The work is limited to a teaching prototype with qualitative bench results. Clinical accuracy, suitability for home care, and medical-device compliance are not established. Future work includes stabler streaming and reconnection after link loss, saved R-peak constants, timed measurements of SSE/REST/UART load sharing, and—after ethics approval—volunteer tests against reference instruments.

TABLE III

QUALITATIVE BENCH OUTCOMES VERSUS INTENDED ACCEPTANCE CRITERIA. "PASS" INDICATES THE FEATURE OPERATED AS EXPECTED IN LABORATORY DEMONSTRATIONS; RESULTS ARE NOT STATISTICALLY VALIDATED AGAINST A CLINICAL REFERENCE.

Test	Criterion	Status	Note
HR/SpO_2 stream	Continuous UI, no freeze	Partial	Occasional freezes
ECG waveform	Stable 5 s trace	Partial	Trace not always clean
Beep vs R-peak	Delay $\leq$100 ms	Not measured	Method defined; timing logs unavailable
Temperature + NVS	Spot measurement; retain last value	Pass	Datasheet accuracy only
NVS persistence	Survive reboot	Pass	Demographics reload
PWA on iPhone 11	Installable + SSE	Pass	Lab SoftAP demonstration
Hot-reconnect	Status $\leq$2 s	Fail	Slower than target
Color/units UI	Consistent palette	Pass	Nextion and PWA
Clinical reference	Error vs gold standard	Not done	Future work + ethics

IV. CONCLUSION

An ESP32 board was integrated with AD8232 ECG, MAX30102 PPG/SpO_2/heart rate, and MLX90614 temperature, and displayed on a Nextion panel and a PWA for laboratory teaching. Values are transmitted over Wi-Fi to the phone and the HMI. Table III summarizes the evaluation so far: HR/SpO_2 still freezes at times, the ECG trace is not always clean, and reconnection after link loss is slower than the 2 s target—so the system is not a clinically ready monitor.

Development proceeded as follows: early software/simulation checks, perforated-board wiring with a common GND, fixing MAX30102/ESP32 timer library clashes, then checking that NVS kept demographics across reboot. Beep latency was not measured against the $\leq$100 ms goal.

At 140 dollars in parts (Table I), the system is a proof-of-concept for teaching laboratories and further firmware work—not a validated medical device. Next steps are firmware hardening and, only after ethics approval, small volunteer validation studies against reference instruments.

Abstract*— Home-based rehabilitation following ankle sprain is often limited by poor adherence and the lack of objective biomechanical monitoring, which may compromise exercise execution and contribute to persistent functional deficits and chronic ankle instability. Objective: This study presents the design, implementation, and preliminary bench-level characterization of AnkleLink, an early-stage wearable prototype developed as a proof-of-concept to investigate the feasibility of providing real-time corrective biomechanical feedback during ankle rehabilitation exercises. Methods: The prototype integrates an ESP32-C3 microcontroller with an MPU6050 inertial measurement unit (IMU), a resistive flex sensor configured as an experimental electronic goniometer to provide a complementary measure of angular displacement, and an array of piezoresistive force-sensitive resistors (FSRs) embedded in a prototype insole to monitor plantar loading patterns. A multimodal sensor-fusion approach combines kinematic and kinetic measurements with configurable baseline thresholds to identify predefined deviations and trigger immediate audiovisual feedback. Results: Preliminary laboratory bench tests and exploratory trials demonstrated the technical feasibility of the multimodal sensing architecture for capturing motion-related parameters across multiple axes, obtaining complementary angular measurements, and detecting predefined deviations from reference thresholds in real time. The combined sensor configuration provided a basis for mitigating the limitations associated with relying on a single inertial sensing modality. Conclusion: The developed system demonstrates the preliminary technical feasibility of a multimodal wearable platform for real-time biomechanical monitoring and corrective feedback during ankle rehabilitation exercises. However, the current findings are limited to early-stage laboratory characterization and exploratory testing. Clinical studies involving patients, formal assessment by rehabilitation professionals, and validation against established reference systems, including optoelectronic motion-capture systems, are required before therapeutic efficacy, clinical utility, or generalizability can be established.

I. INTRODUCTION

Ankle sprains represent one of the most common musculoskeletal injuries in orthopedic and physical therapy consultations. Inadequate rehabilitation protocols or premature cessation of therapy frequently contribute to chronic ankle instability (CAI), recurrent sprains, and long-term functional deficits. While active neuromuscular exercises are critical to restore joint stability, home-based regimens often exhibit high non-compliance and improper movement execution due to the absence of objective supervision [1] [2] [3]

To address unsupervised exercise monitoring, wearable systems based on inertial measurement units (IMUs) have gained significant interest for joint range of motion (ROM) tracking [4] [5]. However, single-modality IMU devices remain vulnerable to cumulative integration drift and magnetic disturbances, while lacking the kinetic capability to assess plantar load distribution or detect improper ground-contact compensation. Conversely, standalone pressure insoles or video-based systems either fail to provide continuous spatial angle tracking or require controlled laboratory environments. Integrating complementary kinematic and kinetic sensors into a synchronized, low-power platform offers a practical approach to overcome these individual sensor limitations [5].

In this context, this paper reports on the design, firmware implementation, and preliminary bench-level evaluation of *AnkleLink*, an early-stage multimodal wearable prototype. The platform combines an MPU6050 IMU, a carbon-polymer flex sensor for absolute angular referencing, and piezoresistive FSR sensors coordinated by an ESP32-C3 microcontroller. Through complementary sensor fusion and configurable threshold routines, the prototype delivers closed-loop audiovisual cues during simulated rehabilitation movements. This study focuses strictly on establishing the baseline technical feasibility, hardware integration, and preliminary sensor-fusion behavior of the prototype, providing a foundational platform for future clinical evaluations with physical therapists and patient cohorts.

A. Background and clinical motivation.

Clinical guidelines emphasize active functional rehabilitation—prioritizing progressive neuromuscular re-

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

education, ROM recovery, and targeted strengthening exercises (such as isometric eversion/inversion and heel raises)—over exclusively passive modalities [2] [3]. Early mobilization and targeted loading restore mechanoreceptor function and strengthen the stabilizing musculature [3].

B. Biomechanical rationale and rehabilitation protocols.

During unsupervised home sessions, patients frequently execute compensatory movements (e.g., hip abduction or lateral trunk tilt instead of pure ankle eversion) or apply premature, excessive plantar loading due to perceived early recovery [2] [3], [4]. Without immediate biofeedback, these errors reinforce dysfunctional motor patterns and increase the risk of recurrence [4]. The integration of synchronized low-power kinematic and kinetic sensors provides an engineering alternative to capture multi-planar motion deviations and ground reaction loading simultaneously, laying the groundwork for objective tele-monitoring platforms [5].

II. METHODOLOGY.

The development of the *AnkleLink* prototype was structured into three functional stages: hardware integration, kinematic/kinetic signal conditioning, and closed-loop biofeedback control logic.

A. Hardware Implementation and Sensor Instrumentation

The wearable architecture is centered on an ultra-compact ESP32-C3 Mini microcontroller, equipped with a 32-bit RISC-V core operating at 160 MHz and integrated 12-bit Analog-to-Digital Converter (ADC) channels [6]. The sensory instrumentation comprises:

Inertial Measurement Unit (IMU): A GY-521 breakout board hosting an MPU6050 sensor (tri-axial accelerometer and tri-axial gyroscope) positioned over the dorsal aspect of the foot. Sensor communication is established via the I^2C protocol at a 400 kHz clock frequency [5].

Resistive Flex Sensor: A 2.2-inch carbon-polymer flex sensor placed longitude finally across the anterior talocrural joint [7] [8]. It functions as a lightweight electronic goniometer to record direct mechanical bending during dorsiflexion and plantarflexion.

B. Signal Conditioning, Kinematic Modeling, and Sensor Fusion

To process the analog inputs, the flex sensor and FSRs were integrated into individual voltage divider circuits connected to the ADC1 channels of the ESP32-C3 [6] [7] [8]. For the flex sensor, the output voltage is modeled by:

$$V_{out} = V_{in} \cdot \frac{R_{flex}}{R_1 + R_{flex}}$$

where $V_{\text{in}} = 3.3$ V and $R_1 = 10$ kΩ is a precision pull-up resistor [6]. The analog voltage V_{out} is digitized and linearized using a second-order polynomial calibration model ($\theta_{\text{flex}} = a \cdot V_{\text{out}} + b$), mapping electrical resistance changes directly to sagittal joint angles (0° to 50°).

For the MPU6050, the static roll (ϕ_{acc}) and pitch (θ_{acc}) angles are estimated from the gravitational acceleration vectors (a_x, a_y, a_z) [9]:

$$\phi_{\text{acc}} = \arctan\left(\frac{a_y}{\sqrt{a_x^2 + a_z^2}}\right) \cdot \frac{180}{\pi}$$

$$\theta_{\text{acc}} = \arctan\left(\frac{-a_x}{\sqrt{a_y^2 + a_z^2}}\right) \cdot \frac{180}{\pi}$$

Relative segment kinematics between the foot and the shank are computed through vector difference:

$$\Delta\theta_{\text{joint}} = \theta_{\text{foot}} - \theta_{\text{shank}}$$

Angular velocity (ω) from the gyroscope is integrated over discrete sampling intervals ($dt = 20$ ms, corresponding to a 50 Hz acquisition loop) [9]:

$$\theta_{\text{gyro}}(t) = \theta_{\text{final}}(t-1) + \left(\frac{\omega}{131}\right) \cdot dt$$

where 131 LSB/(∘/s) denotes the sensitivity scale factor for the configured full-scale range of $\pm 250^\circ/\text{s}$.

To eliminate progressive mathematical drift caused by gyroscope integration while filtering out high-frequency mechanical vibrations from accelerometer signals, a Complementary Filter was implemented [9]:

$$\theta_{\text{final}} = 0.98 \cdot \theta_{\text{gyro}} + 0.02 \cdot \theta_{\text{acc}}$$

The flex sensor measurement (θ_{flex}) acts as an absolute, drift-free physical reference that cross-validates θ_{final}, mitigating cumulative drift during repetitive motion protocols [9].

C. Biofeedback Control Logic and Predefined Biomechanical Thresholds

The firmware executes a continuous monitoring loop running at 50 Hz that evaluates kinematic and kinetic data against predefined clinical safety thresholds established for Phase I ankle rehabilitation [2].

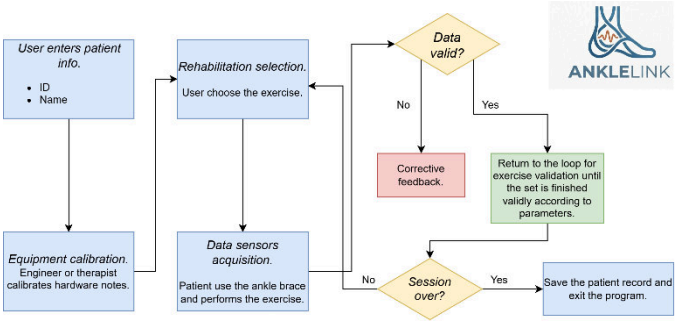

Figure 1. Flowchart represents the operation of the AnkleLink device.

The firmware executes a continuous monitoring loop running at 50 Hz that evaluates multi-axis kinematic and kinetic data against predefined clinical safety envelopes established for Phase I ankle rehabilitation [1] [2].The allowable angular boundary for pure sagittal movement is restricted between $+25^\circ$ (maximum dorsiflexion) and -45° (maximum plantarflexion) to protect healing capsuloligamentous structures while promoting progressive functional mobilization [1] [2] [10].

Concurrently, to isolate true talocrural displacement and prevent maladaptive motor habits, multi-planar compensatory thresholds are enforced: axial rotation (transverse plane) and frontal tilt (inversion/eversion) are bounded within a conservative safety cone of $\pm 15^{\circ}$ [1] [2] [4] [10]. Any rotational excursion exceeding this threshold is classified as a biomechanical compensation—such as unintended external hip rotation, pelvic hiking, or lateral foot rolling—which immediately interrupts the "MOVIMIENTO SEGURO" interface state and triggers synchronized visual and auditory biofeedback alerts to prompt real-time postural correction.

III. Results

The functional performance and baseline technical feasibility of the AnkleLink beta prototype were characterized through bench-level testing under controlled laboratory conditions. The evaluation focused on validating relative multi-axis kinematic tracking, quantifying drift suppression enabled by complementary sensor fusion, verifying discrete calcaneal contact detection, and measuring end-to-end feedback loop latency during simulated rehabilitation protocols.

A. Kinetic Analysis of Plantar Loading (FSR) and Flex Sensor Measurements.

The bench testing protocol was conducted with a convenience cohort of twenty healthy adult volunteers ($N = 20$; 10 males, 10 females; age: 20–25 years). Individuals presenting current joint pain, ligamentous laxity, history of ankle surgical intervention, or acute sprains within the preceding 12 months were excluded [1]. The experimental instrumentation captured multi-segment kinematics and discrete contact transitions through a synchronized multi-transducer arrangement. Segmental kinematics were recorded using two GY-521 breakout boards hosting MPU6050 inertial units: a distal sensor positioned over the dorsal aspect of the midfoot and a proximal counterpart affixed along the anterior distal tibia, enabling the estimation of relative joint displacement through vector subtraction ($\Delta\theta_{\text{joint}} = \theta_{\text{foot}} - \theta_{\text{shank}}$) [9]. To anchor these inertial estimates to an absolute physical baseline, a 2.2-inch carbon-polymer resistive flex sensor was mounted longitudinally across the anterior talocrural joint, directly transducing mechanical bending into sagittal angular displacement [7] [8]. Complementing the kinematic tracking chain, foot-ground interaction was monitored via a single thin-film piezoresistive membrane force sensor (ZD10-100, 500 g nominal limit) embedded within the prototype insole beneath the calcaneus to identify discrete heel-contact and lift-off transitions.

TABLE I. EXPERIMENTAL PROTOCOL AND BIOMECHANICAL THRESHOLDS

Protocol (Plane)	**Biomechanical Monitoring Parameters**		
	Primary Sensors	***Safety Envelope***	***Monitored Compensation***
OP1: Heel Raise *(Sagittal)*	Dual-IMU, Flex, ZD10-100.	$+25^{\circ}$ (DF) to -45° (PF).	Incomplete heel lift-off, premature contact,
		$V_{\text{th}} \geq$ 1.8 V (Heel-off)	sagittal overextension.
OP2: Eversion *(Frontal)*	Dual-IMU (Roll), Flex cross-check	Frontal tilt $\leq \pm 15^{\circ}$; Saggital drift $< 5^{\circ}$	External hip rotation, lateral trunk lean, parasitic flexion.
OP3: Inversion *(Frontal)*	Dual-IMU (Roll), Flex cross-check	Frontal tilt $\leq \pm 15^{\circ}$; Saggital drift $< 5^{\circ}$	Foot supination, parasitic plantarflexion, pelvic tilt

(ROM: Range of Motion; DF: Dorsiflexion; PF: Plantarflexion; V_th: Calcaneal sensor analog voltage threshold. Thresholds follow Phase I clinical functional rehabilitation practice guidelines [1] [2] [10].)

As specified in Table I, three therapeutic exercises were executed: dynamic heel raises (OP1), isometric eversion (OP2), and isometric inversion (OP3) *[2] [3]*.

Each participant completed 3 sets of 8 repetitions per exercise, yielding 100 repetitions per subject and a dataset of 2,000 movement cycles. Transducer signals were acquired at 50 Hz ($dt = 20$ ms) by the ESP32-C3 microcontroller and streamed via USB-serial communication to the custom MATLAB environment (ankleplot) for digital processing, 3-D kinematic reconstruction, and alert logging.

B. Multi-Axis Kinematic Accuracy and Drift Mitigation.

Calibration of the resistive flex sensor demonstrated monotonic impedance variation across the talocrural sagittal arc (0° to 50°). Second-order polynomial linearization yielded a coefficient of determination of $R^2 = 0.984$, with a mean mechanical angular hysteresis of $2.3^{\circ} \pm 0.6^{\circ}$ between bending and unbending phases [7] [8].

TABLE II. KINEMATIC TRACKING ACCURACY, DRIFT SUPPRESSION, AND ERROR ANALYSIS

Modality / Exercise Protocol	**Tracking Error & Stability Metrics**		
	RMSE (deg)	***MAE (deg)***	***Drift Rate (deg/min)***
Standalone Gyroscope Integration	5.84 ± 1.12	4.92 ± 0.96	1.42 ± 0.28
Fused Kinematics: OP1 (Heel Raises)	1.64 ± 0.38	1.28 ± 0.31	0.18 ± 0.07
Fused Kinematics: OP2 (Iso-Eversion)	1.41 ± 0.32	1.09 ± 0.25	0.14 ± 0.05
Fused Kinematics: OP3 (Iso-Inversion)	1.52 ± 0.35	1.18 ± 0.28	0.16 ± 0.06

(Data are expressed as Mean ± Standard Deviation across 20 participants (2,000 cycles total). RMSE: Root Mean Square Error; MAE: Mean Absolute Error.)

As detailed in Table II, uncorrected gyroscopic integration exhibited a drift rate of 1.42°/min, reaching a cumulative offset of 7.10° ± 1.45° at the end of a 5-minute continuous trial. By utilizing the flex sensor as an absolute physical anchor, the complementary filter constrained cumulative drift to 0.18° ± 0.07°/min, achieving an 87.3% reduction in integration error ($p < 0.001$). Across all participants, tracking error remained low, yielding a Root Mean Square Error (RMSE) of 1.64° ± 0.38° during dynamic sagittal motion and below 1.55° during frontal plane isometric tasks.

Figure 2. Graphical user interface (GUI) design illustrating the Contact menu and integrated support functionalities of the proposed application.

Figure 2 illustrates the graphical user interface navigation structure.

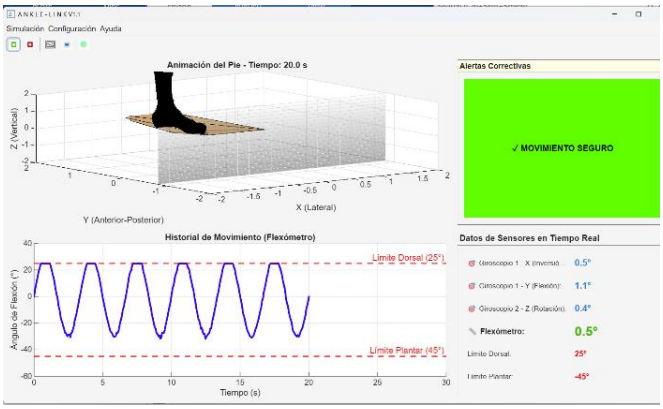

Figure 3. The user interface displays real-time kinematic validation and virtual motion reconstruction by comparing sensor-derived joint angles with actual ankle movement.

Figure 3 shows the real-time operational dashboard in MATLAB during data reception, illustrating virtual segmental animation, angular displacement curves relative to clinical boundaries (+25° dorsal, −45° plantar), and the active feedback alert indicator displaying "MOVIMIENTO SEGURO".

C. Calcaneal Contact and Heel-Off Transition Detection.

The single piezoresistive ZD10-100 sensor under the calcaneus monitored vertical foot-ground contact transitions during heel-raise protocols. The voltage divider circuit yielded a distinct electrical transition between full ground contact and calcaneal lift-off. By calibrating the detection threshold at:

$$V_{\text{th}} \geq 1.8 \text{ V}$$

(Corresponding to an applied vertical unloading threshold of ≈ 15 N), the system identified complete heel-off execution with a true positive accuracy of 98.1%. This thresholding routine discarded false repetitions when participants performed incomplete plantarflexion without lifting the heel off the support surface.

D. Corrective Feedback Latency and Compensation Detection.

The real-time monitoring framework evaluated kinematic and kinetic data against the clinical safety boundaries established in Table I. To validate classification capability, participants performed deliberate compensatory movements during designated sets, including parasitic external hip rotation, lateral trunk leaning, and frontal tilt exceeding ±15°

TABLE III. REAL-TIME BIOFEEDBACK PERFORMANCE AND LATENCY ACROSS EXERCISE PROTOCOLS

Rehabilitation Exercise	**System Evaluation Metrics**		
	Sensitivity (%)	***Specificity (%)***	***Latency (ms)***
OP1: Heel Raises (Sagittal Plane)	94.2 ± 2.1	96.5 ± 1.8	27.4 ± 3.8
OP2: Isometric Eversion (Frontal Plane)	92.1 ± 2.8	95.2 ± 2.2	28.6 ± 4.1
OP3: Isometric Inversion (Frontal Plane)	91.8 ± 3.0	95.4 ± 2.0	29.2 ± 4.5
Combined System Performance	92.7 ± 2.6	95.7 ± 2.0	28.4 ± 4.2

(Values represent classification metrics for detecting intentional compensatory movements (> ±15° roll or premature plantar contact) and end-to-end processing-to-alert latency.)

As reported in Table III, the biofeedback module identified kinematic and kinetic deviations with an overall sensitivity of 92.7% and a specificity of 95.7% . End-to-end feedback latency—defined as the time from physical transducer displacement, on-chip ADC conversion, serial transmission, to MATLAB algorithm decision and visual alert rendering—averaged 28.4 ± 4.2 ms (peak latency: 38.2 ms). This latency falls well within the physiological sensorimotor threshold (< 100 ms), enabling immediate visual and auditory notification prior to motor habituation.

E. Session Data Architecture and Representative Multi-Axis Records

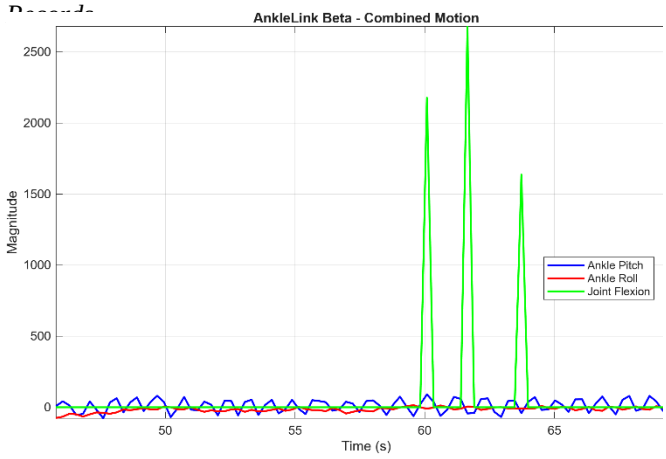

Figure 4. Representative multi-axis experimental output for an individual subject session.

Following protocol execution, the platform executes an automated archiving routine to ensure clinical traceability. Subject metadata and session completion timestamps are logged into a centralized master registry (patients_registry.xlsx). Simultaneously, raw synchronized time-series vectors (kinematics, flex resistance, and calcaneal contact voltage) are exported into individualized spreadsheet workbooks (xlsx) alongside four static diagnostic plots per exercise routine (Figure 4). As illustrated in the representative dataset, these exports provide both a composite tri-axial overview of simultaneous angular excursions and isolated single-plane trajectories for post-session biomechanical verification.

IV. Discussion

Several technical and methodological constraints must be acknowledged when interpreting the performance of the AnkleLink beta prototype. In its current implementation, the system operates strictly as a tethered bench-level testing setup that depends on real-time USB-serial data streaming to a host computer running the program on MATLAB, which limits its immediate deployment as an autonomous wearable telerehabilitation device in domestic environments [3] [4] [5]. Consequently, it is not currently configured as an untethered, standalone wearable medical device suitable for unconstrained home deployment. Furthermore, although internal cross-validation between the dual-IMU architecture and the resistive flex sensor demonstrated high consistency and repeatable drift suppression, the angular estimations and discrete contact events have not yet been benchmarked simultaneously against gold-standard optoelectronic motion capture systems (such as Vicon or Qualisys) or calibrated multi-axis force platforms. Direct comparison against such reference instrumentation represents an indispensable prerequisite before establishing clinical measurement equivalence or asserting therapeutic efficacy [4] [5].

The physical properties of the chosen transducers also introduce specific measurement boundaries. While the second-order polynomial model achieved satisfactory linearity ($R^2 = 0.984$), carbon-polymer flex sensors exhibit inherent mechanical hysteresis ($2.3^\circ \pm 0.6^\circ$) and viscoelastic relaxation under sustained cyclic loading, which can degrade instantaneous angle estimation during rapid ballistic joint reversals [7] [8]. Moreover, securing the sensors to the foot dorsum and distal tibia via elastic straps leaves the setup susceptible to soft-tissue artifacts and subtle sensor migration during repetitive movement sets [5] [9]. Regarding kinetic monitoring, the single piezoresistive ZD10-100 sensor mounted beneath the calcaneus serves strictly as a localized binary contact threshold detector to verify heel-off execution, rather than providing continuous multi-point baropodometric mapping of dynamic plantar pressure gradients across the entire foot [5].

Finally, the preliminary experimental validation was deliberately restricted to a convenience cohort of 20 healthy young adults executing simulated movements within a controlled laboratory environment. While this approach provided a baseline for characterizing sensor fusion mechanics and biofeedback latency, healthy volunteers do not exhibit the altered movement trajectories, antalgic guarding, joint effusion, or restricted ranges of motion characteristic of patients recovering from acute Grade I or II ankle sprains [1] [2] [10]. Future technical iterations will aim to consolidate the discrete breadboard instrumentation into a custom flexible printed circuit (FPC), transfer the processing and thresholding algorithms entirely onto the embedded ESP32-C3 firmware with wireless BLE data transmission [6], and conduct formal usability and validation trials in direct collaboration with physical therapy specialists before evaluating the platform in home-based rehabilitation contexts [3] [5].

***Abstract*— The world population is becoming older, with increased prevalence of cardiovascular diseases. The present work aims to develop a safe and reliable telecardiology system consisting of four modules: an ECG acquisition module for remote self-examination; an edge computer for local processing, automatic detection of life-threatening conditions, and alert issuance; a remote server for secure, reliable data reception and data storage; and a smartphone application for doctor use. The ongoing development of the system shows great promise in terms of utility, reliability, and future application. The system was designed to be easy to use, allow patients to self-record ECGs, and incorporate automatic detection of critical conditions to avoid alarm fatigue. Unlike single-channel acquisition systems, the current six-lead frontal-plane system expands diagnostic possibilities. The smartphone application enables near-real-time receipt of notifications, visualization, and analysis of patient data, allowing continuous follow-up and accelerating emergency care when necessary.**

Keywords—Telecardiology, Home Healthcare, Portable ECG, Edge Computer, Internet of Medical Things (IoMT)

I. Introduction

According to the World Health Organization, one-sixth of the world population will be aged 60 years or older in 2030. Along with this, the prevalence of age-related disorders also increases, mainly cardiovascular diseases (CVDs) [1]. CVDs are the leading cause of death and are one of the main causes of the increasing costs of health care. The Brazilian Unified Health System (SUS) alone is expected to spend approximately BRL 10 billion in the coming years [2], while facing 1,000 deaths daily [3]. Globally, spending on CVD could reach 0.7% of global gross product (US$ 1.4 trillion) [4]. Despite current healthcare efforts, it is estimated that there will be an increase of 73.4% in global cardiovascular deaths by 2050 [5], keeping CVD at the top of the list of mortality and disability illnesses.

This scenario points to the need for effective patient monitoring and risk assessment, as well as measures to prevent strain on healthcare facilities. The Internet of Medical Things (IoMT) addresses this gap by monitoring patients in real time outside the hospital environment [6], thereby allowing doctors to make quick interventionist or therapeutic decisions. This approach benefits both urban and rural areas. This will provide equitable access to healthcare, enhanced agility, reduced costs, lower contagion risks, and increased comfort for both doctors and patients [7]. In addition, cardiac IoMT has proven highly effective at detecting various cardiovascular events and diseases across diverse populations, from children to the elderly [7, 8]. However, a major disadvantage of these numerous technologies is the difficulty of exporting captured information to physicians [9], who are ultimately responsible for diagnosis and clinical decision-making, thereby hindering rapid intervention, which in critical situations (such as cardiovascular events) can be fatal.

Just as the invention of the electrocardiograph was revolutionary for the creation of ICUs (Intensive Care Units) [10], implementing robust cardiac telemedicine and home health care systems is expected to reinvigorate modern medicine. With this in mind, the present work aims to develop a safe and reliable telecardiology system with four components: a compact ECG acquisition module, to be operated by the patient; an Edge computer for pre-diagnosis of life-threatening conditions and transmission of cardiac signals; a central server for secure and reliable reception and storage of data; and a medical application for smartphones, which will receive the alerts and allow the doctor to view and analyze the patient's signal. The system is expected to work flawlessly, ensuring that the patient collects his own signal during moments of discomfort or as advised by medical professionals, issues alerts at pre-established severity levels, and guarantees that the alert and the ECG reach the physician in time for quick intervention when needed.

II. Materials & Methods

Structural and behavioral models of the system were developed using the System Modeling Language (SysML). Fig. 1 presents the main Block Definition Diagram (BDD), in which the **HomeECG** block is decomposed into three main blocks: **ClientSystem**, comprising the **PortableECG** and **EdgeComputer** modules; **RemoteServer**, which receives ECG recordings via Wi-Fi, stores them, and distributes them using Apache Kafka streaming technology; and **PhysicianApp**, which delivers fast and reliable smartphone notifications to the physician.

This study received financial support from the Brazilian agencies CNPq (Grant # 309247/2025-0), CAPES (Grant # 001 and DSc scholarship), FAPERJ (Grant # E26/201.247/2021), and the Brazilian Chamber of Deputies (Parliament Amendment #44890020)

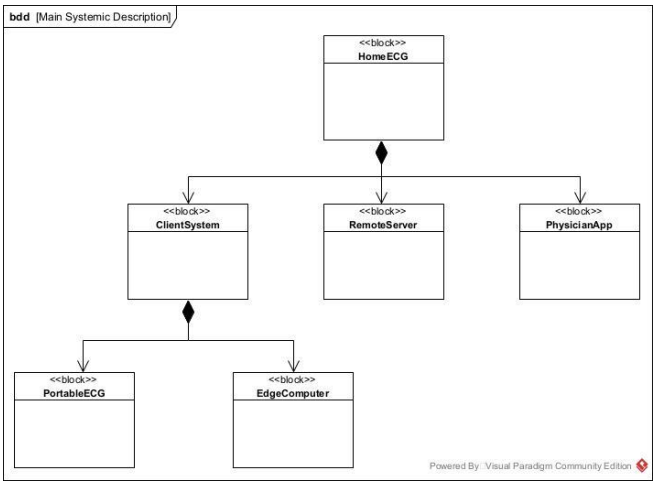

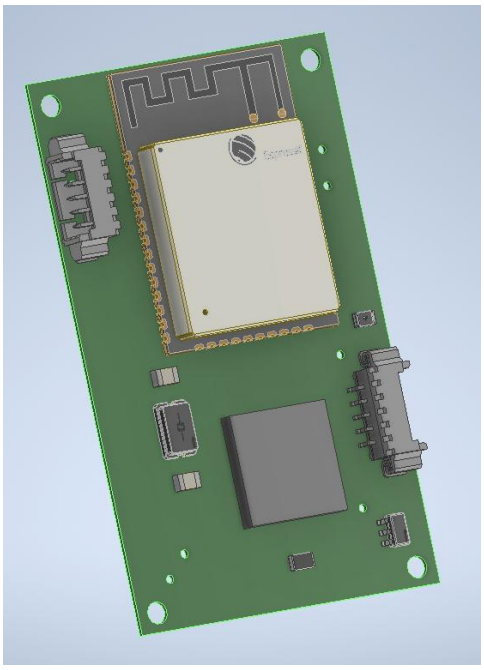

Fig. 1 System block diagram in SysML

A. Portable ECG

The portable ECG module was projected to sample the three bipolar frontal plane ECG Leads I, II and III. The current version of the portable ECG is a stand-alone module with a display, conceived for clinical use by health professionals, testing, and validation of the chosen transducer. It allows a quick view of the patient´s ECG, which can be transmitted to the physician's smartphone or desktop for the issuance of a medical report and recording.

The acquisition modules use two primary electronic components: an ADAS1000-4 3-channel electrocardiographic transducer (Analog Devices) [11] and a low-cost ESP32 microcontroller (Espressif Systems) [12], ideal for IoMT applications. The entire electronic circuit was designed using Altium Designer [13], resulting in a printed board measuring 31 × 50 × 10 mm (Fig. 2).

Fig. 2 Printed circuit board used in portable ECG

The ADAS1000-4 chip operates over the SPI (Serial Peripheral Interface) communication protocol with ESP32. It is configured to acquire signals at a sampling rate of 500 Hz, with a gain of 2,8 V/V (±1% error), providing a resolution of 19 useful bits. Under the manufacturer's test conditions, the integrated circuit exhibits the following typical specifications: 110 dB Common Mode Rejection Ratio with a minimum of 105dB; 1 GΩ in parallel with 10 pF represents the input impedance of the integrated circuit, specified at 10 Hz; and an input-referred noise of 10 µV peak-to-peak for the configured parameters. Its nominal bandwidth is 0.5–150 Hz; in addition, a 3rd-order Butterworth high-pass filter algorithm with a cutoff frequency of 0.5 Hz was also implemented to reduce movement artifacts and baseline fluctuations.

Disposable Ag/AgCl electrodes collect ECG signals via a cable with four vias for the standard Einthoven triangle: Right Arm (RA), Left Arm (LA), Left Leg (LL), and a reference electrode (RLD – Right-Leg Drive). This controls the patient's common-mode voltage and reduces common-mode interference. The ADAS1000- 4 lead-off circuit injects 50 nA DC into each acquisition electrode. When the input voltage falls below or exceeds the typical threshold of 0.2 – 2.4 V, a word indicating the connection or disconnection of a specific electrode is transmitted over the bus [11].

As soon as the ESP32 receives the information captured by the ADAS1000-4 via SPI, it elaborates a data packet as shown in Fig. 3, including a packet counter, the portable ECG battery level, and a CRC (Cyclic Redundancy Check) value. Once structured, this 302-byte packet is transmitted via Bluetooth to the receiver of interest, with latency under 100 ms.

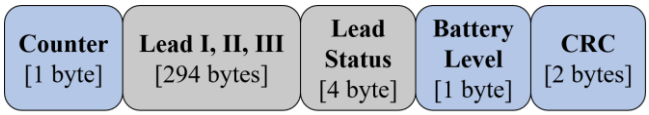

Fig. 3 Data packet transmitted by a portable ECG

The augmented leads (aVR, aVL, aVF) can be easily calculated by the receiver using the following equations:

$$aVR = -\frac{Lead\ I + Lead\ II}{2} \quad (1)$$

$$aVL = \frac{Lead\ I - Lead\ III}{2} \quad (2)$$

$$aVF = \frac{Lead\ II + Lead\ II}{2} \quad (3)$$

Using the Autodesk Inventor 3D modeling software [14], a box was designed to accommodate the printed circuit board and the other electronic components: 3.7 V 1000 mAh battery, USB-C connector, LED, on/off button, 2" ST7789 display, and the connector for the ECG cable. The printed circuit board (Fig. 2) was manufactured in China, and the box was fabricated via additive manufacturing (3D printing) in PET-G, yielding the pilot version (ECGv1, Fig. 4 on the right) of the cardiac signal acquisition module. To evaluate the performance of ECGv1 and ADAS1000-4, we used a Handy Sim HS-30 vital signals generator (Fig. 4 on the left), produced specifically for biomedical equipment assays [15].

Human ECG signal acquisition followed the protocol approved by a Brazilian research ethics committee (CAAE: 97984626.9.0000.5259). For both the simulated ECG signal (Normal Adult, 60 bpm, 1.00 mVpp) and the human ECG signal (from a healthy 28-year-old male), a Bluetooth connection was established with the PEB Workstation ECG analysis software [6]. Five minutes of transmitted data were acquired and stored for each condition to enable post-processing, heart rate variability (HRV) analysis, and comparison between human and simulated ECG signals.

Fig. 4 Integration of the signal generator with the ECGv1

B. Edge Computer

A second version (ECGv2) is being developed for domestic use by patients and operates in integration with an edge computer. In this architecture, the collected ECG is continuously transmitted via the Bluetooth Low Energy (BLE) protocol to the edge computer, which stores the data in an internal buffer. Although the acquisition module uses the same electronics as the ECGv1 (Fig. 2), it differs in its embedded software. It can also be built without a display, since the edge module displays the signal, acquisition warnings, and battery levels (Fig. 5, left). When the edge's push-button is pressed, the system transmits the last 15 seconds of the six-lead ECG signal in JSON (JavaScript Object Notation) format via Wi-Fi to the remote server module using the MQTT (Message Queuing Telemetry Transport) communication protocol. The internal components of the ECGv2 module and edge computer are shown in Fig. 5 (right).

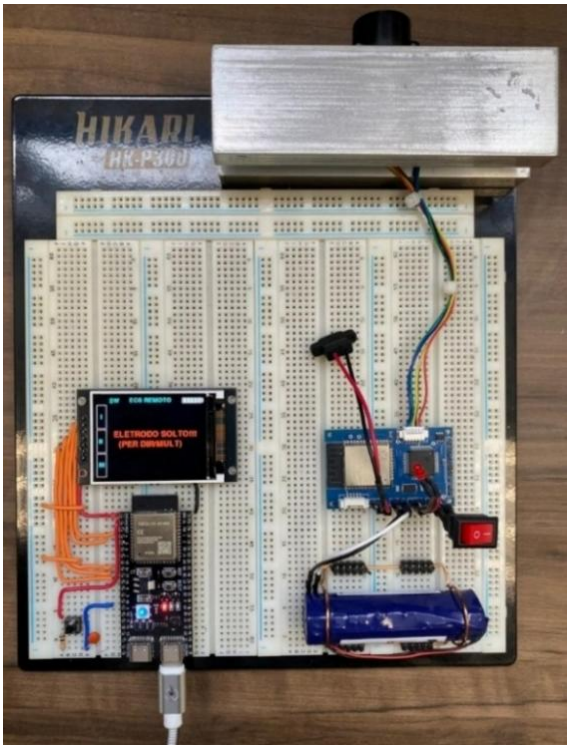

Fig. 5 Edge computer (left) and ECGv2 (right) prototypes under development.

The Edge Computer complements the home ECG. It serves as a visual feedback tool, ensuring the patient has achieved a high-quality ECG signal. Equipped with a 2" ST7789 display, it allows the user to view the collected ECG in real time, displaying warning messages indicating loose electrodes (LA, RA, LL, RLD, or multiple electrodes), acquisition module battery level (ECGv2), connection symbols for Bluetooth (B), Wi-Fi network (W), and MQTT server (T). Finally, a push-button either validates the captured signals and sends them to the server or requests the patient to collect a new, more careful ECG signal.

At the Edge Computer, the ECG will be pre-processed to detect predefined critical conditions, such as atrial fibrillation or ischemic ST changes, including ST-elevation myocardial infarction (STEMI). This automatic detection process screens ECG signals to inform the physician's Mobile Application of an emergency condition [9], which must be urgently confirmed to ensure the patient receives immediate medical care.

C. Remote Server

The server consists of a standard desktop computer running Linux, configured to operate as an MQTT broker. This protocol enables direct communication with many home ECG systems. These systems can operate either as publishers, transmitting ECG data to the server, or as subscribers, receiving guidance messages from the physician. All messages are received in JSON format and stored in an Apache Kafka stream processing broker. This open-source platform, developed by LinkedIn, is currently used worldwide by thousands of large companies [16]. This technology is based on Commit Logs, immutable files that record events in chronological order (date and time). In addition, the Kafka Cluster works by splitting the messages received from its "producers" into partitions and redundantly redistributing them across several different brokers, which can be real or virtual machines, ensuring that its "consumers" have access to all information, even if one of these machines is inoperable [17]. Data anonymization, the development of a proprietary server and the adoption of the SSH (Secure Shell) protocol ensure data encryption and secure access to the acquired clinical and personal databases.

D. Mobile Application

This application will notify physicians on their smartphones in near real time of any cardiac event their patients report. As the ECG signal will be preprocessed, the application will receive both the ECG data and an estimated risk alert indicator, enabling the physician to review and analyze the ECG recording as quickly as possible, only when necessary. When the ECG is considered normal, he can issue a medical report at his convenience. Thus, the automatic pre-diagnosis serves as an information filter for the doctor by pre-processing the signals [9] and avoiding alarm fatigue [18, 19]. This procedure helps speed up decision-making, whether calling emergency contacts or adjusting medication. Consequently, this may increase the chances of a positive prognosis for any event that may occur with patients. The smartphone application will also provide statistical analysis of patient data, ECG history, and emergency contacts. Fig. 6 shows screenshots of the application's main interfaces, written in Portuguese, the only language available now.

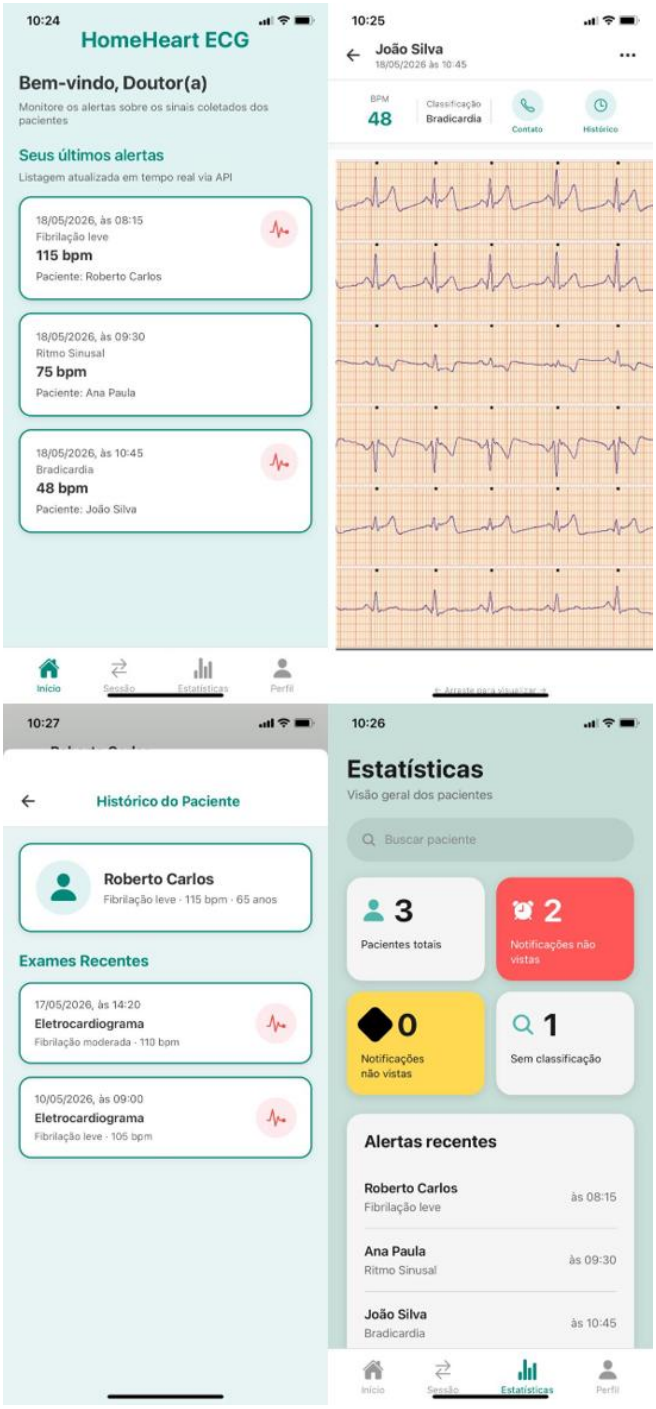

Fig. 6 Screenshots of the app's features

III. Results

The Fig. 7 shows the real-time ECG signals captured by leads I, II, and III by ECGv1, together with the reconstructed augmented leads (aVR, aVL, and aVF), and HRV analysis performed by the Workstation software. At some collection points, 60 Hz noise was observed, consistent with electrical-network coupling, and was easily filtered by applying a notch filter during post-processing or real-time display on the workstation. R-peak detection and HRV values were concise, with markings aligned with the R waves; the simulated signal showed variability tending to zero and an HR of 59.98 bpm; the human signal showed variability and an HR of 60.47 bpm. Although it did not use a data reconstruction algorithm, the CRC protocol proved efficient because all transmissions had zero lost packets. With a consumption of 200 mA, ECGv1 is expected to have an autonomy of 4 to 5 hours, with a conventional Bluetooth communication range of 10 m indoors. The filtering methods adopted are believed to attenuate baseline drift, although this has not been quantified.

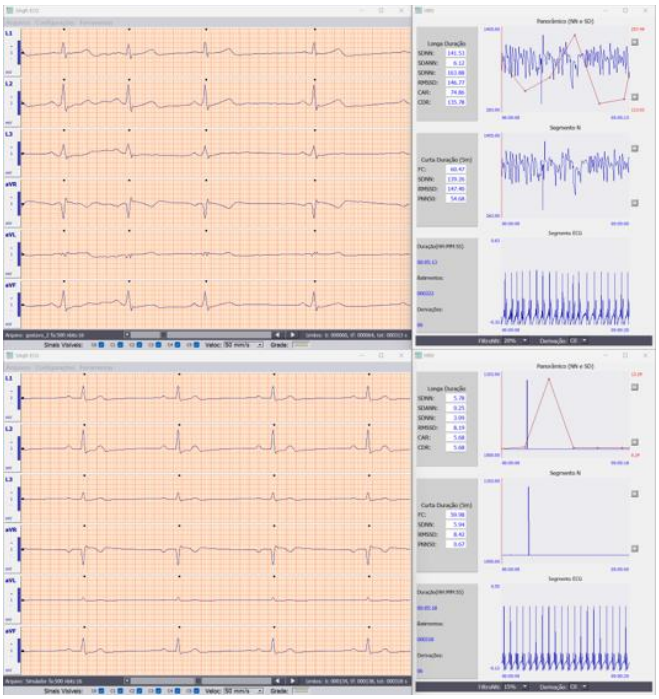

Fig. 7 Workstation interface displaying the six-lead ECG captured by the ECGv1, where the points indicate the detected R_waves, and HRV analysis of a recorded signal. The top image shows the human signal, and the bottom image presents the simulated signal.

IV. Discussion

The developing of this framework shows great promise in terms of utility and reliability. The system provides clean signal acquisitions with little or no interference affecting the signal's morphology. It stands out for its ease of use and possible integration with specialized analysis software and hardware, such as the Workstation [6] and Edge Computer. The current six-lead frontal-plane system expands the possibilities for more comprehensive analyses, including ischemic events such as atrial fibrillation, STEMI, cardioembolic stroke, and branch blocks. The clinical version (ECGv1) allows immediate interpretation by health professionals, while ECGv2, connected to the Edge Computer, allows extending patient treatment to home health care and sending a direct alert to the doctor. By automatically classifying the ECG, it also avoids alarm fatigue [18, 19] and signal-processing overload in other system nodes, since it already exports the analysis results [20]. The Apache Kafka stream service ensures data storage, transmission, and security on its own servers [17], in accordance with the Brazilian LGPD (General Law for the Protection of Personal Data) [21]. The mobile App enables real-time receipt of notifications, as well as visualization and analysis of the patient's signal. In conclusion, the presented system enables patients to perform routine self-monitoring or emergency self-monitoring and accelerates decision-making by doctors and other healthcare professionals.

The limitations of the current study stem from the ongoing development of specific modules, namely the physician application, the automated ECG interpretation algorithms, and

the domestic version of the portable ECG. Therefore, subsequent stages of this research will include bench tests at different rhythms and wave amplitudes, emergency simulations, and home monitoring trials to ensure system robustness and clinical safety. While a specific safety and isolation diagram is omitted, battery safety is ensured by Protection Circuit Module (PCM) that prevents overcharging, overdischarging, overcurrent, and short circuits. Furthermore, the device is protected against operation during USB charging.

In addition, the presented technology has strong potential for incorporation into the Brazilian Unified Health System (SUS), as it already meets most of the criteria established by the National Commission for the Incorporation of Technologies into the SUS (Conitec). According to RDC No. 751/2022, the device is classified as a Class II (medium-risk) medical device. Although the prototype has not yet been registered with the Brazilian Health Regulatory Agency (ANVISA), the Brazilian National Telecommunications Agency (ANATEL) has already certified the ESP32 communication module. Furthermore, its low production cost, ease of use, reliability, and portability are consistent with the ethical and equity principles considered in the Health Technology Assessment (HTA) process adopted by SUS.

ACKNOWLEDGMENT

The authors wish to thank fellow researcher Edgar Norio Taka for providing the calibrated ECG signal generator.

***Abstract*—This article presents the development and technical evaluation of a low-cost wearable prototype for acquiring, processing, transmitting, and visualizing wrist-motion signals relevant to Parkinsonian resting-tremor research. The system is based on the T-Watch 2020 V2 platform, integrating an ESP32 microcontroller, BMA423 triaxial accelerometer, AXP202 power-management unit, TFT display, Wi-Fi, and Bluetooth Low Energy (BLE). Firmware implemented in C++ performs calibration, first-order IIR filtering, resultant-magnitude calculation, a 128-point Fast Fourier Transform (FFT), relative spectral-energy analysis in the 4–6 Hz band, and HTTP/BLE transmission to a containerized web dashboard. Evaluation used controlled functional wrist movements and an internal synthetic 5 Hz test signal; no data were acquired from individuals with Parkinson's disease. At 100 Hz sampling, the 128-sample analysis window provides approximately 0.78 Hz frequency resolution. For the synthetic reference, the observed frequency-bin error was 0.31–0.47 Hz (6.2%–9.4%). Average communication latency was 42 ± 12 ms for HTTP/Wi-Fi and 18 ± 5 ms for BLE; in 30-min tests with 1,406 transmissions, packet loss was 0.14% for Wi-Fi and 0% for BLE. These results demonstrate functional integration of sensing, embedded processing, wireless communication, storage, and visualization, while the prototype remains a technical proof of concept requiring formal clinical validation against reference instruments and standardized clinical scales.**

***Keywords*—Parkinson's disease; resting tremor; wearable device; ESP32; digital signal processing; FFT; digital health.**

I. INTRODUCTION

Parkinson's disease (PD) is a progressive neurodegenerative disorder associated with impairment of motor and non-motor functions. Recent epidemiological studies indicate a significant increase in the global prevalence of the disease, a fact related to population aging and increased life expectancy [1]-[3]. Among the classical motor symptoms, resting tremor stands out as one of the most characteristic signs, usually manifested as involuntary rhythmic oscillations of the extremities in the 4 Hz to 6 Hz range [2]-[3].

Clinical assessment of these tremors is still frequently based on observations performed by health professionals and on subjective scales, such as the Unified Parkinson's Disease Rating Scale. Although widely used, such approaches may vary among evaluators and do not continuously capture symptom evolution outside the clinical environment [1], [3]-[4]. Objective quantification of tremor frequency, amplitude, and temporal pattern can complement medical assessment and support longitudinal patient monitoring [1]-[2], [4]-[5].

In this context, wearable devices based on inertial sensors constitute a promising alternative for continuous, non-invasive, low-cost monitoring. Recent reviews and representative studies indicate that accelerometers and inertial measurement units have been applied in digital health, rehabilitation, and motor monitoring, enabling signal acquisition in natural environments and the generation of quantitative indicators [1], [3], [5]-[9], [11], [24]. This approach is especially relevant for PD, since tremor may vary throughout the day as a function of medication, fatigue, rest, anxiety, and other conditions [7].

This work presents the development and preliminary functional evaluation of a wearable prototype for resting tremor monitoring in Parkinson's disease, integrating inertial

signal acquisition, processing, wireless communication, and real-time visualization. Evaluation used functional tests and artificially generated signals, without data from individuals with Parkinson's disease. The main contribution is an integrated wearable platform that provides a technical basis for future clinical validation and home-based monitoring.

II. BACKGROUND AND RELATED WORK

A. Resting tremor and quantitative monitoring

Parkinsonian resting tremor is characterized by involuntary, regular, and recurrent oscillations evident at rest [1], [2], arising from cerebral oscillatory networks involving the basal ganglia, thalamus, and motor cortex [2]. It can be analyzed through acceleration, angular velocity, or displacement signals, with frequency being a key parameter for differentiating parkinsonian tremor from other involuntary movements. Inertial sensors can objectively quantify tremor through amplitude, dominant frequency, spectral energy, and temporal variation, with these parameters related to clinical assessment [3], [4], [16], [24]-[26]. Patel et al. demonstrated the potential of wearable sensors for monitoring motor fluctuations outside clinical settings [10]. Previous studies have reported wearable and low-cost embedded approaches for tremor detection, quantification, and visualization [4], [6], [12], [25], [26]. This project extends these approaches by integrating acquisition, processing, HTTP/BLE transmission, sensor-acquisition and synthetic-test modes, CSV storage, and a containerized dashboard. Specifications were compared with representative wearable and inertial monitoring systems [5], [9], [10], [25], [26], as summarized in TABLE I.

TABLE I. PROSPECTIVE COMPARATIVE ANALYSIS WITH REFERENCE WEARABLE SYSTEMS

Parameter	Proposed Prototype	Reference Systems
IMU Sensor	Bosch BMA423 (Accel.)	Representative inertial wearables [5], [9], [10], [25], [26]
Sampling Rate	100 Hz	Typically 50–100 Hz in representative implementations [25], [26]
Connectivity	Wi-Fi and BLE	Bluetooth / Wi-Fi / Cellular
Local DSP	Yes (FFT & Filtering on ESP32)	Yes (Embedded frameworks)
Dashboard	Yes (Flask / Docker Web App)	Yes (Proprietary health app)
CSV Export	Yes (Direct API download)	Restricted / Research APIs
Validation	Technical bench/functional validation; no clinical participants	Clinical/experimental validation reported in representative systems [5], [25], [26]
HW Cost	Low Cost (~USD 60)	High Cost (Commercial devices)

B. Wearable devices and inertial sensors

Wearable devices applied to health combine sensors, microcontrollers, batteries, wireless communication, and visualization software in compact systems capable of monitoring physiological or motor signals. Advances in MEMS sensing and wearable monitoring have made it possible to measure subtle accelerations and movements with low power consumption and reduced cost [5], [9], [11], [23], [24]. In the proposed prototype, the Bosch BMA423 acquires accelerations along the X, Y, and Z axes and supports programmable acceleration ranges and digital interfaces suitable for wearable applications [27]. Integrated into the T-Watch 2020 V2 with an ESP32, display, battery, and power-management circuitry, it provides a compact wearable IoT platform [14]. The ESP32 was selected for its integrated processing, Wi-Fi, Bluetooth Low Energy, I2C interfaces, and low-power modes [13], [22], [28]. The AXP202 power-management IC provides battery charging, power-rail control, monitoring, and protection functions for portable systems [14], [19].

III. SYSTEM ARCHITECTURE AND MATERIALS

The system architecture was organized to enable local signal acquisition, embedded preprocessing, identification of tremor patterns, data transmission, storage, and real-time visualization. The solution was built from commercially available hardware components, aiming to reduce cost, simplify replication, and facilitate future adaptations.

The materials included the T-Watch 2020 V2, USB Type-C cable, development computer, local Wi-Fi network, Visual Studio Code with PlatformIO, and ESP32/T-Watch libraries. The firmware was developed in C++, implementing accelerometer acquisition, calibration, digital filtering, vector magnitude calculation, spectral analysis, tremor detection, HTTP/BLE communication, and operating-state visualization on the device display.

The logical operating sequence is shown in Fig. 1. After initialization, the system configures the sensor, display, communication interfaces, and variables, then verifies connectivity, performs calibration, and selects the operating mode.

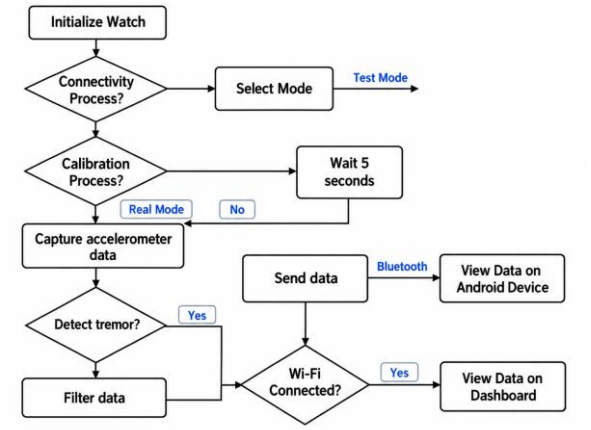

Fig. 1. Logical architecture of the wearable prototype for data acquisition, detection, transmission, and visualization.

In sensor-acquisition mode, acceleration data are acquired from the BMA423, while the synthetic-test mode generates artificial signals for processing validation. In both modes, samples are filtered and processed for magnitude calculation,

spectral analysis, tremor detection, transmission, and visualization.

The smartwatch-like T-Watch 2020 V2 provides a realistic usage scenario by allowing wrist attachment similar to commercial smartwatches, reducing mechanical assembly and improving usability during laboratory tests. During measurements, it was positioned with the display facing upward and consistently oriented relative to the forearm to ensure reproducible inertial signal acquisition. Fig. 2 presents the hardware setup, including the T-Watch 2020 V2, inertial sensing subsystem, and integrated processing and communication resources.

Fig. 2. Hardware elements used in the prototype: wearable platform, inertial sensor, and processing/communication module.

The T-Watch 2020 V2 integrates an ESP32 microcontroller, BMA423 three-axis accelerometer, AXP202 power-management circuit, TFT display, rechargeable battery, and Wi-Fi/Bluetooth Low Energy connectivity, enabling signal acquisition, local processing, user feedback, and wireless transmission. The BMA423 was configured at 100 Hz with a measurement range of ±2 g and 12-bit resolution across the X, Y, and Z axes, with values expressed in g [27]. These settings were maintained throughout the experiments to ensure consistent signal acquisition. TABLE II summarizes the experimental setup and the main prototype specifications.

TABLE II. EXPERIMENTAL SETUP AND SMARTWATCH PROTOTYPE SPECIFICATIONS.

Parameter	Value
Microcontroller	ESP32
Accelerometer	BMA423
Sampling frequency	100 Hz *(derived from SAMPLE_MS = 10 ms)*
Accelerometer range	±2 g
Device mass	58.5 g *(commercial LilyGO T-Watch 2020 V2 nominal mass)*
Battery capacity	350–400 mAh *(integrated 3.7 V Li-Po battery)*
Estimated autonomy	~4 h continuous operation *(1–3 days standby/optimized; USB-powered during tests)*
Acquisition window duration	1.28 s per FFT window *(128 samples at 100 Hz)*
Communication protocols	Wi-Fi (HTTP POST) / BLE (GATT)

The complete system architecture is presented in Fig. 3 and organized into five functional layers. The first layer comprises the wearable embedded device, responsible for acquiring X-, Y-, and Z-axis acceleration signals and executing the main firmware routines. The second performs preprocessing and feature extraction, including calibration, gravitational-component removal, noise reduction, moving-average filtering, FFT computation, and estimation of dominant frequency, amplitude, signal magnitude, and spectral energy. The third layer manages wireless communication. Processed data can be transmitted through Wi-Fi using HTTP requests and JSON messages sent to a REST API, or through BLE notifications based on the GATT protocol. This dual communication strategy allows the prototype to operate both with a local server and with nearby mobile or edge devices [22].

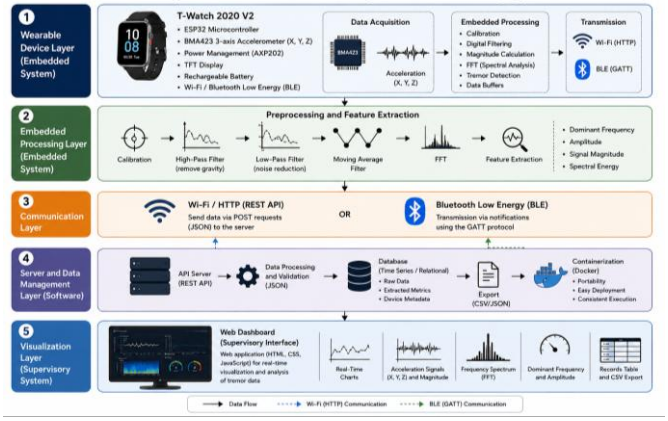

Fig. 3. Proposed layered architecture of the resting tremor monitoring system, integrating the wearable embedded device, local signal processing, wireless communication, server and database infrastructure, Docker containerization, and web-based supervisory interface.

The fourth layer comprises the software infrastructure for data reception and management. A server API receives and validates the transmitted records, which are then stored in a database together with the extracted metrics and device metadata. The backend and its dependencies are organized in Docker containers [17], improving portability, reproducibility, and consistency across different execution environments.

The fifth layer comprises the web-based supervisory system, displaying acceleration signals, vector magnitude, dominant tremor frequency, spectral information, device records, and CSV/JSON exports for real-time monitoring and analysis. The layered architecture separates hardware, firmware, communication, backend, storage, and visualization, facilitating maintenance, component replacement, remote integration, and future adoption of advanced signal-processing or machine-learning methods.

A. Functional firmware structure

The firmware uses independent routines for initialization, communication, acquisition, calibration, processing, detection, and transmission, improving maintainability and modular testing. Initialization configures the display, BMA423, Wi-Fi, BLE, and state variables, while the main loop handles sampling, filtering, magnitude calculation, and tremor detection. Calibration parameters are stored in non-volatile memory for reuse and can be updated to compensate

for wrist-position changes, which affect the accelerometer's gravitational component.

The simplified flow presented in Fig. 4 summarizes the main stages of embedded operation. Although it is an abstract representation, it shows the essential project sequence: initialize the device, collect accelerometer information, process samples, send data, and make visualization available. This view helps explain the transition between hardware, firmware, and web applications.

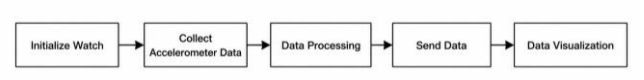

Fig. 4. Simplified flow of the prototype operation stages.

IV. SIGNAL ACQUISITION AND DIGITAL PROCESSING

Acquisition is performed from acceleration components along the three axes. Before analysis, the data undergo calibration to reduce reading deviations and compensate offsets. Preprocessing routines are then applied to attenuate noise, remove static components associated with gravity, and preserve variations compatible with tremor.

To improve repeatability, raw triaxial acceleration first undergoes static-bias calibration. During a stationary phase, the mean of N = 200 samples is estimated independently for each axis and subtracted from subsequent measurements: $a_c,i[n] = a_i[n] - \bar{a}_i$, for $i \in \{x, y, z\}$. The calibrated signals are then processed by first-order recursive filters to reduce the static gravitational component and high-frequency noise before feature extraction.

At the 100 Hz sampling rate (T_s = 10 ms), the firmware uses two first-order Infinite Impulse Response (IIR) stages. The DC-removal/high-pass stage follows $y_HP[n] = \alpha_HP \cdot (y_HP[n-1] + x[n] - x[n-1])$, with $\alpha_HP = 0.95$; this coefficient corresponds to a pole-equivalent corner of approximately 0.82 Hz and is used to suppress quasi-static gravity and slow drift. The smoothing low-pass stage follows $y_LP[n] = y_LP[n-1] + \alpha_LP \cdot (x[n] - y_LP[n-1])$, with $\alpha_LP = 0.20$. For this exact discrete-time implementation, the −3 dB frequency is approximately 3.57 Hz (the frequently used continuous-time approximation $\alpha/(2\pi T_s)$ gives 3.18 Hz). Because this corner lies below the 4–6 Hz target band, the implemented smoother attenuates—but does not eliminate—tremor-band components by approximately 3.5 to 5.8 dB. It is retained here because it is the filter actually used in the evaluated firmware; moving the low-pass corner above 6 Hz or redesigning the band-pass response is identified as a future optimization when amplitude preservation is required.

After filtering, the three spatial components are combined into an orientation-reduced scalar feature using the Euclidean norm $a_r[n] = \sqrt{(a_x,f^2[n] + a_y,f^2[n] + a_z,f^2[n])}$. This resultant dynamic magnitude is the primary time-series feature used for subsequent spectral analysis and detection. The approach reduces dependence on exact sensor orientation while preserving overall oscillatory activity [3], [10].

Resting-tremor-related activity is characterized in the frequency domain using a 128-point Fast Fourier Transform (FFT) applied to a Hamming-windowed frame. Rather than computing a fully normalized power spectral density, the firmware accumulates squared FFT magnitudes over discrete frequency bins. The relative spectral-energy ratio in the target band is defined as $R_4–6 = (\Sigma_\{f_k \in [4,6]\} |X[k]|^2) / (\Sigma_k |X[k]|^2)$.

This embedded formulation avoids additional normalization overhead while preserving the relative distribution of spectral energy needed for the decision logic. With f_s = 100 Hz and N = 128, the FFT-bin spacing is $\Delta f = f_s/N$ = 0.78125 Hz, which limits the resolution of the reported dominant frequency.

The decision rule compares $R_4–6$ with a predefined threshold T = 0.30. A tremor-like event is flagged when $R_4–6 > T$, i.e., when more than 30% of the spectral energy of the filtered resultant signal falls between 4 and 6 Hz. In this study, this threshold is an engineering criterion for functional testing and must not be interpreted as a clinically validated diagnostic threshold.

The embedded implementation prioritizes computational simplicity, ESP32 compatibility, and real-time execution. To evaluate the processing chain under controlled conditions, the runFakeDataMode() routine generates a 5.0 Hz synthetic tremor-like reference. The signal directly supplied to the detection routine is $m(t) = 1.8 + 0.6 \cdot \sin(2\pi \cdot 5t) + \eta(t)$, in g, where η(t) is a bounded pseudo-random term generated by the firmware with approximately ±0.05 g amplitude. Thus, the implemented test source uses sinusoidal modulation plus bounded uniform-like pseudo-random noise, not Gaussian noise. The signal is sampled at 100 Hz and processed in 128-sample windows (1.28 s); the parameters are summarized in Table III.

TABLE III. PARAMETERS OF THE SYNTHETIC SIGNAL GENERATED IN TEST MODE (RUNFAKEDATAMODE)

Parameter	Value	Description
Fundamental frequency (f_0)	5.0 Hz	Reference oscillation within the 4–6 Hz target band
Sampling frequency (f_s)	100 Hz	Sampling period T_s = 10 ms
Window size (N)	128 samples	FFT window duration = 1.28 s; Δf = 0.78125 Hz
Signal composition	Sinusoid + bounded pseudo-random noise	$m(t) = 1.8 + 0.6 \sin(2\pi \cdot 5t) + \eta(t)$
Target band	4.0–6.0 Hz	Spectral-energy band used by decision logic
Magnitude baseline	1.8 g	DC level used by the internal synthetic reference
Oscillation amplitude	0.6 g peak	Amplitude of the 5 Hz sinusoidal modulation
Noise term η(t)	approximately ±0.05 g	Bounded pseudo-random term generated from random(−100,100); not Gaussian
Detection threshold	T = 0.30 (30%)	Tremor-like event flagged when $R_{4–6} > T$

In addition to the sensor-acquisition mode, the firmware includes an internal synthetic-test mode that validates the processing chain without relying on volunteers or patients. This mode generates a controlled 5 Hz reference with known amplitude and bounded pseudo-random noise, allowing magnitude calculation, filtering, spectral analysis, detection logic, transmission, and dashboard updating to be checked under repeatable conditions. It is an engineering test source and does not represent physiological tremor.

V. TECHNICAL VALIDATION METHOD

The prototype uses two communication strategies. The first is based on HTTP over Wi-Fi, allowing measurements to be sent to a local or remote server. HTTP was chosen because of its broad adoption in web applications and because it facilitates integration with APIs, backend services, and dashboards [15], [20], [21]. The second strategy uses Bluetooth Low Energy (BLE), which is suitable for local tests, transmission to mobile devices, and low-power short-range communication supported by the ESP32 platform [13], [28].

The web dashboard was implemented to receive, display, and record the data transmitted by the device. The interface presents tremor magnitude in real time, a record table, detection status, battery level, and a CSV export option. These functions facilitate the organization and inspection of acquired measurements during experimental tests and subsequent analysis. Clear and organized data visualization is particularly relevant for monitoring and interpreting wearable-sensor measurements in digital-health applications [18].

To facilitate environment deployment and replication, the dashboard was containerized with Docker. Containerization allows the application, dependencies, and settings to be packaged into a portable unit, simplifying deployment on different computers and reducing environment incompatibility problems [17]. This approach contributes to the reproducibility of the prototype, particularly in academic and laboratory contexts.

Fig. 5 presents the dashboard interface. The chart allows monitoring of the temporal evolution of signal magnitude, while the table provides visualization of samples and detection states. The CSV export function facilitates subsequent analyses using statistical tools, spreadsheets, or processing scripts. This structure transforms raw accelerometer measurements into organized information for experimental analysis and validation.

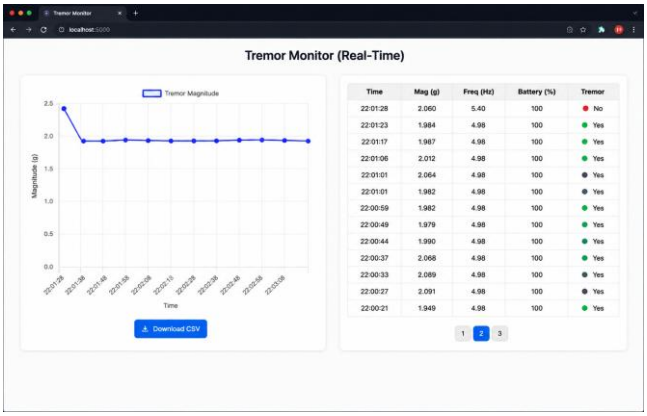

Fig. 5. Web dashboard for real-time visualization, record table, and data export.

A. Functional validation protocol and metrics

The initial validation protocol was designed to verify the consistency of the complete engineering chain, from accelerometer reading to presentation in the web interface. Tests were conducted under controlled conditions using three situations: normal/voluntary wrist activity, manually generated tremor-like wrist oscillations, and the firmware's internal synthetic test mode. The manual tremor-like condition evaluated acquisition and detection through controlled human movement but is treated strictly as a functional movement test, not as physiological or clinical validation. The synthetic mode provided a known 5 Hz reference for evaluating detection logic, transmission, and dashboard updating.

The evaluation considered acquisition stability, dashboard updating, device-state coherence, sample logging, CSV export, display response, and communication continuity. The end-to-end (E2E) path comprises BMA423 acquisition over I²C, ESP32 filtering and FFT processing, HTTP POST or BLE transmission, backend reception, and dashboard rendering. E2E latency was defined as $L_{E2E} = t_{display} - t_{sample}$, where t_{sample} is the timestamp associated with the acquired sample/window and $t_{display}$ is the corresponding dashboard-update timestamp. The 1.28 s FFT accumulation window is reported separately from communication/display latency.

Packet loss was defined as $PL(\%) = 100 \cdot (N_{tx} - N_{rx})/N_{tx}$, where N_{tx} is the number of transmitted records and N_{rx} is the number successfully received and processed. Sequence counters in the transmitted payloads were used to identify missing records. Signal evaluation considered resultant magnitude, temporal behavior, dominant frequency, and FFT spectral concentration in the 4–6 Hz band [2], [3], [10].

The prototype is not intended to replace medical assessment. The present measurements quantify engineering behavior under controlled functional conditions and provide a basis for future comparison with standardized clinical observations and reference devices.

In addition to functional tests, the reproducibility of the software environment was evaluated. PlatformIO facilitates firmware compilation across different computers, while the Docker-based dashboard packages application dependencies into a portable execution environment [17]. This organization supports academic reproducibility by allowing researchers to replicate the architecture, replace components, and evaluate new processing strategies with reduced configuration effort. The modular design integrates wearable hardware, embedded firmware, communication, signal processing, and data visualization into a functional and reproducible system architecture.

Wireless transmission integrity was evaluated by comparing the 5 Hz synthetic reference generated by runFakeDataMode() with the series stored/exported by the dashboard. Root-mean-square error was computed as $RMSE = \sqrt{[(1/N)\cdot\Sigma_i(x_i - y_i)^2]}$, where x_i is the reference sample and y_i is the corresponding received/stored sample.

The resulting RMSE was approximately zero within floating-point precision, indicating that the tested serialization and network path did not introduce measurable amplitude distortion. This result is specific to the synthetic transmission test and does not imply absence of sensor noise,

packet loss under all network conditions, or clinical measurement accuracy.

VI. RESULTS AND DISCUSSION

The wearable prototype was evaluated using BMA423 acceleration data sampled at 100 Hz and analyzed in 128-sample windows (1.28 s) with a 128-point FFT. The detection decision was based on dominant frequency and relative spectral energy in the 4–6 Hz band. Normal/voluntary movement conditions produced frequencies below 2.34 Hz and R_4–6 = 12.4% ± 4.2%. The internal synthetic test signal produced R_4–6 = 88.5% ± 3.1%, whereas manually generated tremor-like wrist movements produced R_4–6 = 41.8% ± 5.6%. Controlled tremor-like movements yielded dominant frequencies of 4.69–5.47 Hz and exceeded the predefined 30% threshold. These measurements demonstrate the behavior of the engineering detection criterion under the tested conditions; they do not constitute physiological or clinical tremor validation.

The signal-processing pipeline was evaluated through static calibration, digital filtering, and spectral analysis. At 100 Hz with N = 128, the FFT frequency resolution is 0.78125 Hz. Relative to the 5.00 Hz synthetic reference, observed dominant-bin errors were 0.31–0.47 Hz (6.2%–9.4%), consistent with the finite FFT resolution. Post-calibration residual noise remained below 0.008 g and the measured signal-to-noise ratio exceeded 31 dB under the reported test conditions.

The communication subsystem was evaluated using HTTP REST over Wi-Fi and Bluetooth Low Energy (BLE), considering processing time, end-to-end latency, packet loss, and data integrity. Embedded processing required less than 4.2 ms per 1.28 s analysis window. Average communication/display latency was 42 ± 12 ms for HTTP/Wi-Fi and 18 ± 5 ms for BLE. During 30-min tests with 1,406 transmissions, packet loss was 0% for BLE and 0.14% for Wi-Fi. Comparison between the synthetic reference and the stored dashboard series yielded RMSE ≈ 0 within floating-point precision, indicating no measurable amplitude distortion attributable to serialization and transport in that test.

The integrated prototype was also evaluated through controlled manual movement tests and continuous operation of the embedded and web infrastructure. Voluntary arm movements produced predominantly low-frequency components below 2.0 Hz and spectral ratios below 15%, whereas manually generated tremor-like wrist movements showed dominant frequencies of 4.69–5.47 Hz and spectral ratios above the 30% detection threshold. Under these controlled conditions, no false-positive triggering was observed for the evaluated voluntary movements. During operation, the display updated every 1.28 s and changed state when the criterion was exceeded, while the detection state was simultaneously transmitted to the backend. The corresponding device states are illustrated in Fig. 6.

The Flask-based web infrastructure successfully received and processed JSON data, enabling visualization of acceleration magnitude, frequency, spectral information, and device status. Overall, the results demonstrate the functional integration of sensing, embedded processing, tremor detection, wireless communication, and remote visualization in a single wearable platform. As the experiments used simulated signals and controlled functional tests rather than data from individuals with Parkinson's disease, the results represent a technical validation of the prototype rather than clinical validation of tremor detection.

Fig. 6. States displayed by the device during tests: normal operation, tremor detected, and simulated mode.

VII. REPLICABILITY ANALYSIS AND APPLICATION POTENTIAL

The proposed architecture was conceived with a focus on replicability. The use of a commercial wearable platform, widely available libraries, and open development tools reduces barriers for reproducing the system in academic activities, embedded systems laboratories, and digital health research. This characteristic differentiates the prototype from closed or proprietary solutions, which often hinder modification of acquisition and analysis algorithms.

The ESP32 supports system expansion through Wi-Fi, BLE, I2C, GPIOs, and low-power modes, enabling new sensors, sampling adjustments, local alerts, smartphone connectivity, and home-based applications [22], [28]. Wi-Fi/HTTP facilitates dashboard and server integration [15], [20], [21], while BLE supports short-range mobile connectivity [13], [28]. The dashboard enables real-time monitoring, detection-state verification, communication-failure identification, and data export, with future extensions including frequency charts, user history, automated reports, and session comparison based on user-centered visualization principles [18].

In digital health, the prototype supports educational and experimental applications by integrating sensing, embedded processing, web visualization, and CSV export for reproducible analysis in Python, MATLAB, spreadsheets, or statistical tools. This architecture enables future filtering, feature extraction, detection/classification, and comparison with clinical scales, subject to ethical, privacy, and data-security requirements.

Although it is a prototype, the integration between wearable hardware, embedded processing, and web application demonstrates a viable path for low-cost solutions. Replacing or complementing the BMA423 with sensors including gyroscopes, increasing battery autonomy, and adding communication encryption may raise the technological maturity of the solution. Likewise, incorporating machine learning may allow distinction among resting tremor, essential tremor, voluntary movements, and artifacts of daily use.

Future development should address sensitivity to voluntary movements, lack of clinical validation, and energy consumption through adaptive filtering, robust feature extraction, machine-learning classifiers, and optimized Wi-Fi, BLE, and display operation. Further work should include clinical validation with volunteers and clinical scales, authentication and encryption, integration with clinical

information systems, and dashboard expansion with history, reports, and session-based metrics.

VIII. LIMITATIONS AND FUTURE WORK

Despite the positive results, the system has limitations that must be considered. Detection based on a fixed spectral-energy threshold may be insufficient in real-world scenarios with complex movements, different watch positions, and individual variability. The implemented $\alpha_LP = 0.20$ smoothing filter has an exact discrete-time −3 dB frequency of approximately 3.57 Hz at 100 Hz sampling and therefore attenuates the 4–6 Hz target band; although detection remained functional in the reported tests, a revised low-pass or band-pass design with a corner above 6 Hz should be evaluated when quantitative amplitude preservation is required. Energy autonomy also requires dedicated prolonged-use measurement with the sensor, display, Wi-Fi/BLE, and local processing simultaneously active.

The current firmware has no local storage buffer or message-retry mechanism; therefore, samples processed during Wi-Fi or BLE disconnections are discarded. Nevertheless, the ESP32 continues acquisition, FFT processing, and real-time detection, updating status and frequency on the T-Watch TFT display. BLE automatically restarts advertising and reconnects after disconnection, whereas Wi-Fi/HTTP only checks connectivity through isWiFiConnected() and skips transmission when unavailable, with no explicit dashboard alert. This limitation is acknowledged as future work, including circular buffering, resilient reconnection, and data retransmission.

Future work will clinically validate the system using individuals with Parkinson's disease and age-matched controls, with standardized resting tests under different medication and postural conditions. Measurements will be compared with UPDRS Part III assessments and a validated medical-grade wearable, analyzing frequency, amplitude, spectral energy, duration, and cross-device agreement through correlation, Bland–Altman analysis, sensitivity, and specificity. This protocol is planned for future validation and is not part of the present experimental results.

Amplitude repeatability metrics (mean, standard deviation, and coefficient of variation) were not collected in the original trials, which focused on real-time mean magnitude, FFT peak frequency, and tremor detection. As these parameters cannot be retrospectively derived without baseline records, dedicated controlled tests are proposed for future evaluation.

As future work, embedded artificial intelligence algorithms are recommended for classifying tremor patterns, including lightweight models capable of running on the ESP32 or edge devices. The dashboard may also be expanded with clinical metrics, session reports, patient history, configurable filters, and integration with digital health platforms. Another improvement involves the use of security and authentication protocols for the transmission of sensitive data, especially in clinical or home-based applications.

Finally, it is suggested to compare the prototype with reference instruments, expand the test dataset, and investigate the combined use of accelerometer and gyroscope. Including contextual data, such as time, medication, posture, and activity performed, may increase the clinical relevance of records. These extensions can transform the prototype into a research platform for biomedical engineering and digital health.

IX. CONCLUSION

This work developed and technically evaluated a wearable prototype based on the T-Watch 2020 V2, integrating ESP32, BMA423, Wi-Fi, BLE, FFT processing, and a containerized web dashboard. The system captured and processed acceleration signals, identified oscillations in the typical 4–6 Hz range under controlled manual and synthetic test conditions, and provided real-time visualization, achieving its objective as a low-cost, portable proof of concept. Nevertheless, the study did not include clinical validation with individuals with Parkinson's disease; functional evaluation was limited to synthetic signals and controlled manually generated tremor-like wrist movements, representing an initial technical validation of the proposed architecture. Future work should include formal clinical validation with patients, improve algorithm robustness against voluntary movement artifacts, optimize power consumption, implement health-data encryption, and investigate intelligent classification methods to support applications in clinical and digital health research.

Abstract*—Quantitative gait analysis supports the diagnosis and rehabilitation of motor disorders. The optoelectronic systems taken as the gold standard, however, are expensive and tied to specialized laboratories. This work presents the development and bench validation of a low-cost, wireless, wearable system for angular and temporal gait measurement. Sensor nodes built around the MPU-6050 and the ESP32 talk to a receiver over ESP-NOW in a star topology, so nothing is cabled to the body. The knee flexion–extension angle is reconstructed on-line on the receiver node through a per-segment complementary filter ($\alpha = 0.98$) and streamed to a monitoring application, while gait-cycle segmentation is performed offline by gyroscope-based peak detection. Two independent protocols were applied. Angular accuracy was assessed statically on a rigid bench fixture against a digital protractor ($\pm 0.5^{\circ}$), which characterizes the measurement subsystem in isolation from soft-tissue artifact. A first acquisition showed the prototype underestimating every angle by 2.37°. Inspection traced this to a tilted sensor package; the component was resoldered and the acquisition repeated. The mean absolute error then fell below the resolution of the reference instrument, to 0.025°, with a residual that no longer favoured either direction and an unchanged within-angle repeatability of 0.056°. Both figures bound the residual error rather than quantify it. The swing duration derived from the detected gait events was compared with two-dimensional videogrammetry during slow-cadence walking, yielding a mean absolute error of 0.02 s, of the order of one video frame at 60 frames per second; absolute event instants on a common time base were not compared. The wireless link was characterized separately during walking over 211,007 packets: no packet was lost, and the standard deviation of the inter-arrival interval remained below 4 ms. Link-level latency, measured over 1000 frames per node, had a median one-way value of 1.0–1.2 ms with a 99th percentile below 13 ms, an order of magnitude under the limit specified for medical wireless body area networks. Dynamic knee kinematics were not validated against a kinematic reference; this is stated as a limitation. With a total material cost of approximately BRL 94 (about USD 17), the results support the technical feasibility of the wireless architecture as a basis for future clinical validation.

***Index Terms*—Gait analysis, wearable system, ESP32, ESP-NOW, inertial sensors, wireless body area network.**

I. Introduction

Human gait depends on the integrated action of the central nervous system, the sensory system, and the musculoskeletal apparatus. Changes in the walking pattern are frequently among the first observable indicators of functional decline or underlying pathology, and walking speed has been proposed as an additional clinical indicator in geriatric assessment [1]. Neurological conditions such as stroke and Parkinson's disease, orthopedic disorders, and natural aging alter gait parameters and increase the risk of falls, a relevant public health problem among the elderly [2].

Three-dimensional optoelectronic systems combined with force platforms remain the reference method, and they deliver millimetric precision. They also cost tens of thousands of dollars and need fixed laboratory space, trained operators, and controlled capture conditions [3]. In Brazilian public services and university hospitals, that combination keeps quantitative gait assessment out of reach.

Microelectromechanical systems (MEMS) inertial sensors make compact, low-power wearables possible at a fraction of that cost [4]. Going wireless lifts the spatial constraint of fixed cameras, so data can be collected in corridors, outdoors, or at home [5]. Among the available wireless technologies, the ESP-NOW protocol developed by Espressif Systems operates in the 2.4 GHz band without requiring network infrastructure or association handshakes, allowing direct peer-to-peer transmission with low reported latency and reduced energy consumption [6], [7].

This work presents the development and bench validation of a low-cost, wireless, wearable system for the acquisition of

kinematic gait parameters, based on inertial sensor nodes controlled by ESP32 microcontrollers and communicating through ESP-NOW. In contrast to a purely offline pipeline, the knee angle is reconstructed on-board the receiver node and made available on-line through a dedicated monitoring interface. The primary contribution reported here is the wireless, cable-free node architecture and its metrological characterization on a bench fixture; clinical gait accuracy is explicitly outside the scope of this validation and is identified as the next stage of the work.

II. Materials and Methods

A. System Architecture

The system is a Wireless Body Area Network (WBAN) in a star topology [7]: mobile sensor nodes on the body segments and a fixed concentrator node. Each node samples its inertial sensors and transmits raw packets over ESP-NOW to the master. Two configurations are used, validated independently (Fig. 1).

In the *temporal configuration* (Fig. 1a), a single node is placed on the distal shank (lateral tibia). The master acts as a data concentrator that forwards the raw stream over the serial interface, and the gait-event segmentation is performed offline. Because a single camera cannot record both limbs without occlusion, each lower limb was instrumented and validated separately, one at a time.

In the *angular configuration* (Fig. 1b), two nodes are placed on the thigh (distal femur) and shank (proximal tibia), aligned with the knee flexion axis. Here the master does more than concentrate: it reconstructs the knee flexion–extension angle on-board and streams it to a workstation for live display and recording. This on-board reconstruction is the main architectural change with respect to the earlier, fully offline version.

B. Hardware Development

Each node integrates an ESP32 microcontroller and an MPU-6050 inertial sensor in a compact assembly powered by an autonomous supply composed of a lithium battery managed by a TP4056 charging module and controlled by a physical on/off switch. The circuit was designed in Proteus Design Suite, with the schematic drawn in the ISIS environment and the printed circuit board (PCB) layout defined in the ARES environment. Communication between the ESP32 and the MPU-6050 used the I2C bus operating at 3.3 V, with the clock line (SCL) on GPIO 22 and the data line (SDA) on GPIO 23.

A ground plane covers the empty areas of the board to mitigate electromagnetic interference between the radiofrequency transceiver and the high-sensitivity MEMS sensor [11]. The layout was transferred to the substrate by laser mask ablation, which gives finer track resolution than conventional thermal methods [12], and the exposed copper was removed in ferric chloride. The assembly was encapsulated in heat-shrink tubing, and adjustable hook-and-loop straps fix it to the body segment while limiting motion artifacts [13].

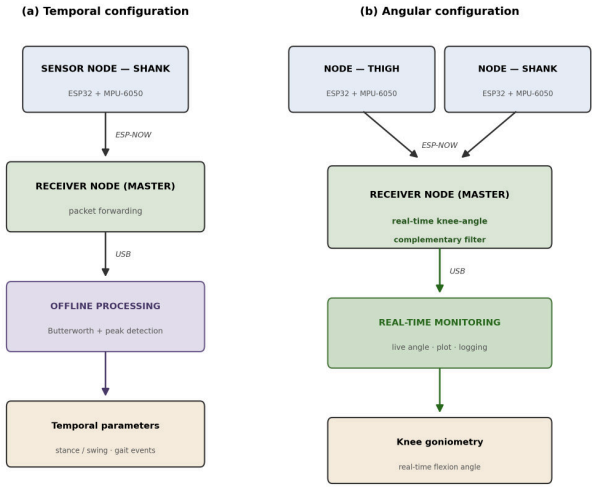

Fig. 1. Block diagram of the two operating configurations: (a) the temporal configuration, with a single shank node and offline event segmentation; (b) the angular configuration, with thigh and shank nodes and on-line knee-angle reconstruction on the receiver node.

C. Firmware and Link Characteristics

Each sensor node configures the MPU-6050 with a full-scale range of ± 2 g for the accelerometer and $\pm 250^\circ$/s for the gyroscope, with the internal digital low-pass filter enabled at approximately 44 Hz as an anti-aliasing mechanism [14]. It should be noted that this cutoff sits close to the 50 Hz Nyquist limit of the 100 Hz output rate, so the attenuation available between 44 and 50 Hz is modest and the anti-aliasing margin is narrow; components above the Nyquist frequency are attenuated rather than suppressed. The ± 2 g range was selected to maximize resolution for the inclination estimate that anchors the complementary filter, since the fusion relies on the gravity vector; this choice, however, may saturate the accelerometer during high-impact transients such as heel strike, and the vertical accelerometer axis is therefore used only as a qualitative corroboration of the detected events, never as a quantitative input to the angle reconstruction. An automatic 3 s calibration routine, executed with the node stationary, estimates the static gyroscope bias, which is subtracted from subsequent readings; the accelerometer output retains the gravity component required for inclination estimation. Each node reads the six inertial axes at a nominal rate of 100 Hz, controlled by timer interrupts, and transmits them as raw data packets through ESP-NOW. This sampling rate is justified by the Nyquist theorem and by the spectral characteristics of human movement, whose kinematic power lies mostly below 6 Hz, providing sufficient oversampling to capture fast transients [15].

The receiver node operates in continuous reception mode. A single packed data structure holds the six inertial axes, a per-node timestamp, and an explicit side identifier that unambiguously routes each packet to the thigh or shank buffer. Nodes do not share a common time base: each node timestamps

its own samples from its local timer, and the master aligns the two segment streams by arrival order, which is adequate for the sagittal difference of (2) at the cadences tested but does not constitute clock synchronization in the strict sense. The receiver firmware includes a characterization mode that timestamps every reception with microsecond resolution and logs it together with the originating node timestamp, which supports the direct measurement of packet delivery, inter-arrival jitter, and relative clock drift reported in Section III-A. The difference between the two timestamps cannot yield absolute latency, since it contains an unknown clock offset. Link-level latency was therefore measured separately through the transmission-complete callback of the ESP-NOW stack, which fires when the frame has been transmitted and acknowledged at the MAC layer: the receiver learns each node address from the incoming stream, then issues 1000 frames of the same 29-byte payload to one node at a time and records the elapsed time on a single clock, avoiding any dependence on inter-node synchronization. The resulting figure is a MAC-level round-trip time and does not include sensor sampling or host-side processing, so it bounds the transport contribution rather than the full acquisition-to-display path.

In the temporal configuration, the master forwards the received stream for offline segmentation. In the angular configuration, the master updates a per-segment complementary filter (Section II-D) and outputs the reconstructed knee angle over the USB serial port at 115200 baud in a lightweight comma-separated format; a single-character serial protocol then allows the operator to reset the angular reference (pose-based zeroing) and to select the sagittal rotation axis without reflashing the device.

D. Signal Processing

The processing was divided into two paths with distinct timing requirements. The angular reconstruction runs on-line on the receiver node, whereas *the temporal event segmentation is performed entirely offline*, in Python (Google Colab), after the acquisition session; no gait event is detected on-line by the present firmware. Sensitivity factors of 16384 LSB/g for the accelerometer and 131 LSB/°/s for the gyroscope were applied to convert raw digital values into physical units [14].

For each segment, a complementary filter fuses the low-frequency stability of the accelerometer with the fast response of the gyroscope, correcting the gyroscope drift [16], [17]:

$$\theta(t) = \alpha\,[\theta(t-\Delta t) + \omega\,\Delta t] + (1-\alpha)\,\theta_{\mathrm{acc}}, \qquad (1)$$

with Δt derived from the packet timestamps. The weighting factor was set to $\alpha = 0.98$, which places the gyroscope–accelerometer crossover near 0.3 Hz at the 100 Hz update rate, below the 0.5–6 Hz band of interest for gait. It was chosen empirically as the lowest weighting that held a flat plateau during static postures without admitting visible accelerometer noise. Drift correction is thus continuous and implicit: the accelerometer term permanently re-anchors the integrated gyroscope estimate, so no high-pass detrending or periodic re-zeroing is applied during a session. The accelerometer inclination

Fig. 2. Monitoring interface during a sustained flexion, showing the instantaneous knee angle, the rolling angle plot and the link status.

θ_{acc} is obtained from the gravity vector through the `atan2` function in the sagittal plane; the accelerometer–gyroscope innovation is wrapped to the $[-180°, 180°]$ interval before fusion, ensuring continuity across the angular discontinuity of `atan2` at large flexion angles. The knee flexion–extension angle is obtained by the algebraic difference between the shank and thigh angles, referenced to a static pose calibration acquired in the neutral position [18], as expressed in (2):

$$\theta_{\mathrm{knee}}(t) = \theta_{\mathrm{shank}}(t) - \theta_{\mathrm{thigh}}(t) - \theta_{\mathrm{offset}} \qquad (2)$$

where θ_{offset} is captured on demand through the serial reset command. Because the fusion preserves the accelerometer anchoring without high-pass detrending, the reconstructed angle sustains static postures without drifting back toward zero, a prerequisite for goniometric use.

For the temporal path, a fourth-order Butterworth low-pass filter with a 6 Hz cutoff was applied offline to the gyroscope signal [15]. A peak-detection algorithm identified the large-amplitude valleys corresponding to mid-swing; from this reference, search windows located the heel strike (zero crossing of angular velocity immediately after the valley) and the toe-off (positive angular-velocity peak immediately before the valley) [19]. Cadence, swing time, and stride time were then computed automatically.

E. Monitoring Interface

A desktop application receives the serial stream, displays the instantaneous knee angle and a rolling time plot, triggers the pose-based zeroing, and logs the data to file. Fig. 2 shows it during a sustained flexion, with the stable plateau characteristic of the on-board complementary filter. It confirmed the feasibility of on-line operation, but the quantitative validation reported below relied on controlled acquisitions rather than on the interface.

F. Experimental Protocols

Experiments were conducted in a controlled indoor environment on a flat, obstacle-free surface under constant artificial lighting. Data were collected through self-experimentation with a single healthy volunteer with no history of musculoskeletal or neurological disorders, in accordance with the

ethical principles of CNS Resolution No. 466/2012. Because the study consisted of technical instrumentation validation without clinical intervention, it was treated as an engineering bench and functionality test.

In Protocol 1 (dynamic, temporal parameters), a single node was fixed to the lateral shank (distal tibia), chosen for its higher angular acceleration during swing [17]. A tripod-mounted camera perpendicular to the sagittal plane at 2.5 m recorded at 60 frames per second [3], and a strong vertical foot stomp before walking synchronized video and sensor signals [20]. The subject walked barefoot along a linear path at a slow, controlled pace, five alternating steps, capturing two complete cycles of the instrumented limb within the camera field of view. This protocol assesses the *duration between detected gait events* only; the knee angle was not reconstructed or compared against any reference during walking.

In Protocol 2 (static, angular parameters), accuracy was assessed on a bench fixture rather than on the limb, so that reference angles could be imposed with known uncertainty. The two modules were rigidly fixed to the arms of a digital protractor ($\pm 0.5^{\circ}$) acting as an articulated ground truth, each aligned to one arm so the inter-arm angle matched the reconstructed joint angle. The fixture is mechanically repeatable but not traceable to a national standard; a calibrated rotary stage is identified as future work. Four target angles spanning the functional flexion range (30°, 60°, 90°, 120°) were set, with five repetitions each and a full zero recalibration between repetitions. Each posture was held stationary and the mean over the stable plateau compared against the protractor reading.

G. Validation Procedure

Validation has two stages that answer different questions and must not be conflated. The static stage characterizes the *angular precision and trueness of the measurement subsystem* on the bench: reconstructed angles were compared with the protractor readings, and absolute and relative errors, within-angle repeatability and a linear regression against the reference were computed. The dynamic stage characterizes the *duration between discrete gait events* during walking, with heel strike and toe-off identified frame by frame in Kinovea [21], [22]; absolute event instants on a common time base were not compared. Dynamic angular accuracy, the agreement of the continuous knee-angle trajectory against a kinematic reference, was not assessed in either stage. Mean absolute error (MAE) is the primary metric in both domains [23], [24].

III. Results and Discussion

A. Wireless Link Characterization

The low-latency premise behind the architecture had never been checked against measurement, so the link was characterized during walking. This is both the condition of interest and the one where body shadowing hurts a 2.4 GHz channel most. Both nodes transmitted at the nominal 100 Hz while the subject walked the path used in Protocol 1. Three repetitions were acquired under normal laboratory conditions and a fourth with a deliberate 2.4 GHz interferer, a mobile device sustaining a large download, about 1 m from the nodes. Packet delivery was inferred from discontinuities in the per-node timestamp stream. Jitter was taken as the standard deviation of the reception intervals, with the intervals adjacent to a discontinuity excluded. Relative clock drift came from the slope of the difference between reception time and node timestamp across the session. In total, 211,007 packets were analyzed across the four acquisitions.

Table I summarizes the results. No packet was lost on either node in any acquisition, giving a packet delivery ratio of 100% under movement and comfortably above the 90% specified for wireless body area networks [8]. Across the three repetitions, inter-arrival jitter was 3.63 ± 0.40 ms for the thigh node and 2.33 ± 0.41 ms for the shank node, an order of magnitude below the 50 ms jitter limit of the same standard [8] and below the 16.7 ms frame interval of the video reference used in Section III-D; over 99.5% of the reception intervals fell within one video frame of the nominal 10 ms period. The interval distribution carries a long upper tail, with 99th percentiles between 16 and 22 ms. That is what one would expect from the slotted, retransmission-based channel access reported for ESP-NOW in field evaluations [9]. Dispersion across repetitions was small, so the link behaves reproducibly under this walking protocol.

Link-level latency was measured over 1000 frames per node, with no transmission failure or timeout in either case. The round-trip time distribution is strongly right-skewed and is best described by its median and percentiles rather than its mean: the median one-way latency was 1.22 ms for the thigh node and 1.04 ms for the shank node, rising to 8.79 ms and 7.38 ms at the 95th percentile and to 12.87 ms and 11.72 ms at the 99th percentile. A pronounced floor near 1.38 ms round trip, corresponding to about 0.69 ms one way, held 32% and 41% of the frames. This is of the same order as the 1.06 ms reported for a single-byte payload in a controlled comparison of ESP-NOW against other protocols [10], although the two figures are not strictly comparable because the reference does not state whether its value is a one-way or a round-trip delay, and the payload sizes differ. Above this floor the distribution decays smoothly rather than in discrete steps, which is compatible with a variable number of channel-access attempts under the slotted access reported for ESP-NOW [9], although the present data do not resolve individual retransmission events. Taking one video frame at 60 frames per second as the reference scale, 99.7% and 100% of the frames respectively had a one-way latency below that interval. All values remain more than an order of magnitude below the 125 ms latency specified for medical applications in wireless body area networks [8].

Relative clock drift was -50.8 ± 2.9 ppm for the thigh node and -67.0 ± 1.4 ppm for the shank node. Each node repeated its own value far more closely than the two nodes agreed with each other, which points to the crystal oscillator rather than to a measurement artifact. This quantifies the absence of a shared time base noted in Section II-C: at 100 Hz, a drift of this magnitude accumulates less than one sampling

TABLE I
ESP-NOW LINK CHARACTERIZATION DURING WALKING (TWO NODES AT 100 HZ)

Metric	Thigh	Shank	Req.
Three repetitions, normal conditions			
Packets analyzed	75558	75538	–
PDR (%)	100.00	100.00	> 90
Jitter σ (ms)	3.63 ± 0.40	2.33 ± 0.41	< 50
Jitter P99 (ms)	20.6–22.5	16.5–18.5	–
Clock drift (ppm)	-50.8 ± 2.9	-67.0 ± 1.4	–
Link-level latency, 1000 frames per node			
Latency median (ms)	1.22	1.04	< 125
Latency P95 (ms)	8.79	7.38	–
Latency P99 (ms)	12.87	11.72	–
Tx failures	0	0	–
Single acquisition, 2.4 GHz interferer at 1 m			
PDR (%)	100.00	100.00	> 90
Jitter σ (ms)	2.72	1.75	< 50

Requirements from IEEE Std 802.15.6 [8]. Mean $\pm$ SD across repetitions; no packet lost in any acquisition. Latency is a MAC-level round-trip time halved (Section II-C).

interval over several minutes, which is compatible with the duration analysis reported here but would become relevant for applications requiring long-term inter-node alignment. Under the interference condition, the packet delivery ratio remained at 100% and the jitter was no higher than in the uncontaminated repetitions (2.72 ms and 1.75 ms); the tested interferer therefore produced no detectable degradation, which should be read as a limitation of the severity of the test rather than as evidence of immunity to radiofrequency interference in general. Taken together, these measurements bound, under movement, the loss and delay contributed by the wireless link, independently of the segmentation results reported in Section III-D.

B. Developed System

The result is two compact wearable devices with no cabling on the sensor nodes. The system is modular: temporal analysis uses a single node on the lateral shank, while knee goniometry uses both nodes aligned with the femur and tibia. Validation was unilateral, but the architecture scales, and bilateral use would enable gait symmetry analysis. Fig. 3 shows both configurations. Each node weighs about 20 g and runs from a 1200 mAh lithium-polymer cell; at roughly 50 mA in active operation the estimated autonomy is around 24 h. Total material cost was approximately BRL 94 (about USD 17 at 2025 exchange rates).

C. Static Bench Validation of the Measurement Subsystem

The angular accuracy of the reconstruction was assessed against the digital protractor at four target angles spanning the functional flexion range, with five repetitions per angle and a full zero recalibration between repetitions. These figures describe the instrument under stationary bench conditions and are not estimates of in-vivo goniometric accuracy.

A first acquisition showed the prototype reading low at every angle. The absolute error stayed between 2.36° and 2.38°, moving by only 0.02° across a 90° span, and it carried the same sign throughout. An error that constant does not come from the angle or from noise; it comes from a fixed source.

Fig. 3. Positioning of the prototypes on the volunteer's lower limb, illustrating the intended body mounting: the single-sensor configuration used in the temporal protocol (walking trials) and the two-sensor configuration for knee-angle reconstruction. The angular accuracy reported in Table II was obtained on the bench protractor fixture of Protocol 2, not on the limb shown here.

Regression against the reference returned a slope of 0.9999, which ruled out a scale error in the fusion algorithm and left misalignment between the sensitive axes and the mechanical reference as the likely cause. Inspecting the assembly, we found the sensor package visibly tilted with respect to its printed circuit board. The component was resoldered and the acquisition repeated in full.

Table II reports the measurements obtained after remounting. The systematic offset is no longer observed: the individual errors are $+0.03^\circ$, -0.05°, 0.00° and $+0.02^\circ$, alternating in sign, with a mean signed error of 0.00° and a mean absolute error of 0.025°. The residual disagreement is therefore no longer systematic, and is consistent with the finite resolution of the reference and the intrinsic dispersion of the device. The regression against the reference gives a slope of 1.0001 with $R^2 \approx 1.000$.

Two observations point back to the mounting as the origin of the offset. The error went from a constant 2.37° bias to a residual with no preferred direction, which is what removing a trueness error looks like, not what a change in noise would produce. Repeatability, meanwhile, barely moved: the mean standard deviation across the four angles was 0.056° before and after remounting, with worst cases of 0.082° and 0.078°. A tilted mount displaces the reading without adding noise, so correcting it should erase the bias and leave the dispersion alone. That is what happened. The evidence remains observational, though. We ran no controlled comparison isolating the remounting from the rest of the handling, so the attribution is plausible rather than proven.

It should be emphasized that the resulting mean absolute error of 0.025° lies well below the $\pm 0.5^\circ$ resolution of

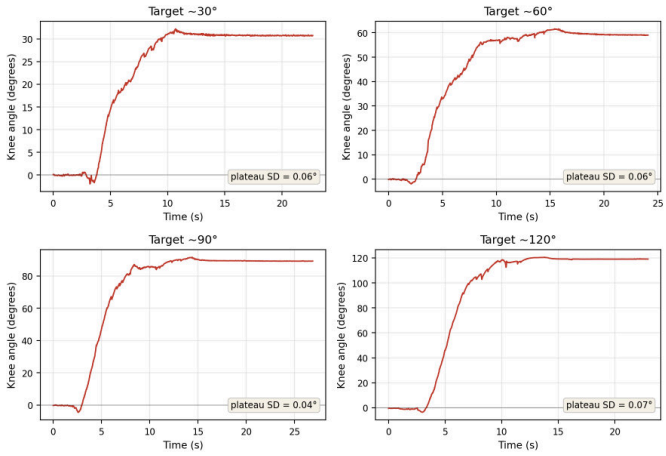

Fig. 4. Representative knee-angle series measured by the prototype during held postures on the bench fixture, showing stable plateaus without drift.

TABLE II
STATIC BENCH VALIDATION AFTER SENSOR REMOUNTING: PROTOTYPE VERSUS DIGITAL PROTRACTOR (FIVE REPETITIONS PER ANGLE)

Reference (°)	Mean (°)	SD (°)	Abs. error (°)	Rel. error (%)
29.98	30.01	0.041	0.03	0.10
60.01	59.96	0.065	0.05	0.08
89.99	89.99	0.078	0.00	0.00
119.97	119.99	0.039	0.02	0.02

Reference: mean digital-protractor reading. SD: within-angle standard deviation over five repetitions. Mean absolute error $0.025°$, below the $\pm 0.5°$ resolution of the reference.

the digital protractor. This figure must therefore be read as evidence that the residual error is no longer resolvable with the present reference, and not as a claim of accuracy at that level; establishing the actual accuracy would require a reference of finer resolution, such as a calibrated and traceable rotary stage, which is identified as future work. The same caveat applies to the reported repeatability, whose dispersion is roughly one order of magnitude finer than the reference resolution. It should also be noted that this repeatability is a measure of internal precision, the dispersion of repeated readings of the device under a nominally fixed angle, and not of agreement with the reference. Both figures remain well within the $2°$–$5°$ inter-examiner variability reported for manual goniometry [24], a comparison developed in Section III-E as context for the intended application. The time series (Fig. 4) remained flat during the held postures, with no observable slope, confirming that the complementary filter sustains static positions without drift over the durations tested.

D. Dynamic Validation of Swing Duration

In the dynamic stage, acquisition covered both lower limbs. Because of the field-of-view restriction of the single-camera 2D videogrammetry, the left and right legs were recorded in independent trials under the same slow, controlled walking protocol. Two-dimensional videogrammetry is itself subject to perspective and out-of-plane errors relative to three-dimensional optoelectronic capture [27], so it is adopted here as an accessible temporal reference rather than as a kinematic gold standard. Fig. 5 shows the raw gyroscope signal, the filtered angular velocity with the automatically detected events, and the raw vertical accelerometer axis, whose impact peaks qualitatively corroborate the detected events.

TABLE III
SWING DURATION: PROTOTYPE VERSUS VIDEOGRAMMETRY

Limb	Sensor mean (s)	Video mean (s)	Abs. error (s)
Left	0.59	0.61	0.02
Right	0.64	0.66	0.02
Overall	0.61	0.63	0.02

Video mean from frame counting between toe off and heel strike. One frame at 60 fps ≈ 0.017 s.

Over two consecutive cycles per limb, mean stance and swing times were 1.08 s and 0.59 s on the left (roughly 65%/35%) and 0.96 s and 0.64 s on the right, the latter close to the 60%/40% ratio reported for normal gait [15]. Cycle durations near 1.6 s are longer than those typical of comfortable-speed walking, reflecting the deliberately slow cadence used to keep the limb within the camera field of view; the values therefore describe this specific condition and should not be compared with normative data acquired at self-selected speed. With a single subject and few cycles, these proportions are illustrative rather than statistically representative.

Table III details the swing-duration comparison against videogrammetry. The quantity compared is the *swing duration*, that is, the interval between the detected toe-off and the subsequent heel strike, and not the absolute instant of either event on a common time base. The mean absolute discrepancy was 0.02 s in both limbs. Considering that the camera operated at 60 frames per second, one frame corresponds to approximately 0.017 s, so the observed discrepancy is of the order of a single frame, that is, at the resolution limit of the reference.

The scope of this result should be stated carefully. Because a constant delay in the acquisition chain affects the detected toe-off and heel strike equally, it cancels in the difference between them; a duration comparison is therefore insensitive to fixed transmission delay and cannot be used to bound it. What the agreement in Table III supports is that the segmentation algorithm recovers the swing interval to within the resolution of the video reference. The delay of the wireless chain is bounded separately and directly by the latency measurement of Section III-A. Nor does the comparison establish that the prototype is more or less precise than the video, since the reference cannot discriminate differences below its own frame interval. Absolute event-timing error, which would require both signals expressed on a common time base through the stomp synchronization, was not quantified and is identified as future work. It should also be noted that the left and right limbs were recorded separately, so bilateral synchrony was not assessed.

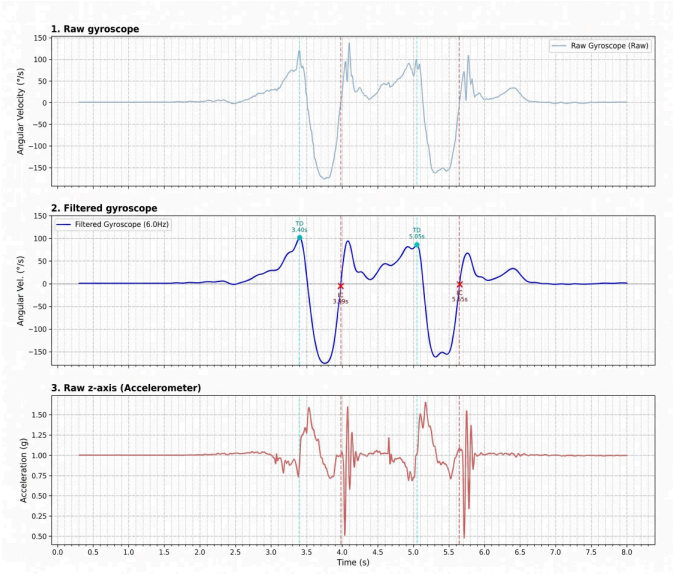

Fig. 5. Gait event detection for one limb: raw gyroscope signal, filtered angular velocity with the automatically detected toe-off and heel-strike events, and raw vertical accelerometer axis. All processing shown was performed offline.

E. Comparison with Previous Studies

The post-remounting bench accuracy and the sub-0.1° repeatability are finer than the 2°–5° inter-examiner variability reported for manual goniometry [24], though both are bounded by the resolution of the reference used here. This says the measurement subsystem is not the limiting factor relative to the manual instrument it might replace. It does not establish clinical equivalence, since the in-vivo error budget should be dominated by soft-tissue artifact rather than by the instrument.

Against other academic prototypes the difference is architectural. Many previous designs wire the lower-limb sensors to a processing unit at the waist, which restricts movement and adds a tripping risk that can alter the very gait pattern under assessment [4], [5], [25]. Independent nodes communicating over ESP-NOW remove that cabling. ESP-NOW is also reported as advantageous over classic Bluetooth, which can introduce variable latency and packet loss in body networks [26]; we adopt that as a design premise and offer no comparative measurement against Bluetooth Low Energy, which remains open.

F. Limitations

The validation was a single-subject case study with a healthy volunteer, a proof of concept focused on the hardware architecture rather than a statistically generalizable evaluation. For the same reason, formal agreement analyses such as Bland–Altman plots, limits of agreement and test–retest reliability were not applied to the angular data: they require a representative sample of paired measurements across subjects, and they remain necessary steps in future multi-subject validation.

The scope of the angular validation is the most consequential limitation. It was performed on a rigid bench fixture, which isolates the measurement subsystem from soft-tissue artifacts but does not reproduce in-vivo fixation; the reported accuracy characterizes the instrument, not the in-vivo joint-angle estimate, where soft-tissue motion should dominate the error budget. Static agreement at held postures also does not validate dynamic knee kinematics. The continuous angle trajectory during walking was never compared against a kinematic reference, and we make no claim about dynamic angular accuracy. Establishing it would require comparison against optical motion capture, or validated commercial inertial units, in multiple participants, reporting bias, limits of agreement, event-timing error and test–retest reliability.

Because the two segment streams are aligned by arrival order rather than by a shared clock, a misalignment of a single sample, that is 10 ms at the 100 Hz rate, is possible. At the segment angular velocities observed during swing in these trials, of the order of 10^2 °/s, such a misalignment would translate into an instantaneous error of a few degrees in the reconstructed knee angle. This reinforces, rather than weakens, the decision not to claim dynamic angular accuracy.

Regarding the wireless link, the latency reported in Section III-A is a MAC-level round-trip time measured on a single clock and halved; it therefore bounds the transport contribution but excludes sensor sampling and host-side processing, and it assumes a symmetric link. The full acquisition-to-display latency was not measured and would require instrumentation at both ends of the chain. The interference test employed a single interferer at close range and produced no detectable degradation, so it does not establish robustness under the denser radiofrequency environments typical of clinical settings; robustness was likewise not evaluated with more than two nodes or at extended range. In addition, ESP-NOW imposes an upper bound on the number of simultaneously registered peers, which constrains the proposed expansion to a full kinematic chain and would require either peer management at run time or a hierarchical topology.

At the sensor level, the ± 2 g range may saturate during heel-strike transients, and the noise floor of the MPU-6050 was not characterized. Without a magnetometer, absolute three-dimensional orientation is unrecoverable, which motivated the sagittal-plane formulation: axial rotations and abductions are not discriminated and may introduce error, and the sagittal axis must be reconfirmed whenever the mounting changes. The system also does not quantify stride length, walking velocity or three-dimensional joint trajectories, whose inertial estimation requires double integration and would demand robust fusion such as Kalman filtering [17], [28].

IV. Conclusion

This work developed and bench-validated a low-cost wireless wearable prototype for gait measurement, removing the cabling that constrains movement in comparable academic prototypes. Pairing the ESP32 with the MPU-6050 yielded small, easily attachable devices, and the ESP-NOW link was stable throughout the acquisitions. Moving the angular recon-

struction on-board the receiver delivered the knee angle online, sustaining static postures without drift.

Three quantities were characterized here, and they answer different questions. Under stationary bench conditions, an initial systematic error of 2.37° was traced to a tilted sensor package and eliminated by remounting the component, after which the mean absolute error fell to 0.025° with unchanged repeatability; both figures lie below the resolution of the reference instrument and therefore bound the residual error rather than quantify it. During walking, the swing duration recovered from the detected events agreed with videogrammetry to within 0.02 s, of the order of one video frame; absolute event timing was not compared on a common time base. The wireless link was characterized under the same movement condition, with no packet loss over 211,007 analyzed packets and an inter-arrival standard deviation below 4 ms, substantiating by measurement the low delay-variation premise of the architecture. Link-level latency had a median one-way value of about 1 ms with a 99th percentile below 13 ms and no transmission failure over 2000 frames. Dynamic knee kinematics, however, were not validated against a kinematic reference, and no result reported here should be read as evidence of clinical gait accuracy.

The contribution reported here is therefore the wireless, cable-free node architecture together with its metrological characterization on the bench. Future work includes physical optimization using surface-mount components, instrumentation of the full acquisition-to-display latency, evaluation under denser radiofrequency environments and with additional nodes, expansion of the topology for full kinematic-chain reconstruction and synchronous bilateral validation [7], characterization of the residual angular error against a traceable rotary stage of finer resolution, comparison against optical motion capture in multiple participants, evaluation in pathological gait such as Parkinson or post-stroke populations, and the incorporation of magnetometers for nine-axis sensor fusion together with Kalman filtering and zero-velocity update (ZUPT) techniques to enable estimation of velocity and distance [4], [28].

***Abstract*—Several studies on Electrical Impedance Tomography (EIT) and impedance image reconstruction using the EIDORS framework have been reported in the literature. However, the implementation of complete EIT systems remains challenging due to the complexity of the analog front-end, current injection circuitry, signal acquisition, and image reconstruction. This work presents a noninvasive 16-electrode EIT system for reconstructing electrical impedance images of cylindrical phantoms using open-source software. The proposed architecture comprises a modified Howland current source configured for a nominal 1 mA excitation current at 47.3 kHz, analog signal conditioning, electrode multiplexing, an ESP32-based data acquisition unit, and image reconstruction using the EIDORS framework in GNU Octave. A 16-electrode adjacent stimulation protocol was adopted, providing 208 measurements per acquisition cycle. Experimental results obtained with insulating objects immersed in a conductive phantom demonstrate that the proposed system is capable of detecting conductivity perturbations and qualitatively identifying changes in their relative positions, demonstrating the functional operation of the acquisition and image reconstruction chain under the tested phantom conditions.**

***Index Terms*—Electrical Impedance Tomography, ESP32, biomedical instrumentation, Howland current source, image reconstruction, data acquisition.**

I. Introduction

Electrical Impedance Tomography (EIT) is a non-invasive and radiation-free imaging technique based on the application of low-amplitude alternating electrical currents through electrodes positioned on the boundary of an object and the measurement of the resulting boundary voltages [1], [2]. From these measurements, the internal conductivity distribution, or changes in this distribution, can be estimated through an image reconstruction algorithm. This technique has been applied in areas such as quality control, fault detection, geological exploration, bioimaging, and disease monitoring, particularly of the lungs [3], [4].

Compared with other medical imaging techniques, such as X-ray, computed tomography (CT), and positron emission tomography (PET), EIT offers advantages including the absence of ionizing radiation, portability, and the potential for high temporal resolution. However, EIT has relatively low spatial resolution and an ill-posed inverse problem, making accurate reconstruction challenging and more suitable for repeated functional monitoring than for high-resolution anatomical diagnosis [10].

Several EIT systems have been reported in recent years using embedded platforms, dedicated analog front-ends, and open-source reconstruction software [4]–[7], [12]–[17], [23], [24]. These studies have contributed to the development of compact and reproducible experimental platforms for instrumentation research and algorithm evaluation.

This study proposes an Electrical Impedance Tomography (EIT) system for impedance image reconstruction using 16 electrodes and commercially available electronic components. The proposed architecture comprises a modified Howland current source, analog signal conditioning, electrode multiplexing, an ESP32-based data acquisition unit, and image reconstruction using the open-source EIDORS framework in GNU Octave. Experimental evaluation was performed using a cylindrical phantom filled with tap water, with insulating objects introduced at different positions to assess the ability of the system to detect conductivity perturbations and qualitatively reproduce changes in their relative positions.

II. Theoretical Background

Under the quasi-static approximation, the electric potential in Electrical Impedance Tomography (EIT) is governed by the conductivity equation [2], [12]:

$$\nabla \cdot (\sigma \nabla U) = 0 \tag{1}$$

where σ is the electrical conductivity distribution and U is the electric potential.

The forward problem in EIT can be represented using the Complete Electrode Model (CEM), which accounts for electrode dimensions and contact impedance and provides a realistic representation of practical electrode measurements [20]. Within the conductive domain Ω, and for each electrode e_l, the corresponding equations include

$$\nabla \cdot (\sigma \nabla U) = 0, \qquad \text{in } \Omega, \tag{2}$$

$$U + z_l \sigma \frac{\partial U}{\partial \eta} = U_l, \qquad \text{on } e_l, \tag{3}$$

where U_l is the electrode potential, z_l is the contact impedance, and η denotes the outward normal direction.

The forward problem computes boundary voltages from a known conductivity distribution, whereas the inverse problem estimates the internal conductivity distribution, or changes in this distribution, from boundary measurements. Since the inverse problem is ill-posed, regularization techniques are generally required to obtain stable solutions [9], [11], [21].

In this work, conductivity changes were reconstructed using difference EIT, in which measurements acquired from a homogeneous phantom were used as the reference dataset. Image reconstruction was performed using the EIDORS framework, as described in Section III-D.

III. METHODOLOGY

A. System Overview

The developed EIT system integrates hardware and software modules for data acquisition and image reconstruction. A constant-current excitation strategy was adopted using a modified Howland current source, a topology commonly employed in EIT and bioimpedance instrumentation [8]. The current source was configured for a nominal excitation current of 1 mA at 47.3 kHz during the experiments.

Fig. 1 illustrates the functional architecture of the proposed EIT system. A sinusoidal excitation signal at 47.3 kHz is applied to the modified Howland current source. The excitation current is routed to the phantom through an analog switching network composed of four analog multiplexers, which select the current injection (I_{inj}), current return (I_{ret}), and voltage measurement (V_{meas}) electrode pairs.

The measured differential voltage is amplified by an instrumentation amplifier, filtered by an active band-pass filter, and processed by a logarithmic magnitude detector. A reference signal derived from the excitation oscillator is applied to the detector reference input, allowing the magnitude output (V_{MAG}) to represent a logarithmic amplitude ratio between the measured and reference signals. Although the detector also provides a phase output, only V_{MAG} was acquired and used in the present implementation. Finally, an ESP32-based data acquisition unit digitizes the detector output, controls the multiplexers through GPIO signals, and transmits the acquired data to a host computer, where conductivity-change images are reconstructed using the EIDORS toolbox in the GNU Octave environment.

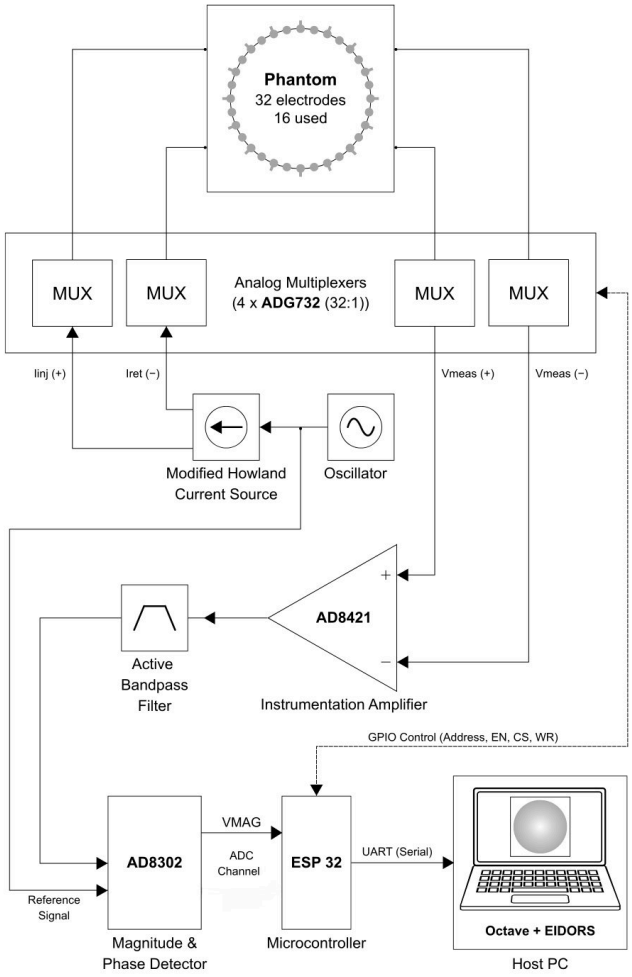

Fig. 1. Block diagram of the developed EIT system.

B. Hardware Design

The analog front-end of the developed EIT system was organized as a modular architecture comprising the excitation signal generator, a modified Howland current source, a voltage acquisition and conditioning circuit, a magnitude detection stage, an analog multiplexing network, and a digital control interface. Figure 1 illustrates the functional architecture of the system, while the following subsections describe the implementation of each hardware module.

The circuit was powered from external $+12$ V and -12 V supply rails. A regulated $+5$ V rail was locally generated from the $+12$ V supply using a linear voltage regulator. This voltage supplies the AD8302 detector, whose specified supply

range is 2.7–5.5 V [23]. The other analog stages operate from the ± 12 V supply.

The excitation signal generator, shown in Fig. 2, produces the sinusoidal reference signal used throughout the EIT system. This signal drives the modified Howland current source and simultaneously provides the reference input for the magnitude detection stage.

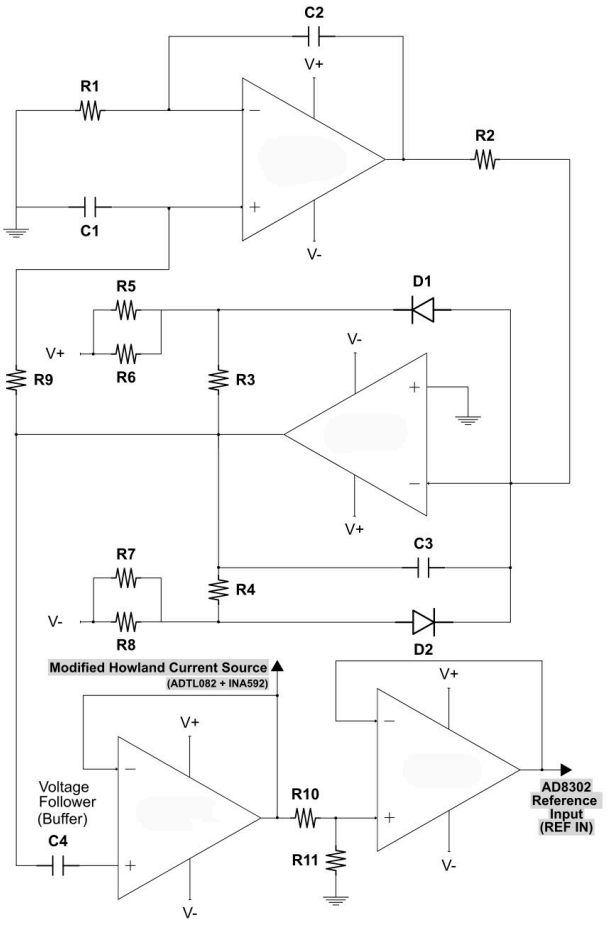

Fig. 2. Simplified schematic of the excitation signal generator based on the ADA4001-2 operational amplifier.

The generator is based on a Wien bridge oscillator, a well-established topology for producing sinusoidal waveforms using a small number of analog components [24], [25]. The oscillator was adjusted to operate at 47.3 kHz, which was adopted as the excitation frequency throughout the experimental measurements.

To stabilize the output amplitude, the oscillator employs a nonlinear amplitude-control network based on diode limiting. As the oscillation amplitude increases, the diodes modify the loop gain, limiting further amplitude growth [25].

The oscillator output is buffered by a voltage follower implemented with an ADA4001-2 operational amplifier. This stage isolates the oscillator from the following analog circuitry and reduces loading of the oscillator output [29].

A second buffered output is routed to the reference input of the AD8302 magnitude and phase detector. Thus, the detector receives a reference signal derived from the same oscillator used to drive the current-injection stage, allowing estimation of the measured signal magnitude [23].

The current injection stage, illustrated in Fig. 3, is based on a modified Howland current source. This topology is commonly employed in bioimpedance and EIT instrumentation, where a high output impedance is desirable to reduce variations in the excitation current caused by changes in load impedance [22], [34].

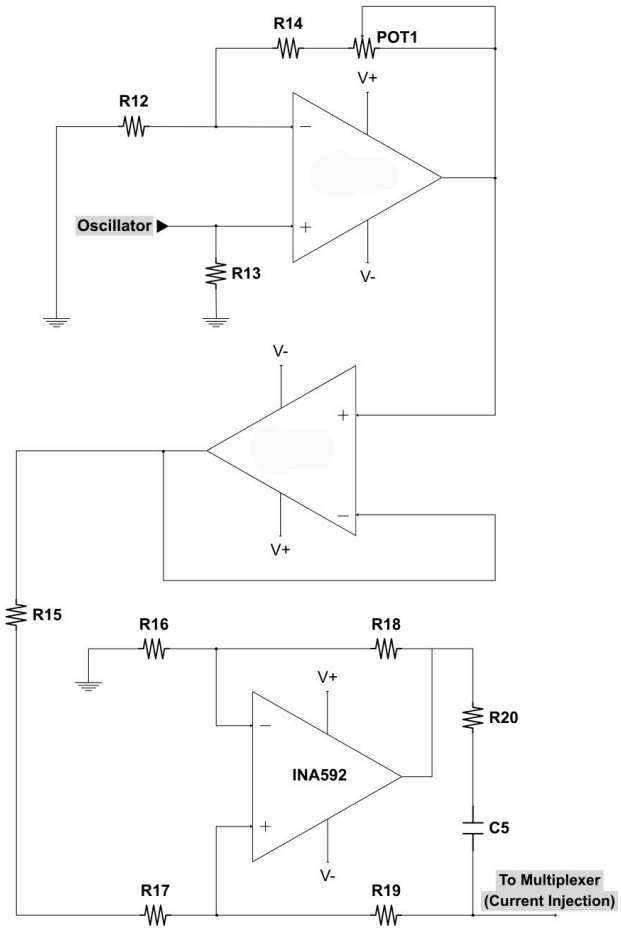

Fig. 3. Simplified schematic of the current injection stage.

The excitation signal generated by the oscillator is first applied to a non-inverting amplifier implemented with an ADA4001-2 operational amplifier. The feedback network, composed of a fixed resistor and the trimming potentiometer POT1, allows adjustment of the excitation amplitude and, consequently, of the nominal injected current.

The amplified signal is subsequently buffered by a second ADA4001-2 operational amplifier configured as a unity-gain voltage follower. This stage isolates the adjustable-gain stage from the following current-source circuitry, reducing loading of the preceding stage.

The buffered excitation voltage drives the modified Howland current source implemented with an INA592 difference amplifier. The resistor network establishes the voltage-to-current conversion and the resistor-ratio matching required by the Howland topology. Ideally, matching the corresponding resistor ratios increases the output impedance of the current source and reduces the dependence of the output current on load variations [22], [34].

The bridge balance condition is expressed as

$$\frac{R_2}{R_1} = \frac{R_4}{R_3}, \tag{4}$$

where matching the corresponding resistor ratios is important for obtaining a high effective output impedance in the Howland topology [34].

The INA592 was selected as the difference-amplifier element of the current-source circuit. According to the manufacturer, the device incorporates a precision matched internal resistor network and provides wide bandwidth and high common-mode rejection [28]. These characteristics are suitable for the implementation of the resistor-ratio relationships required by the adopted circuit topology.

The current source was configured for a nominal output current of 1 mA at 47.3 kHz. However, load-dependent current variation, output impedance, compliance voltage, and harmonic distortion were not independently characterized in the experiments reported here. Therefore, the 1 mA value is reported as the nominal design value rather than as an experimentally validated current amplitude.

The voltage acquisition stage receives the differential voltage selected by the analog multiplexers and conditions it before magnitude detection. As illustrated in Fig. 4, the circuit comprises an input filtering network, an AD8421 instrumentation amplifier, an active filtering stage, and a voltage buffer preceding the AD8302 logarithmic magnitude detector.

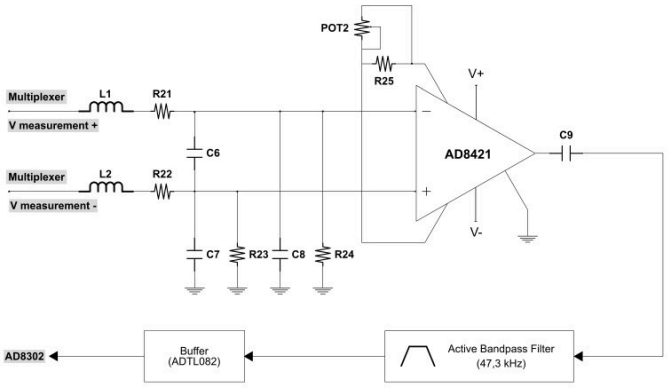

Fig. 4. Voltage acquisition and conditioning stage preceding the AD8302 magnitude detector.

The differential voltage measured across the selected electrode pair is routed from the analog multiplexers to the conditioning circuit. Before amplification, the input signals pass through a passive network composed of ferrite beads, resistors, and capacitors, which provides frequency-dependent attenuation of unwanted signal components before differential amplification.

Signal amplification is performed by an AD8421 instrumentation amplifier, selected for its high common-mode rejection ratio (CMRR), low input voltage noise, and high input impedance [26]. The amplifier provides differential amplification while rejecting common-mode components present at its inputs. Its gain is adjusted through potentiometer POT2 according to the required signal level for the subsequent conditioning stages.

The amplifier output is AC-coupled to an active filtering stage designed to condition the signal around the operating frequency of 47.3 kHz. The resulting signal is then buffered by an ADA4001-2 operational amplifier configured as a voltage follower before being applied to the measurement input of the AD8302 [29]. This buffer reduces loading of the preceding filtering stage.

Logarithmic magnitude detection is performed using the AD8302 gain and phase detector. Although the device provides both magnitude and phase outputs, only the magnitude output was acquired in the present implementation. As illustrated in Fig. 5, the conditioned measurement signal is applied to one detector input, while an amplitude-adjusted reference signal derived from the excitation oscillator is applied to the other.

The reference signal is conditioned by an ADA4001-2 operational amplifier and AC-coupled to the AD8302. Potentiometer POT3 allows adjustment of the reference-signal amplitude, while the conditioned measurement signal is also AC-coupled to the detector. According to the AD8302 transfer characteristic, the magnitude output is a linear function of the logarithmic ratio between the amplitudes of its two input signals [23].

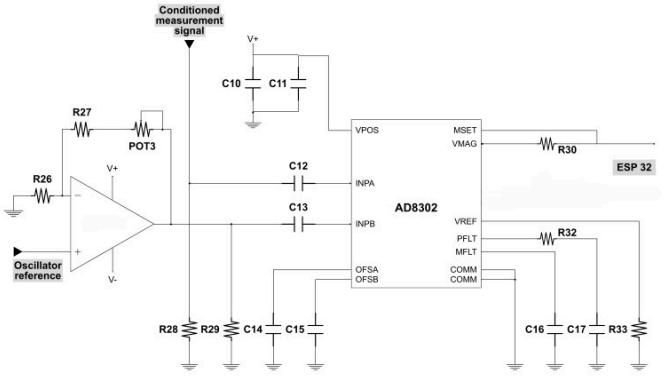

Fig. 5. Simplified schematic of the AD8302-based magnitude detection stage.

The magnitude output is subsequently filtered and digitized by the internal analog-to-digital converter (ADC) of the ESP32 after each electrode measurement. The acquired values are then transmitted to the host computer through the UART interface for subsequent processing and image reconstruction.

Electrode selection and signal routing are performed using four ADG732 analog multiplexers, as shown in Fig. 6. Two multiplexers are used to select the electrode pair for current injection, while the other two select the electrode pair from which the differential voltage is acquired. This arrangement allows the current-injection and voltage-measurement paths to be independently selected under digital control.

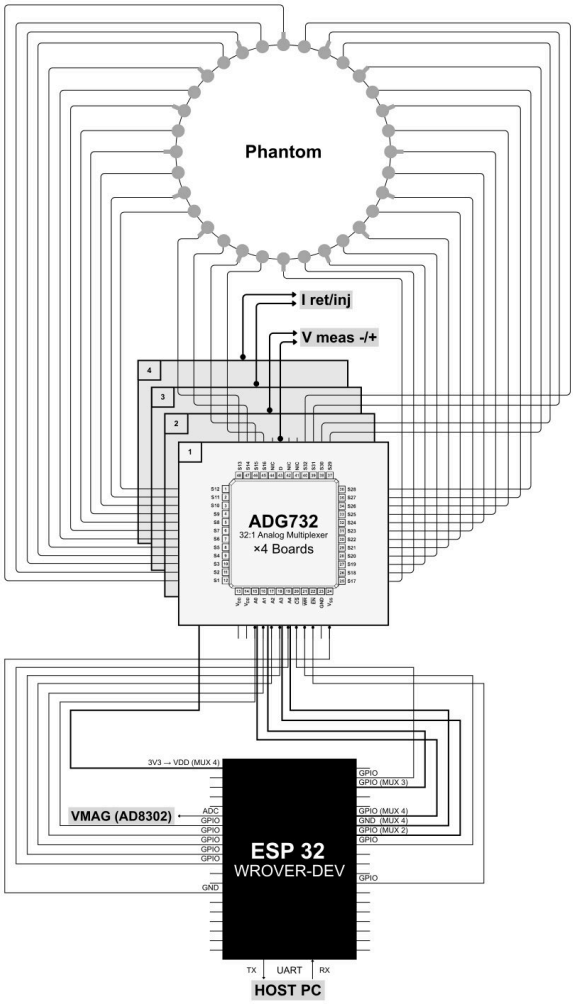

Fig. 6. Simplified architecture of the analog switching network based on four ADG732 multiplexers controlled by the ESP32-WROVER-DEV microcontroller for electrode selection and data acquisition.

The multiplexers are controlled by the ESP32 through five shared address lines (A0–A4), which select one of the 32 available channels. Individual chip-select signals determine which multiplexer is addressed, while the write and enable signals control the switching operation. The ESP32 coordinates the multiplexing sequence, ADC acquisition, and communication with the host computer according to the measurement protocol described in Section III-C.

Figure 7 shows the assembled prototype used in the experimental evaluation. The analog front-end implemented on a custom PCB, the multiplexing circuitry mounted on a dedicated breakout board, the ESP32-based control unit, and the electrode connections were integrated into the prototype employed for the phantom measurements.

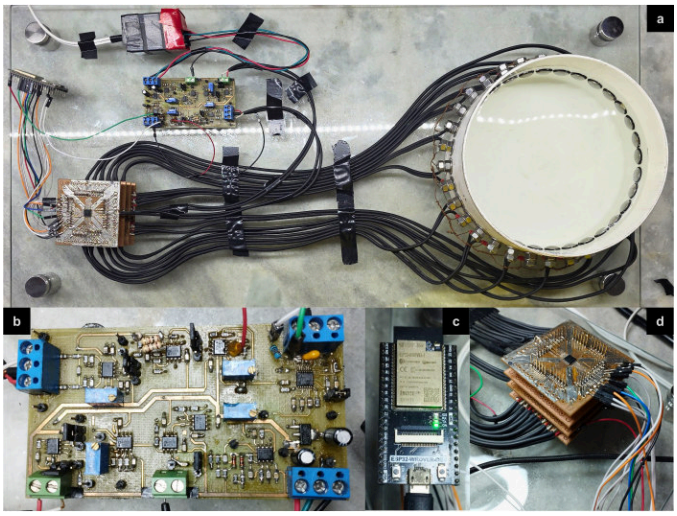

Fig. 7. Photographs of the developed EIT prototype: (a) complete experimental setup; (b) analog front-end PCB; (c) ESP32-WROVER-DEV development board; and (d) ADG732 multiplexer breakout board.

C. Image Acquisition Procedure

After hardware initialization, the ESP32 executes the data acquisition sequence by controlling the four analog multiplexers. The multiplexers share a common five-bit address bus, while the control signals configure the current-injection and voltage-measurement channels according to the acquisition protocol.

For each electrode configuration, the ESP32 sequentially selects the current-injection and differential voltage-measurement pairs. After switching, a programmable settling interval is applied before sampling the VMAG output of the logarithmic magnitude detector with the internal 12-bit ADC. Each measurement is obtained by averaging 1000 ADC conversions, and only the resulting average is retained for subsequent processing. A firmware scale factor of 1.344 is then applied to the averaged ADC output.

Although averaging was employed during acquisition, noise level, signal-to-noise ratio (SNR), and overall measurement uncertainty were not independently characterized in the present experimental evaluation.

The adjacent-adjacent protocol was implemented using 16 electrodes selected alternately from the 32 equally spaced physical electrodes. For each of the 16 adjacent current-injection pairs, voltage measurements were acquired from 13 adjacent electrode pairs that did not include the current-carrying electrodes, resulting in 208 acquired measurements per frame. Considering reciprocity, 104 of these measurements are independent [2], [18].

Considering the programmed delays associated with multiplexer switching and the 20-ms settling interval preceding each

measurement, a complete 208-measurement frame includes approximately 8.35 s of programmed delay. The execution time required for ADC conversions, processing, and serial communication is not included in this value; therefore, the actual acquisition time per frame is greater than 8.35 s.

The acquired values are transmitted to the host computer through the UART interface at 115200 baud. On the host computer, each received magnitude-related value V_i is numerically transformed according to the processing implemented in the acquisition script. Specifically, $q_i = (V_i - 0.9)/0.03$ is first calculated, followed by $d_i = 10^{q_i/10}$. The resulting 208 values are assembled into the measurement vector supplied to EIDORS. A new homogeneous reference dataset was acquired before each experimental configuration. The corresponding reference and perturbed measurement vectors were then used for difference image reconstruction.

D. Image Reconstruction Procedure

Image reconstruction was performed in GNU Octave using the EIDORS toolbox [30]. A two-dimensional circular finite-element inverse model with 16 electrodes was created using the `c2c2` model provided by `mk_common_model`. The adjacent stimulation and measurement patterns were generated using `mk_stim_patterns`, according to the acquisition protocol described in Section III-C.

Difference imaging was performed by comparing the measurement vector acquired from the homogeneous phantom with that obtained after introducing an inclusion. The reference and perturbed measurement vectors were supplied to the EIDORS `inv_solve` function to estimate the corresponding conductivity change.

Because only the magnitude output of the AD8302 was acquired, phase information was not included in the reconstruction. Consequently, the reconstructed images were interpreted as qualitative relative conductivity changes with respect to the homogeneous reference state rather than as calibrated absolute conductivity distributions.

E. Experimental Evaluation

The experimental evaluation was performed using a cylindrical phantom constructed from a PVC pipe. The dimensions of the phantom, electrodes, and test objects reported in this section were measured using a caliper. The phantom has an internal diameter of approximately 183 mm, a total height of 100.22 mm, and a wall thickness of 3.15 mm. It was filled with tap water to a height of approximately 60 mm. The conductivity and temperature of the water were not instrumentally recorded during the experiments. No predefined stabilization interval was adopted before data acquisition.

The electrode array consists of 32 equally spaced stainless-steel carriage bolts, approximately 5.6 mm in diameter and 15 mm in length, mounted around the phantom circumference and fully submerged during the measurements. Electrical connection to each electrode is made using a ring terminal fastened to the external threaded portion of the bolt.

Conductivity perturbations were introduced using a glass cup and a rectangular plastic bar. The glass cup had a height of 92 mm and diameters of approximately 47 mm and 66.6 mm at its narrower and wider sections, respectively, and was partially filled with water during immersion. The rectangular plastic bar measured approximately $135.9 \times 31.10 \times 31.20$ mm.

Two experimental configurations were considered. In the first, the glass cup and plastic bar were simultaneously positioned inside the phantom to evaluate whether two conductivity perturbations could be distinguished in the reconstructed image. In the second, the glass cup was placed at four different positions within the phantom to qualitatively evaluate whether changes in object position were reflected in the reconstructed images.

IV. RESULTS AND DISCUSSION

Figures 8 and 9 present the experimental results obtained with the proposed EIT system. The experiments evaluated whether conductivity perturbations produced by the test objects could be detected and whether changes in their relative positions were reflected in the difference images.

Figure 8 shows the experiment in which the glass cup and the plastic bar were simultaneously positioned inside the phantom. Two spatially distinct perturbation regions are visible in the reconstructed image, corresponding qualitatively to the presence of the two test objects. Although the reconstruction does not reproduce their exact geometry, the result indicates that the measurement and reconstruction chain can distinguish the two perturbations under the tested configuration.

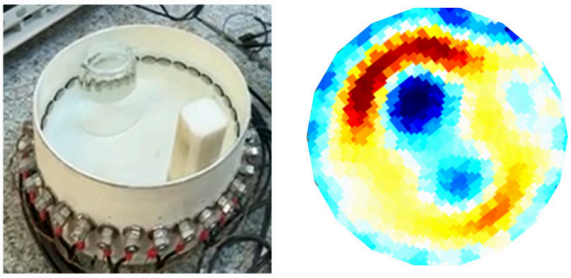

Fig. 8. Experimental setup (left) and corresponding reconstructed difference image (right) for the glass cup and plastic bar simultaneously positioned inside the phantom. Colors represent qualitative relative changes in the reconstructed image; no calibrated conductivity scale is assigned.

Figure 9 presents the reconstructed images obtained with the glass cup placed at four different positions within the phantom. As the cup position changes, the main reconstructed perturbation region changes accordingly, qualitatively reproducing the relative displacement of the object within the imaging domain.

The reconstructed images exhibit spatial spreading and boundary artifacts, which are consistent with the limited spatial resolution and ill-posed nature of the EIT inverse problem [18]. The experimental evaluation was qualitative. The exact coordinates of the test objects and repeated measurement frames for each configuration were not recorded during the

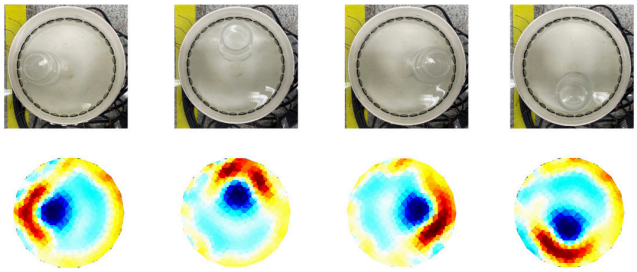

Fig. 9. Glass cup at four different positions within the phantom (top) and the corresponding reconstructed difference images (bottom). Colors represent qualitative relative changes in the reconstructed images; no calibrated conductivity scale is assigned.

original experiments; therefore, quantitative localization error and inter-frame variability could not be retrospectively determined. Accordingly, the results are interpreted as a functional demonstration of perturbation detection and relative position changes rather than as a quantitative validation of localization accuracy or measurement repeatability.

Furthermore, the current acquisition time limits the present implementation for applications requiring high temporal resolution. Future improvements should therefore investigate optimization of the multiplexer switching and settling intervals, ADC averaging, and data-transfer procedure to increase the acquisition rate without compromising measurement quality.

V. CONCLUSION

This work presented the development and experimental evaluation of an Electrical Impedance Tomography (EIT) system based on an ESP32 microcontroller. The proposed architecture integrates a modified Howland current source, analog multiplexing, signal conditioning, logarithmic magnitude detection, and image reconstruction using the open-source EIDORS framework.

Experimental results obtained with a cylindrical phantom showed that the system can detect conductivity perturbations produced by the test objects and qualitatively reflect changes in their relative positions within the imaging domain. These results demonstrate the functional operation of the complete acquisition and reconstruction chain under the tested phantom conditions. The present evaluation remains qualitative, and the acquisition rate and absence of phase information limit the scope of the current implementation.

Future work will focus on quantitative characterization of the current source, repeatability and noise assessment, acquisition-time optimization, and evaluation using phantoms with controlled conductivity properties and tissue-like materials.

Demonstration videos showing the operation of the complete EIT system are available in [32], [33].

***Abstract*— Skin cancer remains one of the most prevalent malignancies worldwide, and early detection significantly improves patient survival. Malignant skin lesions exhibit altered metabolic activity and vascularization, often leading to localized superficial hyperthermia relative to surrounding healthy tissue. Clinically reported temperature differences range between 0.6 and 2.2 °C. This work investigates the technical feasibility of a Fiber Bragg Grating (FBG)-based optical biosensor for detecting such clinically relevant thermal variations. An experimental calibration was conducted in the temperature range of 20 to 40 °C, resulting in an average thermal sensitivity of approximately 9.84 pm/°C. Based on this sensitivity, expected Bragg wavelength shifts associated with lesion-related temperature increments were calculated to range between 6 and 22 pm. Spectral simulations were performed using experimentally acquired baseline data at 34 °C to model localized temperature increases. The results demonstrate that the predicted wavelength shifts fall within the measurable resolution range of standard optical interrogators. A dual-point differential configuration is proposed, where one FBG is placed over healthy skin as a reference and a second one over the lesion area. Differential measurement enhances robustness against environmental fluctuations and systemic thermal variations. Overall, this proof-of-concept study supports the feasibility of a non-invasive, high-resolution optical patch sensor for detecting localized thermal anomalies associated with suspicious skin lesions.**

Keywords—Fiber Bragg Grating, Optical biosensor, Skin cancer detection, Thermal sensing, Differential measurement, Biomedical instrumentation

I. INTRODUCTION

Skin cancer, including melanoma (MEL), basal cell carcinoma (BCC), and squamous cell carcinoma (SCC), represents one of the most prevalent malignancies worldwide. Early diagnosis significantly increases survival rates, however, current detection methods still rely primarily on visual inspection followed by invasive biopsy confirmation.

According to the Global Cancer Observatory statistics for 2022, a total of 331,722 new cases of MEL were diagnosed globally, resulting in 58,667 deaths [1]. In addition, 1,234,533 new cases of non-MEL skin cancers were reported, with 69,416 associated deaths. The incidence of skin cancer varies considerably across geographical regions, with generally higher occurrence rates observed in men compared to women [2]. In the United States alone, approximately 108,270 new MEL cases were reported, including 64,220 cases in men and 44,050 in women, along with 13,120 deaths attributed to the disease [2].

From a global perspective, Europe accounts for 44.1% of MEL incidence, and 44.6% of MEL-related mortality, whereas North America represents 49.2% of the incidence of non-MEL skin cancers. In contrast, Asia accounts for 46.1% of mortality associated with non-MEL skin cancers [1]. Furthermore, projections indicate a concerning increase in disease burden, with melanoma incidence expected to rise by more than 50%, reaching approximately 510,000 new cases annually by 2040. Mortality is also projected to increase by approximately 68%, reaching 96,000 deaths per year [3]. These trends highlight the urgent need for improved prevention strategies and, critically, the development of reliable early detection technologies.

From a physiological standpoint, malignant tissues exhibit increased metabolic activity due to enhanced glycolysis and angiogenesis [4]. This metabolic rewiring leads to elevated energy consumption and heat generation, producing localized thermal gradients at the skin surface. Infrared thermography studies have reported superficial hyperthermia in MEL lesions, ranging from approximately 0.6 to 2.2 °C relative to adjacent healthy skin [4], [5], [6], suggesting that these temperature differences can serve as a measurable physical biomarker for early detection.

Literature review of dermatological studies provides the clinical foundation for the proposed system. Infrared thermography images, as shown in Fig. 1, consistently reveal localized thermal anomalies in malignant lesions, typically represented using color-coded temperature scales. These scales range from cooler tones (blue/green) to warmer tones (yellow/red), corresponding to increasing surface temperatures. In these images, malignant regions are highlighted by higher intensity colors, indicating localized hyperthermia relative to surrounding healthy tissue.

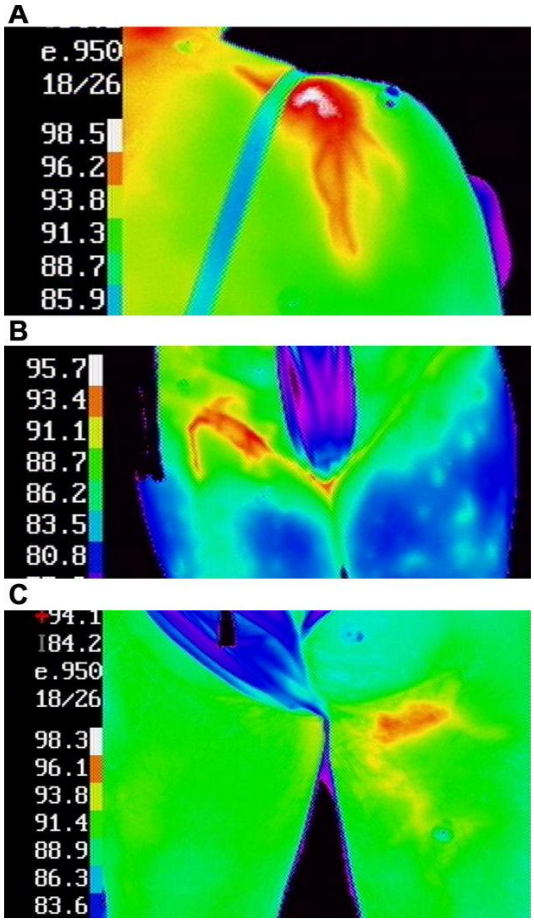

Fig. 1. Representative infrared thermography images of skin lesions, illustrating localized temperature variations using a color-coded scale [6].

Shada et al [6], reported temperature differences, such as shown in Table 1, which compiles affected anatomical regions and corresponding thermal variations. These values were used to define the clinically relevant input range for the proposed sensing approach.

TABLE I. TABLE TYPE STYLES

Case	Lesion Temp (°F)	Normal Skin Temp (°F)	ΔT (°F)	ΔT (°C)
A (Shoulder)	98–99	95–97	2–4	1.1–2.2
B (Groin)	95–96	92–94	1–3	0.6–1.7
C (Thigh)	98–99	96–97	1–3	0.6–1.7

FBG sensors offer an attractive solution for non-invasive thermal monitoring due to their high wavelength sensitivity, immunity to electromagnetic interference, and compatibility with wearable configurations [7], [8], [9], [10].

In recent years, FBG-based sensors have been widely explored in the biomedical field for applications such as body temperature monitoring, respiratory and cardiac activity sensing, minimally invasive surgical instrumentation, and smart textile integration for continuous health monitoring [11], [12]. Their capability to provide real-time, high-resolution measurements, combined with their small size and flexibility, make them particularly suitable for direct contact with biological tissues.

Additionally, FBG sensors have been employed in medical environments where conventional electronic sensors are limited, such as in magnetic resonance imaging (MRI) settings, where electromagnetic immunity is essential. Their multiplexing capability also allows for multiple sensing points along a single optical fiber, enabling distributed sensing systems for spatially resolved physiological measurements.

The Bragg wavelength is defined as

$$\lambda_B = 2n_{eff}\Lambda, \tag{1}$$

where n_{eff} is the effective refractive index, and Λ is the grating period.

Temperature variations modify both parameters, producing a wavelength shift, as shown in Fig. 2, described by

$$\Delta\lambda = S\Delta T, \tag{2}$$

where $S\Delta T$ represents thermal sensitivity.

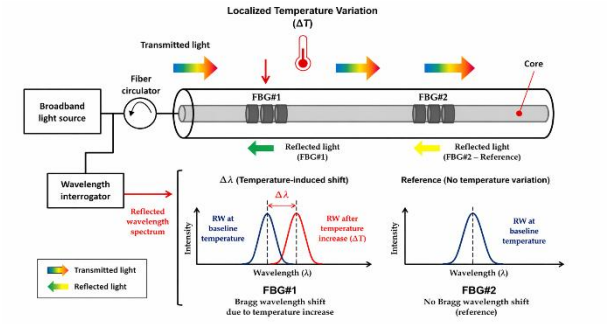

Fig. 2. Physical operating principle of the dual-FBG sensing system under localized temperature variation [13].

In this context, the following research question is formulated:

Can a FBG-based optical patch sensor reliably detect clinically relevant differential temperature variations between healthy skin and malignant lesions through measurable Bragg wavelength shifts suitable for future screening-oriented applications?

This work should be interpreted as a proof-of-concept study aimed at evaluating the technical feasibility of detecting clinically relevant thermal variations using FBG technology. The proposed approach does not assess diagnostic performance in patients and does not replace clinical diagnostic procedures. Instead, it establishes an experimental framework for future validation using biological phantoms, ex vivo tissues, and clinical datasets, while proposing a dual-point differential optical patch architecture to reduce the influence of environmental and systemic thermal fluctuations.

II. METHODOLOGY

The proposed methodology is structured into three main stages: clinical foundation, sensor characterization, and system simulation and design.

A. Clinical Foundation

A comprehensive review of dermatological literature was conducted to identify physiological markers associated with malignant skin lesions, with particular emphasis on localized thermal variations between healthy and cancerous tissues. Infrared thermography studies, such as the work by Shada et al. [6], report temperature differences between malignant lesions and surrounding healthy tissue ranging from 0.6 to 2.2 °C. This range was adopted as the clinically relevant detection interval for the proposed sensing system.

B. Sensor Characterization

The experimental procedure focused on the thermal characterization of the FBG sensor. The Bragg wavelength was continuously monitored using an optical interrogator (Hyperion si255), while the reflected spectral peak was tracked for subsequent analysis.

The optical source was configured using an Anritsu MS9740A optical spectrum analyzer (OSA), as shown in Fig. 3. A broadband super luminescent diode (SLD) was connected to the measurement system through an optical isolator to prevent back reflections and ensure stable emission during spectral acquisition. The OSA wavelength span was set between 1500 and 1600 nm, covering the operational range of the FBG sensor.

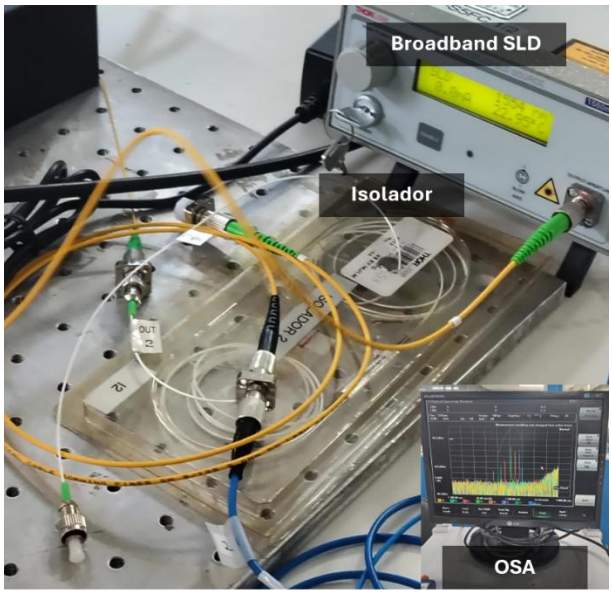

Fig. 3. Experimental setup for optical source characterization. The broadband SLD is connected to the optical spectrum analyzer through an optical isolator to suppress back reflections and ensure stable spectral measurements.

The Bragg wavelengths of the FBG sensors were determined using the reflection-based configuration shown in Fig. 4. In this setup, the broadband SLD was connected to port 1 of an optical circulator, whereas the FBG under test was connected to port 2. The reflected signal from port 3 was directed toward both the OSA and the optical interrogator (Hyperion si255) for spectral acquisition and high-resolution wavelength tracking. This configuration allows for accurate monitoring of the reflected Bragg peak while maintaining system stability.

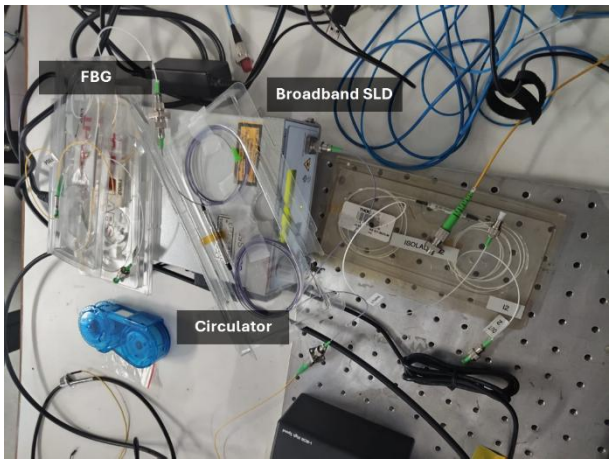

Fig. 4. Experimental setup for Bragg wavelength identification using a reflection configuration. The broadband SLD is connected to port 1 of the optical circulator, the FBG is connected to port 2, and the reflected signal from port 3 is routed to the optical spectrum analyzer OSA.

The thermal calibration was performed using a Peltier module controlled by a temperature driver. As illustrated in Fig. 5, the FBG was placed in direct contact with the Peltier surface using mechanical support to ensure proper thermal coupling and minimize temperature gradients along the grating region.

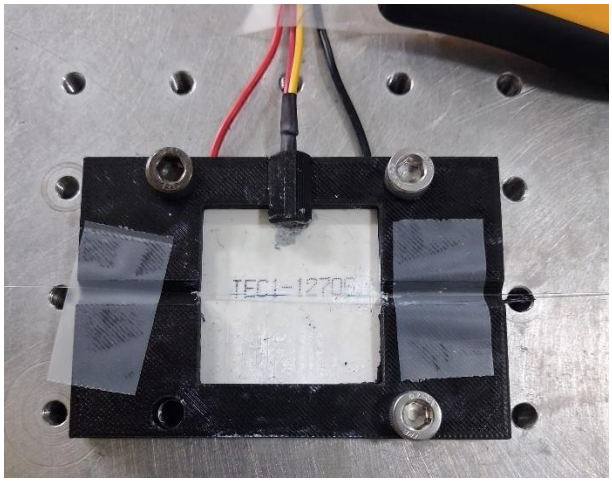

Fig. 5. Peltier module for thermal calibration.

Five complete thermal cycles were conducted. In each cycle, the temperature was increased stepwise from 20 to 40 °C in increments of 2 °C. Subsequently, the temperature was decreased back to 20 °C using the same step size. At each temperature step, sufficient time was allowed to ensure thermal stabilization before acquiring the reflected spectrum. Both heating and cooling phases were recorded to evaluate thermal sensitivity and hysteresis behavior.

The Bragg wavelength was extracted from each spectrum after signal processing, and a linear regression model was applied to establish the relationship between temperature variation and wavelength shift, allowing the determination of the sensor's thermal sensitivity.

To assess the repeatability of the thermal response, the sensitivity values obtained from the five independent heating–cooling cycles were analyzed statistically. For each phase, the mean sensitivity, standard deviation, and

coefficient of variation were calculated. In addition, 95% confidence intervals were estimated using Student's t-distribution, considering the limited number of experimental cycles (n = 5) [14]. The confidence interval was calculated as:

$$CI95\% = \bar{x} \pm t\alpha_{/2} * \frac{s}{\sqrt{n}}, \quad (3)$$

where $\bar{x}$ is the sample mean, s is the sample standard deviation, n is the number of experimental cycles, and $t\alpha_{/2}$ is the critical value of the Student's t-distribution. Since five thermal cycles were analyzed, the number of degrees of freedom was n − 1 = 4. For a two-tailed 95% confidence level, the corresponding $t\alpha_{/2}$ value was 2.776. Therefore, this analysis allowed estimating the uncertainty range of the experimentally obtained thermal sensitivity.

C. Simulation and System Design

Using the experimentally measured spectrum as a baseline representing healthy skin conditions, spectral shifts were simulated according to the calibrated thermal sensitivity. These simulations were performed within the clinically relevant temperature range identified in the literature.

Based on this analysis, a dual-point differential sensing architecture was proposed, as shown in Fig. 6. In this configuration, one FBG sensor is positioned over healthy skin to act as a reference, whereas a second sensor is placed over the lesion area. The diagnostic variable is defined as

$$\Delta\lambda = \lambda_{lesion} - \lambda_{healthy}, \quad (4)$$

which enables compensation for global temperature variations and enhances the sensitivity to localized thermal anomalies.

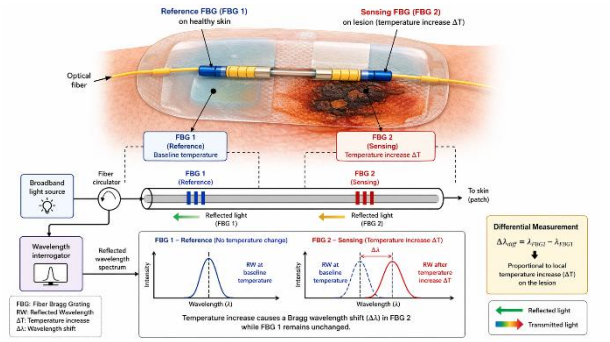

Fig. 6. Proposed dual-point differential FBG configuration for temperature comparison between healthy skin and lesion area [13].

III. Results and Discussion

The experimental results are presented following the methodology stages, including optical source verification, thermal characterization, and system validation through simulation.

A. Optical Source Verification

The measured spectra confirm the expected broadband emission of the SLD within the 1500–1600 nm observation window of the OSA. This spectral range fully covers the operating region of the FBG sensors, ensuring proper interrogation of the Bragg wavelength.

B. Thermal Characterization

Fig. 7 shows the spectral response of the FBG sensor during incremental temperature variation from 20 to 40 °C. A progressive shift of the Bragg wavelength toward higher values is observed as temperature increases, which is consistent with the combined thermo-optic effect and thermal expansion of silica.

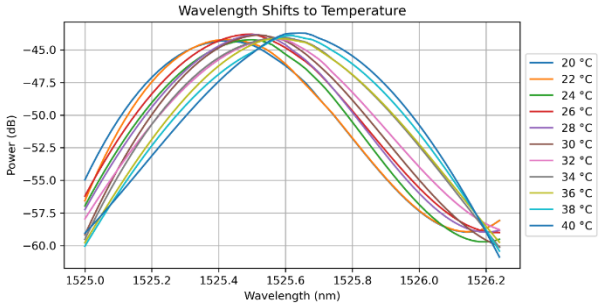

Fig. 7. FBG spectral response during incremental temperature from 20 to 40 °C.

Fig. 8 illustrates the heating–cooling response corresponding to Cycle 1. Clear hysteresis behavior is observed between both phases. For this cycle, the maximum thermal hysteresis reached 40 pm, corresponding to 16.67 % of the full-scale response.

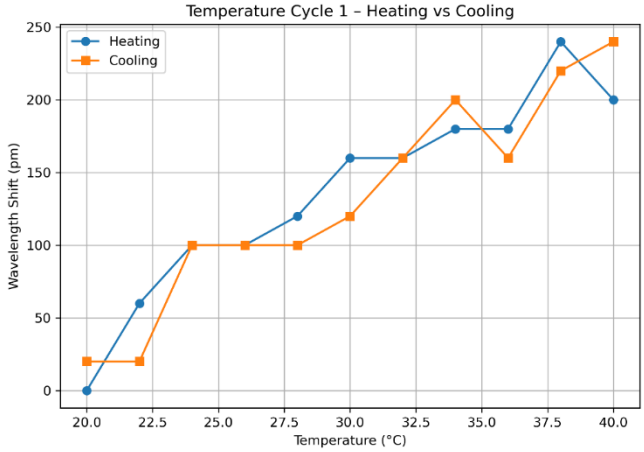

Fig. 8. Hysteresis behavior of the FBG sensor during temperature cycle 1.

Since the measured hysteresis exceeded 5% of the full-scale (FS) response, defined as the total Bragg wavelength shift across the calibrated temperature range, separate linear regression models were fitted for the heating and cooling phases, as shown Fig. 9. This approach provides an initial software-based compensation strategy for the path-dependent thermal response. During heating, the thermal sensitivity was 9.82 pm/°C (R^2 = 0.9014), whereas during cooling it increased to 10.64 pm/°C (R^2 = 0.9237). These values are consistent with the expected contributions of the thermo-optic coefficient and thermal expansion of the fiber.

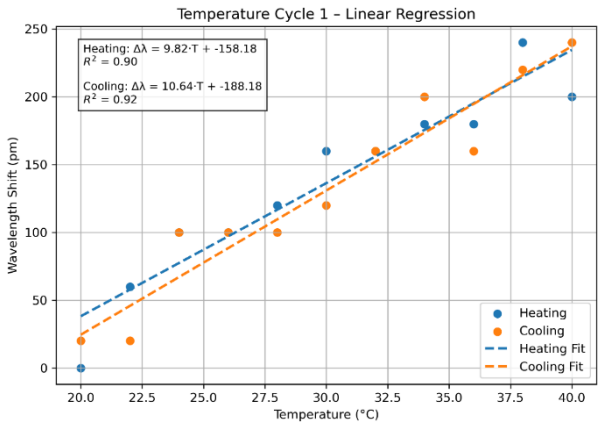

Fig. 9. Linear regression models of the FBG sensor under temperature variation (Cycle 1).

The difference in slopes between heating and cooling phases indicates a path-dependent thermal response, which is consistent with the observed hysteresis. The distinct intercept values further confirm that the temperature trajectory is not fully reversible.

The multi-cycle characterization results are summarized in Table II. Five independent thermal cycles were analyzed to evaluate the repeatability of the FBG sensor under controlled heating and cooling conditions. The heating phase showed an average thermal sensitivity of 9.84 pm/°C, with a standard deviation of 0.92 pm/°C and a coefficient of variation of 9.34%. The cooling phase presented an average sensitivity of 10.15 pm/°C, with a standard deviation of 0.42 pm/°C. These results indicate an acceptable level of repeatability for a proof-of-concept study, although additional long-term stability and drift analyses are still required for wearable deployment.

TABLE II. MULTI-CYCLE TEMPERATURE CHARACTERIZATION RESULTS.

Cycle	Sensitivity Heating (pm/°C)	Sensitivity Cooling (pm/°C)	Max Thermal Hysteresis (pm)
1	9.82	10.64	40.00
2	10.00	9.73	40.00
3	11.27	10.27	40.00
4	8.91	10.45	60.00
5	9.18	9.64	60.00

To further quantify the dispersion of the experimental response, 95% confidence intervals were estimated using Student's t-distribution due to the limited number of cycles. As shown in Table III, the heating phase presented a mean sensitivity of 9.84 pm/°C with a standard deviation of 0.92 pm/°C, resulting in a 95% confidence interval of 8.70–10.98 pm/°C. The cooling phase showed a slightly higher mean sensitivity of 10.15 pm/°C and a lower standard deviation of 0.42 pm/°C, with a 95% confidence interval of 9.63–10.67 pm/°C. These results indicate that both phases exhibited relatively consistent thermal responses, although the lower dispersion observed during cooling suggests greater repeatability in that phase.

TABLE III. CONFIDENCE INTERVALS

Parameter	Mean ± STD	95% CI
Heating sensitivity (pm/°C)	9.84 ± 0.92	8.70–10.98
Cooling sensitivity (pm/°C)	10.15 ± 0.42	9.63–10.67

Considering that the subsequent detectability analysis focuses on clinically relevant temperature increases, the heating phase was selected as the reference for estimating the expected Bragg wavelength shifts. Future real-time implementations should incorporate software-based compensation strategies, including adaptive baseline correction, hysteresis compensation through lookup tables, and dynamic calibration models that account for the heating and cooling trajectory, contact pressure, ambient temperature, and long-term drift. This is particularly relevant because the experimental characterization showed thermal hysteresis values ranging from a minimum of 40 pm to a maximum of 60 pm across the evaluated cycles. These algorithms could improve diagnostic robustness by continuously updating the reference FBG response and reducing false thermal differences caused by environmental or mechanical artifacts.

C. Clinical Range Mapping and Detectability

Based on the calibrated sensitivity obtained from the heating phase, the clinically reported temperature variations (0.6 to 2.2 °C) correspond to Bragg wavelength shifts between approximately 6 and 22 pm.

Considering that the optical interrogator Hyperion si255 provides a resolution on the order of 1 pm or better, these wavelength shifts fall well within the detectable range of the system. This suggests that clinically relevant thermal variations are technically measurable using the proposed FBG-based sensing approach.

D. Spectral Simulation and System Validation

The simulated spectral responses, shown in Fig. 10, demonstrate that temperature increments associated with pathological conditions produce measurable and resolvable Bragg wavelength displacements. The spectral shift is observed as a horizontal translation of the Bragg peak relative to the baseline condition, without distortion of its shape, confirming operation within the linear regime.

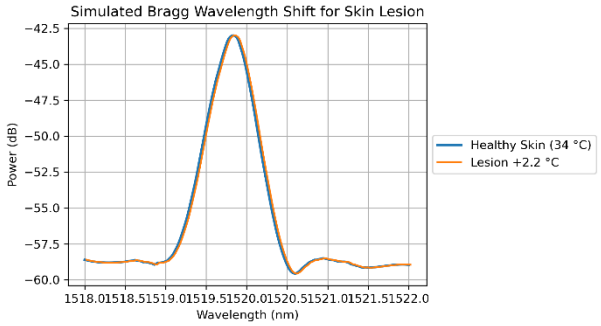

Fig. 10. Simulated spectral response of the FBG sensor under baseline (34 °C) and elevated temperature conditions (+2.2 °C).

Finally, the proposed differential configuration enhances measurement robustness. By comparing the wavelength response of the reference FBG (healthy skin) with that of the sensing FBG (lesion area), the system effectively

compensates for global temperature variations and improves sensitivity to localized thermal gradients.

E. Practical Considerations for Wearable Deployment

In addition to the sensing principle, wearable implementation requires careful consideration of ergonomics, miniaturization, sensor packaging, and long-term usability. In a practical implementation, the FBG sensors could be embedded within a thin, flexible, and biocompatible polymer substrate, such as medical-grade silicone or polyurethane, forming a lightweight and low-profile skin-adherent optical patch. This configuration would ensure conformal contact with curved skin surfaces while minimizing discomfort during use. Proper encapsulation is also necessary to protect the optical fiber from mechanical strain, perspiration, and repeated handling, without significantly increasing the thermal resistance between the skin and the sensing region. The patch could be attached using hypoallergenic medical adhesive, and thin thermal interface layers could be incorporated to improve heat transfer between the skin surface and the sensing element [15], [16]. Such design considerations would support stable placement over the lesion and adjacent healthy tissue during short screening sessions or prolonged monitoring.

IV. Conclusion

This study demonstrated the technical feasibility of using a calibrated FBG sensor to detect clinically relevant differential thermal variations associated with suspicious skin lesions. The experimentally obtained sensitivity, derived from the heating phase of the calibration, enabled the detection of Bragg wavelength shifts between approximately 6 and 22 pm for the clinically reported temperature range of 0.6 to 2.2 °C. These shifts are within the resolution limits of high-precision optical interrogators, and the spectral simulations confirmed that they are resolvable without significant distortion of the spectral response.

The dual-point differential configuration proposed in this work enhances measurement robustness by comparing the wavelength response of a reference FBG positioned over healthy skin with that of a sensing FBG positioned over the lesion area. This strategy allows partial compensation of global temperature variations and improves sensitivity to localized thermal gradients. From an experimental perspective, the FBG sensor exhibited an average thermal sensitivity of approximately 9.84 pm/°C. However, the presence of thermal hysteresis, cycle-to-cycle variability, and moderate dispersion indicates that additional compensation and calibration strategies are required before wearable implementation.

The present study should be interpreted as a proof-of-concept rather than a clinically validated diagnostic system. The validation was performed under controlled laboratory conditions using simulated thermal scenarios derived from published clinical data, rather than biological tissues, tissue phantoms, ex vivo samples, or human subjects. In addition, temperature-based detection does not provide high diagnostic specificity by itself, since localized hyperthermia may also occur in inflammatory processes, infections, wound healing, vascular abnormalities, or other physiological conditions. Therefore, the proposed sensor should be considered as a complementary screening-oriented technology capable of identifying suspicious thermal anomalies that may require further clinical evaluation.

Several practical factors may also influence measurement accuracy in real-world wearable applications, including motion artifacts, variable skin-contact pressure, perspiration, local blood perfusion changes, environmental temperature fluctuations, mechanical deformation, durability, and long-term thermal drift. Although the proposed differential architecture can mitigate part of these effects, future studies should experimentally quantify their impact under realistic operating conditions.

Overall, the results support the potential of FBG-based optical sensing as a non-invasive and high-resolution approach for detecting small differential thermal variations associated with suspicious skin lesions. Future work will focus on validation using tissue phantoms, ex vivo samples, and clinical data, as well as on the integration of the optical patch into wearable platforms. Further investigations should also address software-based compensation strategies, including adaptive calibration and hysteresis correction methods, to improve robustness under real-world wearable conditions. In addition, future studies should evaluate whether different skin cancer types, including melanoma, basal cell carcinoma, and squamous cell carcinoma, exhibit distinguishable thermal signatures associated with their vascularization patterns and metabolic activity.

Abstract: Ultrasound imaging is widely used for diagnostic applications; however, its image quality is often limited by low contrast and spatial resolution. Gas vesicles (GVs), protein shelled nanostructures naturally produced by microorganisms, have emerged as promising ultrasound contrast agents due to their low cost, biocompatibility, and ability to generate strong ultrasound backscatter signals. In this study, the structural stability and imaging performance of wild-type gas vesicles (GVWT) and modified gas vesicles (Δ GV) were evaluated under different ultrasound incident conditions. Agarose phantoms containing the GVs samples were imaged using a B-mode ultrasound system operating at frequencies of 16 and 21 MHz, with relative transmitted power settings of 1%, 5%, 10%, 20%, and 30%. The optical density of the GV samples was measured at 500 nm (OD500), while ultrasound performance was assessed by measuring grey level intensity from B-mode images. Increasing the ultrasound frequency enhanced the backscatter signal intensity but also promoted gas vesicle collapse. GVWT samples exhibited greater mechanical stability and maintained higher signal intensity than modified ΔGV samples, particularly at higher transmitted relative power. In contrast, the modified gas vesicles showed greater susceptibility to collapse, which was attributed to the absence of the GvpC protein that provides structural reinforcement to the gas vesicle shell. These findings demonstrate that both ultrasound frequency and transmitted power strongly influence the performance of gas vesicles as ultrasound contrast agents and indicate that GVWT exhibits superior imaging performance under the evaluated experimental conditions.

Keywords: ultrasound imaging; gas vesicles; ultrasound contrast agents; ultrasound backscatter; B-mode imaging; GvpC.

I. Introduction

Ultrasonography (US) is a technique widely used in medicine that employs high-frequency sound waves to generate real-time images without causing damage to biological tissues. Commonly used for diagnosing and monitoring health conditions, US operates in a frequency range between 1 and 20 MHz and is an accessible, low-cost, and efficient tool [1] for evaluating orthopedic, cardiac, and ophthalmic lesions. A specific application of this technique is ultrasonic biomicroscopy (UBM), a variation of conventional B-mode ultrasound. UBM employs frequencies ranging from 20 to 100 MHz, enabling the acquisition of high-resolution images at microscopic scales [5], [13]. However, the quality of ultrasound images can be limited by low resolution and contrast, which makes it difficult to visualize fine anatomical structures. To overcome these limitations, ultrasound contrast agents (UCAs), such as microbubbles (MBs), have emerged; these improve image contrast, enabling a more accurate assessment. [5], [9].

Although effective, MBs are expensive, which limits their application in research and clinical practice. A promising alternative comes from gas vesicles (GVs), nanoscale structures produced by microorganisms such as the cyanobacterium *Anabaena flos-aquae* (ANA). These vesicles consist of a gas-filled compartment encapsulated by structural proteins, and when exposed to ultrasound waves, they can act similarly to microbubbles, generating echoes and improving image contrast. GV offer advantages, such as their significantly lower cost and the possibility of structural modifications that enhance their performance as ACUs.[8], [1], [10].

Previous research indicates that modifying GVs, such as removing specific proteins, can increase their response to ultrasound, making them more effective in imaging processes. However, such modifications can also affect the stability of the vesicles, altering their collapse pressure [3] . This study aims to explore the use of modified GVs as contrast agents in ultrasonography by comparing the backscatter signal of the samples when exposed to different ultrasound frequencies (16 MHz and 21 MHz) and relative transmitted US powers (1%, 5%, 10%, 20%, and 30%) in tests conducted with phantoms.

II. Methodology

A. GVs production and purification

The 1403/13F strain of Anabaena flos-aquae was commercially acquired and used as the initial source for GV

production. A 70 mL intermediate culture was established from the original stock and subsequently used to inoculate three parallel cultures in Erlenmeyer flasks. The cultures were maintained in ASM-1 medium [2] under controlled aeration and a 12-hour photoperiod for 20 days. After the growth period, an inoculum from each Erlenmeyer flask was transferred to a new Erlenmeyer flask to renew the culture. For GV production, the culture was transferred to previously sterilized separatory funnels lined on the sides with aluminum foil, allowing light to enter through the top of the funnel. The separatory funnels were kept in a natural environment for 1 to 3 days to allow GV production. Next, the cells were collected in a Falcon tube and a lysis solution (0.5% Tween 20, 500 mM sorbitol, 10 mM Tris, pH 7.5, diluted in PBS) was added. The GVs were then purified by a series of centrifugations at 300 × g at 4 °C for 24 hours. The three parallel cultures were pooled before purification and therefore represented a single batch of GV purification.

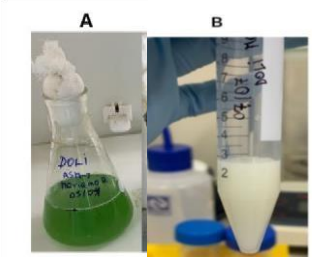

Figure 1. Production and purification of gas vesicles from *Anabaena flos-aquae*. (A) *Anabaena flos-aquae* culture under standard cultivation conditions. (B) Purified gas vesicles (GVs).

B. Optical density measurement

OD measurements were performed using a microvolume UV-Vis spectrophotometer (Thermo Scientific™ NanoDrop™ One C; River Oaks Parkway, San Jose, CA, USA), operating at a wavelength of 500 nm (OD_{500}). For the analysis, 3 µl of the stored GV solution was added, with PBS buffer used as the zero-absorbance standard. The measurement was conducted both to standardize the samples to an OD_{500} of 2 and to verify changes in optical density before and after ultrasound imaging, taking into account the different ultrasonic power levels applied.

C. Removal of the GvpC protein from GVs

The GvpC protein was removed from GVs adjusted to an OD_{500} = 2 with PBS. A solution containing 10 M urea and 100 mM Tris-HCl (pH 8.0) was added in a 3:2 ratio. The suspension was centrifuged at 200 g for 24 h at 4–8°C, resulting in two phases: a white phase (GVs in the supernatant) and a clear phase, which was discarded. The white layer was resuspended in a solution of 6 M urea and 60 mM Tris-HCl (pH 8.0) and centrifuged at 300 g for 4 h at 4–8°C. This process was repeated to remove the GvpC protein from the GVs [4]. The GvpC-free GVs, named ΔGV, were stored in PBS at 4°C for up to one week.

Protein extraction was confirmed by SDS-PAGE [7]. In this case, the proteins were visualized with Coomassie Blue, and the image was recorded using the GelDoc system (BioRad). To enhance the contrast of the bands, ImageJ software (Version 1.53t) was used to process the image, improving the contrast. The absence of the GvpC band (~25 kDa) in the urea treated sample, compared to the control sample, was consistent with GvpC depletion [4].

D. Preparation of Ultrasound Phantoms

The phantoms were prepared using 2% agarose in PBS. The mold, with a diameter of 2 cm and a height of 7 cm, was produced using a 3D printer to form the wells in which the samples were stored, as shown in Fig. 2. Once the phantom had solidified, a GV sample was added in a 1:1 ratio with 2% (m/v) agarose at an OD_{500} of 2. After filling the wells, a layer of agarose was placed over them to seal the openings, and the phantom was left to solidify at room temperature for approximately 1 hour.

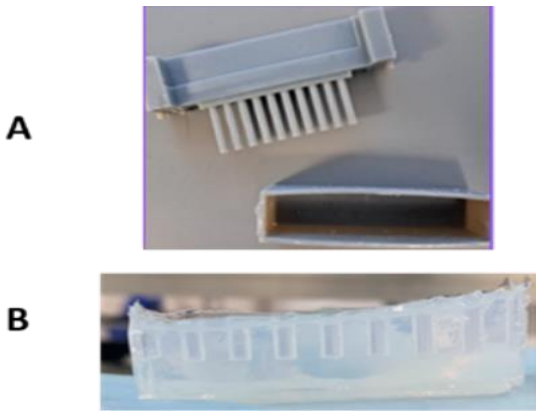

Figure 2: Phantom Mold. In (A) *Phantom* mold created by a 3D printer with a diameter of 2 cm and 7 cm in height. In (B) *Phantom* produced with 2% agarose in PBS, with molded wells.

E. Acquisition and analysis of ultrasound images and quantification by optical density

Ultrasound images of the phantom were acquired using a B-mode ultrasound imaging system (Vevo 2100, isualSonics, Toronto, Canada) equipped with 16- and 21MHz transducer (MS-550D, VisualSonics, Toronto, Canada), operating at relative transmitted power settings of 1%, 5%, 10%, 20%, and 30%. For each experimental condition, a cine loop consisting of 100 B-mode frames was acquired, from which a single image was generated using the Maximum Intensity Projection (MIP) method. Regions of interest (ROIs) were defined on the MIP image, corresponding to the phantom areas containing gas vesicles (GVs) or the negative control (PBS), for quantitative analysis of ultrasound signal intensity.

Following image acquisition, the samples of the control an of GVs in the phantom wells were assessed, a 3-µL aliquot collected and their corresponding OD_{500} was measured using a microvolume UV-Vis spectrophotometer (Thermo Scientific™ NanoDrop™ One C). For each experimental condition, four independent phantom wells were evaluated (n = 4). The four wells were prepared from the same GV culture and purification batch and therefore represent technical/experimental replicates rather than independent biological replicates.

III. Results and Discussion

A. Analysis of OD_{500} for GV_{WT} and ΔGV Concentrations

Figures 3 and 4 show the values for OD_{500} of GV_{WT} and ΔGV, measured by at OD_{500}, for the control group (samples not exposed to ultrasound) and after exposure to relative ultrasound transmit power settings of 1%, 5%, 10%, 20%, and 30% at 16 MHz (Figure 3) and 21 MHz (Figure 4). All experiments were performed in quadruplicate (n = 4), and all samples were standardized to an initial OD_{500} of 2.

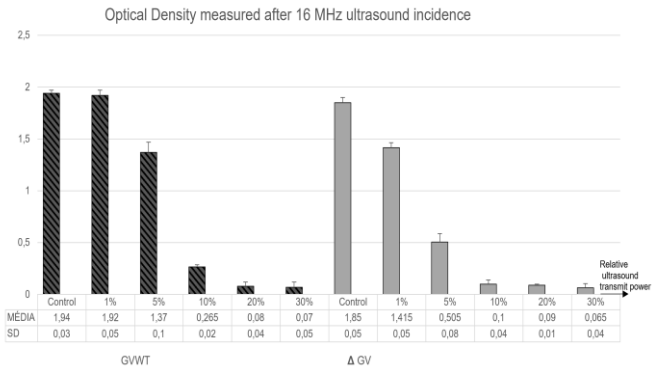

Figure 3. Mean (± SD) OD_{500} for gas vesicles exposed to 16 MHz ultrasound at relative transmit power settings of 1%, 5%, 10%, 20%, and 30%, for control samples and samples exposed to 16 MHz ultrasound at relative transmit power settings of 1%, 5%, 10%, 20%, and 30%. Hatched bars represent GVWT samples, whereas gray bars represent ΔGV samples.

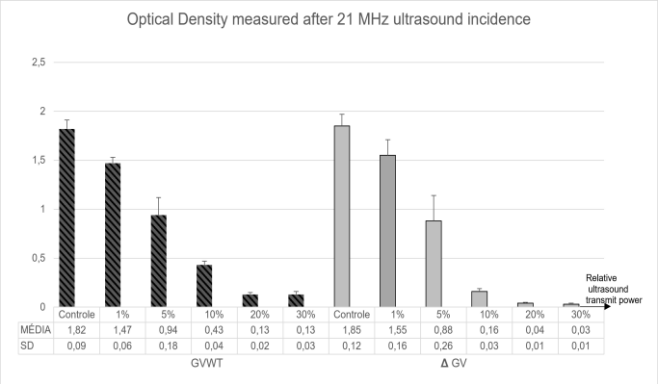

Figure 4. Mean gas vesicle concentration at 21 MHz. Mean optical density at 500 nm (OD_{500} ± SD) for control samples and samples exposed to 21 MHz ultrasound at relative transmit power settings of 1%, 5%, 10%, 20%, and 30%. Hatched bars represent GVWT samples, whereas gray bars represent ΔGV samples.

A reduction in OD_{500} for GV_{WT} relative to the control was observed after exposure to 1% relative transmit power at both 16 MHz (1.03%) and 21 MHz (19.5%). These findings indicate that increasing the ultrasound frequency was associated with a greater reduction in OD500 for GVWT under the conditions evaluated. This trend was consistently observed across all tested power settings, with GVWT exhibiting a higher extent of collapse at 21 MHz than at 16 MHz.

The ΔGV samples exhibited a response that differed from the behavior expected based on previous reports [6], [8]. Nevertheless, the overall results indicate that ΔGV samples are less resistant to ultrasound exposure than GVWT samples, consistent with previous studies. As shown in Table 1, the reduction in OD500 for GVWT relative to the control was evaluated at 16 MHz across different relative power levels (1%, 5%, 10%, 20%, and 30%). Similarly, Table 2 presents the corresponding results obtained at 21 MHz.

	GVwt samples				
	1%	5%	10%	20%	30%
16 MHz	1,03%	29,38%	86%	95,88%	96,40%
21 MHz	19,5%	48,35%	76,37%	92,86%	92,86%

Table 1: Comparison of the reduction in OD_{500} for GVwt relative to the control at frequencies of 16 MHz and 21 MHz at different relative power levels (1%, 5%, 10%, 20%, and 30%)

	Δ GV samples				
	1%	5%	10%	20%	30%
16 MHz	23,24%	73,43%	94,60%	95,14%	96,76%
21 MHz	16,21%	52,43%	91,35%	97,84%	98,38%

Table 2: Comparison of the reduction in in OD_{500} for ΔGV relative to the control at frequencies of 16 MHz and 21 MHz at different relative power levels (1%, 5%, 10%, 20%, and 30%)

ΔGV samples exhibited a distinct response. At a relative transmit power of 1%, their OD_{500} decreased by 23.24% at 16 MHz and by 16.27% at 21 MHz. Unlike GV_{WT} samples, ΔGV samples lack the GvpC protein, which decreases the elasticity of the gas vesicle shell. Consequently, one possible explanation is that these structures can better withstand the resonance induced by ultrasound, thereby shifting-up their collapse pressure.

However, at higher relative transmit power settings, ΔGV samples exhibited a reduction in OD_{500} greater than that for GV_{WT} samples, indicating lower mechanical resistance under these conditions. Furthermore, exposure to relative transmit power levels above 10% resulted in a decrease in the OD_{500} of all gas vesicle samples (Tables 1 and 2). This behavior is likely due to the higher acoustic pressures generated at increased transmit powers, which may be associated with increased destabilization or collapse

B. Ultrasound Image Analysis

Phantom B-mode ultrasound images were acquired at different relative transmitted US power settings and using frequencies of 16 MHz and 21 MHz are presented in Figures 5 and 6, respectively, with PBS used as the negative control. Figures 7 and 8 present the grey level US image intensity of the phantom with gas vesicles at relative transmitted power settings of 1%, 5%, 10%, 20%, and 30% for 16 MHz (Figure 7) and 21 MHz (Figure 8), respectively. All experiments were performed in quadruplicate (n = 4), and the samples were standardized to an initial OD_{500} of 2.

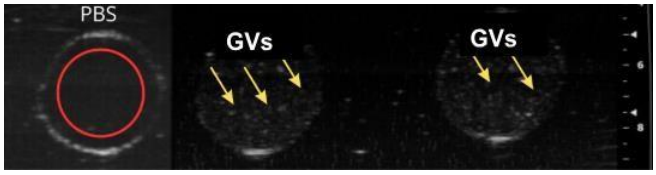

Figure 5. B-mode ultrasound (BMU) images of gas vesicles acquired at 16 MHz. Bmode ultrasound images of PBS (negative control) and GVWT samples (indicated by the yellow arrows) obtained at a relative transmit power of 1% using a B-mode ultrasound system operating at 16 MHz. The red circular outline indicates the region of interest (ROI) selected within the PBS medium.

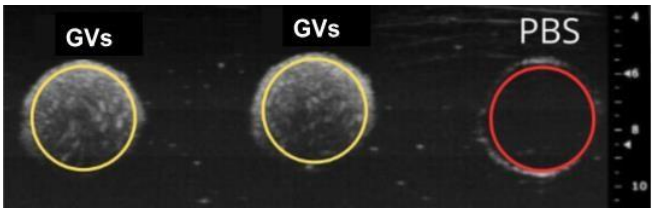

Figure 6. B-mode ultrasound (BMU) images of gas vesicles acquired at 21 MHz. Bmode ultrasound images of PBS (negative control) and GVWT samples obtained at a relative transmit power of 1% using a B-mode ultrasound system operating at 21 MHz. The yellow and red circular outlines indicate the regions of interest (ROIs) selected for the gas vesicle and PBS media, respectively.

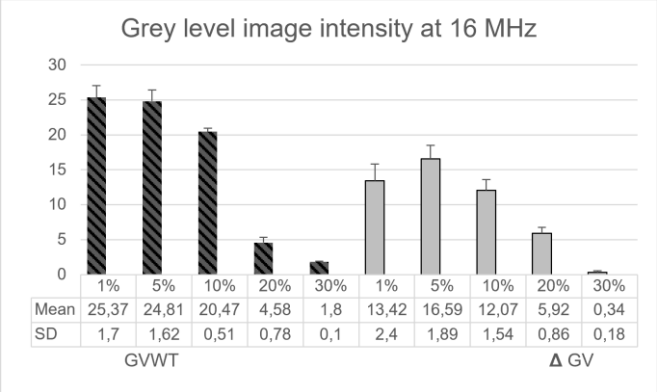

Figure 7. Mean grayscale intensity of US images of phantoms with gas vesicles at 16 MHz. Mean signal intensity (± SD) measured from B-mode ultrasound images of gas vesicle samples exposed to relative ultrasound transmitted power settings of 1%, 5%, 10%, 20%, and 30% using the ultrasound image system operating at 16 MHz. Hatched bars represent the results for GV_{WT} samples, whereas gray bars represent the results for ΔGV samples.

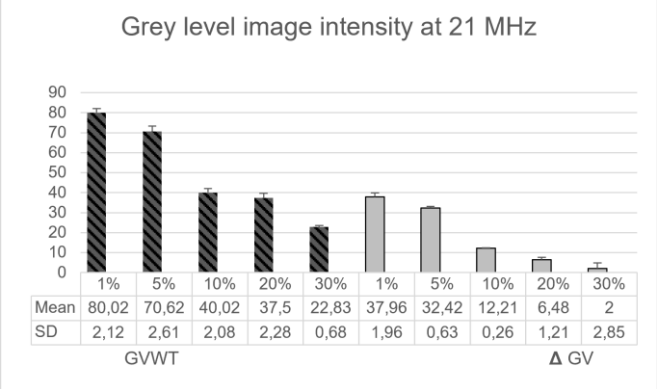

Figure 8. Mean grayscale intensity of gas vesicles at 21 MHz. Mean signal intensity (± SD) measured from B-mode ultrasound images of gas vesicle samples exposed to relative ultrasound transmit power settings of 1%, 5%, 10%, 20%, and 30% using a Bmode ultrasound system operating at 21 MHz. Hatched bars represent the results for GVWT samples, whereas gray bars represent the results for ΔGV samples.

Comparison of the ultrasound image grey level intensity from GV_{WT} samples at 16 MHz and 21 MHz revealed a marked increase in signal intensity at the higher frequency. The mean (±SD) signal intensity was 80.02 (± 2.12) at 21 MHz, compared with 25.37 (± 1.70) at 16 MHz This increase with frequency reflects the greater resonance efficiency of gas vesicles at higher ultrasound frequencies, consistent with the findings of Marsh et al. (1998), who reported that higher frequencies generate stronger backscatter signals, resulting in improved image contrast.

Comparison of signal intensity across the different relative ultrasound transmitted power settings showed that GV_{WT} samples produced the highest grey level intensity at a relative transmitted US power of 1% at both 16 MHz and 21 MHz. Increasing the relative transmitted power to 10%, 20%, and 30% resulted in a substantial reduction in signal intensity, reaching up to 92.91% under some experimental conditions. This marked decrease is consistent with increased GV destabilization or collapse at higher relative transmitted power, supporting previous studies demonstrating that excessive ultrasound pressure can exceed the collapse threshold of gas vesicles [3].

For the ΔGV samples (Figure 7), analysis at 16 MHz showed that the highest signal intensity was obtained at a relative transmitted power of 5%. Increasing the relative transmitted power to 10% and 20% produced significant reductions in signal intensity, with a decrease of up to 64.32% at 20% relative transmitted power. At a relative transmitted power of 30%, the signal intensity was comparable to that of the negative control, suggesting nearly complete collapse of the gas vesicles. At 21 MHz, a similar trend was observed, with the highest signal intensity recorded at 1% relative transmitted power, followed by progressive decreases as the transmit power increased. This effect was more pronounced for ΔGV samples, indicating greater sensitivity to increasing acoustic pressure. The reduced mechanical stability of ΔGV is likely associated with the absence of the GvpC protein, which decreases the structural reinforcement of the gas vesicle shell and increases susceptibility to collapse under elevated ultrasound pressures [11].

IV. Conclusion

The ultrasound backscatter signal was strongly influenced by both ultrasound frequency and relative transmitted power. GV_{WT} samples exhibited a substantially higher mean image grey level signal intensity at 21 MHz (80.02 ± 2.12) than at 16 MHz (25.37 ± 1.70), indicating enhanced resonance efficiency at the higher frequency. This observation is consistent with previous studies reporting that higher ultrasound frequencies produce stronger backscatter signals and improved image contrast [12].

For both frequencies, the highest backscatter signal from GV_{WT} samples was observed at a relative transmitted power of 1%. Increasing the relative transmitted power to 10%, 20%, and 30% progressively reduced signal intensity, with reductions of up to 92.91% under some experimental conditions. These findings indicate that increasing acoustic pressure promotes gas vesicle collapse once the collapse threshold is exceeded, in agreement with previous reports [3].

A similar trend was observed for ΔGV samples. At 16 MHz, the highest signal intensity occurred at a relative transmitted power of 5%, whereas increasing the transmitted power to 10% and 20% resulted in reductions of up to 64.32%. At 30% relative transmitted power, the signal intensity approached that of the negative control, suggesting nearly complete gas vesicle collapse. At 21 MHz, the maximum signal intensity was observed at 1% relative transmitted power, followed by a progressive decrease with increasing transmitted power. Overall, ΔGV samples exhibited greater sensitivity to elevated acoustic pressures than GV_{WT} samples, likely due to the absence of the GvpC protein [11].

***Abstract*—**This paper presents a technical reassessment of the Perin-Mag Hall-effect multichannel sensing architecture for pelvic floor biomechanics and proposes a redesign suitable for quantitative biomedical instrumentation. The original experimental record describes a flexible intravaginal probe with two four-channel arrays, neodymium magnets, A3144 Hall devices, embedded acquisition, and bench loading from 0 to 6 N. No volunteers were recruited. Because raw repeated measurements and a complete circuit schematic were not available, the present work does not claim new bench validation. Instead, the published calibration plot was digitized as a secondary analysis. Eleven points, sampled at 0.5 N intervals over 0.5–5.5 N, were extracted from the plot, yielding an estimated slope of 0.046 mV/N and $R^2 = 0.985$. These metrics are plot-derived estimates and are not traceable measurements with quantified uncertainty. The main technical limitation is the use of the A3144, a Hall-effect switching device with threshold and hysteresis rather than a linear ratiometric analog output. Accordingly, the paper reframes the contribution as a functional architecture review and redesign proposal centered on replacing the switch with a linear ratiometric Hall sensor and implementing a documented acquisition and metrological chain. The available evidence supports feasibility of the concept, but not clinical force measurement or validated eight-channel force distribution.

Keywords—Hall-effect sensor, magnetic transducer, biomedical instrumentation, pelvic floor biomechanics, multichannel sensing, metrology, rehabilitation engineering.

I. INTRODUCTION

Pelvic floor muscle dysfunction is associated with urinary incontinence, pelvic organ prolapse, and impaired quality of life. Objective assessment supports rehabilitation planning, but current methods provide different and complementary measurands: manual palpation provides ordinal clinical grades, perineometry provides intravaginal pressure, electromyography measures electrical activation, and ultrasound provides anatomical or kinematic information [1]–[6]. Multidirectional sensing has therefore been investigated as a means of obtaining localized mechanical information [7].

The Perin-Mag was developed as an intravaginal prototype based on magnets, Hall-effect devices, embedded electronics, and a flexible mechanical interface. The original record reports bench tests using a dynamometer, oscilloscope, multimeter, and regulated power supply, with loads reported from 0 to 6 N [8]. The same record explicitly states that testing was performed without volunteers and that clinical correlation remained a future requirement [8].

The present manuscript responds to a technical reassessment of that work. The objective is not to defend an unsupported analog calibration, but to identify what the available evidence demonstrates, what it does not demonstrate, and how the sensing architecture should be redesigned for quantitative transduction. The contributions are: (1) documentation of the evidence boundary; (2) transparent secondary digitization of the published calibration plot; (3) reconciliation of the reported continuous curve with the electrical behavior of the A3144; and (4) a proposed architecture based on a linear ratiometric Hall sensor and a complete, traceable acquisition chain.

II. TECHNICAL REASSESSMENT OF THE SENSING ARCHITECTURE

A. Measurand and transduction chain

The intended measurand is mechanical loading applied to a compliant probe. The physical transduction concept is magnet displacement relative to a Hall element: deformation changes the magnet-to-sensor geometry, which changes the magnetic field at the sensing location. For a quantitative instrument, the complete chain must therefore be defined as mechanical load → displacement → magnetic field → electrical output → digitization → calibration model → force estimate.

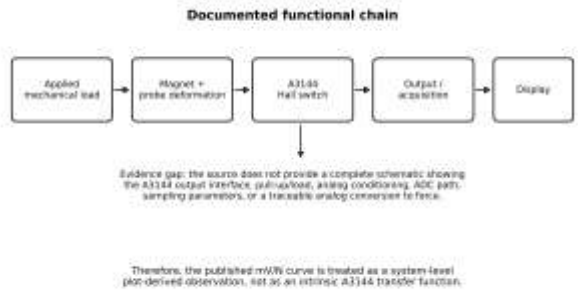

Fig. 1. Documented functional chain of the prototype. The source record does not provide the complete electrical schematic required to establish a traceable analog force conversion.

The available record documents the use of an A3144 Hall-effect device and an Arduino Mega acquisition platform [8]. However, it does not contain a complete circuit showing the A3144 output interface, pull-up resistor or load, analog

conditioning stage, ADC configuration, sampling parameters, or an explicit transfer function from electrical output to force. Consequently, these missing elements cannot be reconstructed without speculation.

B. A3144 device behavior and interpretation

The A3144 is a Hall-effect switch. Its internal architecture includes a Hall element, amplifier, Schmitt trigger, and open-collector output; the output changes state when the magnetic field crosses defined operate and release thresholds, with built-in hysteresis [9]. Allegro distinguishes such switching devices from linear Hall ICs, whose outputs vary continuously and are commonly ratiometric with supply voltage [10]. Therefore, the A3144 should not be treated as an intrinsic linear millivolt-per-newton transducer.

This distinction does not invalidate the mechanical concept. A complete system could, in principle, exploit switching events or a separate analog signal in the acquisition chain. However, the available documentation does not identify such a signal or circuit. The continuous mV-versus-force curve must therefore be treated as a system-level observation from the previous record, not as a direct transfer characteristic of the A3144.

III. SECONDARY ANALYSIS OF THE AVAILABLE CALIBRATION RECORD

A. Data provenance and digitization

The quantitative analysis in this paper is a secondary analysis of Fig. 23 from the authors' previous experimental record [8]. The underlying numerical worksheet was not available. The figure was rendered from the source PDF at 300 dpi and the plotted markers were manually digitized using the labeled axes. Eleven points were extracted at 0.5 N intervals from 0.5 to 5.5 N. The approximate output values read from the plot were 0.22, 0.23, 0.25, 0.26, 0.30, 0.33, 0.36, 0.38, 0.39, 0.42, and 0.43 mV. The extracted values are provided only to reproduce the secondary analysis; they are not raw experimental observations.

TABLE I. POINTS EXTRACTED FROM THE PUBLISHED CALIBRATION PLOT

Force (N)	Output (mV)
0.5	0.22
1	0.23
1.5	0.25
2	0.26
2.5	0.3
3	0.33
3.5	0.36
4	0.38
4.5	0.39
5	0.42
5.5	0.43

B. Fitting procedure

Ordinary least-squares regression was applied to the digitized pairs using $V = aF + b$, where V is the plotted output in millivolts and F is force in newtons. The calculation produced $V = 0.046F + 0.187$ mV, with $R^2 = 0.985$, root-mean-square residual of 0.00896 mV, and maximum absolute residual of 0.01855 mV. The fitting was implemented with a short Python script using NumPy; the script and the point table accompany the revised manuscript package. Because the digitization process introduces reading error and the original repetitions are unavailable, none of these metrics is presented as a traceable metrological result.

IV. AVAILABLE EXPERIMENTAL EVIDENCE

A. Prototype and channel visualization

Fig. 2. Finished Perin-Mag prototype (original Fig. 16).

The completed prototype integrates the flexible probe, cable, and acquisition console. The original record reports that the probe was tested under applied force and that the interface was designed to provide flexible mechanical coupling [8]. The figure establishes the existence of the integrated prototype but does not constitute evidence of clinical suitability.

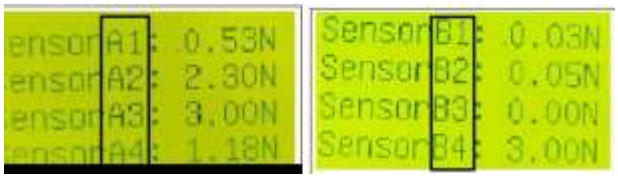

Fig. 3. Representative displayed channel values for Array 1 (original Fig. 19) and Array 2 (original Fig. 20).

The displayed values demonstrate that the prototype can present channel-specific numerical outputs. They should not be interpreted as validated force measurements because channel calibration, reference uncertainty, and the analog acquisition path are not documented sufficiently to establish traceability.

B. Channel response plots

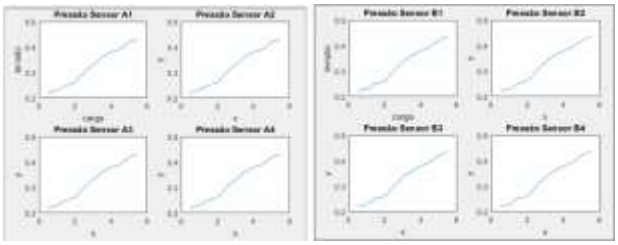

Fig. 4. Previously reported response curves for Array 1 (original Fig. 21) and Array 2 (original Fig. 22).

The eight plotted responses show broadly similar monotonic trends. This observation supports the existence of a common mechanical-sensing behavior, but it does not establish eight-channel quantitative force distribution. Between-channel slope statistics, cross-talk tests, loading/unloading cycles, and repeated measurements were not available.

C. Representative calibration plot

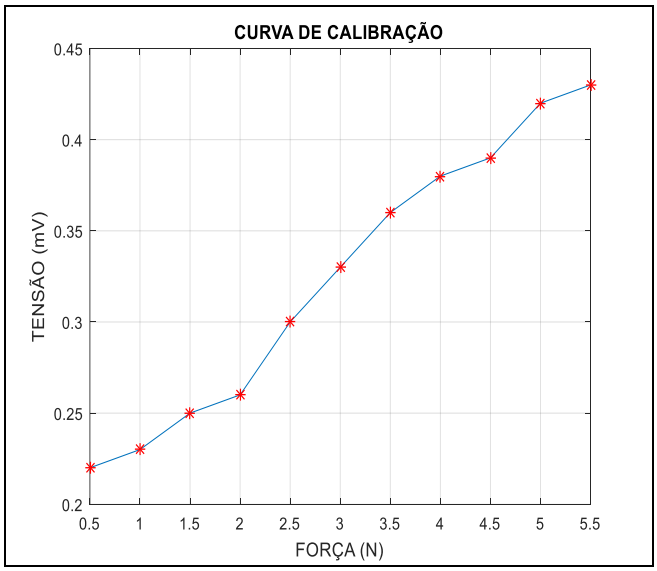

Fig. 5. Previously reported representative calibration curve (original Fig. 23), used only for secondary digitization.

The digitized curve is approximately linear over the plotted interval, but the present analysis must be interpreted as evidence of a previously observed system-level trend. It cannot establish sensor sensitivity, repeatability, hysteresis, resolution, or uncertainty because those quantities require raw repeated observations and a defined measurement chain.

TABLE II. EVIDENCE STATUS OF THE CURRENT PROTOTYPE

Claim	Evidence status
0–6 N bench loading	Reported in previous record
Monotonic channel responses	Supported by plotted curves
Sensitivity 0.046 mV/N	Plot-derived estimate only
$R^2 = 0.985$	Plot-derived estimate only
Repeatability / hysteresis	Not established
Eight-channel force distribution	Not established
Clinical validity	Not assessed

V. REDESIGN FOR QUANTITATIVE BIOMEDICAL INSTRUMENTATION

A. Linear Hall transducer and complete acquisition path

The primary redesign recommendation is to replace the A3144 switching device with a linear ratiometric Hall-effect IC selected according to the magnetic field range generated by the chosen magnet and mechanical geometry. A linear device provides a continuous analog output that can be directly conditioned and digitized, making sensitivity and calibration physically interpretable [10].

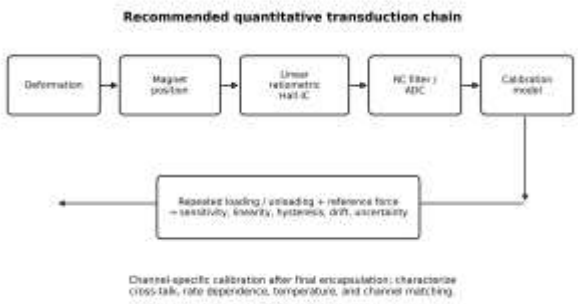

Fig. 6. Proposed redesign for traceable quantitative transduction using a linear ratiometric Hall sensor.

The proposed electrical chain is: linear Hall IC → defined RC conditioning/anti-alias filter → ADC → channel-specific calibration → force estimate. The mechanical stage should first be characterized as magnetic field versus gap, followed by force versus gap and force versus electrical output. This separates the magnetic, mechanical, and electronic transfer functions and permits identification of the dominant source of nonlinearity.

B. Metrological validation protocol

Before any clinical study, each channel should undergo repeated loading and unloading cycles using a traceable force reference. The protocol should quantify sensitivity, linearity, hysteresis, repeatability, drift, resolution, loading-rate dependence, temperature dependence, channel matching, and cross-talk. An uncertainty budget should then combine Type A contributions from repeated measurements with Type B contributions from the reference force instrument, ADC,

geometry, environmental conditions, and calibration model [11].

Only after this characterization should an eight-channel force map be reported. Even then, channel position should be described as a measurement location rather than an anatomical muscle identifier unless independently validated by imaging or clinical examination.

VI. LIMITATIONS AND FUTURE VALIDATION

The principal limitation of the present paper is the absence of raw repeated calibration data and a complete electrical schematic for the original prototype. The numerical values obtained from Fig. 23 are therefore secondary, plot-derived estimates. The second limitation is the A3144 device choice, which prevents a straightforward interpretation of a continuous analog calibration without additional circuit evidence. The third is the absence of volunteer testing; no conclusion regarding pelvic floor muscle force, clinical diagnostic accuracy, or rehabilitation effectiveness can be drawn.

Future work should first implement the linear Hall redesign and document the complete circuit, sensor model, magnet grade and dimensions, supply voltage, ADC resolution, sampling rate, filtering, calibration equations, and uncertainty budget. The next stage should compare the redesigned transducer against a traceable mechanical reference, followed by comparative evaluation against established pelvic floor assessment methods. Ethical approval and clinical validation are required before human measurements are reported.

VII. CONCLUSION

The technical reassessment shows that the Perin-Mag provides a meaningful functional concept for spatially distributed magnetic sensing of mechanical deformation, but the available evidence does not support the original interpretation as a quantitatively validated pelvic floor force instrument. The published calibration curve can be reproduced only as a secondary, plot-derived analysis, yielding approximately 0.046 mV/N and $R^2 = 0.985$ for the extracted points; these values are explicitly not traceable measurements. The decisive engineering correction is to replace the A3144 Hall switch with a linear ratiometric Hall transducer and to implement a fully documented acquisition and metrological chain. This reframing preserves the novelty of the multichannel magnetic architecture while aligning the manuscript's claims with the evidence actually available.

ACKNOWLEDGMENT

The authors acknowledge the University of Brasília and the Federal Institute of Brasília for the infrastructure supporting prototype development and laboratory experimentation.

***Resumo*—This structured review maps the development of acquisition, preprocessing, and/or classification systems for EEG signals implemented in hardware. A total of 22 articles published between 2020 and 2026 were analyzed, selected from the ACM Digital Library, IEEE Xplore, Scopus, and PubMed. The studies were categorized into three groups: systems with acquisition (Group 1), systems without acquisition (Group 2), and application-specific integrated circuits (Group 3). Results show a predominance of dry electrodes and the ADS1299 converter in Group 1, the use of FPGAs in Group 2 to balance efficiency and flexibility, and ASICs in Group 3 for ultralow power consumption. The concentration of development in Asian countries highlights Latin America's technological dependence. We conclude that protocol standardization and real-world validation are essential for the clinical consolidation of these devices. Ultimately, the insights from this review will underpin a broader research initiative aimed at developing a hardware device for monitoring individuals with Autism Spectrum Disorder (ASD) and dementia.**

***Index Terms*—electroencephalogram, wearable, portable, hardware, acquisition.**

Foundation for Science and Technology of the State of Pernambuco (FACEPE)

I. Introduction

Wearable electroencephalogram (EEG) devices have established themselves as one of the most promising frontiers in biomedical engineering and neuroscience. These devices are characterized by their portability, light weight, wireless connectivity, ergonomic design, and the use of dry electrodes, which eliminate the need for conductive gels. This simplifies the signal acquisition process outside traditional clinical settings [1], [2]. When integrated with artificial intelligence (AI) algorithms, wearable EEG systems have demonstrated performance comparable to that of clinical equipment in tasks such as epileptic seizure detection, emotional state recognition, screening for neurodegenerative disorders, and the control of brain-computer interfaces (BCIs) [3], [4]. This opens new avenues for applications in mental health, cognitive well-being, and assistive technologies for individuals with severe motor impairments [5], [6].

In this context, convolutional neural networks (CNNs), recurrent models (LSTMs), and classical machine learning (ML) methods have been instrumental in extracting electrophysio-

logical biomarkers from EEG signals, thereby enhancing the accuracy of differential diagnoses among neurodegenerative conditions [5], [6]. The combination of preprocessing techniques (band-pass filters, independent component analysis) with feature extraction in the temporal and spectral domains enables classification accuracies exceeding 90% in tasks such as emotion recognition [7]. Embedded processing in low-power systems enables real-time analysis [8], [9].

This review serves as a theoretical foundation for the development of a wearable EEG system aimed at the assistive and diagnostic monitoring of individuals with Alzheimer's disease and Autism Spectrum Disorder (ASD). Recent advances in the development of wearable EEG devices are systematically reviewed herein, examining acquisition hardware architectures, signal processing strategies, and classifier performance in clinical and neurophysiological applications.

II. Methodology

This is a non-systematic literature review employing a structured search strategy. The guiding research question for this work was: How are wearable embedded systems for EEG signal processing currently being developed? In this context, this review aimed to map the development of hardware-implemented systems designed for the acquisition, preprocessing, and/or classification of these signals. The literature search was conducted across four databases: ACM Digital Library, IEEE Xplore, Scopus, and PubMed. The core search string was: (”wearable”OR ”wireless”OR ”portable”) AND ”EEG”AND (”hardware”OR ”system design”OR ”dry electrodes”OR ”BCI”) AND (”Alzheimer”OR ”autism”OR ”neurodevelopmental”OR ”neurodegenerative”OR ”dementia”OR ”emotion recognition”), applied to titles, keywords, and abstracts. Articles published between January 2020 and May 2026 were included, encompassing both journal articles and conference proceedings, given that the most recent advances in this field are typically disseminated primarily through conferences.

The included studies involved hardware implementation of at least one stage of development, regardless of controller type, communication modality, or the degree of system portability. Review articles, out-of-scope studies, design-only proposals, and software-only implementations were excluded. The review process followed three stages: study identification, title and abstract screening, and full-text evaluation. Finally, the pre-selected studies were reviewed in full, and their hardware and performance characteristics were extracted.

III. Results

Figure 1 presents the main results of the stages of this review. Initially, 179 studies were identified based on the search string and automatic filtering criteria for publication date and venue. Fifty-five duplicate articles were removed manually. The remaining 124 articles proceeded to the screening phase; after abstract review, the following were excluded: 18 review articles, 46 software development studies, 20 out-of-scope studies, and 1 experimental design proposal. This screening yielded 39 articles for full-text assessment, of which 17 were excluded for the following reasons: out of scope (5), development projects (3), software development (4), microcontroller used solely to toggle an LED via external command (1), unclear methodology (1), and unavailability of the full text (3). Finally, 22 full-text articles were analyzed.

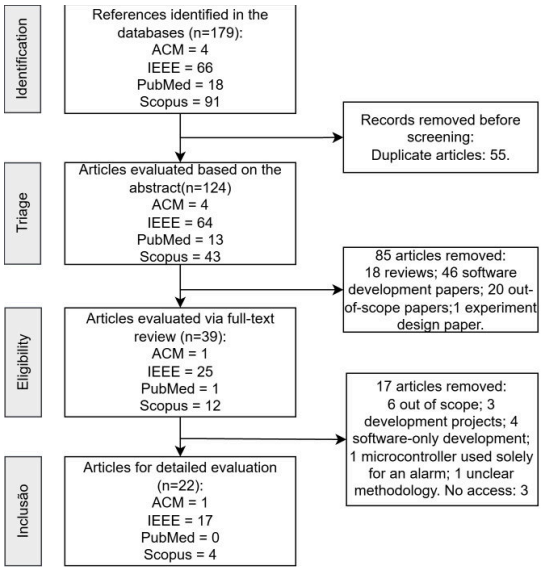

Figura 1. Complete workflow for the article survey.

Regarding the temporal distribution of publications, the year 2020 recorded the highest absolute number of studies (4). However, it is important to note that the data for 2026, comprising 3 publications, cover only the first four full months of the year, suggesting a potential for continued growth. Between 2021 and 2025, the publication counts were, respectively: 3 (2021), 1 (2022), 3 (2023), 3 (2024), and 4 (2025). Regarding geographical origin, based on the institutional affiliation of the first author of each study, Figure 2 indicates that South Korea, China, and India lead the publication ranking with 4 studies each, followed by Pakistan and Germany, with 2 publications each.

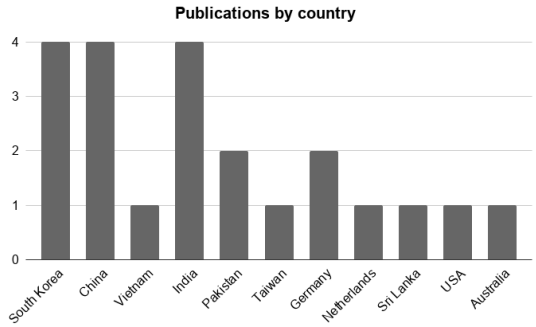

Figura 2. Number of articles by country.

The studies were grouped based on the hardware platform utilized: those that employed commercial prototyping chips (Groups 1 and 2) and those that synthesized and/or fabricated an application-specific integrated circuit (ASIC). Among the

studies based on commercial platforms, those that developed the acquisition system within their embedded pipeline were assigned to Group 1. Group 2, in turn, comprises studies dedicated exclusively to signal preprocessing and/or classification.

Group 1 comprised 10 of the 22 studies [7], [10]–[18], Group 2 included 8 [9], [19]–[25], and Group 3 consisted of the remaining four [26]–[29].

A. Group 1: Systems with Data Acquisition

The main results of this group are summarized in Table I. Initially, emotion recognition emerges as the predominant application, accounting for 60% of the applications in the analyzed studies. Only two studies implemented additional stages beyond signal acquisition. Negi et al. (2025) [14] performed analog filtering of the signals from the ADS1115 converter, employing an AD6020 amplifier and a TL084 filter. In turn, Subashri et al. (2026) [13] were the only researchers to implement the complete embedded pipeline, encompassing acquisition, preprocessing, and classification.

Regarding the acquisition interface, most systems utilized dry electrodes and low-density configurations, ranging from 1 to 8 channels, with the exception of the study by Mannatunga et al. (2020) [16], which employed 128 channels. Furthermore, the use of wireless communication modules, such as Bluetooth, Bluetooth Low Energy (BLE), and Wi-Fi, was predominant.

Regarding hardware validation metrics, only Mannatunga et al. (2020) [16] and Shi et al. (2022) [18] reported specifications beyond power consumption. Mannatunga et al. (2020) [16] detailed the front-end latency ($\sim 0.86\mu s$) and the total system latency, accounting for a 512-sample FIFO (1.07 ms). The input-referred noise averaged $\sim 3\mu V$, with a common-mode rejection ratio (CMRR) of $\sim$ 81 dB. The authors also validated the system's reliability through a one-hour continuous recording using 128 channels at 31.25 kSPS, with no recorded sample loss. In turn, Shi et al. (2022) [18] reported an average input-referred noise of $1\mu V$ peak-to-peak for their system.

B. Group 2: Systems Without Data Acquisition

In this group, studies focused exclusively on the development of preprocessing and/or classification systems. Following the trend observed in the previous group, 62.5% of the studies addressed the task of emotion recognition. Only the study by Nguyen-Duy e Dinh-Duc (2026) [9] did not implement real-time classification; instead, the authors developed an encryption system for EEG signals transmitted via Bluetooth. Notably, FPGA-based platforms were employed in half of the studies.

For validation, a subset of the studies utilized established datasets (SEED, DEAP, DREAMER, and FEXD) [9], [21], [22], whereas the remaining articles [19], [23]–[25] employed commercial devices. Wireless communication remained predominant. Most studies in this group reported detailed hardware performance metrics. Table II details power consumption, energy per classification, latency, and hardware resource utilization, along with other specifications.

C. Group 3: ASIC-Based Systems

Table II also presents the main results of the studies focused on the development of ASICs. This group exhibits greater diversity in the applications addressed. Aslam and Altaf (2020) [26] were the only researchers to design and fabricate a chip encompassing the entire embedded pipeline. However, performance validation for emotion recognition was conducted using well-established datasets from the literature (DEAP and SEED). Consequently, the system's acquisition module was not evaluated in practice. This study was the only one in the group to report system latency. Another relevant metric considered was the silicon area, detailed by all studies in this category, with the exception of de Bruin et al. (2020) [28].

IV. Discussion

The geographical analysis of the publications reveals the dominance of Asian countries in global hardware development, highlighting the absence of contributions from Latin America. This scenario reinforces the region's status as a technology importer, which directly impacts the clinical efficacy of these devices. Designing circuits for distinct climatic conditions and population profiles overlooks physiological variations, such as drastic changes in perspiration and skin conductivity, which affect signal acquisition in tropical environments. Furthermore, a methodological disproportion is evident: of the 124 unique articles screened, 50 focus exclusively on software development. Therefore, there is an urgent need for investments in the prototyping of high-fidelity acquisition hardware that accounts for these operational variables.

From a technical perspective, Group 1 highlights the widespread adoption of dry electrodes in low-density configurations, driven by the demand for wireless wearable systems. However, the inherent imbalance in skin-electrode contact impedance critically degrades the CMRR. Among the 10 studies, only Mannatunga et al. (2020) [16] reported the practical CMRR (approximately 81 dB). This value is consistent with the specifications of the converter used (Intan RHA2132); however, it falls short of the theoretical 110 dB of the ADS1299. Although the ADS1299 component was employed in 50% of the studies due to its optimization for biopotential signals, the authors omitted the measurement of the system's CMRR under operating conditions. The failure to specify the data acquisition conditions precludes test reproducibility and exacerbates the risk of suboptimal performance on skin characteristics differing from those originally tested.

Regarding energy efficiency, reporting only total nominal power can be misleading for systems that do not operate the entire embedded pipeline continuously. To establish more rigorous hardware metrics, the literature should stratify power consumption by task (acquisition, preprocessing, and classification). Another critical omission in the analyzed literature is system latency, precluding direct comparisons. Only Mannatunga et al. (2020) [16] reported this metric; however, given that it involves a 128-channel device with a wired (USB) connection, the result does not reflect the realities of

daily data acquisition using wearable devices in naturalistic environments.

The validation of the acquisition modules in this group was primarily based on the performance achieved during the classification stage. With the exception of Luo et al. (2025) [11], the systems achieved accuracies exceeding 79%. The lower performance reported by Luo et al. (2025) [11] illustrates a potential methodological flaw: the model was trained using the SEED dataset and tested on in vivo recordings from only two participants. Optimizing algorithms on established software datasets and testing them on real-world analog signals frequently results in severe accuracy degradation, as the model is unfamiliar with the specific acquisition artifacts introduced by the hardware. In contrast, Wang et al. (2025) [17] and Shi et al. (2022) [18] employed robust physical validation by correlating the signals from their devices with those from commercial equipment (including the use of gel electrodes). Both studies achieved a correlation exceeding 95%, corroborating the potential viability of low-cost portable systems.

The studies in Group 2 focused primarily on the implementation of embedded classification algorithms. The sole methodological exception was the study by Nguyen-Duy and Dinh-Duc (2026) [9], who proposed an encryption system for data previously acquired using an ADS1299. In this study, the reported metrics specifically reflect the computational cost of the security layer, which consumed only 1.2 KB of flash memory (out of a total of 85.8 KB) and introduced 5.3 ms of latency (within a total pipeline of 47.5 ms).

To evaluate the efficacy of these proposals, it is necessary to categorize the studies into those that integrated processing with commercial acquisition systems [19], [23]–[25] and those that validated their algorithms using pre-recorded datasets from the literature [9], [20]–[22]. In dataset-based studies, critical questions remain regarding the fidelity and real-world utility of these devices. Although the reported latency metrics support the designation of ”real-time”operation, this claim lacks methodological validity when the processing is not subjected to the continuous, noisy data stream of actual biological acquisition.

Regarding energy efficiency, FPGA-based and dedicated processor architectures exhibited extremely low continuous power consumption. The study by Aslam et al. (2021) [20] is particularly notable, reporting a power consumption of only $8.65\mu W$; however, the authors failed to report the energy cost per classification event. In contrast, the studies by Chen et al. (2023) [21] and Gonzalez et al. (2020) [22] detailed the efficiency of their logical operations. The system by Chen et al. (2023) [21] achieved a performance of 9.26 GOPS/W, which is lower than the 11 GOPS/W achieved by Gonzalez et al. (2020) [22], highlighting an architectural trade-off: the latter system attained greater energy efficiency despite operating with more channels, owing to the use of lower sampling rates and resolution.

Regarding clinical efficacy, classification performance plateaued between 75% and 86% accuracy, underscoring the urgent need for more robust feature extraction methods for edge processing. Studies that utilized commercial devices for real-time classification exhibited greater diversity in hardware and electrode configurations. In these instances, the reported latency more accurately reflects the complete processing cycle (from acquisition to classification). However, the systematic omission of fundamental metrics by a significant portion of the authors precludes any fair quantitative comparison. This superficiality in documenting results compromises experimental reproducibility and reflects a severe lack of scientific rigor, thereby hindering the consolidated advancement of the biomedical instrumentation field.

The third group encompasses studies focused on the development of ASICs. Among the four analyzed studies, only Aslam and Altaf (2020) [26] performed the physical fabrication of the chip and integrated the acquisition module. The result was a 6 mm^2 microchip featuring the complete embedded pipeline, exhibiting an energy consumption of 16 μJ per classification and a latency of 48 s. However, the authors conducted validation using the pre-recorded DEAP and SEED datasets. Consequently, the reported energy and time metrics do not reflect the continuous operation of the complete pipeline in practice, highlighting a methodological flaw by isolating the fabricated hardware from real-world analog acquisition conditions. Nevertheless, the merit of the design in unifying the acquisition, preprocessing, and classification stages on a single silicon die is undeniable. The remaining three studies were limited to computational simulations (synthesis or post-layout phases) without physical silicon implementation. Despite lacking physical validation, these proposals stand out for their rigorous optimization, reporting power and area values considerably lower than those of the commercial systems in the previous groups. The most notable achievement in miniaturization is that of Bahadur and Boppana (2025) [27], who designed a noise-removal circuit occupying an area of only 0.004571 mm^2.

It is essential to acknowledge the inherent limitations of this review, which stem from the time and formatting constraints characteristic of a conference paper. The literature search was restricted to four databases and included conference proceedings, which frequently present preliminary or partial research findings. Furthermore, the scope of the search string must be considered, as it may have omitted relevant studies indexed under alternative technological nomenclatures.

V. Conclusion

This review outlines guidelines for the development of low-cost wearable EEG devices aimed at monitoring ASD and dementia syndromes, highlighting the urgent need for complete, rigorously documented, and validated embedded pipelines. The concentration of research in Asia underscores the technological dependence of Latin America. From a technical standpoint, the state of the art consolidates the use of dry electrodes and the ADS1299 converter in the analog front-end, the adoption of FPGAs to balance efficiency and flexibility, and the design of ASICs for ultra-low power consumption scenarios. However, methodological heterogeneity

and the systemic underreporting of hardware metrics preclude direct comparisons and limit reproducibility. Therefore, future research must prioritize the adoption of standardized reporting protocols and the comprehensive validation of these systems in real-world clinical and data acquisition scenarios.

VI. Declaration on the Use of Artificial Intelligence

***Abstract*—Diabetic peripheral neuropathy (DPN) is a common complication of Diabetes Mellitus, and its early diagnosis remains challenging. Quantitative Sensory Testing (QST) is a well-established psychophysical technique for assessing thermal perception and pain thresholds associated with small-fiber dysfunction. This work presents an updated version of the X-QST module integrated into the SDC-X platform for thermal sensory assessment. Compared with the previous prototype, the system was redesigned to improve thermal performance and usability through the incorporation of a contact thermistor, a compact copper thermode with reduced thermal mass, a closed-loop water-cooling system, and a wireless response unit. In addition, support for both the Method of Limits (MLI) and the Method of Levels (MLE) was implemented, expanding the psychophysical testing capabilities of the platform. Experimental characterization showed approximately linear thermal ramps close to $1\,^{\circ}$C/s within the clinically relevant range around the $32\,^{\circ}$C baseline, consistent with the recommendations of the German Research Network on Neuropathic Pain (DFNS). These improvements position the X-QST as an open, low-cost, and customizable platform, whose clinical and metrological performance remains to be validated, with potential applications in clinical research and multimodal screening of diabetic peripheral neuropathy.**

***Index Terms*—QST, DPN, X-QST, Updated.**

I. Introduction

Diabetes Mellitus (DM) represents a major public health challenge due to its high prevalence and the progressive impact of its chronic complications [1]. Among these complications, Diabetic Peripheral Neuropathy (DPN) stands out because of its high incidence and its association with neuropathic pain, sensory loss, plantar ulceration, and an increased risk of lower-limb amputation [2], [3].

The early detection of DPN remains a significant clinical challenge, as impairments in small nerve fibers (Aδ and C fibers) may precede the involvement of large nerve fibers. Consequently, conventional methods such as the Semmes-Weinstein monofilament test and nerve conduction studies may not be sufficiently sensitive to detect early alterations in thermal and pain perception [4]. In this context, Quantitative Sensory Testing (QST) enables the assessment of thermal detection and pain thresholds, constituting an important tool for the functional evaluation of small nerve fibers [5].

Despite its clinical relevance, the widespread application of QST remains limited by the high cost of commercial equipment, limited portability, the need for dedicated infrastructure, and difficulties in integrating with digital health platforms. These limitations have motivated the development of low-cost instrumented systems featuring appropriate thermal control, wireless communication, and automated data acquisition.

In this context, the SDC-X platform has been developed as a modular solution for screening DM-related complications by integrating different physiological assessment modules, including X-CARDIO, X-EYE, and X-ESC [6]–[9]. As part of this platform, X-QST was developed to determine thermal detection thresholds, thermal pain thresholds, and paradoxical thermal sensations, aiming to identify sensory alterations associated with DPN [10]. Furthermore, this approach establishes a foundation for future peripheral neurological assessments, such as X-NCS, which is intended to evaluate large peripheral nerve fibers [11].

A preliminary version of the X-QST system demonstrated the feasibility of a thermal stimulation device based on a Peltier module, embedded data acquisition, and communication with a centralized software platform [12]. The present version improves thermal sensing, stimulus control, firmware, and the acquisition interface: the temperature sensor was replaced with an $F\mu$ thermistor [13], the Method of Levels (MLE) was incorporated for its higher repeatability and lower

bias in detection-threshold assessment [14]–[16], a water-cooling system was added, and the thermode was redesigned with reduced dimensions and a copper contact surface for its superior thermal conductivity [17]. These changes enable its evaluation as a more complete instrumentation prototype for future sensory screening studies.

Therefore, this work presents the evolution of the X-QST system integrated into the SDC-X platform, describing the implemented instrumental and methodological improvements, its thermal characterization, and its potential as a complementary tool for the early assessment of sensory alterations associated with DPN.

A. Related Work

Since the standardization of the protocol by the *German Research Network on Neuropathic Pain* (DFNS), commercial systems have become the reference standard for performing thermal sensory testing [18].

Among the most widely used devices is the *Thermal Sensory Analyzer* (TSA-II), later incorporated into the Pathway platform, both developed by Medoc. These systems employ a Peltier-based *thermode* with closed-loop temperature control and execute all major DFNS-standardized thermal tests—cold and warm detection thresholds (CDT, WDT), cold and heat pain thresholds (CPT, HPT), the thermal sensory limen (TSL), and paradoxical heat sensation (PHS)—using both the Method of Limits (MLI) and the Method of Levels (MLE). Owing to their high accuracy and repeatability, they are considered the reference standard for clinical and research use, although they rely on proprietary architectures and involve high acquisition and maintenance costs [5], [19].

Another widely adopted system is the *MSA Thermal Stimulator*, developed by Somedic SenseLab AB. The device employs a fluid-cooled Peltier-based *thermode*, closed-loop temperature control, interchangeable thermodes of different sizes, and dedicated software for protocol configuration and automated data acquisition. Despite its high metrological performance, its elevated cost limits its use primarily to specialized pain centers and research laboratories [20], [21].

To increase the accessibility of QST, several research groups have developed portable and lower-cost devices. Among them, the *NerveCheck*, proposed by Ponirakis *et al.* [22], performs cold, warm, vibration, and thermal pain assessments using a Peltier-based *thermode*. The device was clinically validated against the Medoc TSA-II, demonstrating comparable diagnostic performance for the assessment of DPN at an approximate cost of US$500. However, like commercial systems, it remains a proprietary solution with limited flexibility for hardware modifications and the implementation of new experimental protocols [22].

II. Materials and Methods

This section describes the methodology adopted for the prototype, including the updates implemented in the current version and the materials used in its development.

A. QST screening method

The clinical QST protocol proposed by the *German Research Network on Neuropathic Pain* (DFNS) standardized the quantitative assessment of thermal, mechanical, vibration, and pressure sensitivity [5]. In the present study, only thermal tests were considered, as they are the most relevant for the early detection of DPN [23]–[25]. The tests were performed only on the dominant hand and foot, since these regions are sufficient for DPN assessment [26].

The DFNS protocol employs the MLI, in which a *thermode* is initially applied to the skin at the baseline temperature of $32°$C. The temperature is then increased or decreased at approximately $1°$C/s to perform the CDT, WDT, CPT, HPT, and PHS tests. During the detection tests (CDT, WDT and PHS), participants indicate the moment they first perceive a cold or warm sensation. During the pain threshold tests (CPT and HPT), the response is given when the thermal stimulus becomes painful, typically by pressing a response button [5], [27]. The MLI procedure is illustrated in Fig. 1(a).

In addition to the MLI, MLE, based on adaptive psychophysical staircase procedures, was incorporated into the X-QST system [28], [29]. The test begins with a stimulus $4°$C above or below the baseline temperature, after which the thermode immediately returns to the adaptation temperature. Participants respond "YES" or "NO", either verbally or using a two-button joystick, indicating whether the stimulus was perceived. Positive responses decrease the intensity of the subsequent stimulus, whereas negative responses increase it. Whenever the response sequence changes (YES–NO or NO–YES), the step size is reduced by half until it reaches $0.2°$C. The initial $4\,°$C step provides rapid convergence toward the threshold, the successive halving at each response reversal refines the estimate following the transformed up–down staircase rule, and the $0.2\,°$C minimum step defines the resolution at which the procedure stops [28], [29]. Table I and Fig. 1(b) illustrate an example of the stimulus sequence considering a baseline temperature of $32°$C.

The MLI and MLE provide highly consistent estimates of thermal thresholds. However, the MLI generally yields slightly higher threshold values because of the participant's reaction time when pressing the response button, an effect that can be mathematically compensated [16].

TABLE I
Example of the MLE progression.

Temp. (°C)	Response	Step	Step Size
36	YES	$\uparrow 4$	Initial $\uparrow 4$
34	NO	$\downarrow 2$	Halved
35	YES	$\uparrow 1$	Halved
34.5	YES	$\downarrow 0.5$	Unchanged
34	NO	$\downarrow 0.5$	Halved
34.2	YES	$\uparrow 0.2$	Final

B. New Equipment

The X-QST prototype underwent updates throughout its hardware architecture. For clarity, the system is divided into

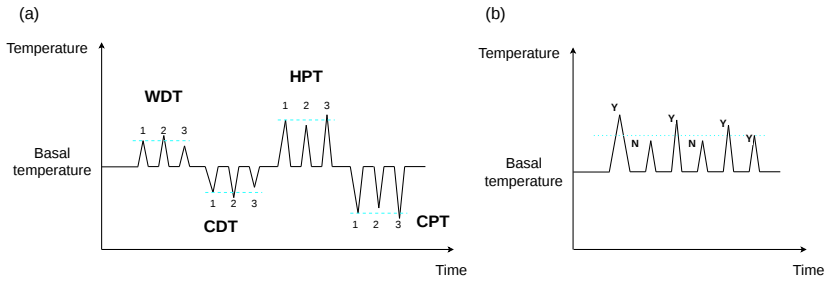

Fig. 1. (a) Method of Limits and (b) Method of Levels.

four modules: the thermal induction module, temperature sensing module, cooling module, and response unit module. The system is powered from either a 127 VAC or 220 VAC mains supply, which is converted to a regulated 12 VDC output through an AC/DC converter. Figure 2 presents the electrical and communication architecture of the complete system.

In addition, the thermode structure was redesigned to improve thermal performance and the execution of QST procedures.

1) Thermal Induction Module: The thermal stimulation module is based on the TEC1-12706 Peltier device [30], which is widely employed in QST systems according to the literature [12]. The module measures 40×40 mm and operates at up to 12 V, as recommended by the manufacturer. Thermal stimulation is achieved through the Peltier effect, in which one surface absorbs heat while the opposite surface dissipates it. Reversing the current direction inverts the heating and cooling surfaces.

Current reversal is performed using a BTS7960 H-bridge driver, allowing bidirectional current control through PWM signals generated by an ESP32 microcontroller. The ESP32 is responsible for controlling the thermal stimulation process as well as the wireless communication of the system via Wi-Fi and Bluetooth. The microcontroller is powered through an L7805 voltage regulator, which converts the 12 V supply from the AC/DC converter to 5 V.

Temperature is regulated by a discrete PID controller running on the ESP32, using the contact-thermistor reading (Eq. 1) as feedback. The controller output (± 255) is mapped to the PWM duty cycle of the H-bridge, with its sign selecting the heating or cooling channel, so that a single loop drives the Peltier device in both directions. The gains were determined empirically during the baseline and stimulation onset phases of the test.

2) Temperature Sensing Module: The previous version of the X-QST employed an infrared temperature sensor, whose measurements were affected by factors such as surface emissivity, sensing distance, field of view, and ambient temperature, compromising the thermal control performance. To improve temperature regulation, the sensor was replaced by a direct-contact Fμ thermistor (223Fμ5183), enabling faster and more accurate thermal feedback required to maintain the heating and cooling rate of approximately 1°C/s specified by the DFNS protocol [5].

The thermistor is attached directly to the thermode, providing improved accuracy, repeatability, and thermal ramp control, while increasing patient safety through reliable monitoring of the operating limits, restricted to temperatures between 0°C and 50°C to prevent skin damage [31]. The selected sensor offers an accuracy of $\pm 0.5\%$, a thermal time constant between 52 and 70 ms, and is specifically designed for medical applications [13].

The thermistor is read through a resistive divider—a 15 kΩ pull-up between the 3.3 V rail and the acquisition node, with the thermistor to ground and a 10 μF filtering capacitor—sampled by the 12-bit analog input of the ESP32. Each temperature value is obtained by averaging 80 consecutive samples, and the resulting signal is streamed at 1 Hz. The thermistor resistance is computed as $R_{\mathrm{NTC}} = R_{\mathrm{p}}\, V/(V_{\mathrm{cc}} - V)$, with $R_{\mathrm{p}} = 15$ kΩ, and converted to temperature by the β-parameter equation

$$\frac{1}{T} = \frac{1}{T_0} + \frac{1}{\beta}\,\ln\!\left(\frac{R_{\mathrm{NTC}}}{R_0}\right), \tag{1}$$

where $R_0 = 14015\ \Omega$ is the nominal resistance at $T_0 = 298.15$ K (25 °C) and $\beta = 3454$ K is the datasheet coefficient, with T in kelvin. A per-sample outlier rejection and an adaptive exponential filter are then applied to reduce electrical noise. The 0–50 °C operating range is enforced in firmware: the temperature setpoint is clamped to these limits and, if the estimated contact temperature reaches either bound, the Peltier drive is switched off and the test is aborted, preventing skin damage.

3) Cooling Module: The cooling module is a new component introduced in the current version of the X-QST. It consists of a closed-loop water-cooling system driven by an SC-300T water pump controlled by the ESP32 through a MOSFET-based switching circuit. A flyback diode is included to suppress the inductive voltage generated during pump switching, protecting the electronic circuitry.

The cooling system comprises a water block, a TEC1-12706 Peltier module, a heat sink, and a cooling fan. The hot side of the Peltier device is coupled to the heat sink and fan for heat dissipation, while the cold side is attached to an aluminum water block. Water circulating through the block is cooled and then pumped to the thermode, which incorporates a

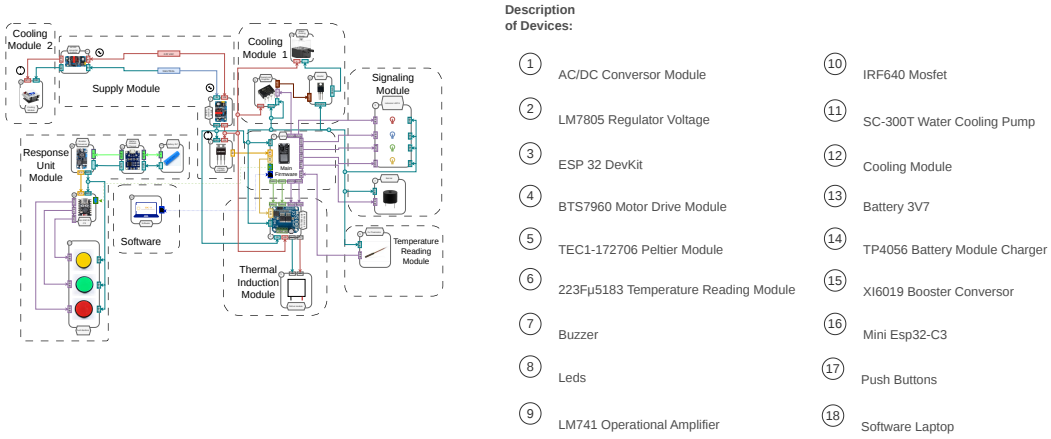

Fig. 2. Electrical and communication diagram of the X-QST system.

similar aluminum water block for heat exchange. After passing through the thermode, the water returns to the reservoir, forming a closed-loop cooling circuit that operates continuously throughout the QST procedure.

The purpose of this module is to improve heat dissipation from the hot side of the thermode Peltier device, thereby increasing cooling efficiency and thermal stability during temperature stimulation. Efficient heat removal minimizes thermal asymmetry between the hot and cold surfaces of the Peltier module, improving the accuracy of thermal stimulation. The cooling fan and the Peltier device are powered by an independent 12 V supply.

4) Response Unit Module: The response unit, already present in the previous version of the X-QST, was updated to support both QST methods. While the previous design included a single response button for MLI, the current version incorporates two additional buttons labeled ”YES” and ”NO” for the MLE, allowing participants to indicate whether the thermal stimulus was perceived.

The main improvement in this module is the replacement of the wired interface with Bluetooth communication. The response unit is based on a mini ESP32-C3 microcontroller, which communicates wirelessly with the main ESP32 whenever a response button is pressed. The module is powered by a rechargeable 3.7 V lithium battery managed by a TP4056 charging circuit and a boost converter that provides the required 5 V supply to the microcontroller.

The response unit also includes four status LEDs indicating power, Bluetooth connection, the MLI operating mode, and the MLE operating mode. The visual and acoustic signaling circuits were maintained from the previous version, as they had already been implemented and described in detail elsewhere [32].

5) Thermode Structure: The thermode was completely redesigned to improve the thermal performance of the X-QST system. The previous version consisted of a 191 $\times$ 234 $\times$ 116 mm enclosure containing a $40 \times 20 \times 40$ mm aluminum block that served as the stimulation surface. A TEC1-12706 Peltier device was attached to the opposite side of the block, while the generated heat was dissipated through a heat sink and cooling fan [10].

In the proposed design, the aluminum block is no longer used as the stimulation interface. Instead, it acts as a water-cooled heat exchanger integrated with the cooling module described in Section II-B3. The hot side of the Peltier device is coupled to this aluminum block, whereas the cold side is attached to a 0.1 mm thick copper plate (40×40 mm), which is placed in direct contact with the participant’s skin. In addition, the thermode enclosure dimensions were reduced to 70 $\times$ 30 $\times$ 50 mm.

This redesign substantially reduces the thermal mass of the stimulation interface, since only the thin copper plate must be heated or cooled instead of an entire aluminum block. Consequently, the Peltier device reaches the desired temperature more rapidly, improving heat transfer, thermal stability, and the ability to maintain the heating and cooling rate of approximately 1°C/s required by the DFNS protocol. Furthermore, the reduced dimensions improve the ergonomics of the device, making it easier to position on different anatomical regions during QST examinations.

C. Firmware and Software

The firmware and software were updated to support the hardware modifications introduced in the new X-QST system. The firmware continued to be developed in C++ using the Arduino IDE for the ESP32 microcontroller, maintaining the software architecture adopted in the previous version [32].

The main firmware updates include the implementation of both the MLI and the MLE, allowing the system to perform different psychophysical testing protocols. In addition, the temperature acquisition routine was modified by replacing the previous I^2C communication with an analog input associated with the new contact thermistor. Bluetooth communication with the ESP32-C3 microcontroller was also implemented to support the wireless response unit.

The host software remained developed in Python 3.6.9 using a graphical interface designed in Qt Designer and implemented through the PyQt5 framework. Communication between the software and the embedded system continues to rely on the *websocket-client* library for transmitting examination parameters and receiving real-time data. The software was updated to support the new testing methods and the wireless response unit while preserving the overall architecture of the previous version.

III. Results

A. New Equipment

The updated X-QST system, incorporating the redesigned thermode, wireless response unit, water-cooling module, and contact temperature sensor, is shown in Fig. 3.

The redesigned thermode (Fig. 3(a)) is substantially smaller and lighter, exposing only a thin copper plate as the skin-contact surface, with heat dissipation transferred to the external water-cooling module. The response unit (b) adds two buttons for the MLE and replaces the wired link with Bluetooth, improving participant mobility. The cooling module (c) circulates cooled water through the thermode, increasing heat dissipation and thermal stability during stimulation. Finally, the concentrator box (d) houses the main circuitry in a redesigned acrylic enclosure with the pump relocated to a separate housing; these changes serve mechanical organization and do not directly affect the thermal performance of the system.

B. Firmware and Software

The firmware architecture remained consistent with the previous version. The main update was the integration of the wireless response unit through the ESP32-C3: depending on the selected method, the main ESP32 enables the MLI or MLE buttons over Bluetooth and the participant's responses are transmitted wirelessly, allowing the test sequence to proceed automatically. The communication flow is illustrated in Fig. 4.

The host software required only minor modifications to support the new functionality. As shown in Fig. 5, two additional controls were incorporated to allow the operator to select either the MLI or the MLE protocol, while the remaining interface and communication structure were preserved.

C. Thermal characterization

The thermal behavior of the redesigned thermode was evaluated from bench runs recorded directly by the contact thermistor at a sampling rate of approximately 1 Hz, all starting from the $32\,^{\circ}$C adaptation baseline. Two cooling and two heating runs are reported. During the adaptation phase the setpoint is held at the $32\,^{\circ}$C baseline (gains $K_p = 3.5$, $K_i = 0.15$, $K_d = 1.0$); during stimulation, the setpoint is advanced at the target rate of $1\,^{\circ}$C/s and an auxiliary rate loop ($K_p = 5.0$, $K_i = 0.5$, $K_d = 1.0$) keeps the ramp close to this value. The gains were tuned empirically; the near-linear ramps and the baseline hold within about $\pm 1\,^{\circ}$C reported in Fig. 6 provide experimental evidence of stable regulation, although a formal stability analysis was not performed.

For each run, the ramp rate was obtained as the slope of a linear regression of temperature versus time over the range of interest around the baseline (32 to $12\,^{\circ}$C for cooling and 32 to $42\,^{\circ}$C for heating). The coefficient of determination (R^2) of this fit is used as a measure of ramp linearity, that is, how close the rate is to a constant value; an R^2 near 1.0 indicates a straight, constant-rate ramp, which is the behavior required for reproducible threshold estimation. Three aspects were assessed: the ramp rate (which should approach the $1\,^{\circ}$C/s recommended by the DFNS protocol), the ramp linearity, and the agreement between repeated runs as a first indication of repeatability.

Figure 6 summarizes the results. Figure 6(a) overlays the two cooling runs: both produced a ramp of $-0.76\,^{\circ}$C/s with $R^2 \approx 1.00$ and differed from each other by less than 1%, so the two curves are almost indistinguishable. Figure 6(b) shows the two heating runs, which followed closely matching slopes and gave average rates of 0.87 and $0.84\,^{\circ}$C/s over the full excursion (32 to $48\,^{\circ}$C), that is, agreement within about 2% with $R^2 \geq 0.99$. Near the baseline the heating rates were slightly more variable (0.78–$0.89\,^{\circ}$C/s over 32–$42\,^{\circ}$C), as one run started somewhat more slowly before settling onto the common slope. For cooling, the rate decreased toward the $0\,^{\circ}$C limit (to about $0.25\,^{\circ}$C/s over the full excursion), as expected from the reduced heat-pumping capacity of the Peltier device near its extremes. The thermode was held near the $32\,^{\circ}$C baseline within about $\pm 1\,^{\circ}$C, and the firmware kept the temperature inside the 0–$50\,^{\circ}$C range throughout.

These results are favorable in the region that matters most for QST. The cooling ramps were close to the $1\,^{\circ}$C/s DFNS target, highly linear ($R^2 \approx 1.00$), and nearly identical between runs (within 1%), while the heating ramps agreed to within about 2% over the full excursion ($R^2 \geq 0.99$), indicating good short-term repeatability in both directions, with the near-baseline heating segment showing slightly larger variability. These values were obtained from a small number of runs: a systematic repeatability study covering both directions, together with overshoot, settling-time, and hysteresis analyses, is still required to fully establish the metrological performance and is left for future work.

IV. Discussion

The modifications implemented in the updated X-QST represent a technical evolution over the previous prototype, both in hardware design and in compliance with international QST protocols. The copper stimulation surface and the Fμ contact thermistor [13], [17] enabled thermal ramp rates of approximately $1\,^{\circ}$C/s, consistent with DFNS recommendations and of the same order of magnitude as the rates targeted by commercial systems [5], [19], [20], whereas the previous prototype exhibited rates from $1\,^{\circ}$C/s to $2\,^{\circ}$C/s. The thermal characterization (Fig. 6) confirmed near-linear ramps of the order of $1\,^{\circ}$C/s in both directions around the baseline, with good short-term repeatability: the two cooling runs agreed to within 1% and the two heating runs to within about 2%

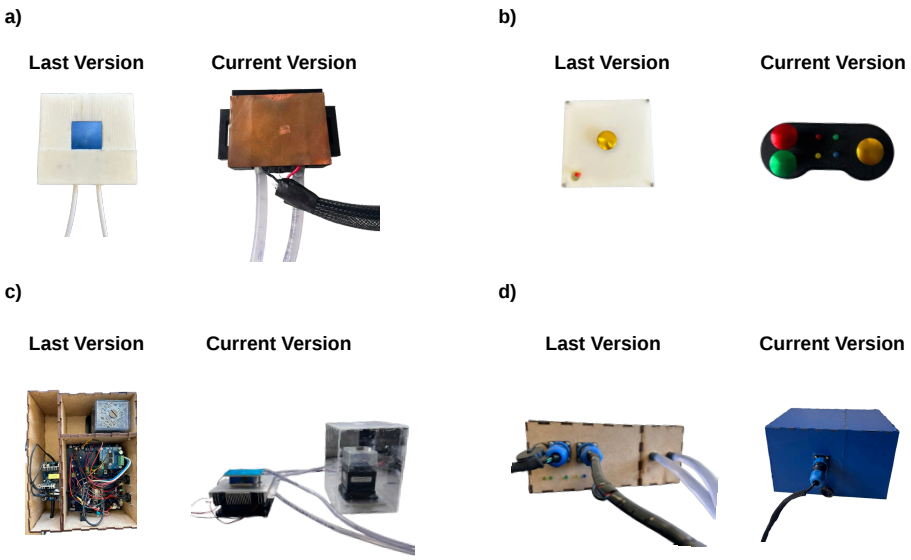

Fig. 3. Previous and current X-QST system: (a) thermode, (b) response unit, (c) cooling module, and (d) concentrator box.

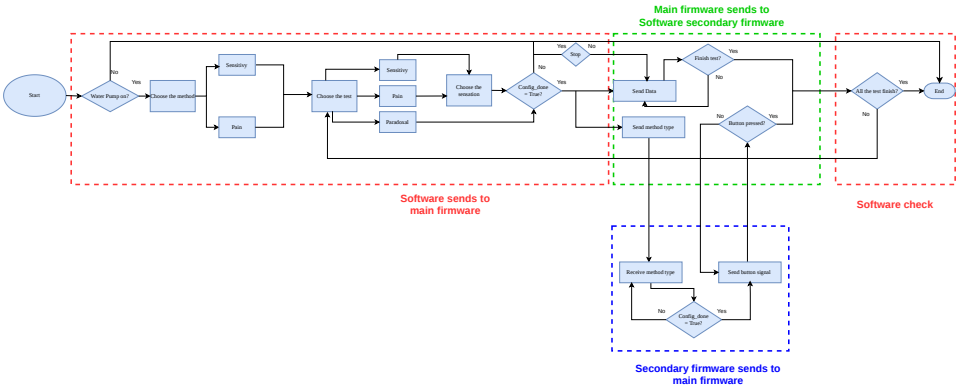

Fig. 4. Communication flow of the X-QST system.

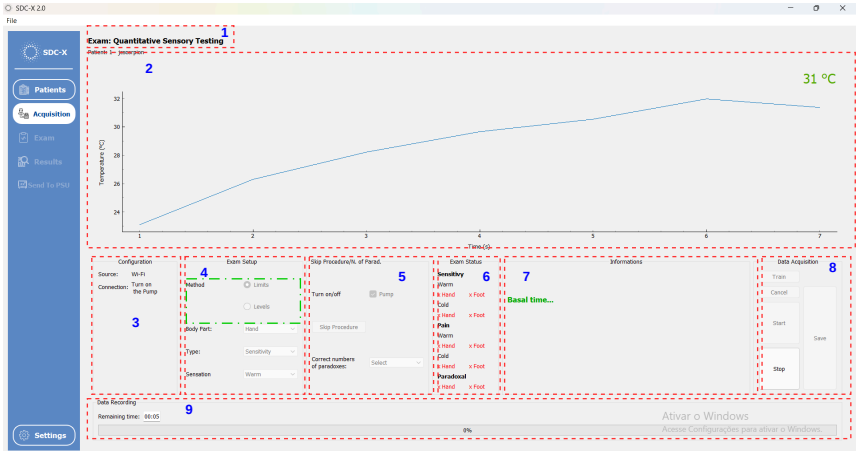

Fig. 5. Acquisition interface of the updated X-QST software.

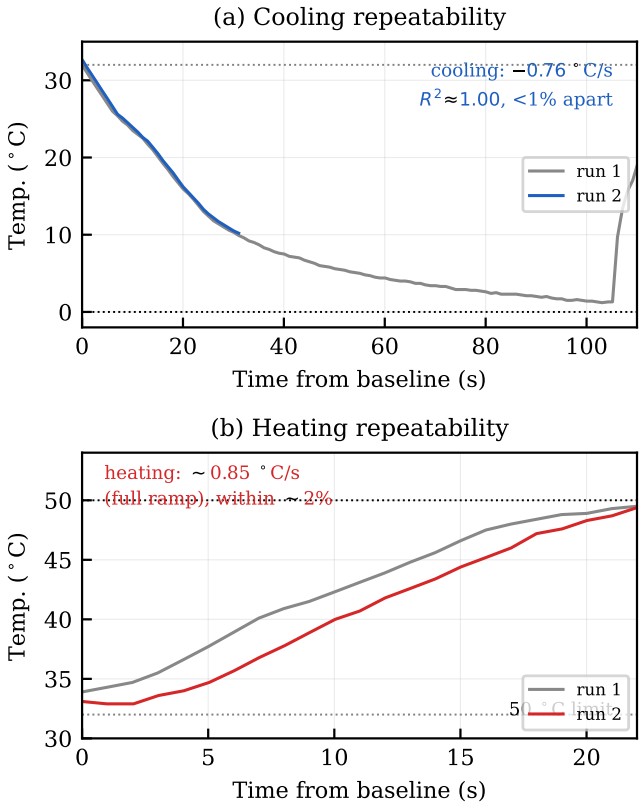

Fig. 6. Thermode temperature recorded from the contact thermistor. (a) Two cooling runs overlaid, showing near-identical ramps ($-0.76\,^{\circ}$C/s, $R^2 \approx 1.00$, agreement within 1%); (b) two heating runs with closely matching slopes (0.87 and $0.84\,^{\circ}$C/s over the full excursion, within about 2%).

over the full ramp. A larger repeatability study across different conditions remains pending.

The redesigned architecture also improved the usability of the system. The reduced thermode dimensions and the introduction of a Bluetooth-based wireless response unit made the device more compact and ergonomic without changing the examination protocol. Furthermore, the incorporation of the Method of Levels (MLE) extends the experimental capabilities of the platform, since this psychophysical procedure is less affected by participant reaction time and provides higher repeatability for thermal detection thresholds than the MLI [14]–[16].

Compared with representative QST systems, the proposed X-QST incorporates the core functionalities found in commercial devices, including bidirectional thermal stimulation, closed-loop temperature control, and automated execution of DFNS-compatible protocols. At the same time, it provides features that are generally unavailable in proprietary systems, such as an open hardware and software architecture, wireless communication, implementation of custom psychophysical protocols, and low-cost development. Compared with the portable NerveCheck system [22], which was primarily designed for clinical screening, the proposed platform offers greater flexibility for research applications through its customizable hardware and software.

A further distinguishing feature is the integration of the X-QST into the SDC-X platform rather than functioning as a standalone device, allowing QST results to be analyzed together with autonomic, pupillometry, sudomotor, and nerve conduction assessments—a multimodal approach uncommon in commercial and portable QST devices, which are generally limited to thermal sensory assessment alone. Overall, these advances establish a low-cost, open, and flexible platform with potential for future clinical research, contingent upon further validation.

Although the proposed system demonstrated improvements in thermal performance and protocol compatibility, additional clinical validation involving larger cohorts of participants with different stages of diabetic peripheral neuropathy is still required. Furthermore, direct comparisons with commercial QST systems under identical experimental conditions will be important to further establish the clinical performance of the proposed platform.

Table II summarizes the key characteristics of representative commercial and low-cost QST systems, highlighting only the functionalities implemented in the proposed X-QST.

V. Conclusion

This work presented an updated version of the X-QST module, integrated into the SDC-X platform, for quantitative thermal sensory assessment. The updated system incorporates a contact temperature sensor for direct monitoring at the thermode, a liquid-cooling module for heat dissipation during Peltier operation, a redesigned low-thermal-mass thermode supporting DFNS-compatible temperature ramps, a wireless response unit that reduces cabling during the examination, and firmware and software supporting both the MLI and the MLE.

Bench characterization showed near-linear heating and cooling ramps close to $1\,^{\circ}$C/s around the baseline, with the two cooling runs agreeing to within 1%. Overall, these updates consolidate the X-QST as a more modular and open research platform within the SDC-X ecosystem, whose clinical and metrological maturity still depends on future work: a full repeatability analysis, clinical validation in larger participant cohorts, and direct performance comparisons with commercial QST systems.

***Abstract*—Electromyography (EMG) is a non-invasive technique widely used to evaluate muscle electrical activity, supporting clinical assessment, rehabilitation, and human–machine interaction studies. Despite its relevance, the acquisition hardware required for reliable EMG monitoring is often cost-prohibitive for hospitals, clinics, and research laboratories with constrained budgets. This paper presents the design and validation of a low-cost, portable, single-channel testbed for surface EMG acquisition and initial signal classification. The proposed system integrates surface electrodes, an instrumentation amplifier, active analog filtering stages, and a dedicated signal-conditioning circuit connected to a microcontroller for sampling and communication. The system transmits acquired signals to a server for storage, organization, and downstream analysis. A proof-of-concept evaluation used hand-related muscle activations (e.g., fist and grasp), and an unsupervised segmentation approach based on K-Means clustering separated resting and contraction intervals in the absence of precise temporal labels. The results demonstrate the feasibility of an end-to-end pipeline—from acquisition and conditioning to data management and machine-learning-based processing—indicating the platform's potential applicability in physical therapy, sports training, and biofeedback scenarios.**

***Index Terms*—Electromyography (EMG), Low-cost system, Acquisition channel, Machine learning algorithms.**

I. Introduction

Electromyography (EMG) is a technique for evaluating and recording the electrical activity of skeletal muscles, with established applications in medicine, physical therapy, biomedical engineering, and prosthetic device control. By detecting bioelectrical signals from muscle contraction, EMG supports clinical diagnoses, physiological studies, and the development of rehabilitation systems [1].

The non-invasive version of the technique, known as surface electromyography, uses electrodes placed on the skin to capture electrical signals from muscles. This approach has gained prominence for its practicality, safety, and clinical applicability, as well as for enabling functional tests in dynamic situations and providing greater patient comfort. Electromyographic signals can be used for various purposes, such as assessing muscle fatigue, controlling prostheses, biofeedback, ergonomics, and monitoring rehabilitation [2]. The signals obtained represent the sum of action potentials from active motor units and are influenced by factors such as electrode placement, muscle morphology, and tissue electrical characteristics [3].

Despite EMG's advantages, the high cost of commercially available equipment and reliance on imported technology remain significant barriers to its widespread use in Brazil. Many currently available devices are aimed at cutting-edge research, making them economically unfeasible for clinics, public hospitals, and educational institutions with limited resources. The growing demand for accessible technological solutions is driving the development of low-cost, portable, and customizable EMG acquisition systems. In parallel, 3D printing and open-source robotic prosthesis models have gained traction as a promising alternative for producing personalized, low-cost devices. Technologies such as Fused Deposition Modeling (FDM) enable the fabrication of mechanical components tailored to individual needs, contributing to the democratization of prosthetic access. In this context, the InMoov project, conceived by [6], stands out as one of the first robotic hand models developed entirely with open-source code and intended for 3D printing. This project offers advantages such as modularity, replicability, and extensive documentation, making it appropriate for both educational purposes and for prototyping assistive devices.

This work proposes developing and validating a low-cost testbed for acquiring and classifying EMG signals. The proposal aims to integrate electronics, computing, embedded systems, and three-dimensional printing into a functional, easily replicable, and applicable kit for teaching and research. This proposal is expected to contribute to technological accessibility, interdisciplinary training, and the advancement of biomedical engineering.

The rest of this work is organized as follows: the second section presents an in-depth exploration of the background that informs the methodologies used in this research. The third section addresses the electronic component, including circuit development and the methodological steps required to create a multidisciplinary educational kit for evaluating EMG signals. The fourth section presents the initial results of a clustering process toward an intelligent EMG signal classification using machine learning (ML) algorithms. Finally, the concluding chapter presents the main insights and considerations from the research effort.

II. Theoretical Background

This section presents the basic concepts essential for understanding this work. This section introduces EMG signals and outlines the steps for constructing a low-cost EMG signal acquisition prototype.

A. Electromyography Signals

Electromyography is a technique that examines muscle function by detecting the electrical potential generated during contraction of specific muscle groups. These bioelectrical signals result from the flow of ions across muscle fiber membranes and are recorded by electrodes on the skin surface or inserted into the muscle [3].

The electromyographic signal allows the estimation of muscle strength, activation time, impulse conduction velocity, and motor coordination across different tasks. The application of electromyography extends from clinical contexts—such as the diagnosis of neuromuscular diseases, fatigue assessment, and biomechanical diagnosis- to engineering applications, including active prostheses and human-machine interfaces.

Beyond its diagnostic use, EMG signal analysis is important in rehabilitation and biofeedback. In therapeutic contexts, the signal is used to monitor muscle activation patterns and train patients to optimize the use of muscle groups affected by injuries or neurological dysfunctions [5].

Electromyographic signals are also strategic in the development of biomechatronic devices. According to [2], myoelectric signals captured on the skin can be processed in real time and used as inputs for prosthesis control, enabling more natural and responsive movements. This principle underlies myoelectric prosthetic systems that respond more accurately to the user's intention.

Another relevant aspect is the stochastic nature of the EMG signal even under controlled conditions. This variability requires robust methods for acquisition, amplification, filtering, and interpretation to ensure data reliability and applicability in clinical or technological contexts.

Therefore, understanding the fundamentals of electromyography is essential not only for correctly interpreting data obtained in research and clinical applications but also for developing integrated solutions that incorporate sensors, embedded systems, and assistive devices.

1) Surface Electromyography: Surface electrodes capture the potential difference generated by muscular electrical activity during contraction, with signal intensity depending on muscle fiber depth, inter-electrode distance, skin impedance, and motor unit geometry [5].

The nature of the EMG signal is complex: it is a low-amplitude wave (generally between 0.1 mV and 5 mV) with a wide frequency range, varying mostly between 10 Hz and 500 Hz. Because it is a low-amplitude signal that is easily contaminated by external noise, acquisition systems need adequate circuits for amplification, filtering, and electrical isolation. The integrity of the captured signal depends directly on electrode quality, cabling type, and the efficiency of the electronic system's signal-conditioning stages [2].

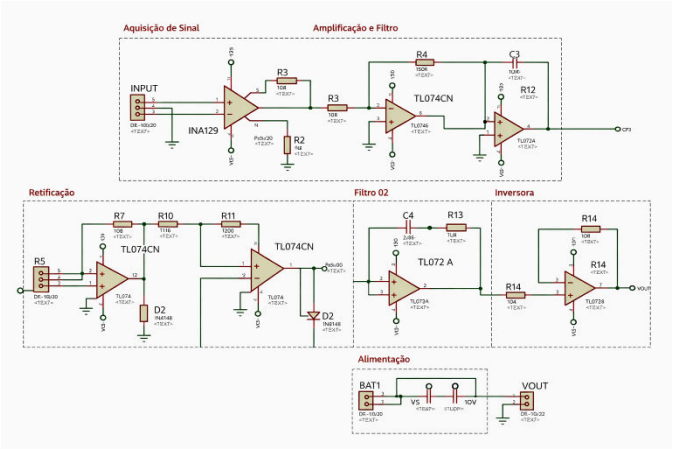

Fig. 1. Diagram of Prototype V03.

The EMG signal amplitude can range from 1 mV to 10 mV (peak-to-peak) or from 0 to 1.5 mV (rms) and contains components up to 10 kHz. The most significant energy in the EMG signal lies between 5 Hz and 500 Hz. Although harmonics exist up to 400 Hz, about 95% of the signal energy is contained within this range, with the harmonic between 400 Hz and 450 Hz being the last one of interest.

B. Electronic Instrumentation

Signal acquisition and conditioning in Prototype V03 rely on operational amplifiers from the TL07x family (TL072, TL074) and the INA129 instrumentation amplifier. These components were selected for their high input impedance (on the order of $10^{12}\,\Omega$, low input-referred noise, and adequate common-mode rejection ratio (CMRR $>$ 90 dB), which are essential to preserve the integrity of low-amplitude EMG signals (typically below 5 mV) [1], [2]. The TL074 integrates four amplifiers into a single package, reducing cost and board complexity compared with multiple discrete TL072 units, at the expense of a higher input offset voltage; this trade-off was mitigated by offset adjustment in the final gain stage.

Signal conditioning follows a classical chain: differential amplification via the INA129, a band-pass filter to isolate the frequency range of interest, active rectification, and low-pass smoothing to extract the signal envelope. Performing most of the noise rejection and envelope extraction in the analog domain reduces the computational load on the microcontroller. It limits the impact of electrode-skin artifacts, power-line interference, and adjacent-muscle crosstalk on the acquired signal.

III. EMG Signal Acquisition

The EMG signal acquisition prototype used in this work, Prototype V03, is a refined version that consolidates lessons learned from previous versions and implements a more complete, integrated approach to acquiring, processing, and using EMG signals (Figure 1).

Efficient PCB routing is fundamental in bioinstrumentation projects, as it reduces parasitic capacitance, trace inductance,

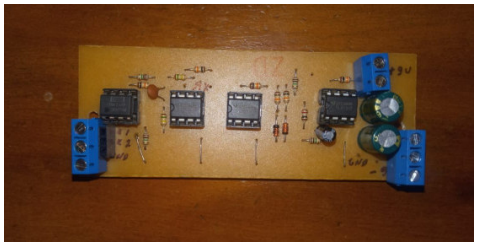

Fig. 2. Image of the final version of the Prototype V03.

and unwanted coupling that can compromise the fidelity of low-amplitude signals such as EMG. Accordingly, the layout of Prototype V03 was carefully planned to separate power, signal, and ground plane traces, minimize noise coupling between analog and digital signals [2], and reduce trace lengths between the amplifiers and the electrode input connectors, thereby limiting the system's vulnerability to ground loops, capacitive reference interference, and radio-frequency/AC power-line noise.

This component configuration was designed to optimize SNR, providing high CMRR and reducing the influence of electromagnetic noise and potential variations between electrodes, following the classic recommendation in biomedical instrumentation projects to separate power, signal, and ground-plane traces.

The Prototype V03 architecture presents well-defined stages for amplification, filtering, and offset adjustment, adequately conditioning the signals before digitization by the Arduino microcontroller. The use of DIP (Dual In-line Package) components also facilitates eventual replacements during the testing phase.

In the Prototype V03 final version, all essential signal-conditioning steps were consolidated onto a single board, including amplification, filtering, rectification, and smoothing. This integration significantly improved the quality of the signal supplied to the microcontroller and, consequently, the prosthesis's functional performance (Figure 2).

The Prototype V03 circuit comprises multiple carefully tuned stages: amplification, performed with low-noise amplifiers, raises the EMG signal to levels suitable for digitization without introducing unwanted distortion or saturation. Active high-pass and low-pass filters were implemented to attenuate content outside a band centered near 106 Hz, reducing external noise and physiological artifacts at the cost of narrowing the pass-band relative to the full theoretical EMG bandwidth. Rectification: the AC EMG signal was converted to a DC component to facilitate interpretation by the prosthesis control system. Smoothing: smoothing techniques, such as moving average filters or integrators, were used to ensure a stable signal free of rapid, non-physiological oscillations.

Integrating all signal-processing stages into a single board resulted in a more compact, less interference-susceptible, and more reliable system for practical applications. The acquired signal is then sent to the Arduino microcontroller, which receives it already amplified and rectified, performs the analog-to-digital conversion, and enables real-time visualization through the serial interface. One practical application is that the acquired EMG signals can be used immediately to control the prosthesis servomotors (Figure 3).

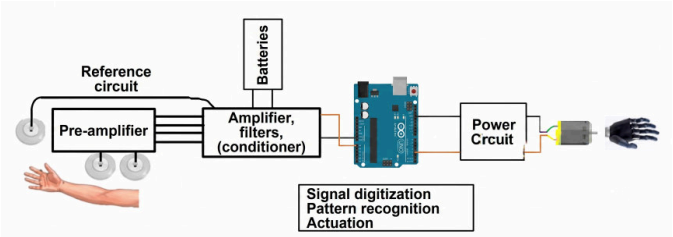

Fig. 3. Complete diagram of the acquisition and prosthesis movement system developed in this work.

The INA129 was used as a differential amplifier to amplify the myoelectric signal. The equation for the applied gain was $G = R_1/R_2$, with $R_1 = 1\text{M}\Omega$ and $R_2 = 1\text{k}\Omega$, with a total gain of 1000. After initial amplification, a non-inverting amplifier with moderate gain was implemented to compensate for potential filtering losses. This gain is $G = 1 + (R_3/R_1)$, with $R_3 = 150\text{k}\Omega$ and $R_1 = 1\text{M}\Omega$, resulting in a gain of approximately 1.15, sufficient to maintain the signal at operational levels without distortion.

Cascading a first-order high-pass and a first-order low-pass stage with an identical corner frequency f_c does not produce a flat pass-band spanning f_c to arbitrarily higher or lower frequencies; instead, it yields a first-order band-pass response peaking at f_c. Solving $|H(j\omega)| = 1/\sqrt{2}$ of the peak value for this cascade gives -3 dB corner frequencies at $\omega_c(\sqrt{2}-1)$ and $\omega_c(\sqrt{2}+1)$, which for $f_c \approx 106$ Hz correspond to approximately $f_{\text{low}} \approx 44\,\text{Hz}, and f_{\text{high}} \approx 256\,\text{Hz}$.

This is substantially narrower than the 10–500 Hz range discussed in Section II-A: signal content below approximately 44 Hz and above approximately 256 Hz is attenuated by more than 3 dB, which, combined with the effective sampling rate limitation discussed in Section V-A, further restricts the fraction of the theoretical EMG bandwidth that is faithfully captured by the current implementation. Assigning independent R/C values to the high-pass and low-pass stages, corner frequencies near 20 Hz and 450 Hz, respectively, would allow the filter to approximate the intended pass-band and is identified as a concrete design revision for future hardware iterations.

Signal rectification was performed with TL074 amplifiers and 1N4148 diodes, forming an active rectification circuit. This configuration eliminates negative half-cycles with minimal voltage loss, an essential characteristic for low-amplitude signals such as myoelectric signals.

This process was fundamental to extracting the signal envelope, which represents muscle intensity over time—a relevant data point for applications in prosthesis control, biofeedback, and clinical analysis.

After rectification, an active low-pass filter was used to smooth the signal and form the envelope. With the values

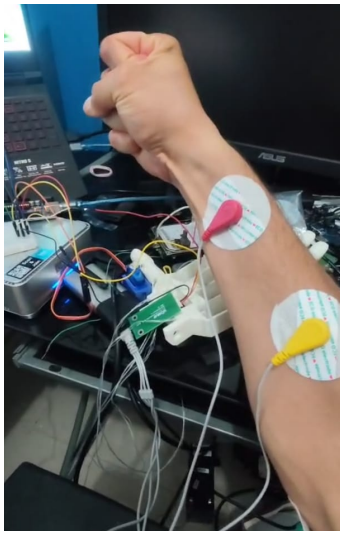

Fig. 4. Electrode position for EMG signal acquisition.

$R = 80.2\text{k}\Omega$ and $C = 1\mu\text{F}$, and applying the following formula, we have:

$$f_c = \frac{1}{2\pi RC} \Rightarrow f_c \approx 1{,}98\,\text{Hz} \quad (1)$$

This value allows the envelope to be obtained without rapid oscillations, facilitating visualization and clinical interpretation.

In the final stage, an inverting amplifier with gain control via a potentiometer was used, which allows the signal amplitude to be adjusted as needed. The formula used was $G = -R_{\text{POT}}R_{14}$, with $R_{\text{POT}} = 20\text{k}\Omega$ and $R_{14} = 1\text{k}\Omega$, resulting in a variable gain of up to -20 times, with the possibility of signal inversion as required by the output circuit.

IV. EMG Signal Acquisition System

Figure 4 illustrates the procedure for positioning the surface electrodes, strictly following the guidelines proposed by [1], which recommend cleaning the skin with isopropyl alcohol and aligning the electrodes along the muscle fibers. Correct skin preparation is critical to signal quality, as skin impedance and the presence of oil or residue can significantly compromise the system's SNR.

The choice of Ag/AgCl surface electrodes with conductive gel is justified by their low contact impedance and widespread use in EMG studies. To ensure accurate data acquisition, an inter-electrode distance of 20 mm was maintained. Furthermore, strategies were adopted to reduce external interference, such as using twisted and shielded cables, in accordance with the recommendations of [4].

After collecting the myoelectric signals described previously, the next step was to read and interpret them using a microcontroller. For this purpose, we developed C/C++ code in the Arduino IDE to capture and process real-time EMG signals.

Figure 5 illustrates a real example of an EMG signal captured by Prototype V03, with defined peaks and variations consistent with muscle contraction and rest cycles. This visualization helps identify noise artifacts, such as tremors or involuntary movements, and adjust the filters and activation thresholds in the embedded code.

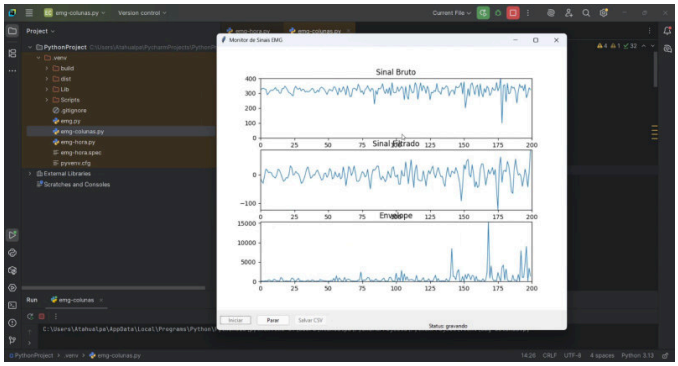

Fig. 5. Image illustrating the screen with the EMG signal capture process using Prototype V03.

Furthermore, this step reinforces hardware-software integration, bringing the system closer to functional biofeedback, where the user can observe the effects of their neuromuscular activity in real time. This approach is highlighted by [7] as promising in assisted rehabilitation and prosthetic control systems using myoelectric signals, especially in contexts that require user adaptation to the device.

The next development stage involved integrating Prototype V03 with the data acquisition system and storage software. Acquired EMG signals were automatically exported to a spreadsheet containing, for each sample, a timestamp and the corresponding captured voltage value, providing a solid foundation for subsequent statistical analysis and digital processing. This structured format enabled both qualitative and quantitative analysis of the signals, allowing verification of interference presence, filter quality, and the effectiveness of the amplification gain applied to the circuit. The interpretation of this signal followed the methodological recommendations described by [2], which guide the analysis of parameters such as dominant frequency, signal energy, and waveform integrity.

V. EMG Signals Identification

The development and implementation of Prototype V03 represented a significant advance in the proposed system's technical and functional trajectory. Integrating EMG acquisition hardware, electronic processing, and actuator control demonstrated the viability of a low-cost testbed for EMG signal acquisition.

The development of an automated system for data export and storage, with spreadsheet generation and graphical visualization of the signals, also contributed to validating the results by providing a consistent basis for subsequent analyses and inter-subject comparisons, in accordance with the methodologies adopted by [7].

To validate the acquired EMG signal, two hand movements were chosen: grasp and fist. The main goal is to evaluate

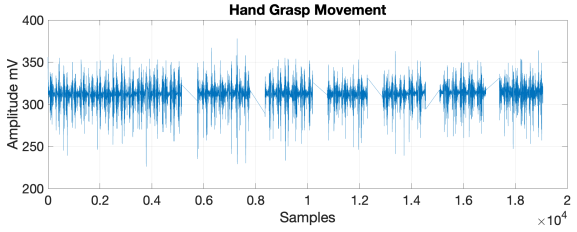

Fig. 6. Time-domain hand grasp movement signal acquired by Prototype V03.

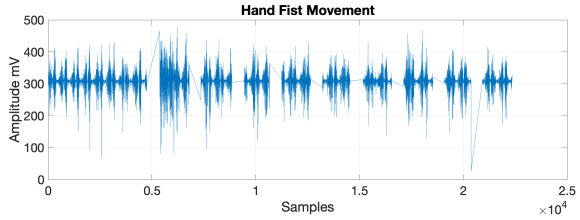

Fig. 7. Time-domain fist grasp movement signal acquired by Prototype V03.

whether ML algorithms can classify them or, at least, identify them. The choice of these two hand movements is explained as follows.

The first movement is grasping, which remains a challenging problem in prosthetics due to complex control requirements. For individuals with prosthetic hands, the ability to perform basic movements, such as grasping objects of various shapes, is vital. EMG signal analysis is the primary method for providing input to prosthetic devices to enable grasping [8]. The time-domain hand grasp movement signal acquired by Prototype V03 can be seen in Fig. 6. The signal consists of sequences of grasps followed by the hand's resting position, to facilitate identifying the moments when the hand is performing a grasp.

The second movement is the hand fist, which is important for evaluating hand force [9]. The time-domain hand fist movement signal acquired by Prototype V03 can be seen in Fig. 7. The signal consists of sequences of fist movements followed by the hand's resting position, to facilitate identifying moments when the hand is performing a fist movement.

Because no prior labels indicate the exact moments of muscle activation, the K-Means algorithm ($k = 2$) was used to segment each recording into Rest and Contraction states. The mean signal envelope was computed over sliding windows with 50% overlap; the window length was set to 150 ms, based on the effective sampling rate measured from the acquired timestamps (approximately 450 Hz), which is consistent with feature-extraction window lengths commonly reported in the surface EMG literature. Class assignment was performed through centroid analysis: the cluster with the lower numerical centroid value was labeled as *Rest*, and the cluster with the higher centroid value as *Contraction*.

This effective rate reflects the throughput of the ASCII-formatted serial logging pipeline rather than a fundamental limitation of the microcontroller's analog-to-digital converter, which can support substantially higher conversion rates. Serializing each sample as human-readable text (timestamp, raw, filtered, and envelope values) introduces per-sample transmission and formatting overhead that caps the achievable logging rate well below the theoretical maximum implied by the serial baud rate alone. The results presented in this section should be interpreted as demonstrating the feasibility of the acquisition-to-classification pipeline under the current logging throughput, rather than as evidence of full-bandwidth signal fidelity. Increasing the effective logging rate via a higher baud rate or a binary transmission protocol in place of ASCII formatting is a direct, low-cost path to closing this gap.

This procedure yielded 291 windows for the hand grasp recording and 303 windows for the fist/pinch recording, with a Rest/Contraction split of 70.4%/29.6% and 88.1%/11.9%, respectively — consistent with contractions occupying a smaller fraction of the total recording time than rest periods in both movements. Fig. 8 illustrates the distribution of these windows over time, showing a clear separation between low-energy (Rest) and high-energy (Contraction) periods for both movements.

To quantitatively assess the separability of the two classes, we trained a K-Nearest Neighbors (KNN, $k = 3$) classifier on the K-Means-derived labels for each movement. Because the feature windows overlap by 50%, a naively shuffled train/test split can result in near-duplicate windows appearing in both sets, artificially inflating accuracy. To avoid this, the dataset was evaluated using (i) a chronological hold-out, in which the last 20% of each recording (in time) was reserved for testing, and (ii) 5-fold *TimeSeriesSplit* cross-validation, in which every fold is contiguous in time, and no fold is trained on windows that occur after the ones it is tested on.

Table I summarizes, for each movement, the overall hold-out and cross-validated accuracy alongside the per-class precision, recall, and F1-score on the hold-out set. The hold-out accuracy reached 98.31% for the hand grasp movement and 100.00% for the fist/pinch movement, with cross-validated accuracies of 99.58% $\pm$ 0.83% and 99.60% $\pm$ 0.80%, respectively. Fig. 9 shows the corresponding confusion matrices.

It should be noted that the labels used to train and evaluate the KNN classifier were derived from the K-Means segmentation itself, rather than from an independently annotated ground truth (e.g., manual onset/offset annotation or a synchronized reference signal). Consequently, these results should be interpreted as a measure of the internal consistency and separability of the extracted feature, rather than as a validation against an external gold standard. Establishing such a gold standard is left as future work.

TABLE I
PER-CLASS CLASSIFICATION METRICS (HOLD-OUT SET)

Movement	Class	Precision	Recall	F1
Hand grasp	Rest	0.978	1.000	0.989
	Contraction	1.000	0.933	0.966
Fist/pinch	Rest	1.000	1.000	1.000
	Contraction	1.000	1.000	1.000

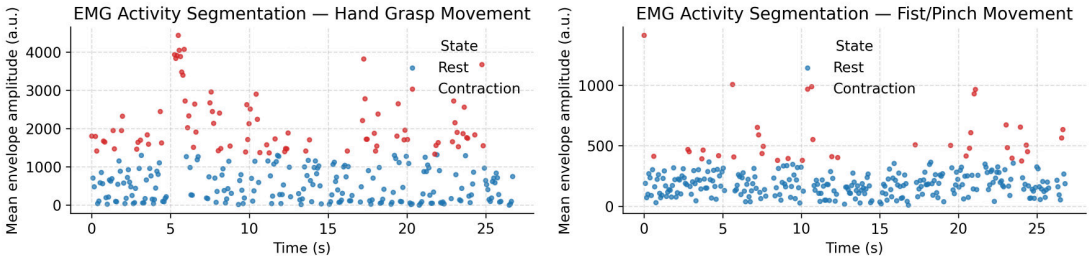

Fig. 8. EMG activity segmentation via K-Means clustering for the hand grasp (left) and fist/pinch (right) movements. Datapoints correspond to temporal windows, color-coded by cluster assignment (Rest vs. Contraction).

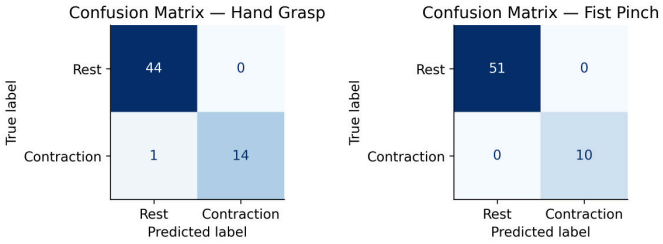

Fig. 9. Confusion matrices for the hand grasp (left) and fist/pinch (right) movements (hold-out set).

VI. Conclusion

This study successfully developed and validated Prototype V03, a low-cost surface electromyography acquisition system designed to democratize access to biomedical instrumentation. By consolidating the amplification, filtering, rectification, and smoothing stages into a single, layout-optimized printed circuit board, the proposed design reduces electromagnetic interference and supports signal conditioning suitable for educational and proof-of-concept human–machine interaction applications; achieving the acquisition bandwidth required for full clinical-grade fidelity will require increasing the effective data logging rate, as discussed below.

Experimental validation using hand grasp and fist movements demonstrated the feasibility of the end-to-end pipeline. Applying the K-Means algorithm showed that the acquired signals exhibit discriminative characteristics that enable automatic segmentation of muscle activity states (contraction versus rest) based on signal envelope energy. The successful clustering of these states indicates that the proposed hardware and processing approach can support myoelectric control use cases. Overall, this work delivers a functional, replicable, and accessible platform that bridges electronics, computing, and biomedical engineering, supporting experimentation and learning in resource-constrained environments. Future work will focus on increasing the effective data logging rate — through a higher serial baud rate or a binary transmission protocol — to meet the $\geq$1 kHz sampling requirement discussed in Section II-A, alongside real-time validation with participants, broader functional performance analysis under diverse conditions, and the integration of more advanced classification models to enable robust multi-gesture recognition. Furthermore, commercial equipment is being acquired in order to compare the performance of the proposed low-cost system.

***Abstract*—Continuous physiological monitoring is central to neonatal intensive care, yet conventional NICU sensing, adhesive electrodes, contact pulse oximeters, and wired thermistors carry documented limitations, including skin injury, restricted mobility, and interference with family-centered developmental care. Over the past decade, flexible, wireless, and fully contactless alternatives have proliferated. Still, the resulting evidence remains fragmented across distinct technical communities, with no unified mapping of the conventional and emerging sensor ecosystem. Following the PRISMA-ScR guidelines and a Population, Concept, and Context (PCC) framework (Population, neonates in the NICU; Concept, sensors used in physiological monitoring; Context, the hospital NICU), searches in PubMed, Scopus, and IEEE Xplore retrieved 197 records, reduced to 166 after deduplication; 40 *primary* studies published between 2016 and 2026 were included after two-stage screening. Review articles were excluded from this count and used only as external triangulation, not as primary evidence. Emerging solutions predominate (26 of 40, 65%), optical transduction leads (15 of 40), and flexible or wearable form factors outnumber rigid designs (23 of 40 versus 9 of 40). Activity concentrates on respiratory rate (20 of 40) and heart rate (18 of 40), whereas electroencephalography and transcutaneous bilirubin each appear in only 1 of 40 studies and blood pressure only as a secondary channel (3 of 40). Under an explicit maturity rubric, no emerging paradigm reached multicenter, adequately powered, head-to-head validation, and 85% of studies omit regulatory status. We consolidate these findings into a cross-parameter gap matrix and a research-priority roadmap intended to guide future validation-focused work and enable direct cross-technology comparison.**

***Index Terms*—neonatal monitoring, sensors, neonatal intensive care unit, scoping review.**

I. Introduction

Neonates admitted to Neonatal Intensive Care Units (NICUs), particularly those born prematurely, depend on continuous multiparametric physiological monitoring to detect life-threatening events such as apnea, bradycardia, desaturation, and thermal instability [1]. According to the World Health Organization (WHO), approximately 15 million neonates are born prematurely each year worldwide, and prematurity-related complications remain the leading cause of death among children under five, making monitoring technology a direct determinant of population-level outcomes. Current practice relies predominantly on adhesive ECG electrodes, contact pulse oximeters, and wired thermistors connected to bedside monitors [2]. This architecture, although clinically effective, imposes well-characterized limitations: the structurally immature skin of the preterm neonate is highly vulnerable to adhesive-related injury [3]; cable tangle restricts spontaneous movement and complicates caregiving [4]; and the visual complexity of a wired setup creates psychological barriers to parental skin-to-skin contact and bonding, now recognized as critical to neurodevelopmental outcomes [4], [5]. In response, the past decade has witnessed a proliferation of alternative sensing proposals spanning flexible electronics, textile-integrated sensors, wireless wearables, and fully contactless approaches based on camera imaging and radar [2], [5].

This research, however, remains fragmented across distinct technical communities, biomedical engineering, materials science, computer vision, and clinical neonatology, and further segmented by parameter, with no comprehensive mapping that situates conventional and emerging solutions side by side and identifies which parameters remain disproportionately underserved.

This scoping review systematically maps conventional and emerging sensor technologies for neonatal physiological monitoring across nine parameter categories: peripheral oxygen saturation (SpO_2), electrocardiography and heart rate (ECG/HR), body temperature, respiratory rate, blood pressure, electroencephalography (EEG), transcutaneous bilirubin, blood glucose, and movement and body position. Specific objectives are to characterize transduction principles and form factors per parameter, quantify conventional versus emerging representation, assess validation and regulatory transparency using an explicit maturity rubric, and identify underrepresented parameters as priority targets. The synthesis is deliberately descriptive and quantitative-distributional, as befits a mapping objective [6], and culminates in a cross-parameter gap matrix and a research-

priority roadmap, the review's principal contribution, rather than an efficacy appraisal of any single intervention, unlike recent reviews focused on specific vital-sign subsets [2], [5].

This mapping is restricted to physiological monitoring. A complementary and increasingly prominent axis, behavioral monitoring of pain, clinical state, and neurodevelopmental status, falls outside the PCC Concept as defined here but shares much of the same sensing infrastructure (cameras, microphones, and physiological sensors). As documented in a co-authored companion work [7], AI-based automated neonatal pain assessment faces translational barriers structurally analogous to those identified here.

II. Methods

This section presents the review design, information sources, search strategy, study selection, and data extraction and appraisal procedures.

A. Study Design and Protocol

This scoping review followed the PRISMA-ScR guidelines [6]. The review question and eligibility criteria were structured with the PCC framework: Population, neonates, infants within the neonatal period (up to 28 days of postnatal age), including preterm infants of any gestational age, admitted to the NICU; Concept, sensors employed in physiological monitoring equipment; Context, the hospital NICU setting. No restrictions were imposed on study design, sensor maturity, or validation method, to capture the full spectrum from proof-of-concept proposals to clinically validated devices. The protocol was not prospectively registered; to support reproducibility, we report the a priori PCC criteria and the exact database queries in full below, and the complete per-study extraction dataset is openly available [8]. Consistent with the scoping methodology, we treated review articles (narrative, systematic, or scoping) as secondary sources: they were excluded from the 40 included primary studies, used only to contextualize the Introduction and Discussion and for backward snowballing, and never counted as primary evidence.

B. Information Sources and Search Strategy

Searches were conducted in PubMed, Scopus, and IEEE Xplore, with institutional access via Centro Universitário FEI, on June 16, 2026, to ensure complementary coverage of the biomedical, engineering, and multidisciplinary literature. The strategy combined three Boolean domains joined by AND operators: (1) neonatal population terms, (2) sensor/monitoring technology terms, and (3) NICU context terms. Iterative calibration was required because excessive AND-linked terms yielded near-zero retrieval while insufficient restriction produced unmanageable volumes; the final calibrated string was applied uniformly across databases using platform-appropriate syntax. In Scopus, we restricted the publication year to 2017 onward and the document type to articles and reviews. The exact strings are reported below.

PubMed:
```

```

The search strategy was iteratively refined to broaden its sensitivity: initial queries proved overly restrictive for the heterogeneous terminology spanning engineering and clinical databases, and were progressively expanded to improve recall of relevant studies.

C. Study Selection

Selection followed a two-stage process. Records were imported into Rayyan (Rayyan Systems Inc., Cambridge, MA, USA) for deduplication; the initial search retrieved 197 records (PubMed 24, Scopus 81, IEEE Xplore 92), reduced to 166 unique records. The first author performed screening and extraction, resolving uncertain cases at both stages in consultation with the senior authors. During title-and-abstract screening against the PCC criteria, 60 records were excluded (reviews without original sensor data, content unrelated to sensors, or context/population outside the inclusion criteria), leaving 106 reports to be retrieved. Of these, 54 could not be retrieved because the full text was not openly accessible under our institutional subscriptions, and the remaining 52 advanced to full-text assessment (per-reason counts in Fig. 1). Full-text assessment excluded a further 12 records for absence of extractable sensor-level data (including reviews and commentaries identified only at full text), population or context outside the neonatal-NICU criteria, or insufficient methodological detail to characterize sensor and validation attributes, yielding 40 studies for synthesis.

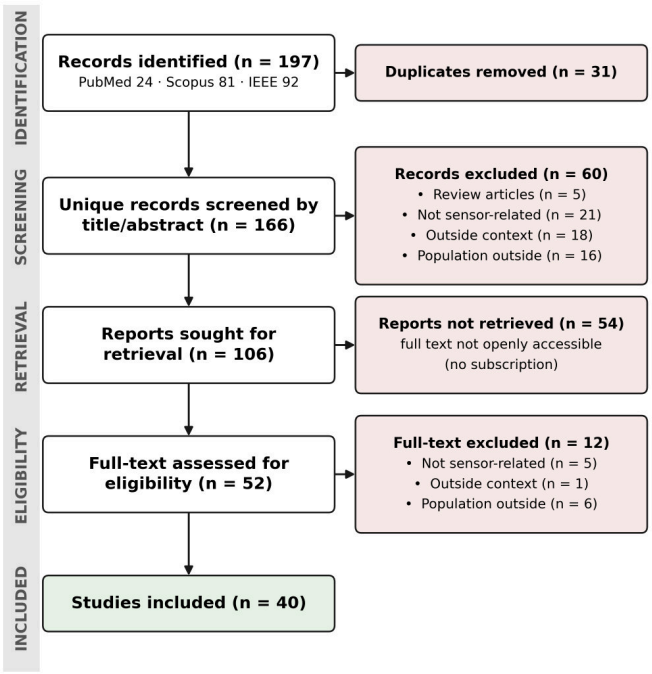

Fig. 1. PRISMA-ScR study selection flow diagram.

D. Data Extraction and Maturity Appraisal

For each of the 40 included studies, a predefined form captured: monitored parameter(s); sensor type and physical transduction principle; form factor (rigid, flexible, textile, wearable, implantable, or camera-based); validation type; population sample; reference standard; performance metrics; regulatory aspects; and author-acknowledged limitations. We counted studies addressing more than one parameter in each relevant category. Because PRISMA-ScR does not mandate formal risk-of-bias appraisal, we instead applied a design-appropriate maturity rubric, assigning each study its highest attained validation stage: Stage 0, theoretical/conceptual (no experimental data); Stage 1, bench, in vitro, phantom, or simulation; Stage 2, in vivo in non-target subjects (adult volunteers or animals); Stage 3, in vivo in neonates, typically single-center and small-sample; Stage 4, multicenter, adequately powered, head-to-head validation against the clinical reference standard. Studies using several approaches were assigned their highest stage to avoid double counting. The complete study-level table (population, sensor, reference standard, sample size, and metrics) is openly available [8]; Table I summarizes the parameter-level synthesis.

III. Results

This section reports study characteristics, technology distribution across parameters, validation status, reported metrics, and author-acknowledged limitations.

A. Overview of Included Studies

The 40 studies were published between 2016 and 2026, concentrated in 2017–2020 and 2022–2023 (Fig. 2), reflecting two waves of activity coinciding with the emergence of flexible epidermal electronics and, later, the post-pandemic acceleration of contactless monitoring. Most propose emerging solutions, experimental, prototype, or alternative to the current standard (26/40, 65%); 8/40 (20%) are hybrid adaptations of established commercial technology; and 6/40 (15%) evaluate the conventional standard directly.

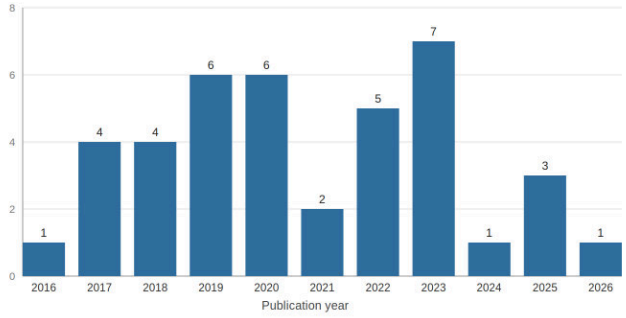

Fig. 2. Temporal distribution of the 40 included studies (2016–2026).

B. Distribution by Monitored Physiological Parameter

Fig. 3 presents the distribution across the parameter categories. Because studies addressing more than one parameter are counted in each, parameter occurrences exceed the number of studies; all percentages use the 40 studies as the denominator. Respiratory rate and ECG/HR together account for nearly half of all occurrences (20/40 and 18/40, respectively), reflecting their central role in detecting apnea, bradycardia, and acute cardiorespiratory events. Temperature (10/40), movement/body position (7/40), and SpO_2 (6/40) follow; blood glucose (4/40), blood pressure (3/40), crying/vocalization (2/40), and incubator-microenvironment variables (humidity and gas composition, 3/40) complete the distribution. In marked contrast, EEG and transcutaneous bilirubin each appear in only 1/40 studies, and blood pressure only as a secondary channel within multiparameter platforms, with no dedicated sensing principle proposed. This asymmetry is clinically significant: EEG is the primary tool for neonatal seizure detection and neuroprotection, and bilirubin measurement is critical for hyperbilirubinemia screening, yet both remain underrepresented relative to their clinical weight.

C. Conventional versus Emerging Technologies

Eleven of the 40 studies integrate three or more parameters into a single platform [9]–[19], generally using flexible wireless wearables that replace multiple cables and adhesive electrodes with a pair of soft, skin-conformable patches. Representative examples include the battery-free binodal epidermal systems of [11], later expanded into the commercial ANNE One platform [9], [19], [20], the e-textile NeoWear system [21], and platforms with textile piezoresistive sensors [12].

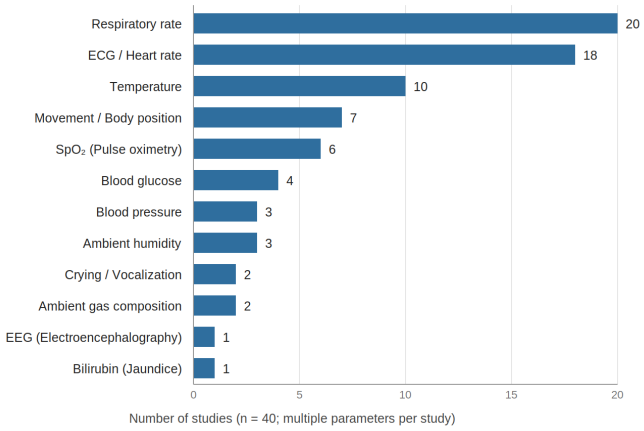

Fig. 3. Distribution of included studies by monitored physiological parameter.

D. Physical Principles and Sensor Forms

Optical sensors predominate (15/40), mainly contact or remote photoplethysmography, whose versatility across heart rate, respiratory rate, and SpO_2 explains this share. Thermal/infrared (9/40) and resistive/piezoresistive sensors (7/40) follow, concentrated in temperature/thermographic respiration and respiration/movement applications, respectively. Electrochemical sensors (6/40) are almost exclusively in glucose monitoring; electrical sensors (5/40) mainly in ECG platforms; and electromagnetic/radar sensors, the most recent frontier, account for 4/40. Regarding form factor, flexible (13/40) and wearable (10/40) sensors together (23/40) already outnumber rigid designs (9/40), while contactless camera (5/40) and radar (4/40) systems form a growing group (9/40). No implantable sensors were identified, consistent with a noninvasive orientation.

E. Technological Mapping by Parameter

1) ECG and heart rate: Beyond the multiparameter wearables already described, dedicated ECG/HR solutions include capacitive and textile electrodes embedded in a smart mattress [22], enabling passive acquisition without skin attachment; a handheld dry-electrode detector for delivery-room resuscitation [23]; and a forehead reflectance-photoplethysmography heart-rate monitor [24]. Among contactless approaches, camera-based imaging photoplethysmography extracts cardiac pulse from spatiotemporal variations in skin reflectance [25]–[27], while Doppler/FMCW radar detects chest-wall microdisplacements unaffected by light or clothing [28], [29]. The coexistence of these two contactless principles reflects a field still diversifying, with no single modality yet established as a preferred alternative to the adhesive-electrode standard.

2) Respiratory rate: Respiratory rate is the most investigated parameter (20/40), reflecting apnea-of-prematurity detection and the signal's accessibility to mechanical, thermal, optical, and electromagnetic transduction. Piezoresistive pressure-sensitive mats beneath the mattress detect thoracic displacement without skin contact [30]. Low-power PVDF-film pyroelectric sensors transduce thermal airflow variations and suit battery-powered wearables [31], [32]. Near-infrared spectroscopy, conventionally used for cerebral oxygenation, has been adapted to extract respiratory rate from the same signal without additional hardware [33]. Long-wave infrared thermal cameras detect the thermal plume of nasal/oral airflow, and camera-based methods track respiratory motion [34], [35], while Doppler/FMCW radar detects sub-millimeter chest-wall displacement, operating through incubator walls and bedding [36]. This breadth reflects intense investment but the absence of a single dominant alternative to conventional impedance pneumography.

3) SpO_2 and pulse oximetry: SpO_2 occupies a distinct position: rather than proposing novel principles, the literature validates the established pulse-oximetry standard in specific neonatal subpopulations [37], having largely converged on conventional contact PPG, with open questions clinical (poor perfusion, motion, pigmentation) rather than technological. When SpO_2 appears in innovation-oriented studies, it is almost exclusively an integrated channel within multiparameter flexible/wearable platforms [9], [11], [13], [16], [19], where innovation resides in system-level miniaturization and packaging rather than the transduction principle, an important distinction under the PCC framework. The relative absence of fundamentally novel SpO_2 principles, such as contactless remote-PPG oxygen estimation, is a noteworthy gap, likely reflecting the difficulty of extracting reliable saturation from non-contact optical signals under variable neonatal perfusion and pigmentation.

4) Temperature: Conventional thermistors in multiparameter incubator systems [14] represent the clinical standard: accurate yet subject to the mobility and contact limitations of wired sensing. Contactless infrared thermopile sensors integrated into flexible wearable patches [16] reduce contact burden while preserving the body-proximate architecture. At the most innovative tier, thermal-and-RGB camera fusion with deep learning enables continuous, contactless temperature estimation across the body surface, approaching contact thermometry accuracy with the added capability of spatial mapping [38], [39]. Computational demand and illumination sensitivity remain the main translational barriers, and none of these studies addresses regulatory pathway or deployment-scale validation.

5) Blood pressure: No study proposed a dedicated noninvasive sensing principle for neonatal blood pressure. It appeared in only three studies, exclusively as a secondary channel within multiparameter systems [9], [11], [17], despite clinical reliance on invasive arterial catheters or intermittent oscillometric cuffs. This is consistent with Senechal et al. [2], who similarly identified only isolated reports. Although cuffless approaches based on pulse transit time, PPG waveform analysis, and ballistocardiography have been extensively investigated in adults, their translation to neonates remains largely unexplored.

6) Blood glucose: The four glucose studies share a common approach: rather than novel neonatal-specific principles, all adopt commercial continuous glucose monitors (Medtronic,

Dexcom) using minimally invasive subcutaneous electrochemical biosensors with 1–5-minute wireless readings [40]–[43]. Recurrent limitations include reduced accuracy during therapeutic hypothermia, when peripheral vasoconstriction impairs interstitial glucose delivery precisely when monitoring is most needed [40]; interstitial–blood discrepancies during rapid glycemic change; and the absence of neonatal-specific calibration in platforms validated against adult physiology. This near-exclusive reliance on repurposed adult CGM technology reflects both a translational gap and an opportunity for neonatal-specific glucose sensing.

7) Electroencephalography: Only one study addressed neonatal EEG sensor technology, evaluating low-cost dry electrodes as an alternative to conventional wet electrodes [44]. Although the system achieved signal quality sufficient for seizure screening, elevated electrode–scalp impedance and increased susceptibility to motion and EMG artifacts remain barriers to replacing the clinical gold standard. Given the central role of EEG in seizure detection, neuroprotection, and neurodevelopmental assessment, this limited engineering activity contrasts sharply with its clinical importance.

8) Transcutaneous bilirubin: Neonatal hyperbilirubinemia affects 60–80% of neonates in the first week of life and, if inadequately monitored, carries risks of kernicterus and permanent neurodevelopmental damage, yet only one study addressed bilirubin sensing. That study describes a prototype wireless transcutaneous jaundice meter using optical reflectance spectroscopy [45], extending established commercial bilirubinometry (e.g., Dräger JM-105, Natus BiliChek) with wireless connectivity for continuous rather than episodic measurement, but reporting only proof-of-concept results without validation against serum bilirubin across the relevant concentration, pigmentation, or gestational-age range. Neither Senechal et al. [2] nor Williams et al. [5] identify bilirubin as an active frontier. This convergent absence flags this parameter as a genuine field-wide deficit.

9) Movement and body position: Movement and body position (7/40) extends beyond motor-activity detection to neurological assessment, pain quantification, and prevention of positional complications. Under-mattress ballistographic sensors detect micro-mechanical vibrations from movement, respiration, and cardiac activity without body contact, though they remain susceptible to environmental mechanical noise [46]; fiber-mat systems similarly enable continuous, unobtrusive movement quantification in preterm infants over long durations [47]. E-textile platforms with integrated inertial measurement units enable spatially resolved posture quantification while remaining skin-contact-free [21], with applications to objective assessment of general movements. Accelerometers, as dedicated channels within broader multiparameter wearables, are the most common implementation [9], [10], [12], [15], [19] and also enable motion-artifact detection. The absence of standardized movement metrics remains the primary barrier to comparative evaluation.

10) Incubator microenvironment (boundary of scope): A small set of studies targets the incubator microenvironment, humidity (three studies) and gas composition (two), overlapping across three distinct studies [14], [15], [48], rather than body-directed physiological signals, using conventional capacitive humidity, electrochemical oxygen, and resistive temperature sensors within microcontroller platforms with wireless transmission. Humidity control limits transepidermal water loss in extremely preterm skin, and gas monitoring maintains FiO_2 targets, since both hyperoxia and hypoxia carry risks of retinopathy of prematurity and bronchopulmonary dysplasia. These components are technologically mature; the engineering challenge is integration, miniaturization, and electromagnetic compatibility rather than transduction innovation.

F. Validation Status under the Maturity Rubric

Under the rubric of II-D, 26/40 studies (65%) reached Stage 3 (in vivo neonatal validation), though typically with small, single-center samples (Section III-H). Three reached Stage 2 (two adult-volunteer, one animal), seven Stage 1 (five bench/in vitro, two phantom/simulation), and four Stage 0 (theoretical), summing to 40. Critically, no study reached Stage 4: none reported multicenter, adequately powered, head-to-head validation against the clinical reference standard, the explicit threshold we adopt for translational readiness. Regulatory transparency is poor: 34/40 (85%) omit regulatory status; of the remaining six, five mention the FDA and one IEC/ISO, none in sufficient detail to assess deployment readiness. This profile reflects the field's predominantly proof-of-concept maturity and echoes, on a larger scale, the methodological-quality concerns of Senechal et al. [2], reinforcing the case for standardized reporting that discloses regulatory pathway alongside performance metrics.

G. Reported Performance Metrics

Reported metrics are markedly heterogeneous and largely incommensurable: accuracy, Pearson/intraclass correlation, mean absolute (percentage) error, RMSE, Bland–Altman bias and limits of agreement, sensitivity/specificity, F1/AUROC, and signal-to-noise ratio all appear, often within the same parameter category. Absent a standardized protocol specifying reference standard, metric, statistical method, and test conditions, the evidence cannot be synthesized into a coherent comparative ranking of competing technologies. A consensus validation framework analogous to ANSI/AAMI/ISO 81060-2 (noninvasive blood pressure) or ISO 80601-2-61 (pulse oximeters), but designed for neonatal physiology, is a concrete, high-priority need; the CONSORT-adapted checklist proposed by Senechal et al. [2] is a meaningful step toward it. Complete per-study metrics are openly available [8].

H. Limitations Reported by Primary Studies

The limitations acknowledged by primary authors are recurrent and structurally interconnected. Small sample size combined with single-center design is the most pervasive, restricting statistical power and generalizability; Senechal et al. [2] corroborate this at scale, reporting a median sample of only 10 patients. Motion-artifact susceptibility is the second

most common, particularly in contactless camera- and radar-based systems, and is most acute during clinical events (apnea, seizures, handling), when reliability matters most. Reduced accuracy under specific pathophysiological conditions, glucose sensors during therapeutic hypothermia, optical sensors affected by perfusion or pigmentation, creates an inverse relationship between clinical need and reliability.

These limitations map onto distinct translational dimensions that should not be conflated: feasibility (can the signal be acquired?), accuracy (does it agree with the reference?), safety (does it avoid harm, e.g., skin injury or thermal load?), and implementation (can it be deployed and sustained in routine care?). Caregiver and clinician burden, setup time, alarm handling, workflow disruption, and the parental-bonding benefit of contactless designs were rarely quantified, despite being decisive for adoption. Collectively, these point to a need for larger, multicenter, long-duration studies with standardized metrics and head-to-head comparisons as a prerequisite for evidence-based translation.

IV. Discussion

The mapping converges on a field in active technological transition, but the picture is uneven and qualified by important exceptions rather than uniform.

A. An Uneven Technological Transition

The clearest signal is a broad shift away from wired, adhesive-dependent, single-parameter architectures toward two paradigms: integrated flexible wireless multiparameter wearables (ECG/HR, SpO_2, temperature, respiratory rate, and, secondarily, blood pressure via soft chest/limb patches) and fully contactless sensing (camera PPG, infrared thermography, radar), the latter at an earlier stage but advancing rapidly. This converges with two independent contemporaneous reviews: Senechal et al. [2], covering 60 contactless/wireless studies, report respiratory rate (72%) and heart rate (51%) dominating; Williams et al. [5] document the proliferation of wireless/wearable proposals for heart rate and oxygenation. Convergence across three independent reviews with distinct databases suggests a genuine research trajectory rather than a sampling artifact. The transition is not uniform, however, and framing it as a simple "innovation versus standardization" dichotomy risks overstating coherence. Two exceptions matter: for SpO_2, the field has effectively converged on conventional pulse oximetry as a validated standard, so the corresponding studies characterize that standard rather than propose new principles; conversely, many "emerging" proposals remain at bench or theoretical stages (Stages 0–1) and are far from the maturity of the wearables dominating the ECG/HR and respiratory-rate literature. The transition is thus best described as parameter-dependent and concentrated in the most technically accessible signals.

B. Clinically Consequential Gaps and Priority Criteria

We designate a parameter a high-priority gap when it satisfies three explicit criteria: representation at or below $\sim$1/40 among emerging studies (or presence only as a secondary channel); well-established, high clinical relevance; and corroborated underrepresentation across at least two independent external reviews. Transcutaneous bilirubin (1/40; near-universal clinical relevance; absent as a frontier in both external reviews), neonatal EEG (1/40; central to seizure and neuroprotection monitoring), and noninvasive blood pressure (3/40, secondary channel only; no dedicated neonatal principle, corroborated by 1/60 in [2]) each meet all three. We triangulate these designations against reviews whose scope exceeds our date and language limits; a definitive priority ranking would require complementary searches in additional databases and gray literature, and we present the criteria so others can reproduce or contest them.

C. Regulatory Pathways and Clinical Adoption

Translation requires navigating regulatory pathways that the reviewed literature largely ignores. In the United States, most such devices would follow the FDA 510(k) route when a substantially equivalent predicate exists, the De Novo pathway for low-to-moderate-risk devices without a predicate, or premarket approval for higher-risk cases [49]; software-driven and AI-enabled functions additionally fall under Software-as-a-Medical-Device and evolving AI/ML guidance [50]. In the European Union, the Medical Device Regulation (2017/745) governs CE marking and has raised the clinical-evidence bar [51]. Beyond approval, adoption depends on prospective validation in the target population, interoperability with existing monitors and electronic records, reimbursement and health-technology-assessment evidence, and demonstrated reductions in caregiver burden. The near-total absence of engagement with these pathways is itself a marker of proof-of-concept maturity and a barrier that standardized reporting frameworks must address by requiring disclosure of the intended regulatory route alongside performance metrics.

D. A Research-Priority Roadmap

Table I consolidates the cross-parameter analysis into a gap matrix and a pragmatic roadmap, ranking parameters by representation, clinical need, and highest validation stage reached. Two priorities emerge. First, consolidation: for respiratory rate and ECG/HR, where many competing principles already reach Stage 3, the pressing need is head-to-head, multicenter validation to identify preferred modalities, not further principle proliferation. Second, filling structural gaps: EEG, transcutaneous bilirubin, and noninvasive blood pressure combine high clinical need with minimal engineering activity and warrant targeted development. Contactless temperature and remote-PPG SpO_2 occupy an intermediate position, feasible but requiring accuracy and safety validation before adoption.

E. The Physiological–Behavioral Frontier

The PCC framework restricts the Concept to physiological sensing, appropriately excluding a growing parallel domain: behavioral monitoring of pain, clinical state, and neurodevelopmental status, which draws on the same infrastructure

TABLE I
CROSS-PARAMETER GAP MATRIX AND RESEARCH-PRIORITY ROADMAP.

Parameter	n/40	Need	Stage	Priority
Respiratory rate	20	High	3	Consolidate
ECG / heart rate	18	High	3	Consolidate
Temperature	10	Med	3	Validate
Movement/position	7	Med	3	Standardize
SpO_2	6	High	3*	Validate
Blood glucose	4	Med–High	3	Calibrate
Blood pressure	3†	High	3	**Fill gap**
EEG	1	High	2	**Fill gap**
Transcut. bilirubin	1	High	0	**Fill gap**

Representation counts parameter occurrences across the 40 primary studies; "Stage" is the highest validation stage reached by any study for that parameter (Section II-D).
*Conventional pulse oximetry is an established standard.
†Present only as a secondary channel.

(cameras, IMUs, microphones, physiological sensors). As documented in a companion work [7], AI-based neonatal pain assessment, integrating facial coding, body-movement analysis, cry acoustics, and contextual physiological data, faces barriers mirroring those found here: single-center datasets, non-standardized protocols, absent shared benchmarks, and regulatory opacity. Multimodal platforms acquiring physiological and behavioral signals from a shared architecture are a natural extension of this work, with barriers that are less technological than organizational and regulatory.

F. Limitations of this Review

Several limitations qualify these findings. The search was restricted to three databases and English-language indexed literature, potentially underrepresenting specialized vocabularies (e.g., neonatal invasive blood pressure, better indexed in Embase, Cochrane, Engineering Village, or Google Scholar) and early-stage engineering work that first appears in conference proceedings, preprints, or gray literature—an acknowledged publication-bias risk for a fast-moving field, partially mitigated by triangulation with the broader-scope reviews of Senechal et al. [2] and Williams et al. [5], which corroborated rather than contradicted the gaps identified here. Reports not retrieved because the full text was not openly accessible may introduce selection bias if not randomly distributed across parameters or venues. The protocol was not prospectively registered, and screening and extraction were performed principally by the first author with senior-author adjudication rather than fully duplicate independent review. Finally, consistent with the mapping objective, the synthesis is descriptive and quantitative-distributional; formal bibliometric analysis (co-authorship and keyword co-occurrence networks, citation clustering) was beyond scope and is a natural next step.

V. CONCLUSION

This scoping review mapped 40 primary studies on conventional and emerging sensors for neonatal physiological monitoring across nine parameter categories (2016–2026). Emerging solutions predominate (26/40, 65%), flexible/wearable form factors outnumber rigid designs (23/40 vs. 9/40), and optical transduction leads (15/40), reflecting an uneven but real convergence toward integrated wireless multiparameter platforms and contactless sensing, corroborated by two contemporaneous reviews [2], [5]. Against this backdrop, EEG and transcutaneous bilirubin (1/40 each) and noninvasive blood pressure (3/40, secondary only) stand out as externally corroborated, clinically consequential priority gaps. No emerging paradigm has reached multicenter, adequately powered, head-to-head validation, and 85% of studies omit regulatory status, underscoring the field's proof-of-concept maturity. The consolidated gap matrix and roadmap (Table I), together with adoption of standardized validation and reporting frameworks [2] and explicit engagement with regulatory pathways, are offered as concrete steps toward rigorous cross-technology comparison and evidence-based clinical translation.

***Abstract*—Since its introduction in 2014, Laser-Induced Graphene (LIG) has gained increasing attention for flexible and biomedical sensing applications. This study presents a quantitative bibliometric mapping of LIG-based biomedical sensing research, focusing on thematic structure, temporal evolution, and international collaboration. A total of 734 records published between 2014 and April 27, 2026, were retrieved from the Web of Science Core Collection and analyzed using VOSviewer. Keyword co-occurrence analysis identified 60 terms organized into six thematic clusters related to sensing properties, electrochemical biosensing, energy storage, hybrid nanostructures, synthesis parameters, and computational intelligence. Occurrence and Total Link Strength indicators complemented the network interpretation. Temporal mapping showed increasing attention to electrochemical detection, nanomaterials, and machine learning, while country co-authorship analysis identified 25 countries, with China, the United States, South Korea, and India accounting for the largest publication volumes. Machine learning appeared as a comparatively recent and less connected theme, suggesting opportunities for greater integration between data-driven methods, sensing, and LIG fabrication. Overall, the study provides an exploratory quantitative overview of the evolution and current structure of LIG-based biomedical sensing research.**

***Index Terms*—Laser-Induced Graphene, Biomedical Sensors, Bibliometrics, VOSviewer**

I. Introduction

In 2014, Lin et al. introduced Laser-Induced Graphene (LIG), a three-dimensional porous carbon material produced by photothermal conversion of polymeric substrates using a CO_2 laser [1]. Its relatively simple fabrication, high electrical conductivity, mechanical flexibility, and tunable surface properties have supported its expansion toward flexible and biomedical sensing applications [2], [3]. These characteristics enable the detection of both physical stimuli, such as strain and pressure, and biochemical analytes, including glucose, lactate, and pH in wearable configurations [4].

As the LIG literature has expanded, reviews have addressed its material properties, fabrication methods, and applications in sensing and healthcare [5]. More recently, machine-learning approaches have also been incorporated into LIG-based sensing systems for tasks such as signal classification and pattern recognition [6]. However, existing studies are predominantly focused on technological and application-oriented reviews [7], providing limited quantitative characterization of how biomedical sensing themes have evolved over time and how research activity is distributed across international collaboration networks.

This study addresses this perspective through a bibliometric mapping specifically focused on LIG-based biomedical sensing. Using network and overlay analyses [8], the study examines thematic clusters, temporal trends, international co-authorship, and the emerging association of machine learning with biomedical sensing. Rather than evaluating device performance, the analysis provides a quantitative overview of the structure and evolution of the literature, identifying established themes, recent research directions, and patterns of international collaboration.

II. Methodology

A. Search Strategy and Data Collection

The Web of Science Core Collection was selected as the sole bibliographic database because it provides standardized bibliographic and citation metadata suitable for reproducible bibliometric analyses and provides consistent coverage across the selected publication period [9]. The exclusive use of WoS may nevertheless result in the omission of records indexed only in other databases, such as Scopus, Dimensions, or IEEE Xplore, and is therefore recognized as a limitation of the study. The search string was designed to capture the

intersection of Laser-Induced Graphene (LIG) and biomedical sensing applications using Boolean operators: (”Laser-induced graphene” OR ”LIG”) AND (”sensor*” OR ”biosensor*” OR ”electrode*”) AND (”health*” OR ”medical” OR ”biomedical” OR ”wearable*”) spanning from 2014 to April 27, 2026. The initial query yielded 744 records (Articles, Review Articles, Proceeding Papers, Early Access, Letters and Editorial Materials) in English and Chinese, which were exported as plain text files containing full bibliographic records and cited references.

B. Data Cleaning and Quality Assurance

To ensure the technical integrity of the dataset, a manual screening of titles and abstracts was conducted by a single researcher. During this stage, 10 records were excluded as false positives because they were not directly related to laser-induced graphene research [10]. These records were primarily retrieved due to the use of the acronym “LIG” in unrelated contexts, such as lignin-based sensor studies. The final refined corpus consisted of 734 documents. No inter-reviewer agreement assessment was performed.

C. Data Normalization and Pre-processing

Data processing was performed with VOSviewer (v.1.6.20) [8]. A custom thesaurus file was used to normalize the metadata before map generation [11]. This involved merging synonymous terms (e.g., unifying ”LIG”, ”laser-induced graphene”, and ”induced graphene” into a single node) and standardizing plural and singular forms. Furthermore, generic terms that did not provide sufficient thematic specificity (e.g., ”performance”, ”fabrication”, ”design”, and ”challenges”) were removed because their high semantic generality could obscure more specific thematic relationships in the co-occurrence networks.

D. Bibliometric Mapping and Visualization

To map the landscape of the field, the analysis was divided into two specific scopes:

1) Keyword Co-occurrence Analysis: A minimum threshold of nine occurrences was selected as a pragmatic criterion to balance network comprehensiveness and visual interpretability. Lower thresholds generated a larger number of low-frequency terms, increasing network density and reducing the readability of the thematic clusters. This resulted in a network comprising 60 keywords. This analysis aims to identify the thematic pillars and technological clusters within the LIG-sensor domain.

2) Country Co-authorship Analysis: A minimum threshold of six publications per country was adopted to retain countries with sufficient publication activity for meaningful representation in the co-authorship network while avoiding excessive network sparsity. This resulted in 25 countries being included in the network. This mapping identifies the countries with the highest publication activity and the structure of international collaboration in the field.

a) Visualization Modes: For both analyses, *Network Visualization* was used to identify structural clusters and connectivity, while *Overlay Visualization* was utilized to track the temporal evolution and identify emerging trends up to 2026 [12] and [13].

The publication counts were also exported from WoS according to the ”Final Year of Publication” field and used to characterize annual scientific production. An exponential regression was fitted to the annual publication counts as a descriptive model of the observed temporal trend. Because records for 2026 were available only through April 27, 2026, this year was treated as incomplete and any extrapolation to the end of 2026 was considered exploratory rather than predictive.

The overall workflow for record selection, data processing, and bibliometric mapping is summarized in Fig. 1.

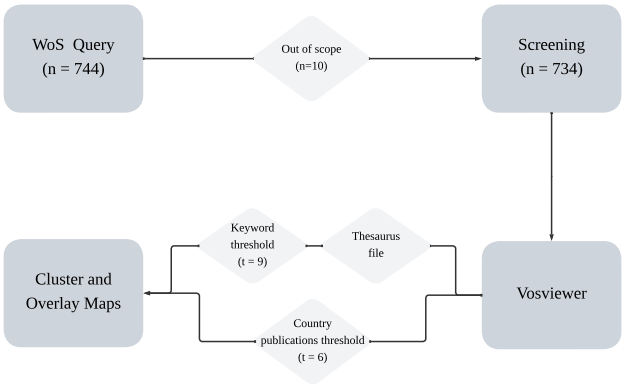

Fig. 1. Flow diagram illustrating the record selection, data processing, and bibliometric mapping thresholds.

III. Results and Discussion

A. Temporal Analysis

Fig. 2 illustrates a marked increase in scientific production on LIG-based biomedical sensing over the analyzed period. Although LIG was introduced in 2014, initial research focused primarily on fundamental materials science and energy-storage applications, such as supercapacitors. Within the scope of the present search, publications specifically addressing biomedical sensors and electrodes became more frequent from 2016 onward, indicating the expansion of LIG toward biomedical sensing applications.

Publication activity increased substantially after 2020, coinciding temporally with the COVID-19 pandemic and the growing interest in flexible point-of-care (PoC) diagnostic and remote health-monitoring technologies [14]. The number of publications increased from 11 in 2019 to 41 in 2020 and continued to rise, reaching 178 publications in 2025. This temporal pattern indicates a marked expansion of research activity in LIG-based biomedical sensing, although the bibliometric data alone do not establish a causal relationship between the COVID-19 pandemic and this increase.

An exponential regression was fitted to the annual publication counts as a descriptive representation of the observed temporal trend. When 2026 was excluded because it represents an incomplete year, the regression yielded $R^2 = 0.95$, indicating a strong fit of the selected function to the observed publication data. This value describes the fit of the model to the available observations but does not demonstrate that exponential growth will continue. Of the 734 documents in the final corpus, 721 contained information in the "Final Publication Year" field, while 13 records did not. For 2026, 90 publications were available as of April 27 and were therefore treated as an incomplete annual observation. An annualized estimate of 270 publications was used only for visualization of the potential full-year output and is not considered an observed publication count. Overall, the temporal analysis indicates rapid growth in research activity while avoiding extrapolation of the incomplete 2026 data as evidence of continued exponential expansion.

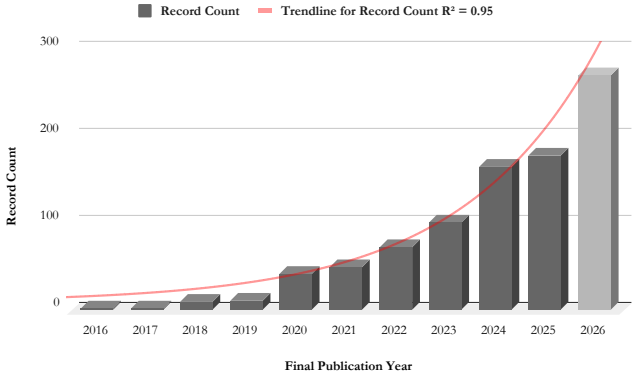

Fig. 2. Temporal evolution of publications on LIG-based biomedical sensing between 2016 and 2026. The 2026 value represents an annualized estimate based on records available through April 27.

B. Keyword Network Analysis

VOSviewer represents keyword co-occurrence as a weighted network in which links indicate the number of documents in which two keywords co-occur. Link strengths were normalized using the association-strength method, and spatial proximity in the map reflects stronger normalized relatedness between terms.

As illustrated in Fig. 3, the 60 selected keywords were organized into six thematic clusters. Table I summarizes representative keywords from each cluster together with their occurrence counts and Total Link Strength (TLS), providing a quantitative complement to the network visualization.

a) Cluster 1 — Sensing Properties: The red cluster is primarily associated with mechanical and wearable sensing applications of LIG. Representative terms include *strain sensor*, *wearable sensor*, and *pressure sensor*, with *strain sensor* showing 50 occurrences and a Total Link Strength (TLS) of 144, followed by *wearable sensor* (27 occurrences; TLS = 78) and *pressure sensor* (23 occurrences; TLS = 67) (Table I). These terms indicate a strong emphasis on the use of LIG as a flexible sensing material for detecting mechanical deformation and pressure, particularly in wearable configurations. The coexistence of these topics within the same cluster suggests an established connection between LIG fabrication and mechanically responsive sensor architectures. Rather than indicating a specific technological transition, the network primarily reflects the strong association of LIG with flexible and wearable sensing applications within the analyzed literature [15].

TABLE I
REPRESENTATIVE KEYWORDS AND BIBLIOMETRIC INDICATORS FOR EACH THEMATIC CLUSTER.

Cluster	Theme	Representative keywords	Occ. / TLS
1	Sensing properties	Strain sensor; wearable sensor; pressure sensor	50/144; 27/78; 23/67
2	Biomarkers and electrochemistry	Electrode; biosensor; electrochemical sensor	85/287; 60/178; 47/143
3	Energy storage	Supercapacitor; energy; energy storage	80/246; 24/73; 11/41
4	Hybrid nanostructures	Nanoparticle; nanocomposite; MXene	41/137; 22/76; 9/24
5	Synthesis parameters	Polyimide; conductivity	42/132; 9/26
6	Computational intelligence	Machine learning	19/36

Note: Occ. = keyword occurrences; TLS = Total Link Strength.

b) Cluster 2 — Biomarkers and Electrochemistry: The green cluster is centered on electrochemical sensing and biosensing applications, with *electrode*, *biosensor*, and *electrochemical sensor* representing prominent terms. Among these, *electrode* presented the highest occurrence and TLS values (85 and 287, respectively), followed by *biosensor* (60 occurrences; TLS = 178) and *electrochemical sensor* (47 occurrences; TLS = 143) (Table I). The strong connectivity of these terms indicates that electrochemical interfaces constitute an important thematic component of LIG-based biomedical sensing research. Their association with terms related to biomarkers and biological targets further reflects the application of LIG electrodes in analytical and biosensing contexts [16]. However, the co-occurrence network identifies thematic associations rather than demonstrating specific analytical performance, selectivity, or clinical applicability.

c) Cluster 3 — Energy Storage: The blue cluster is centered on energy-storage applications and includes *supercapacitor*, *energy*, and *energy storage* as representative terms. Among these, *supercapacitor* showed the highest occurrence and TLS values (80 and 246, respectively), while *energy* and *energy storage* presented 24 and 11 occurrences, with TLS values of 73 and 41, respectively (Table I). Although not

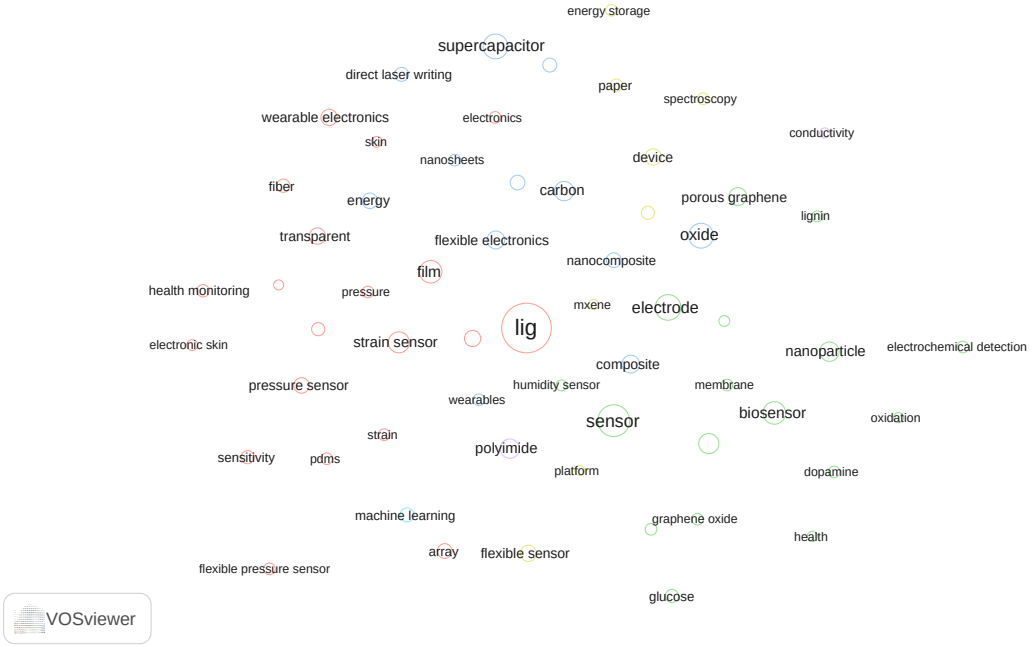

Fig. 3. Keyword co-occurrence map for clusters visualization. Generated using VOSviewer software.

exclusively biomedical, the presence of this cluster indicates that energy-storage research remains an important component of the broader LIG literature represented in the dataset. Similar observations have been reported in broader LIG reviews, where energy devices are described as an important component of the field's technological development [17]. Its coexistence with biomedical sensing themes may indicate potential relevance for self-powered or energy-efficient wearable systems, although the co-occurrence analysis alone does not establish specific technological integration or device performance.

d) Cluster 4 — Hybrid Nanostructures: The yellow cluster is characterized by terms related to the incorporation of nanostructured materials into LIG-based systems. *Nanoparticle*, *nanocomposite*, and *MXene* were selected as representative terms, with 41, 22, and 9 occurrences and TLS values of 137, 76, and 24, respectively (Table I). The relatively strong connectivity of *nanoparticle* and *nanocomposite* indicates that hybrid material architectures constitute a relevant thematic direction within the analyzed literature [18]. The presence of MXene, although less frequent, further indicates the association of LIG research with emerging two-dimensional and composite materials. These associations suggest an expansion of the material combinations investigated for LIG-based sensing, although the bibliometric network alone cannot determine whether such combinations provide superior sensing performance or represent a specific technological progression.

e) Cluster 5 — Synthesis Parameters: The purple cluster is associated with the material synthesis and electrical properties of LIG, with *polyimide* and *conductivity* as representative terms. *Polyimide* presented 42 occurrences and a TLS of 132, whereas *conductivity* showed 9 occurrences and a TLS of 26 (Table I). The prominence of polyimide reflects its strong association with LIG-related research within the analyzed corpus, while the occurrence of conductivity indicates attention to the electrical properties of the resulting material. Together, these terms suggest that substrate selection and material properties remain connected to the development of LIG-based sensing systems [19]. However, the co-occurrence structure does not allow direct conclusions regarding the optimal synthesis conditions or the effect of fabrication parameters on sensor performance.

f) Cluster 6 — Computational Intelligence: The cyan cluster is represented primarily by *machine learning*, which showed 19 occurrences and a TLS of 36 (Table I). Its comparatively lower occurrence and connectivity, together with its concentration around a single representative term, indicate that computational intelligence constitutes a smaller thematic component of the analyzed literature than the more established sensing, electrochemical, and energy-related clusters. Nevertheless, its presence within the keyword network indicates an association between LIG-based sensing and data-driven approaches. The relatively limited connectivity of machine learning with synthesis-related terms may indicate an opportunity for future studies integrating computational methods with material fabrication and sensor optimization [20]. This pattern should be interpreted as a potential research direction rather than evidence that autonomous or closed-loop LIG fabrication is already an established research area.

The combined analysis of the six clusters reveals a progressively interconnected research landscape spanning LIG

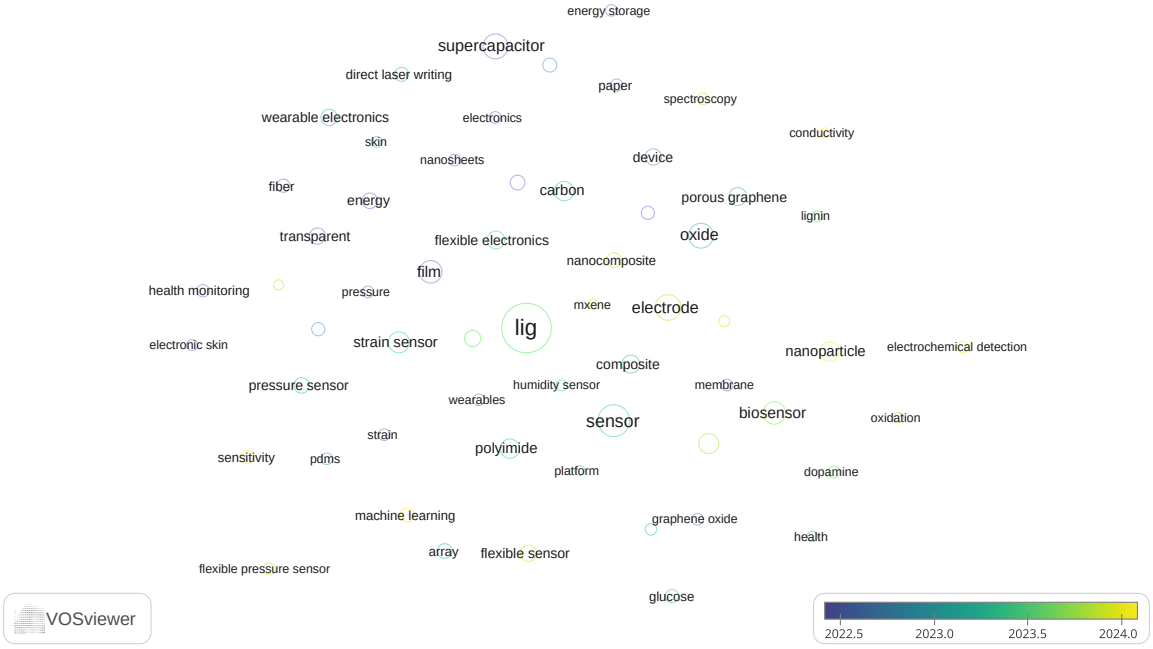

Fig. 4. Keyword co-occurrence map for trend visualization. Generated using VOSviewer software.

synthesis, material engineering, energy-related applications, electrochemical sensing, wearable devices, and computational approaches. Although these thematic groups can be interpreted as complementary stages within the development of LIG-based sensing systems, the co-occurrence network does not establish a strict technological hierarchy among them [2]. The comparatively weaker connection between computational intelligence (Cluster 6) and synthesis-related terms suggests that data-driven approaches remain less integrated with material fabrication than with sensing and signal-processing applications [20]. Rather than representing an established limitation of the field, this pattern may indicate an opportunity for future studies combining computational methods with LIG synthesis and optimization [21].

C. Keyword Overlay Analysis

Overlay visualization was used to examine the average publication year associated with each keyword. As shown in Fig. 4, terms associated with energy storage and material fabrication are concentrated around earlier average publication years (∼2022), whereas terms such as 'machine learning', 'electrochemical detection', and 'nanoparticle' are predominantly associated with later periods (∼2024). This temporal distribution suggests increasing research attention toward intelligent and selective biomedical sensing systems.

The more recent average publication years of terms such as nanoparticle and electrochemical detection are consistent with increasing attention to functionalization and selective electrochemical sensing [22].

Conversely, clusters associated with earlier average years (around 2022), particularly those containing terms such as "supercapacitor", "film", and "energy", reflect the initial focus of LIG research on materials science and energy storage applications. The persistence of these terms as large nodes indicates their foundational role in the field. The co-occurrence of terms such as "health monitoring", "electronic skin", and "wearables" within the same temporal range indicates that biomedical sensing research was already developing alongside established energy-related applications, revealing an early broadening of the LIG research landscape [3].

In summary, the keyword evolution tracks a transition from fundamental material synthesis toward high-level system integration. The recent temporal association of Machine Learning-related terms underscores this transition toward intelligent sensing systems. However, the comparatively weak connectivity between the computational intelligence cluster and the polyimide conversion nodes suggests a potential direction for future research: the development of AI-driven frameworks capable of optimizing both LIG synthesis and sensor performance in a unified manner [21] and [23].

D. Geospatial Collaboration Network

A minimum threshold of 6 publications per country was established for inclusion in the co-authorship network. Of the 61 countries with at least one publication, 25 met this criterion and were included in the final mapping. As shown in Fig. 5, China represents the largest node, with 378 publications and a Total Link Strength (TLS) of 110, followed by the United States (137 publications; TLS = 80), South Korea (91; TLS

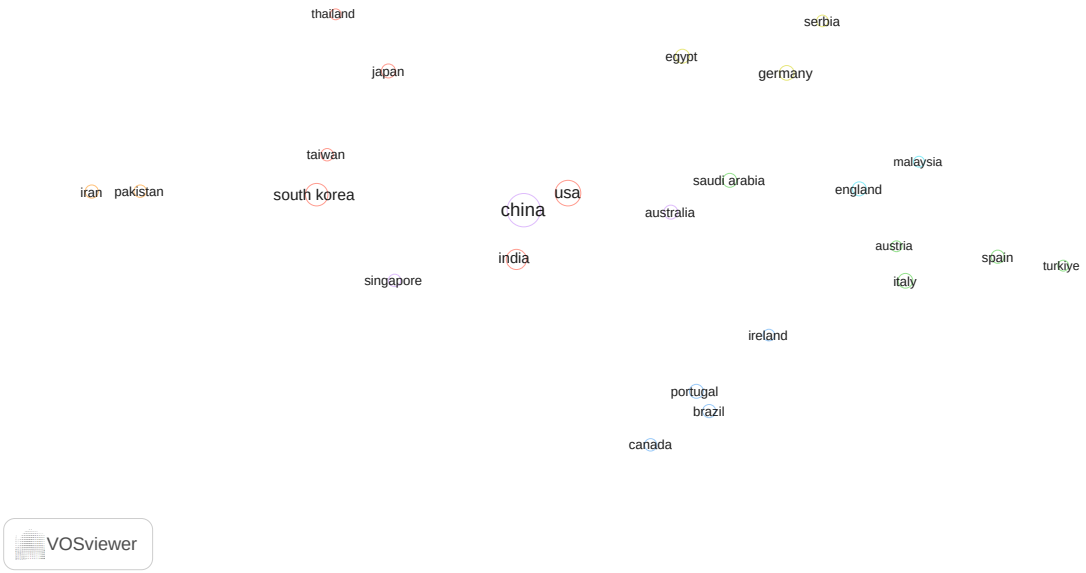

Fig. 5. Country co-authorship map for clusters visualization. Generated using VOSviewer software.

= 48), and India (56; TLS = 16). In contrast, all remaining countries presented fewer than 20 publications, indicating a strong concentration of scientific production within a limited number of nations. The comparatively high TLS values of China, the United States, and South Korea further indicate their strong connectivity within the international co-authorship network. In South America, only Brazil reached the inclusion threshold, with 12 publications, highlighting the comparatively limited regional participation in the analyzed literature. Fig. 5 also reveals the formation of seven distinct collaboration clusters.

Cluster 1 (Red) comprises India, Japan, South Korea, Taiwan, Thailand, and the United States, concentrating the United States and several Asian contributors within the same collaboration group. This cluster reflects a strong concentration of publications and international links involving countries with established activity in flexible electronics and LIG device development [24], [25]. In particular, the United States (TLS = 80) and South Korea (TLS = 48) exhibit the highest connectivity within this group, supporting their prominent positions in the collaboration network. The observed grouping is therefore consistent with substantial research interaction among these countries, although the network topology itself does not establish the technological, institutional, or economic factors underlying these collaborations.

Cluster 2 (Green) groups Austria, Italy, Saudi Arabia, Spain, and Türkiye, forming a collaboration cluster involving countries from Europe and the Mediterranean region. Among them, Saudi Arabia presents the highest Total Link Strength (TLS = 24), despite having 16 publications, followed by Spain (13 publications; TLS = 15) and Italy (18; TLS = 11). These values indicate meaningful international connectivity within the cluster rather than publication volume alone. The observed grouping is also compatible with some degree of regional proximity and shared research interests in nanotechnology and materials science [26], although the bibliometric network itself does not establish the specific factors underlying these collaborations.

Cluster 3 (Blue) comprises Brazil, Canada, Ireland, and Portugal, connecting countries across the Atlantic within the same collaboration group. Portugal presents the highest publication volume in the cluster (16 publications; TLS = 7), while Brazil and Canada show similar connectivity (TLS = 8 each), despite their different publication counts of 12 and 11, respectively. The presence of Brazil and Portugal remains consistent with the possibility that linguistic and historical relationships may contribute to collaborative interactions [27]; however, such factors cannot be inferred directly from the network topology. Overall, this cluster illustrates how countries with comparatively lower publication volumes can still participate in identifiable international collaboration networks within LIG research.

Cluster 4 (Yellow) is composed of Germany, Egypt, and Serbia. Germany presents the highest publication volume and connectivity within the cluster (19 publications; TLS = 18), followed by Egypt (16; TLS = 11) and Serbia (8; TLS = 2). This grouping is consistent with the participation of these countries in nanoscience, laser technologies, and applied materials research [28], although the network itself does not establish a specific bridging role between fundamental and

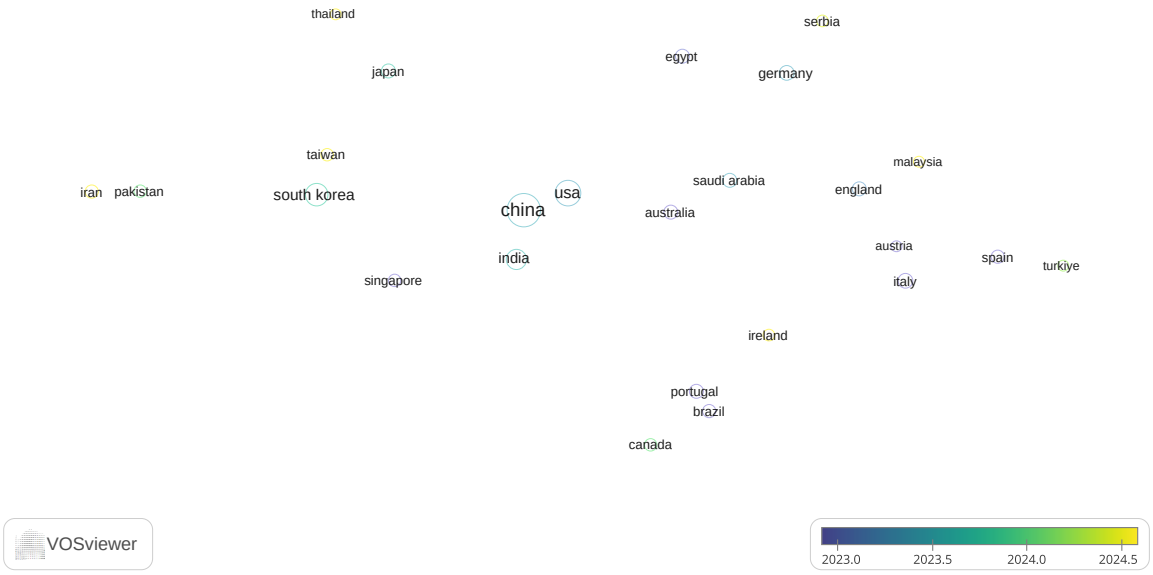

Fig. 6. Country co-authorship map for trend visualization. Generated using VOSviewer software.

applied research.

Cluster 5 (Purple), composed of China, Australia, and Singapore, represents one of the most prominent collaboration groups in the network. China clearly dominates both publication volume and connectivity (378 publications; TLS = 110), while Australia (16; TLS = 21) and Singapore (9; TLS = 9) show smaller but identifiable collaborative participation. This pattern is consistent with the strong presence of the Asia-Pacific region in LIG research, including synthesis, scalability, and interdisciplinary applications [4], [29].

Cluster 6 (Cyan), composed of England and Malaysia, forms a small cross-regional collaboration group. England presents 14 publications and a TLS of 20, whereas Malaysia has 6 publications and a TLS of 3. Their grouping may be compatible with established institutional and international research links [30], although the network itself does not identify the specific factors underlying this collaboration.

Cluster 7 (Orange), composed of Iran and Pakistan, represents a smaller regional collaboration group. Although Iran presents a slightly higher publication volume (12 publications; TLS = 3), Pakistan shows greater network connectivity (9 publications; TLS = 10). The observed grouping is consistent with some degree of regional interaction [31], but geographic or institutional drivers cannot be inferred directly from the co-authorship topology.

Overall, the geospatial network shows a marked concentration of scientific production and international connectivity around China and the United States, which belong to distinct collaboration clusters. This configuration indicates a multipolar collaboration structure rather than a single globally centralized network [32]. Countries with lower publication volumes, such as Brazil, Portugal, and Ireland, also participate in identifiable international connections, indicating that smaller contributors remain integrated into the global collaboration landscape [33]. These patterns describe the structure of scientific cooperation in LIG-based biomedical sensing without establishing the cultural, economic, or institutional factors responsible for the observed associations.

E. Geospatial Collaboration Overlay

As shown in Fig. 6, although China is the largest contributor in terms of publication volume, its average publication year is relatively recent (around 2023), indicating sustained activity across the more recent development of the field rather than predominantly early participation [29]. In contrast, countries such as Brazil, Italy, Australia, Egypt, and Portugal present slightly earlier average publication periods (2022–2023) while remaining comparatively smaller nodes in the network [27], [33].

Countries such as Iran, Malaysia, Ireland, Taiwan, and Thailand present more recent average publication years (around 2024), indicating increasing participation in the recent literature [30]. This temporal distribution suggests a gradual broadening of geographic participation in LIG-based biomedical sensing. The relatively accessible fabrication requirements of LIG, compared with more complex graphene-production techniques such as Chemical Vapor Deposition (CVD), may contribute to this broader participation, since LIG can be produced using comparatively simple CO_2 laser-based systems [17]. However, the bibliometric data alone do not establish

fabrication cost or accessibility as the direct cause of the observed geographic expansion.

IV. Conclusion

This study presented a quantitative and exploratory bibliometric mapping of Laser-Induced Graphene (LIG) research in biomedical sensing from 2014 to April 27, 2026. The results show a marked expansion and thematic diversification of the field, with increasing associations among wearable electronics, electrochemical biosensing, hybrid materials, and computational approaches. Keyword and collaboration analyses further revealed that research activity remains concentrated in a limited number of countries, while smaller contributors also participate in identifiable international networks.

Machine learning emerged as a comparatively recent and less connected theme, with stronger associations with sensing and signal-processing applications than with LIG synthesis. Rather than defining an established technological frontier, this pattern suggests an opportunity for future studies integrating data-driven methods with material fabrication and sensor optimization.

These findings support the continued investigation of LIG for flexible and potentially personalized biomedical sensing applications [34]. Nevertheless, the results should be interpreted considering the exclusive use of Web of Science, the adopted search strategy, the dependence of bibliometric networks on indexed keywords and selected thresholds, the single-researcher screening process, and the continuous updating of bibliographic databases. Future studies may expand database coverage and explore citation, institutional, and translational relationships in greater depth.

***Abstract*—Short-range radar has emerged as a promising contactless technology for respiratory monitoring. However, experiments with human subjects are affected by inter-subject variability, involuntary motion, and limited repeatability of respiratory patterns. This work presents a controlled mechatronic platform driven by thoracic-impedance waveforms from the publicly available BIDMC dataset for benchtop evaluation of the Acconeer XM132 pulsed coherent radar. Twelve recordings of approximately 240 s were reproduced through servo-driven motion and acquired simultaneously by the radar and an auxiliary MPU6050 inertial sensor. Respiratory rate (RR) was evaluated using different analysis-window lengths and estimation methods. FFT-based estimation with 60 s windows yielded a mean absolute error of 1.94 breaths per minute (bpm) and a median error of 0.09 bpm. For complete 240 s recordings, the mean and median errors were 1.49 and 0.03 bpm, respectively; the mean was dominated by one second-harmonic selection error. These results support the use of the platform as a controlled benchtop environment for preliminary characterization of radar acquisition and RR-processing strategies, while independent displacement measurements and human validation remain necessary before conclusions about mechanical or clinical accuracy can be made.**

***Index Terms*—Contactless respiratory monitoring, pulsed coherent radar, RR estimation, mechatronic platform.**

I. Introduction

Respiratory rate (RR) is considered an important vital sign, as changes in the breathing pattern may indicate variations in a patient's clinical condition and, in intensive care settings, may serve as early indicators of clinical deterioration [1], [2]. Furthermore, dysfunctional breathing comprises a set of abnormalities in the respiratory pattern that may be associated with chronic conditions such as asthma and chronic obstructive pulmonary disease (COPD) [3].

Conventional respiratory monitoring methods often require direct physical contact with the patient through adhesive electrodes, chest belts, nasal cannulas, or other body-mounted sensors. Although these approaches are widely used, they may cause discomfort during prolonged monitoring and are susceptible to motion artifacts, sensor displacement, or poor patient compliance. Consequently, wearable and remote sensing technologies have been increasingly investigated for respiratory monitoring applications [4], [5]. Among remote sensing approaches, contactless sensors have attracted considerable attention because they enable respiratory monitoring without direct attachment to the body, a feature that is particularly advantageous in applications requiring continuous observation or reduced patient instrumentation [6].

Short-range radar sensors have been investigated as an alternative for monitoring thoracic and abdominal movements associated with respiration [7]. Different radar technologies, including frequency-modulated continuous-wave (FMCW), ultra-wideband (UWB), and millimeter-wave radars, have been applied to RR estimation, millimeter-scale displacement tracking, and respiratory or cardiorespiratory monitoring in a variety of experimental and clinical scenarios [8]–[12].

In this context, Acconeer sensors based on pulsed coherent radar operating in the millimeter-wave band provide a compact platform for distance measurement, presence detection, motion sensing, and respiratory monitoring applications [13]–[15]. Despite the availability of reference applications, a controlled experimental platform enables the evaluation of acquisition

*These authors contributed equally to this work.

parameters, signal processing techniques, and RR estimation methods before conducting experiments with human subjects.

Mechatronic test benches and respiratory phantoms complement volunteer-based experiments by providing repeatable and adjustable motion patterns [10], [16]. Existing platforms range from simplified programmed trajectories to more elaborate phantoms driven by recorded physiological signals; notably, Eder et al. used recorded thoracic-impedance waveforms to reproduce cardiopulmonary dynamics [16]. Public databases such as the BIDMC PPG and Respiration Dataset provide reproducible respiratory waveforms acquired from real subjects [17]–[19]. Thoracic impedance has also been used for respiratory monitoring and respiratory signal-quality assessment [20], [21].

Motivated by these considerations, this work proposes a mechatronic platform driven by thoracic impedance signals for the experimental characterization of an Acconeer radar sensor applied to respiratory monitoring. The platform reproduces physiologically inspired breathing patterns through a mechanically actuated structure, allowing the respiratory signal estimated by the radar to be compared with the imposed platform motion and with an auxiliary measurement obtained from an MPU6050 inertial sensor. In this study, the inertial sensor is not regarded as a gold standard for displacement measurement but rather as a complementary channel associated with the platform motion that supports RR estimation [22].

The main contributions of this work are:

- a compact benchtop platform that uses publicly available BIDMC thoracic-impedance recordings to drive respiration-like motion, preserving non-sinusoidal temporal variability in a reproducible input waveform;
- integration of the platform with an Acconeer XM132 pulsed coherent radar, an auxiliary inertial sensor, and dedicated acquisition software;
- characterization of RR recovery from the radar signal across analysis-window lengths and estimation methods, together with tracking-log and temporal waveform-similarity analyses.

II. Related Work

A. Radar-based respiratory monitoring

Radar-based respiratory monitoring relies on the periodic displacement of the thoracic and abdominal walls during the breathing cycle, and different radar technologies have been applied to RR estimation and cardiorespiratory monitoring [8], [9], [11], [12], [23]. The Acconeer sensor belongs to a class of pulsed radars operating around 60 GHz, capable of detecting small distance variations through the reflected response from the target [13]. The objective of this work is not to develop a new radar or signal processing algorithm, but rather to establish a controlled experimental environment for evaluating the performance of this sensor in a specific respiratory monitoring application.

B. Respiratory phantoms and emulated motion

Motion platforms and respiratory phantoms are widely used to reduce experimental variability during radar evaluation [10], [16]. Their designs span simplified programmed trajectories as well as physiologically driven systems. Eder et al., for example, incorporated recorded thoracic-impedance signals into a multi-person FMCW-radar phantom [16]. The contribution of the present work is therefore not the first use of physiological waveforms in a phantom; rather, it is a compact single-target implementation centered on the XM132 pulsed coherent radar, driven by public BIDMC respiratory recordings and coupled to inertial sensing, acquisition software, and a comparative analysis of RR estimators and window lengths. This scope complements more elaborate phantom frameworks while retaining a reproducible physiological input. Chest-wall motion itself is multidimensional and may be non-sinusoidal, which remains only partially represented by the one-dimensional mechanism used here [24], [25].

III. Materials and Methods

The proposed system consists of four main stages: acquisition of the reference respiratory signal, mechanical reproduction of thoracic motion, simultaneous data acquisition by the sensors, and signal processing for RR estimation. To this end, a mobile platform reproduces the motion derived from a thoracic impedance signal, while an Acconeer XM132 radar and an MPU6050 accelerometer simultaneously record the system response. The methodological workflow adopted in this study is illustrated in Fig. 1.

The study focuses on radar-based recovery of the imposed RR while documenting acquisition parameters available in the experimental logs, including the radar-derived tracking distance, region of interest (ROI), effective logging rate, and tracking status. An independent noise-floor experiment, a calibrated saturation threshold, and absolute displacement accuracy were not available and are therefore not claimed. The MPU6050 accelerometer was used only as a complementary measurement of the platform response and was not considered a gold standard for thoracic displacement [22], [26].

A. Respiratory signal database

This study employed the publicly available BIDMC PPG and Respiration Dataset from the PhysioNet platform. The dataset contains recordings from 53 patients, each with approximately 8 minutes of data sampled at 125 Hz. The available signals include electrocardiography (ECG), photoplethysmography (PPG), thoracic impedance respiration, and manually annotated respiratory cycles [17]–[19].

In this work, the dataset was used to obtain real respiratory patterns, which were subsequently employed to reproduce breathing-like motions on the experimental platform.

B. Mechatronic platform

A mechatronic platform was developed using a structure fabricated from PLA and acrylic, a gear transmission mechanism, two MG90S servo motors, and an ESP32 development

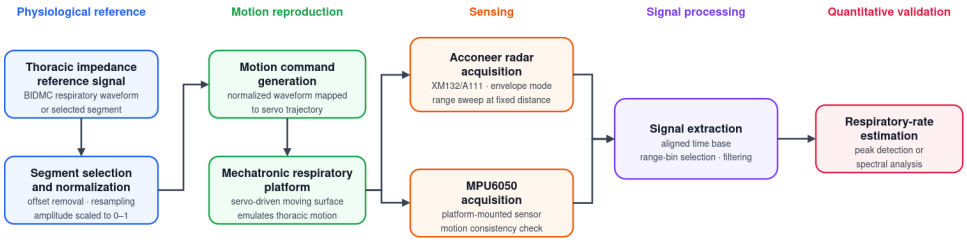

Fig. 1. Overall methodology adopted in this work, including physiological reference, motion reproduction, sensor acquisition, signal processing and respiratory-rate estimation.

board for system control. The gear mechanism converts the rotational motion of the servomotors into an approximately linear displacement, thereby simulating thoracic expansion and contraction. The two servomotors are symmetrically positioned to reproduce the bilateral motion of the rib cage. The acrylic upper plate supports the MPU6050 on its underside, allowing the sensor to move together with the structure, while simultaneously serving as the reference surface for the Acconeer radar, which is mounted in a fixed position to capture the platform motion.

The electronic architecture of the platform, including the connections among the ESP32, the Acconeer XM132 radar, the MPU6050 sensor, the servo motors, and the power supply, is shown in Fig. 2.

The thoracic-impedance respiratory signals from the BIDMC dataset were resampled to 20 Hz, normalized, and mapped to angular position commands for the servo motors. In the experimental logs, the recorded servo command spanned approximately 90–140 degrees across the analyzed trials. The mechanism was designed for an approximate nominal upper-plate travel of 20 mm; however, the displacement produced by the recorded commands was not calibrated with an independent position sensor, so this value is reported only as a nominal mechanical range. Mechanical displacement resolution, hysteresis, gear backlash, and run-to-run repeatability were not independently quantified. The ESP32 received the respiratory command through a serial interface and converted the servo positions into PWM drive signals. During acquisition, the radar's internal tracking reference reported target-distance estimates between approximately 0.394 and 0.460 m across the 12 recordings. These radar-derived distances were used for target tracking and are not treated as an independent measurement of platform displacement.

C. Signal acquisition sensors

RR was estimated from the signals acquired by the radar and the accelerometer, the radar being the primary sensor investigated.

1) Acconeer XM132 radar module: The XM132 module is a radar sensor based on Acconeer's Pulsed Coherent Radar (PCR) technology. The sensor operates in the 60 GHz frequency band, belonging to the class of millimeter-wave (mmWave) radars. Unlike frequency-modulated continuous-wave (FMCW) radars, the A111 radar embedded in the XM132 transmits short-duration electromagnetic pulses and performs coherent reception of the echoes reflected by surrounding objects [13]. This technology combines low power consumption, high spatial resolution, and the capability to detect very small displacements, making it suitable for RR estimation.

In this work, the *Envelope* service, one of the distance measurement methods provided by the XM132, was employed. In this method, the radar records the intensity of the reflected echoes at discrete distance positions (*bins*), generating a one-dimensional profile that represents the reflection amplitude along the monitored range.

Internally, the radar measures a complex signal given by

$$s(r) = I(r) + jQ(r), \tag{1}$$

where $I(r)$ and $Q(r)$ denote the in-phase and quadrature components, respectively. The envelope is obtained as the magnitude of this complex signal:

$$E(r) = \sqrt{I(r)^2 + Q(r)^2} = |s(r)|. \tag{2}$$

The value of $E(r)$ represents the reflection amplitude at each monitored distance. In this study, the platform position was estimated by tracking the dominant reflection within a fixed ROI. The logged ROI width was 70 mm in all 12 recordings, centered on an internally estimated target distance between approximately 0.394 and 0.460 m. The acquisition/playback target rate was 20 Hz; the effective rate of the merged CSV records was 20.00 Hz on average (19.992–20.002 Hz across recordings). The radar module communicates with the laptop through an RS-422 link and a NOVUS USB-I485 converter and is powered by a 12 V supply, as illustrated in Fig. 2.

The analyzed stream was the software-generated `radar_filt` time series stored in the experimental CSV files. The acquisition-side filter coefficients that generated this field were not retained in the merged logs; consequently, the reproducible quantitative pipeline reported here begins from `radar_filt` and applies the offline preprocessing described below. The merged logs contained no missing values in the reference, servo-command, MPU6050 X-axis, or filtered-radar columns. Because radar and ESP32 data were merged asynchronously, repeated or skipped internal frame

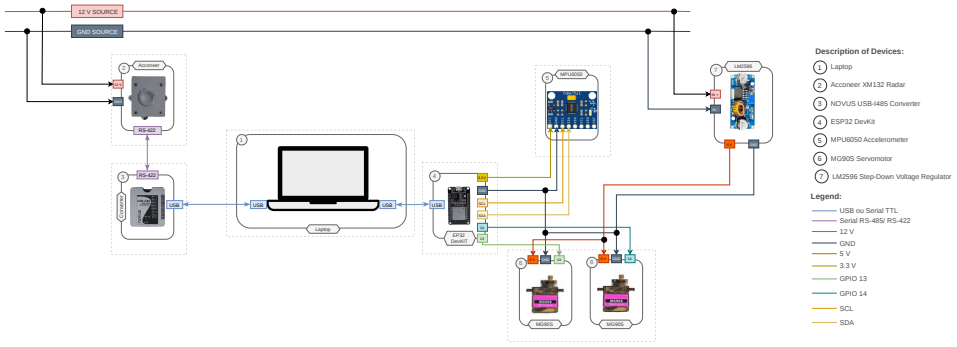

Fig. 2. Hardware architecture of the proposed platform, showing the communication interfaces and electrical connections.

indices in the merged log were not interpreted as a direct measure of source-frame packet loss.

2) MPU6050 accelerometer: In this study, the MPU6050 was used to monitor the mechanical response of the moving platform through acceleration measurements [27]. Although the sensor provides acceleration measurements along three axes, only the X-axis was used because, according to the sensor mounting orientation, it was aligned with the direction of the platform motion.

Before data acquisition, a calibration procedure is performed while the platform remains stationary for $N = 80$ consecutive samples. The baseline of the axis of interest and the calibrated acceleration variation used in the analysis are

$$A_{x0} = \frac{1}{N}\sum_{i=1}^{N} A_x(i), \qquad \Delta_x = A_x - A_{x0}, \tag{3}$$

where A_{x0} represents the sensor baseline (gravitational component plus offset) and Δ_x is the motion-related acceleration along the X-axis; the same procedure applies to the remaining axes.

To reduce noise while preserving the low-frequency components associated with respiratory motion, two low-pass filters are employed. The first is the MPU6050's internal digital low-pass filter, configured with a cutoff frequency of 60 Hz. The second is a first-order infinite impulse response (IIR) filter implemented in the firmware using an Exponential Moving Average (EMA), defined as

$$y[n] = y[n-1] + \alpha\,(x[n] - y[n-1])\,, \tag{4}$$

where $x[n]$ is the current sample, $y[n]$ is the filtered output, and α is the filter coefficient. The cutoff frequency of this filter was set to 2.5 Hz, preserving the typical respiratory frequency range (0.2–0.5 Hz), which may reach approximately 1 Hz in children and neonates [28].

D. Software

A Python-based software application, named *Breathing Platform Monitor*, was developed to integrate the main functionalities of the proposed system, including device configuration, platform control, signal acquisition, real-time visualization, and experimental data storage. The graphical user interface (GUI) was implemented using the PyQt5 library, while signal visualization was performed with PyQtGraph. These libraries were selected because of their suitability for developing graphical applications and their seamless integration with C++-based systems [29].

The software is organized into four tabs, with all communication performed through USB serial interfaces, as illustrated in Fig. 2: (i) serial port detection and device configuration, (ii) loading and playback of the respiratory CSV signal with individual servo testing, (iii) simultaneous acquisition and storage of the radar and MPU6050 signals, and (iv) loading of acquired files for preliminary RR visualization and analysis. The quantitative comparisons reported below were performed offline using the recorded data.

E. Results Analysis

A Google Colab notebook was used for offline analysis of 12 recordings, each approximately 240 s long. The CSV respiratory waveform used to command the servos was treated as the frequency reference; the MPU6050 X-axis and the filtered radar stream were compared with this waveform. Raw and centroid-based radar signals were excluded from the RR tables.

All analyzed signals were placed on a uniform 20 Hz time grid and preprocessed with detrending followed by a third-order Butterworth band-pass filter from 0.10 to 0.70 Hz (6–42 bpm) and z-score normalization. For FFT estimation, a Hann window was applied, the spectrum was zero-padded by a factor of four to the next power of two, and the dominant peak within the respiratory band was refined by parabolic interpolation. Welch estimation used 16 s segments (or the available signal length for shorter records). The other methods were sinusoidal fitting, autocorrelation, positive-going zero crossings, and adaptive peak detection.

The FFT window-length analysis used 15, 20, 30, 45, 60, 90, and 120 s windows with 50% overlap. Method comparison was performed separately on the complete approximately 240 s recordings. For each estimator m, the same estimator was applied to the radar and to the CSV reference, and the absolute error was defined as

$$E_{RR,m} = \left|RR_{\mathrm{radar},m} - RR_{\mathrm{CSV},m}\right|. \tag{5}$$

The same estimator-specific comparison was used for the MPU6050. Uncertainty across recordings was summarized using nonparametric bootstrap confidence intervals; for overlapping-window analyses, resampling was performed at the BIDMC-record level rather than treating overlapping windows as independent. As an exploratory waveform-level comparison, radar and CSV signals were additionally evaluated using absolute zero-lag correlation, maximum absolute cross-correlation within ± 10 s, and respiratory-band spectral coherence. These analyses assess recovery of the imposed respiratory dynamics and do not quantify absolute displacement fidelity.

IV. Results

The results are presented in five parts: (i) system overview, (ii) reproduction of the imposed respiratory frequency, (iii) Acconeer radar tracking, (iv) RR estimation, and (v) agreement analysis.

A. System Overview

A total of 12 respiratory recordings, each approximately 240 s long, were evaluated. The CSV waveform drove the platform motion, the XM132 served as the primary sensor for RR estimation, and the MPU6050 provided a complementary measurement of platform motion. The radar's internal tracking reference reported target-distance estimates of approximately 0.394–0.460 m, with a 70 mm ROI.

Fig. 3 shows the *Breathing Platform Monitor* interface, organized into four tabs corresponding to the experimental workflow. As summarized in the caption of Fig. 3, the tabs provide, respectively: (a) automatic USB port detection and device configuration; (b) loading, previewing and transmitting a respiratory CSV signal to the ESP32, including full-signal and windowed views; (c) starting and stopping the simultaneous acquisition of the radar and the MPU6050, with device status and real-time visualization; and (d) loading the acquired files for automatic RR estimation and visualization of the analysis plots.

B. Respiratory Frequency Reproduction

Table I summarizes the agreement between the reference respiratory signal and the MPU6050 measurements of respiratory rate, in breaths per minute (bpm). Both spectral methods yielded very low estimation errors, suggesting that the mechatronic platform reproduced the dominant respiratory frequency imposed by the reference signal. It should be noted that this agreement concerns the reproduced frequency and not the absolute displacement amplitude, since the MPU6050 is rigidly attached to the moving structure and does not constitute an independent displacement reference.

This low error was expected, since the MPU6050 was fixed to the moving platform and therefore directly measured its mechanical response. The zero Welch error indicates selection of the same discrete Welch frequency bin in the reference and MPU6050 signals; it should not be interpreted as zero physical or displacement error.

TABLE I
Comparison between the reference signal and the MPU6050 measurement.

Method	Mean error (bpm)	Median error (bpm)
FFT	0.08	0.006
Welch	0.00	0.00

C. Acconeer Radar Tracking

The filtered Acconeer radar signal exhibited, for most recordings, a dominant spectral component corresponding to the respiratory frequency imposed by the mechatronic platform. Spectral comparison with the reference signal and the MPU6050 measurement showed good agreement among the dominant peaks within the respiratory frequency range, suggesting that the radar was able to track the imposed respiratory frequency in most recordings under controlled experimental conditions. Representative examples of this spectral behavior are shown in Fig. 4.

An exception was observed, as illustrated in Fig. 4(b), in which both the reference CSV signal and the MPU6050 estimated an RR of approximately 18.5 bpm, whereas the radar FFT selected 36.2 bpm. The corresponding recording retained 100% tracking status with no rejected jumps, supporting interpretation of this event as spectral harmonic selection rather than loss of target tracking. Across all recordings, tracking status was 100% in 11 of 12 trials and 99.98% in the remaining trial; only one rejected-jump event was logged in the complete dataset. No NaNs were present in the key analyzed streams. These observations characterize the stability of the recorded tracking output but do not establish source-frame packet-loss performance or absolute distance accuracy.

D. RR Estimation

RR estimation was evaluated using different analysis window lengths in order to investigate the trade-off between temporal resolution and spectral stability. The results are summarized in Table II.

TABLE II
Radar FFT error versus window length (50% overlap).

Window (s)	N windows	Mean error (bpm)	Median error (bpm)
15	360	2.93	0.54
20	264	2.47	0.31
30	168	2.26	0.19
45	108	1.93	0.12
60	72	1.94	0.09
90	48	1.47	0.05
120	24	2.95	0.03

Median error decreased as window length increased, while the mean error was not monotonic because a small number of harmonic-selection errors produced a heavy upper tail. The lowest mean error occurred at 90 s. The 60 s window is reported as an intermediate time-resolved configuration, providing more frequent RR estimates than 90 s, but it should not be interpreted as an optimal window because no objective

Fig. 3. Breathing platform software: (a) device detection, (b) loading and transmitting respiratory signals from the dataset, (c) platform actuation and simultaneous signal acquisition, and (d) results analysis.

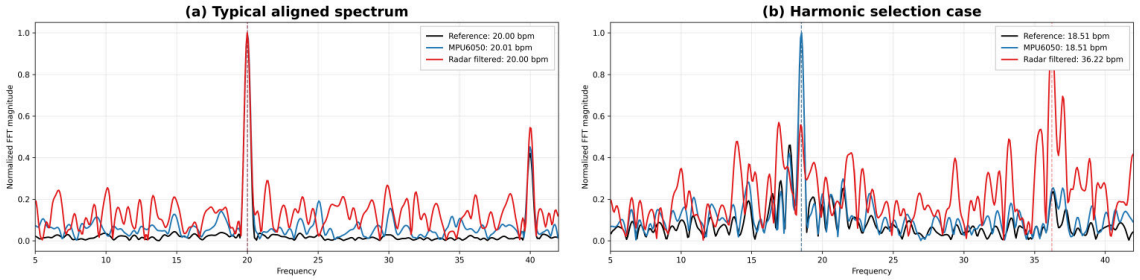

Fig. 4. Normalized spectral comparison between the reference respiratory signal, the auxiliary MPU6050 measurement, and the filtered Acconeer radar signal. FFT magnitudes were normalized to their maximum value to emphasize the dominant frequency components. (a) Representative recording showing agreement among the dominant frequencies of the reference signal, the MPU6050, and the radar. (b) Critical case in which the radar selected a harmonic component at approximately twice the reference respiratory frequency.

criterion combining estimation error and temporal resolution was defined. Record-clustered bootstrap 95% confidence intervals for the mean absolute error were 0.31–4.10 bpm at 60 s and 0.16–3.32 bpm at 90 s; the corresponding median-error intervals were 0.05–0.13 and 0.04–0.08 bpm. Because adjacent windows overlap by 50%, the window counts in Table II must not be interpreted as independent observations. The separate method comparison below uses the complete approximately 240 s recordings.

Different RR estimation methods were also compared using the complete recordings. The corresponding results are presented in Table III.

Using the same estimator on radar and reference signals, FFT and Welch yielded lower radar–reference disagreement than the time-domain approaches, while sinusoidal fitting produced a similarly low mean error. FFT was retained as the primary estimator for consistency with the window-length analysis; no formal computational-complexity benchmark or objective optimization criterion was used to rank the methods.

TABLE III
COMPARISON OF RESPIRATORY-RATE ESTIMATION METHODS FOR THE FILTERED RADAR SIGNAL.

Method	Mean error (bpm)	Median error (bpm)
FFT	1.49	0.03
Welch	1.56	0.00
Sine fit	1.53	0.01
Autocorrelation	3.39	0.21
Zero-crossing	3.59	1.26
Peak detection	5.42	6.01

Autocorrelation, zero-crossing, and peak detection were more sensitive to waveform irregularities in these recordings.

E. Agreement Analysis

Agreement was evaluated across the 12 recordings by comparing estimator-matched RR values from the MPU6050 and filtered radar stream with the CSV command waveform (Tables I and III). For the complete recordings, FFT absolute error was at most 0.038 bpm in 11 of 12 trials; one recording was the exception, with an error of 17.70 bpm caused by selection of a component near twice the reference frequency. Consequently, the 240 s FFT mean absolute error was 1.49 bpm (bootstrap 95% CI: 0.01–4.44 bpm), whereas the median was 0.027 bpm (95% CI: 0.006–0.034 bpm). This wide separation between mean and median emphasizes the sensitivity of the small sample to a single harmonic-selection failure.

The exploratory trajectory analysis provided additional information beyond dominant frequency. Across recordings, the mean and median absolute zero-lag correlations between radar and reference were 0.522 and 0.620; allowing a lag of up to ± 10 s increased the maximum absolute cross-correlation to 0.711 and 0.743, respectively. Mean and median maximum coherence within 0.10–0.70 Hz were 0.821 and 0.842. These values indicate shared respiratory-band temporal structure, but they do not constitute an independent validation of mechanical displacement because the CSV waveform is also the actuator command.

The MPU6050 likewise exhibited low RR error, consistent with its rigid attachment to the moving structure. Overall, the results support preliminary benchtop characterization of RR recovery under the tested conditions, not clinical validation or calibrated displacement accuracy.

V. Discussion

The Acconeer XM132, operated with the *Envelope* service and analyzed after documented respiratory-band preprocessing, recovered the dominant imposed respiratory frequency in most complete recordings. The 0.03 bpm median FFT error should nevertheless be interpreted cautiously: it was obtained from approximately 240 s records, for which long observation time improves spectral discrimination and can obscure transient variation. The 1.49 bpm mean was dominated by a single second-harmonic selection event, despite uninterrupted tracking in the corresponding recording. Thus, target tracking alone is insufficient to guarantee correct identification of the fundamental respiratory component.

FFT and Welch produced lower disagreement than the tested time-domain estimators, while sine fitting performed similarly to the spectral estimators. The window analysis does not support calling 60 s an optimum: 90 s yielded the lowest mean error, whereas 60 s provides more frequent RR estimates. The appropriate window therefore depends on the intended temporal resolution and error tolerance.

The methodological novelty should also be interpreted relative to prior phantom work. Recorded physiological waveforms have been used previously, including thoracic-impedance-driven radar phantoms [16]. The contribution here is the compact integration of public BIDMC waveforms with an XM132 PCR sensor, auxiliary inertial sensing, and an analysis framework that exposes window-length, estimator, tracking, and harmonic-selection behavior. The MPU6050 result (FFT mean error 0.08 bpm) supports reproduction of the imposed frequency, but not absolute displacement fidelity because the sensor is rigidly attached to the mechanism.

Several limitations remain. Motion is one-dimensional, whereas human chest-wall displacement is spatially distributed. No independent linear encoder, laser, or optical reference was available; consequently, the actual motion amplitude, mechanical resolution, hysteresis, backlash, and run-to-run repeatability were not quantified. The nominal 20 mm mechanism range and radar-derived 0.394–0.460 m tracking distances must therefore not be interpreted as calibrated displacement measurements. Although no obvious flat-top behavior was evident in the stored radar-amplitude traces, the logs do not contain a formal saturation flag or full-scale threshold, so saturation cannot be excluded quantitatively. Likewise, the merged asynchronous logs do not permit a defensible estimate of source-frame packet loss. A dedicated stationary acquisition would be needed to quantify a radar noise floor.

The sample comprises only 12 distinct recordings; bootstrap intervals and the per-record behavior reported above illustrate the resulting uncertainty and sensitivity to outliers. In addition, repeated runs of the same waveform were not performed, and the experiments did not constitute dedicated challenges for apnea, tachypnea, irregular breathing, controlled motion artifacts, or human subjects. These are therefore validation gaps rather than demonstrated capabilities. The platform can nevertheless be extended to compare alternative RR estimators, acquisition settings, and radar modules under the same reproducible input framework.

Three practical lessons emerge. First, physiologically derived waveforms do not eliminate spectral ambiguity, as demonstrated by the second-harmonic error. Second, increasing the analysis window generally reduces median error but sacrifices temporal resolution, while mean error can remain non-monotonic because of sparse large errors. Third, close RR agreement does not establish mechanical fidelity when the comparison waveform is also the actuator command. Future work should prioritize independent displacement sensing, formal repeated-run characterization, broader respiratory and motion-artifact protocols, explicit noise/saturation characterization, robust harmonic rejection, and subsequent validation in volunteers or patients.

VI. Conclusion

This work presented a mechatronic platform driven by thoracic impedance signals for the experimental evaluation of the Acconeer XM132 radar for respiratory monitoring. The platform integrates servo motors, an MPU6050 inertial sensor, and dedicated acquisition software, and was evaluated using 12 recordings from the publicly available BIDMC dataset.

Using FFT, the radar yielded a median RR error of $0.09\,\mathrm{bpm}$ and a mean error of $1.94\,\mathrm{bpm}$ with 60 s, 50%-overlapped windows. For complete approximately $240\,\mathrm{s}$ recordings, the mean and median errors were $1.49\,\mathrm{bpm}$ and $0.03\,\mathrm{bpm}$; one second-harmonic selection error accounted for most of the mean error. The study therefore supports the platform as a controlled proof-of-concept environment for preliminary radar and RR-processing characterization. It does not establish calibrated mechanical displacement accuracy or clinical validity. Broader validation requires a larger and repeated signal set, an independent displacement reference, mechanical-amplitude and repeatability characterization, explicit noise/saturation tests, improved harmonic rejection, and subsequent experiments in volunteers or patients.

ACKNOWLEDGMENT

The authors gratefully acknowledge the SENAI Innovation Institute for Embedded Systems for its institutional support and for providing the facilities and infrastructure required to conduct this research. This study was financed in part by the Coordination for the Improvement of Higher Education Personnel – Brazil (CAPES) – Finance Code 001.

***Resumo*—O monitoramento contínuo e não invasivo de parâmetros cardiovasculares ainda depende na prática clínica de profissionais especializados e equipamentos de alto custo. Este artigo apresenta uma prova de conceito de um sistema embarcado desenvolvido para a medição da distensão vascular utilizando um sensor ultrassônico em modo A-Scan. A arquitetura de hardware emprega um microcontrolador STM32 operando em bare-metal, um conversor analógico-digital de 12 bits a 3 MSPS (ADS7883), um amplificador operacional OPA350 no front-end analógico e um transdutor piezoelétrico de 8 mm $\times$ 1 mm excitado por um driver MOSFET TC4420. Os ecos ultrassônicos captados são transmitidos via comunicação serial para um ambiente Python, onde o envelope do sinal é extraído e armazenado em arquivo CSV para a visualização da variação das paredes da artéria radial. Embora modelos biomecânicos elásticos exponenciais correlacionem o diâmetro vascular à pressão arterial, este estudo delimita-se à validação técnica da eletrônica de aquisição sem calibração clínica. Ensaios técnicos de bancada com diferentes tensões de excitação (5, 10, 15 e 20 V) demonstraram que pulsos de 10 V produzem sinais de eco com melhor relação sinal-ruído, evitando atenuação excessiva e distorções. Os resultados confirmam a viabilidade do hardware proposto como instrumentação de baixo custo e etapa fundamental para o futuro desenvolvimento de sistemas de monitoramento contínuo.**

***Palavras chaves*—Pressão arterial, ultrassom, envelope analógico.**

I. Introdução

Sensores e transdutores atuam como primeira camada de interface entre o organismo vivo e o sistema de aquisição eletrônica, onde a função primordial do transdutor é a conversão de uma grandeza física ou bioquímica em um sinal elétrico analógico equivalente [1], [2].

No monitoramento hemodinâmico por métodos acústicos o elemento piezoelétrico quando submetido a um estresse mecânico sofre deslocamento de cargas, gerando uma diferença de potencial elétrico utilizável (efeito direto). A aplicação de um pulso de tensão elétrica de curta duração deforma mecanicamente o cristal e induz a emissão de uma onda de pressão acústica na pele (efeito inverso) [1], [3].

A escolha geométrica e material do transdutor define sua frequência fundamental de ressonância e o comprimento de onda ideal para obter alta resolução na discriminação de interfaces biológicas milimétricas e superficiais, como as paredes vasculares. O ultrassom em Modo-A (Amplitude Mode) representa a forma mais pura e unidimensional da ecografia pulsada. O princípio operacional baseia-se no método de tempo de voo (Time-of-Flight - ToF), onde o sistema transmite um pulso ultrassônico transiente para o interior do tecido e passa a operar em modo de recepção, aguardando os ecos gerados nas transições entre meios de diferentes impedâncias acústicas [1]–[3].

No monitoramento da artéria radial o processamento desse sinal analógico revela dois picos móveis distintos correspondentes às interfaces da parede anterior e posterior do vaso [2], [4]. O rastreamento dinâmico da distância temporal entre esses picos viabiliza a mensuração micrométrica da oscilação do diâmetro arterial ao longo do ciclo cardíaco, considerando a velocidade nominal do som no tecido mole de 1540 m/s [1], [4].

A artéria radial está localizada superficialmente na região do punho, sendo uma região anatômica ideal para o monitoramento hemodinâmico não invasivo. Durante o ciclo cardíaco a propagação da onda de pulso exerce uma pressão hidrostática contra as paredes do vaso, induzindo uma deformação que devido às propriedades viscoelásticas da parede arterial apresenta uma forte correlação matemática com as variações da pressão intravascular. Consequentemente, a captação dessa variação de diâmetro viabilizada por técnicas de ultrassonografia permite modelar a dinâmica vascular e traduzir o comportamento mecânico da artéria [5].

Para transformar a distensão geométrica em milímetros de mercúrio (mmHg), usam-se modelos baseados na complacência arterial (a relação entre variação de volume e variação de pressão) [1], [3]. Antes de aplicar as equações é preciso aplicar uma janela de calibração, ou seja, no mesmo momento que o esfigmomanômetro mede a pressão do paciente, o software de ultrassom registra os diâmetros da artéria, obtendo-se quatro constantes: pressão sistólica e diastólica medidas pelo esfigmomanômetro manual, diâmetro máximo e mínimo medidos através do sistema ultrassônico.

O modelo exponencial (1) é uma das abordagens matemáticas mais precisas usadas na literatura biomédica para calcular a pressão instantânea a partir do diâmetro instantâneo [5].

Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES)

$$P(t) = P_d \cdot \exp\left(\beta\left(\frac{D(t)}{D_d} - 1\right)\right) \quad (1)$$

em que $P(t)$ é a pressão arterial instantânea, P_d é a pressão arterial diastólica medida com esfigmomanômetro, β é o índice de rigidez arterial e D_d é o diâmetro mínimo da artéria durante a diástole (medido com o sensor durante a captura dos sinais).

A parede arterial enrijece conforme dilata e esse comportamento é modelado pela relação de Hughes [5] através de um índice de rigidez β calculado em (2).

$$\beta = \frac{\ln\left(\frac{P_s}{P_d}\right)}{\frac{D_s}{D_d} - 1} \quad (2)$$

em que P_s é a pressão sistólica medida com esfigmomanômetro e D_s é o diâmetro maior durante a sístole (medido com o sensor durante a captura dos sinais).

II. Materiais e Métodos

A. Arquitetura de Hardware e Seleção de Componentes

O sistema de aquisição de sinal de ultrassom em modo *A-Scan* foi projetado como uma prova de conceito para capturar a dinâmica geométrica de distensão que simula o comportamento da artéria radial.

Utilizou-se um transdutor na forma de disco piezoelétrico de Titanato Zirconato de Chumbo (PZT) com 8 mm de diâmetro e 1 mm de espessura. A geometria do cristal foi definida visando duas características fundamentais: a espessura de 1 mm determina uma frequência de ressonância natural na faixa de 2 MHz (considerando a velocidade do som no material), enquanto o diâmetro de 8 mm é adequado para focar o feixe acústico.

Para a excitação do transdutor empregou-se o *driver* de MOSFET TC4420 devido à sua capacidade de fornecer picos de corrente elevados com tempos de subida e descida na ordem de 25 ns. Essa característica é crítica para carregar e descarregar abruptamente a capacitância do disco piezoelétrico, convertendo o sinal lógico de baixa potência do microcontrolador em um pulso de excitação mecânica (onda de choque acústica) de banda larga. Um módulo *Step-UP* fornece tensões entre 5 V e 20 V para o TC4420, enquanto os demais componentes são alimentados com 3.3 V do módulo STM32.

Devido ao eco ultrassônico possuir uma amplitude na ordem de milivolts, utilizou-se um amplificador operacional OPA350 com largura de banda 38 MHz e taxa de variação (*slew rate*) de 22 V/μs. Estas especificações garantem a amplificação linear do sinal do ultrassom sem introduzir distorção de fase ou atenuação indesejada dos picos.

A conversão analógico-digital foi realizada pelo circuito integrado ADS7883, um ADC de arquitetura de aproximações sucessivas (SAR) operando a 3 MSPS (*Mega Samples Per Second*) com resolução de 12 bits. Esta taxa de amostragem atende aos requisitos de captura de transientes rápidos do sinal condicionado, enquanto a resolução de 12 bits (4096 níveis de quantização) confere a faixa dinâmica necessária para discriminar sutis variações de impedância acústica.

Para o módulo microcontrolador, optou-se pelo modelo STM32 NUCLEO-F767ZI em detrimento de arquiteturas voltadas à IoT, como o ESP32. O rastreamento de distensão por ultrassom depende estritamente do tempo de voo (*time-of-flight*), onde atrasos de frações de microssegundos inviabilizam a medição. Enquanto o ESP32 executa operações sobrepostas a um Sistema Operacional de Tempo Real (RTOS) encarregado da pilha de rede, o que introduz um *jitter* (variação de latência) inaceitável nas temporizações, o STM32 (Cortex-M7 a 216 MHz) operando *bare-metal* (sem sistema operacional base) assegura o determinismo do sistema. O uso de temporizadores de hardware e recursos de Acesso Direto à Memória (DMA) garante precisão na comunicação SPI e na temporização dos disparos.

B. Validação de Bancada, Aquisição e Processamento de Sinal

Para validar a instrumentação eletrônica e a resposta do algoritmo em um cenário de aplicação, testes preliminares de prova de conceito foram conduzidos por meio de autoexperimentação ($n = 1$). O transdutor foi posicionado usando uma película fina de gelatina neutra sobre a região da artéria radial no pulso do próprio autor e presa através de elástico para manter a mesma pressão em todas as medições, utilizando-a estritamente como um alvo físico para atestar a viabilidade da medição do tempo de voo acústico e das variações geométricas em tempo real. Por se tratar exclusivamente de uma validação técnica de hardware e calibração de sinais, sem caráter de ensaio clínico, análise populacional ou intervenção de risco, o procedimento caracterizou-se como teste de bancada preliminar, dispensando a submissão a um comitê de ética.

A dinâmica operacional do *firmware* no STM32 é estruturada por interrupções e requisições seriais [8]. Ao receber um comando via UART (*Universal Asynchronous Receiver-Transmitter*), o microcontrolador aciona um pino GPIO que controla a emissão do pulso elétrico no TC4420. Após um tempo de supressão (*blanking time*), projetado para ignorar a saturação do pulso principal de emissão (*main bang*), o microcontrolador inicia a leitura no barramento SPI em alta velocidade, coletando um *frame* de 1000 amostras provenientes do ADS7883. Esse pacote de dados é alocado em memória via DMA, envelopado com um cabeçalho hexadecimal de sincronização e transmitido para o computador a uma taxa de transferência de 460.800 bps.

No ambiente Python um programa realiza a recepção em tempo real e outro faz o processamento do arquivo CSV para plotagem [8]. O *script* monitora o fluxo serial, isolando os quadros de 1000 amostras a partir do reconhecimento do cabeçalho de sincronização, garantindo a integridade dos dados sem rupturas ou perdas de alinhamento estrutural (*frame shift*). Uma vez extraído o vetor de 12 bits, o processamento digital de sinais (DSP) ocorre em quatro etapas sucessivas:

1) **Filtragem:** O sinal sofre a aplicação de um filtro passa-baixa Butterworth para mitigação de ruído térmico de alta frequência e suavização da curva.

2) **Demodulação:** Aplica-se a Transformada Analítica de Hilbert, cujo valor absoluto do vetor complexo extrai o envelope de energia acústica, suprimindo as portadoras indesejadas.
3) **Detecção Estrutural:** Um algoritmo de localização de picos avalia o envelope de ecos respeitando restrições projetadas para a anatomia vascular simulada. São exigidas proeminências específicas de amplitude e distâncias morfológicas aceitáveis (1.5 mm a 8.0 mm) para categorizar estritamente o reflexo das superfícies anterior e posterior do alvo.
4) **Mapeamento Gráfico:** A distância entre os alvos é calculada em milímetros com base no vetor calibrado pela velocidade média do som em tecidos biológicos (1540 m/s). Converteu-se esse valor para milímetros por nanossegundos (0.00154 mm/ns) e através do tempo de amostragem do STM32 (692.6 ns) chega-se à constante de distância da amostra (0.5333 mm), significando que cada índice no eixo da profundidade representa o percurso do eco em exatos 0.5333 milímetros. A interface visual, implementada através da biblioteca *Matplotlib*, plota a distância pontual das paredes, renderizando a evolução temporal contínua em 2D na janela de monitoramento, o que permite a visualização dos ciclos de sístole e diástole a cada quadro gerado.

III. Resultados

O teste inicial foi feito com pulsos de 5 V e os dados brutos recebidos pelo programa Python foram processados para identificar os pontos da sístole e diástole. A Fig. 1 mostra o pico máximo (sístole) e mínimo (diástole) da artéria radial entre 3.0 e 5.5 segundos.

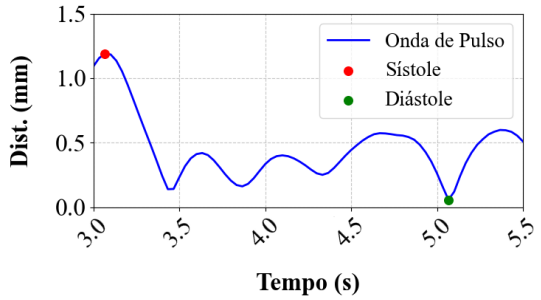

Fig. 1. Representação da sístole e diástole para pulsos de 5V.

O segundo teste foi realizado usando 10 V para emissão dos pulsos ultrassônicos, a Fig. 2 mostra o resultado com os pontos de sístole e diástole.

O terceiro teste usou uma tensão de pulso de 15 V e a Fig. 3 mostra o resultado com os pontos de sístole e diástole para esta tensão.

O quarto e último teste usou uma tensão de pulso de 20 V e a Fig. 4 mostra o resultado com os pontos de sístole e diástole para esta tensão.

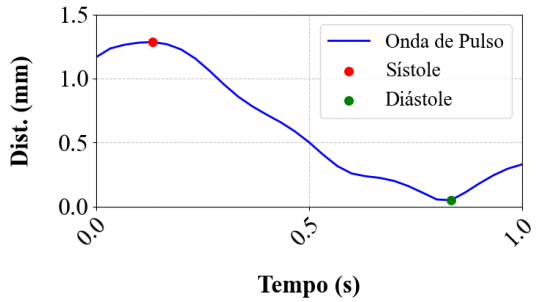

Fig. 2. Representação da sístole e diástole para pulso de 10V.

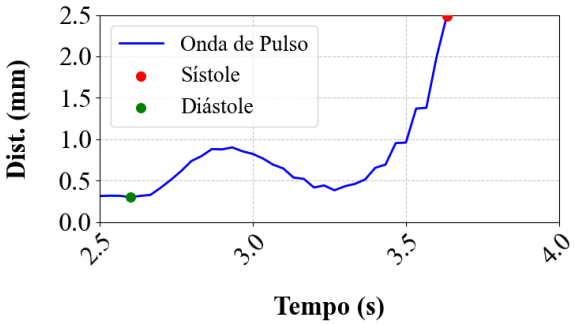

Fig. 3. Representação da sístole e diástole para pulso de 15V.

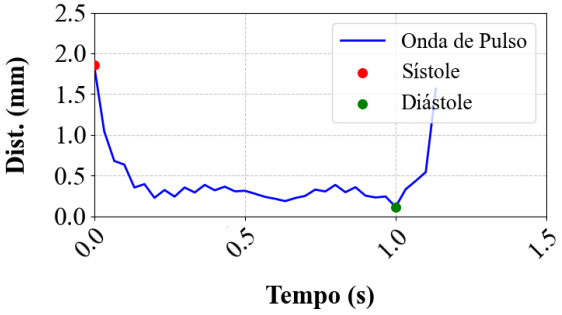

Fig. 4. Representação da sístole e diástole para pulso de 20V.

O gráfico da Fig. 1 não condiz com os gráficos hemodinâmicos encontrados na literatura [6], [7], indicando que uma tensão de 5 V não é adequada para a captação do eco ultrassônico.

Na Fig. 2 temos uma linha representativa de uma hemodinâmica com os pontos de sístole e diástole bem definidos e dentro de um intervalo condizente com a literatura.

Na Fig. 3 e Fig. 4 apesar do intervalo da sístole e diástole estarem dentro do intervalo de aproximadamente 1 segundo, percebe-se que a linha começa a apresentar ruídos e leves variações, possuindo um aspecto diferente da forma representativa de um gráfico ideal.

Para medir a pressão arterial em função do tempo, o valor máximo de D_s e o valor mínimo de D_d devem ser salvos e usando um esfigmomanômetro obtém-se P_s e P_d

padrão do indivíduo, substituindo estes valores em (1) e (2) aplica-se as equações no programa e obtém-se a pressão em função do tempo sem que seja necessário o uso contínuo do esfigmomanômetro.

IV. Discussões e Conclusão

Este artigo apresentou o desenvolvimento e a validação de uma prova de conceito de um sistema embarcado de ultrassom em modo *A-Scan* voltado para o monitoramento da distensão geométrica vascular. A arquitetura de hardware baseada em um microcontrolador STM32 operando *bare-metal* com determinismo temporal, aliada a um condicionamento analógico e ao processamento digital via Transformada de Hilbert, demonstrou ser capaz de rastrear a variação da artéria radial.

A análise comparativa das tensões de excitação do transdutor piezoelétrico revelou que a aplicação de pulsos de 10 V representa o ponto ideal de operação do sistema na bancada. Nessa configuração, o processamento do envelope acústico extraiu a eco-reflexão do alvo, apresentando ciclos com picos de sístole e diástole bem definidos. Constatou-se empiricamente que tensões inferiores (5 V) são insuficientes para uma captação ecográfica adequada do sinal, enquanto tensões superiores (15 V e 20 V) introduzem distorções decorrentes da saturação do front-end analógico.

Os resultados confirmam a viabilidade técnica da instrumentação proposta, validando-a como uma alternativa de baixo custo, não oclusiva e de alta precisão temporal para sistemas de aquisição biomédica. A mensuração bem-sucedida da variação geométrica vascular estabelece a infraestrutura de dados necessária para futuras implementações de modelos biomecânicos de complacência arterial.

Como trabalhos futuros, planeja-se a integração de técnicas avançadas de filtragem e aprendizado de máquina no ambiente Python, bem como a estruturação de ensaios futuros com amostragem ampliada para avaliar a correlação dos sinais obtidos com padrões clínicos de referência.

Agradecimentos

Agradeço à Universidade do Estado de Santa Catarina (UDESC) pelo suporte institucional e à Fundação de Amparo a Pesquisa e Inovação do Estado de Santa Catarina (FAPESC), bem como à Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) pelo suporte financeiro.

***Abstract*—Alterações na frequência respiratória constituem um dos primeiros sinais de deterioração do estado clínico do paciente, o que evidencia a necessidade de soluções portáteis e não invasivas para seu monitoramento contínuo. Este trabalho teve como objetivo desenvolver um sistema de biofeedback respiratório composto por um sensor de pressão piezoresistivo integrado a um microcontrolador XIAO ESP32 C6 mini com comunicação Bluetooth Low Energy (BLE). A unidade sensora, constituída por microcontrolador, regulador de tensão DC-DC e módulo de sensor barométrico com conversor ADC de 24 bits, processa o sinal respiratório em tempo real e transmite os dados ao programa de análise para visualização da curva respiratória e geração de relatórios com frequência respiratória (FR). A calibração foi conduzida em ambiente controlado, com o protótipo conectado em série a um ventilador mecânico Maquet Servo Air e um pulmão artificial. O sistema demonstrou alta fidelidade na detecção da FR, com desvio padrão máximo de 0,83 rpm em relação aos parâmetros simulados. Os resultados confirmam a viabilidade da unidade sensora para aplicações de saúde preventiva em cenários dinâmicos do cotidiano.**

***Index Terms*—Frequência respiratória, Biofeedback, Sensor Piezoresistivo, pressão**

I. Introdução

A respiração é um processo fisiológico essencial para a manutenção da vida, resultante da ação coordenada dos músculos respiratórios e do centro de controle localizado no cérebro. Alterações no ritmo respiratório podem ocorrer como resposta fisiológica, por exemplo, durante o esforço físico, ou indicar condições clínicas relevantes, como insuficiência respiratória e doenças pulmonares obstrutivas crônicas (DPOC) [1], [2]. Em paralelo a essa demanda clínica, o avanço das tecnologias vestíveis (wearables) tem tornado o acompanhamento dos sinais vitais mais acessível, preciso e contínuo. Esses dispositivos, aliados a biossensores, permitem a captação de variáveis fisiológicas – como temperatura corporal, frequência cardíaca, movimento e fluxo respiratório – transformando-as em sinais elétricos ou ópticos que podem ser analisados por softwares especializados [3]. Esse avanço tecnológico encontra na Internet das Coisas (IoT) um potente elemento integrador, que conecta sensores a plataformas digitais e promove a coleta, transmissão e análise contínua de dados fisiológicos em tempo real mesmo fora do ambiente hospitalar [4]. Dentro desse ecossistema tecnológico, destaca-se o conceito de biofeedback, técnica que visa promover a autorregulação por meio do monitoramento e da devolução de informações fisiológicas em tempo real ao paciente. Essa estratégia é amplamente utilizada em programas de reabilitação física, controle do estresse, manejo de doenças crônicas e aprimoramento do desempenho cardiorrespiratório, inclusive em contextos esportivos [5]. Para a captação do sinal respiratório nesse tipo de aplicação, destacam-se os sensores piezoresistivos, notáveis por sua alta sensibilidade na conversão da tensão mecânica em sinal elétrico. Seu princípio de funcionamento reside na variação da resistência elétrica do material conforme ele é deformado, sendo esse processo reversível após cada ciclo respiratório, o que viabiliza um acompanhamento contínuo e preciso da respiração [6]. Diante do exposto, este trabalho teve como objetivo prototipar e calibrar um sistema de monitoramento e análise do fluxo e esforço respiratório, utilizando um sensor de pressão piezoresistivo para a aquisição de dados e modelado para integração em dispositivo vestível. O sistema visa permitir a avaliação contínua e a análise remota simplificada dos parâmetros respiratórios durante atividades de rotina, fornecendo suporte a soluções preventivas e terapêuticas em indivíduos com diferentes perfis respiratórios, tais como asma, DPOC, desvio de septo e apneia do sono, além de viabilizar a análise comparativa entre as curvas de respiração nasal e oral.

II. Materiais e Métodos

A. Calibração do Sensor

Foi prototipada uma unidade sensora, vista na Figura 1, utilizando o MPS20N0040D-S embutido em um módulo junto ao conversor analógico-digital HX710B de 24bits que utiliza o formato de Complemento de Dois na saída.

O MPS20N0040D-S é um sensor analógico piezoresistivo que converte a pressão do ar aplicado em tensão, a leitura da tensão chega ao conversor adc onde é digitalizada com ganho de 128V/V. Com isso, a equação geral do Bit Menos Significativo (LSB) é dado por:

$$LSB = \frac{2 \times V_{ref}}{Ganho \times 2^{24}} \tag{1}$$

No presente estudo, a tensão de referência (V_{ref}) foi de 5V, com isso, a conversão do dado bruto enviado pelo sensor para tensão de saída (V_{out}) em milivolts é dada por:

$$V_{out} = LSB \times DadoBruto \tag{2}$$

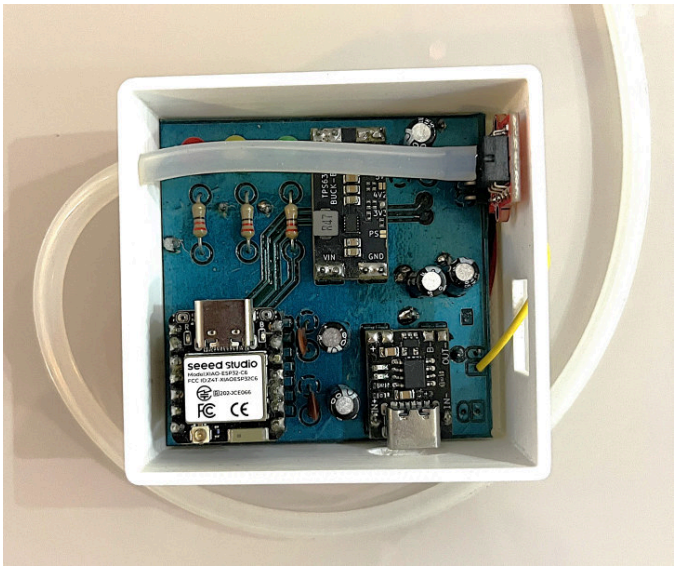

Fig. 1. Unidade sensora (protótipo)

Com essas informações sob registro, foi realizada uma sessão de leituras de pressão do fluxo respiratório utilizando a unidade sensora em série com um ventilador pulmonar MAQUET Servo Air e um pulmão artificial durante ciclos respiratórios de frequência fixa e pico de pressão positiva personalizada que variou de 7cmH2O à 22cmH2O, variando a cada +1cmH2O. A taxa de amostragem do sensor foi de 50ms e foram analisados 951 pontos para cada uma das pressões aplicadas.

Em seguida, foi realizada a identificação dos picos de tensão para cada intervalo associado à pressão aplicada pelo ventilador pulmonar e calculada a média, mediana, moda, variância, desvio padrão, intervalo de confiança, box-plot desses valores e a correlação de Pearson entre a tensão de saída do sensor e a pressão de fluxo aplicada. Após a análise das medidas de tendência central e dispersão, o valor da moda dos picos foi selecionada para melhor representar o comportamento do sensor à pressão associada e utilizado no cálculo de regressão linear para definir o comportamento da tensão de saída em função da pressão aplicada ao sensor.

B. Unidade Sensora

Foi desenvolvido um sistema embarcado autônomo controlado por um XIAO ESP32-C6 Mini responsável por tratar em tempo real as leituras de tensão realizadas pelo módulo do sensor MPS20N0040D-S e por criar um servidor Bluetooth 5.3 que estabelece as regras de comunicação com aplicativo móvel.

O microcontrolador possui dois núcleos de processamento que permite orquestrar de forma assíncrona as tarefas críticas de temporização e gerenciamento da pilha de dados Bluetooth (incluindo o controle físico de rádio, buffers de transmissão e coexistência de rede), o que garante a comunicação sem fio ocorrer sem causar atrasos de sincronização ou perda de pacotes, enquanto o outro se dedica a tratar dos dados do sensor. Isso permite que a comunicação não interfira na precisão e estabilidades das medições.

Visando blindar o sistema contra oscilações de energia, um regulador de tensão buck-boost atua na estabilização contínua da alimentação dos circuitos lógicos e analógicos. Esse regulador assegura que, mesmo com o declínio gradual da carga da bateria, o sensor e o microcontrolador operem sob uma tensão rigorosamente constante, eliminando desvios térmicos ou flutuações que comprometem a calibração e a precisão das leituras de pressão.

C. Modelagem do sistema

O sistema de biofeedback foi desenhado para operar por meio de uma arquitetura de malha fechada, viabilizada pela interação dinâmica entre três agentes principais: o usuário, a unidade sensora(hardware) e o programa de análise(software). O fluxo operacional inicia-se quando o usuário, por meio da interface gráfica do analisador, envia um comando de inicialização via Bluetooth Low Energy para a unidade sensora. Ao receber a instrução, o microcontrolador ativa a rotina de aquisição de dados, realizando a leitura analógica contínua do sensor de pressão respiratória.

Após o tratamento digital local dos sinais de tensão – que envolve a filtragem de ruídos e calibração básica –, as informações de pressão são empacotadas e transmitidas assincronamente de volta ao sistema de análise. No programa, os dados são processados para a renderização em tempo real da curva respiratória e para o cálculo instantâneo dos parâmetros associados.

O ciclo de biofeedback se fecha quando o usuário visualiza o gráfico atualizado continuamente na tela. Esse retorno visual imediato permite que o paciente regule de forma consciente e voluntária o seu esforço, frequência ou padrão respiratório, adaptando sua mecânica pulmonar aos alvos terapêuticos estabelecidos no aplicativo. Vale destacar que a curva positiva

remete ao ciclo expiratório (pressão positiva aplicada ao sensor) e a curva negativa remete ao ciclo inspiratório (pressão negativa).

III. Resultados e Discussão

A modelagem desenvolvida visa ser um método alternativo, confortável e versátil de avaliação da respiração natural – fluxo de ar pelas vias nasais, responsáveis por filtrar, aquecer e umedecer o ar inspirado para propiciar a oxigenação eficiente do organismo – em atividades cotidianas de baixa e média intensidade, cuja estabilidade e precisão permite, à posteriori, o estudo observacional de diferentes perfis respiratórios. Sua aplicação almeja apoiar soluções preventivas e terapêuticas que melhorem a qualidade de vida das pessoas sob diferentes quadros clínicos de restrição respiratória.

A. Calibração (Pressão x Tensão)

A resposta do sensor às diferentes pressões aplicadas pelo ventilador pulmonar foram estáveis, com exceção do pico de pressão à 22cmH2O em que ocorreu a saturação do sensor e sua leitura foi dispensada como dado censurado e excluída da análise. As três medidas de tendência central (média, mediana e moda) convergiram para valores praticamente idênticos em todos os níveis de pressão, com diferenças inferiores a 0,01 mV. Essa concordância indica que a distribuição dos picos de tensão dentro de cada intervalo é aproximadamente simétrica e livre de valores extremos (outliers).

Quanto à dispersão, o coeficiente de variação manteve-se abaixo de 0,14% em todos os 15 níveis de pressão testados, o que evidencia uma repetibilidade muito alta do sensor: ciclo a ciclo, sob uma mesma pressão fixa, a tensão de saída variou, no máximo, cerca de 0,14% em torno de sua média. Os intervalos de confiança de 95%, por sua vez, mostraram-se estreitos em todos os níveis (amplitude inferior a 0,02 mV), reforçando que a média estimada para cada pressão é precisa em relação ao valor esperado de tensão.

A relação entre a pressão aplicada e a tensão de saída do sensor foi modelada por regressão linear simples, resultando na equação de calibração: P = 1.5007V - 0,0181 (P em cmH2O e V em mV), com coeficiente de determinação $R^2 = 0,9997$ e coeficiente de correlação de Pearson $r = 0,9999$ ($p = 2,22 \times 10^{-24}$). A faixa de medição do sensor foi observada entre -90.95cmH2O (≈ -8.9kPa) à +23.30cmH2O(≈+2.3kPa), sendo um intervalo de operação aprovado na literatura para a avaliação da respiração nasal até das vias mais obstruídas e de pacientes com maior esforço de acordo com o Comitê Internacional de Padronização da Rinomanometria que estipula um intervalo útil de ± 0.3kPa [7].

Complementarmente à faixa de medição observada, a resolução prática do sistema de aquisição foi caracterizada por meio de uma captura com a cânula de pressão vedada, isolando o ruído de fundo do conversor sob entrada fisicamente constante. O desvio-padrão das leituras nessa condição foi de $\sigma \approx$ 0,0009–0,0010 cmH2O, correspondendo a uma resolução efetiva de aproximadamente 16,9 bits sobre a faixa total do conversor (nominal de 24 bits, ganho 128). Adotando o critério de resolução livre de ruído (6,6 σ) — que representa a menor variação de pressão distinguível do ruído com margem estatística adequada [8] — obteve-se uma resolução de ≈ 14,1–14,3 bits, equivalente a cerca de 0,006 cmH2O (≈ 0,6 Pa). Esse resultado é consistente com o comportamento documentado para a família de conversores sigma-delta de 24 bits HX711/HX710B, que tipicamente perde 8 a 10 bits nominais para o ruído térmico do amplificador mesmo em condições ideais de medição.

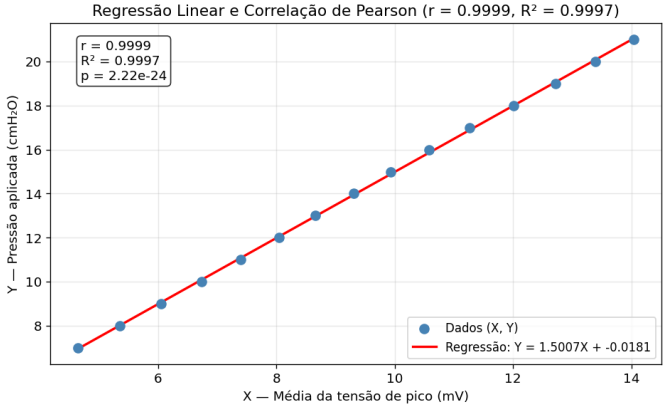

Fig. 2. Função estimada por regressão linear da Pressão x Tensão

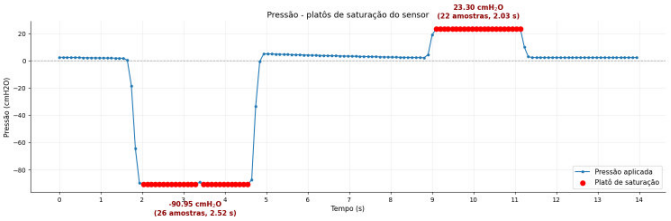

Fig. 3. Platôs de saturação do intervalo de medição do sensor

B. Esforço respiratório natural

A curva do ritmo respiratório obtido no programa de análise após a calibração do sensor foi eficaz para o cálculo da pressão instantânea, análise da forma da curva, cálculo da frequência respiratória e da relação I:E por via nasal, o que pode ser observado na figura4. Tal resultado está coerente com estudos médicos e fisiológicos de procesamento de dados da pressão nasal [9] e permite uma avaliação minuciosa do esforço respiratório do usuário.

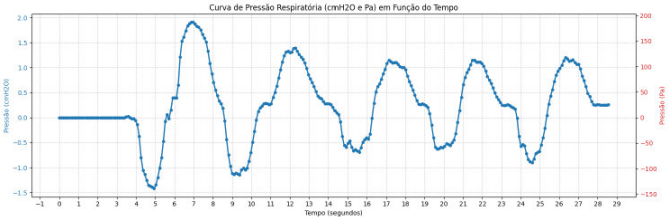

Fig. 4. Curva do esforço respiratório via nasal

IV. Conclusão

Este trabalho demonstrou a viabilidade técnica de um sistema portátil, não invasivo e de baixo custo para o monitoramento contínuo do fluxo e esforço respiratório, utilizando um sensor de pressão piezoresistivo integrado a um microcontrolador com comunicação sem fio. Os ensaios de calibração comprovaram a elevada precisão e repetibilidade do dispositivo na captação dos sinais de pressão e no rastreamento da frequência respiratória. A arquitetura em malha fechada viabilizou a aquisição e a análise remota das curvas de respiração nasal em tempo real, consolidando a solução como uma ferramenta promissora para estratégias de biofeedback e integração em dispositivos vestíveis. Essa abordagem abre caminho para o acompanhamento contínuo e preventivo de indivíduos com diferentes condições respiratórias diretamente em suas atividades cotidianas e na ausência de supervisão clínica presencial.

***Abstract*—Manual positive pressure ventilation (PPV) is the simplest and most common intervention during neonatal resuscitation, yet excessive pressures and volumes can injure the immature lung. Continuous flow monitoring mitigates this risk, but commercial solutions based on hot-wire anemometry remain expensive and proprietary. This work presents a purely computational model of an open-source, low-cost respiratory flow transducer based on an impact disc mounted on a thin cantilever, whose bending is read by a strain gauge. The fluid–structure response was characterized with a sequential workflow: computational fluid dynamics for force extraction, finite element analysis for strain, and an analytical model for the signal-conditioning chain. Under standard neonatal ventilation conditions, over the target range of 0.2 to 9.0 liters per minute, the aerodynamic force on the selected disc geometry reaches about 166 μN, producing a peak bending strain of only about 0.57 $\mu\varepsilon$ at the cantilever root. A demonstration that the base pressure cancels in the net disc force allowed the simulations to be run at zero gauge outlet pressure, removing numerical noise. Linear-elastic behavior let the full operating range be derived from a single reference simulation. A metallic foil gauge was selected for the transducer on grounds of cost, availability and robustness; with this gauge and the present cantilever, the predicted bridge output stays near the practical detection floor of foil technology across the entire range, and falls below it at low flow. This sensitivity shortfall, most severe precisely where the smallest patients are ventilated, is identified as the principal design constraint exposed by the model. No physical prototype has yet been built or calibrated, and the results should be read as a computational feasibility study: they define the geometric and electronic constraints – and motivate a thinner cantilever neck, a full-bridge layout, or a higher-gauge-factor transducer – for a future prototype and its experimental validation.**

***Index Terms*—neonatal ventilation, respiratory flow sensor, strain gauge, computational fluid dynamics, finite element analysis, fluid-structure interaction**

I. Introduction

Positive pressure ventilation (PPV) is the single most effective intervention for a newborn that fails to breathe effectively after birth, yet it can also injure the immature lung: excess volume and pressure cause volutrauma, barotrauma, and biotrauma, driving bronchopulmonary dysplasia [1], [2], while too little volume causes atelectrauma, hypoxemia, and hypercarbia; excessive ventilation additionally produces hypocarbia, linked to white-matter brain injury in preterm infants [3]. This therapeutic window is narrowest precisely in the smallest patients. Yet PPV in the delivery room is most often delivered with self-inflating bags or T-piece resuscitators that give no feedback on delivered volume and flow, so operators routinely misjudge tidal volume, with wide variability between providers [4]. Real-time flow, volume, and pressure monitoring is the practical means of staying within the safe window [5], [6], but is rarely available where resuscitation actually takes place.

Existing flow-measurement technologies carry limitations that are aggravated at neonatal scale [7]. Hot-wire anemometry offers high sensitivity at low flow but is nonlinear, gas-composition-dependent, mechanically fragile, prone to fouling, and supplied only as proprietary hardware. Differential-pressure pneumotachographs are linear only in laminar flow, add dead space and work of breathing, and require correction for oxygen fraction and temperature – hardest precisely at the low flows seen in neonates [8]. Ultrasonic transit-time sensors achieve low dead space but remain sensitive to gas composition and temperature and require costly timing electronics [7]. Across all options, commercial neonatal sensors are proprietary and often single-use, imposing a recurring per-patient cost with no path for open adaptation or local manufacture. What is needed is an open, low-complexity, low-

cost alternative with small dead space and adequate sensitivity at the very low flows characteristic of neonatal ventilation.

This paper models such an alternative: a flow transducer in which an impact disc placed in the airway is deflected by the gas flow, and the resulting bending of a thin cantilever neck is converted into an electrical signal by a strain gauge. The objective is to determine, before any physical prototype is built, whether the aerodynamic forces in the neonatal flow range produce a strain that is measurable with a realistic, low-cost conditioning chain. The analysis follows a one-way fluid-structure workflow: computational fluid dynamics (CFD) extracts the force on the disc, finite element analysis (FEA) converts that force into strain, and an analytical model maps the strain into a bridge output voltage.

II. Methods

The transducer is analyzed with a sequential, one-way fluid–structure workflow: computational fluid dynamics (CFD) yields the aerodynamic force on the impact disc, finite element analysis (FEA) converts that force into the bending strain at the cantilever root, and an analytical model maps the strain into a bridge output voltage. Accordingly, this section first defines the sensing geometry (Section II-A) and the target flow range (Section II-B), and then presents each stage of the chain in turn: force extraction by CFD (Section II-C), strain computation by FEA (Section II-D), and the strain-to-voltage signal model (Section II-E).

A. Drag-disc principle and geometry

The sensing element is a drag-disc, or target, meter: a bluff body placed in the flow whose drag force is measured to infer the flow rate [9]. It consists of a circular disc of area A_s centred in a tube of cross-sectional area A_t, supported by a thin cantilever neck anchored to the tube wall, as shown in Fig. 1. The fraction of the cross-section occupied by the disc is described by the area-restriction figure of merit

$$\phi = \frac{A_s}{A_t}, \tag{1}$$

and, for circular geometries, by the diameter ratio

$$\beta = \sqrt{\phi} = \frac{D_s}{D_t}. \tag{2}$$

Note that ϕ is defined here as the blocked fraction of the cross-section, so that β grows with the size of the obstruction. A larger disc intercepts a greater fraction of the momentum flux and therefore develops a larger force, increasing the sensitivity, but it also raises the flow resistance and intensifies both upstream and downstream disturbances; β must consequently be chosen as a compromise between these competing effects. This trade-off runs opposite to that of an orifice plate, in which the restriction is the aperture rather than the body, and sensitivity therefore grows as β decreases. No standard prescribes β for drag-disc elements at neonatal flow rates: industrial target meters operate at much lower blockage, and the well-established β ranges are those tabulated for orifice-plate meters [10], whose topology is the inverse of the present one. The orifice-plate range was therefore adopted here as a heuristic starting point rather than as a validated criterion, restricting the design space to $0.5 < \beta < 0.7$. The comparatively high blockage that follows is a deliberate consequence of the application: at the lower bound of the neonatal range the aerodynamic force is of the order of a micronewton, so a smaller disc would not develop a measurable signal, and sensitivity must be bought at the cost of pressure drop and dead space.

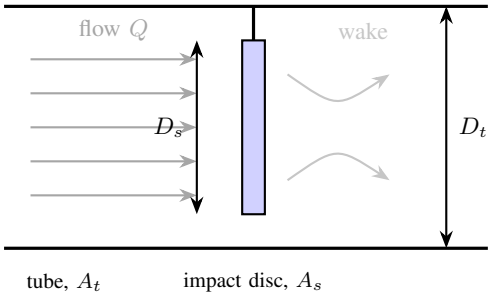

Fig. 1. Schematic longitudinal section of the drag-disc sensing element. A circular disc of diameter D_s and area A_s is centred in a tube of diameter D_t and cross-sectional area A_t, and is supported by a thin cantilever neck anchored to the tube wall. The airflow impinges on the upstream face of the disc, and the resulting axial force bends the neck. The ratio $\beta = D_s/D_t$ determines both the sensitivity and the flow disturbance introduced by the element.

Three candidate disc radii were evaluated: a baseline of $3.5\ \mathrm{mm}$ (denoted r_1), whose β lies in the middle of this range; a radius $20\,\%$ larger, $4.2\ \mathrm{mm}$ (r_2); and a radius $20\,\%$ smaller, $2.8\ \mathrm{mm}$ (r_2). Since the disc area scales with the square of the radius, r_2 and r_3 correspond to about 1.44 and 0.64 times the baseline face area, respectively. For r_2, the face area is $A_s \approx 0.795\ \mathrm{cm}^2$ with $\beta \approx 0.71$, at the upper edge of the design space. The three geometries were simulated independently and compared in Section III-A.

B. Target flow range

The clinical range follows from the smallest and largest patients to be ventilated. Taking the volumetric flow as the tidal volume delivered over an inspiratory time of $\Delta t = 0.5\ \mathrm{s}$, the lower bound corresponds to a 400 g neonate receiving $4\ \mathrm{mL/kg}$, giving $Q_{\min} \approx 0.2\ \mathrm{L/min}$, and the upper bound to a 5000 g neonate receiving $15\ \mathrm{mL/kg}$, giving $Q_{\max} \approx 9.0\ \mathrm{L/min}$. The sensor must therefore operate over 0.2 to $9.0\ \mathrm{L/min}$, a span of roughly $45{:}1$.

C. Simulation for force extraction

The airflow around the disc was simulated with Autodesk CFD 2027 using the finite volume method [11]. The fluid was modelled as air at body-normothermic conditions ($101.325\ \mathrm{kPa}$, $37\ ^\circ\mathrm{C}$), with density $\rho = 1.138\ \mathrm{kg/m^3}$ and dynamic viscosity $\mu = 1.817 \times 10^{-5}\ \mathrm{Pa \cdot s}$, consistent with humidified gas delivered during neonatal resuscitation. The flow was solved as laminar over the entire target range: at the tube diameter and flow rates considered, the Reynolds number

remains well below the transitional threshold ($Re \approx 17$–85 across 0.2–9.0 $\mathrm{L/min}$), which justifies the laminar assumption and avoids the need for a turbulence closure model whose empirical constants are not validated at this scale. The computational domain was discretized using Autodesk CFD's automatic (autosize) meshing algorithm; a single mesh density was used for all reported results, and no mesh independence study was performed (Section IV-D).

Boundary conditions were prescribed as a volumetric flow rate at the inlet (two surfaces) and a fixed static pressure of 0 Pa (gauge) at the outlet (eight surfaces), consistent with the base-pressure cancellation argument below. No inlet velocity profile was imposed manually; the solver distributes the prescribed volumetric flow rate across the inlet surfaces internally.

Convergence was governed by Autodesk CFD's automatic convergence criterion rather than a fixed iteration count. The solver was configured with an iteration budget of 300, but under the automatic criterion execution consistently terminated well before this limit. At 0.4 $\mathrm{L/min}$, for instance, the solver stopped at iteration 110, with residuals of $V_x \approx -5.40\times10^{-3}$, $V_y \approx -1.81$, $V_z \approx -1.02 \times 10^{-1}$, and pressure $\approx 3.56 \times 10^{-2}$; temperature, turbulent kinetic energy, and turbulent energy dissipation residuals were negligible under the laminar, isothermal assumption. While the automatic criterion reflects Autodesk CFD's internal assessment that the solution had stabilized, the y-velocity residual remained roughly an order of magnitude higher than the other velocity and pressure channels at the point of termination; it is not established whether this reflects a converged-but-naturally-noisier component or a channel that would have continued to decay had the automatic stop not triggered.

Standard neonatal PPV parameters were adopted as operating conditions, in accordance with World Health Organization and American Heart Association guidance [12] [13]: positive end-expiratory pressure (PEEP) of 5 $\mathrm{cmH_2O}$, peak inspiratory pressure (PIP) of 20 $\mathrm{cmH_2O}$, respiratory rate of 30 to 60 breaths per minute and tidal volume of 4 to 6 $\mathrm{mL/kg}$. Nineteen steady operating points spanning the target range were solved for each of the three candidate radii (r_1, r_2 and r_3), each geometry being set up and solved independently.

a) Aerodynamic model: The axial force on a bluff body is, to first order,

$$F = \tfrac{1}{2}\, C_d\, \rho\, A_s\, v^2, \tag{3}$$

where ρ is the gas density, v a reference velocity and C_d a drag coefficient. Because the mean velocity scales linearly with the volumetric flow, $v \propto Q$, the ideal scaling is $F \propto Q^2$. The CFD results follow a slightly softer law in the transitional regime,

$$F \propto Q^{1.7}, \tag{4}$$

approaching the quadratic limit only at the highest flows.

b) Base-pressure cancellation: The net axial force on the disc is the difference between the load on the front (impact) face and the load on the rear face,

$$F_{\mathrm{net}} = \int_{A_s} p_f \,\mathrm{d}A - \int_{A_s} p_r \,\mathrm{d}A. \tag{5}$$

For an incompressible flow the absolute pressure level is arbitrary: only the pressure gradient produces force. This can be shown formally by adding an arbitrary uniform base pressure p_0 (representing, physically, the PEEP offset) to both faces:

$$\int_{A_s} (p_f + p_0)\,\mathrm{d}A - \int_{A_s} (p_r + p_0)\,\mathrm{d}A = F_{\mathrm{net}}, \tag{6}$$

since the projected areas of the two faces are equal, the $p_0\, A_s$ terms cancel exactly regardless of the value of p_0. The net force is therefore, by construction, independent of the base pressure level – including the physical PEEP baseline the transducer would actually operate against clinically.

This result has a direct numerical consequence: since F_{net} is provably independent of p_0, the outlet boundary condition can be prescribed at the numerically convenient value of 0 Pa (gauge) instead of at the physical PEEP level, without altering the physical quantity of interest. This choice reads the dynamic pressure directly on the impact face and avoids computing F_{net} as the difference of two much larger, nearly equal absolute-pressure integrals, which would otherwise leave the physical signal degraded by round-off and iterative solver noise. Equation (6) therefore justifies the boundary condition choice on physical grounds first; the reduction in numerical noise is a beneficial byproduct of an already-correct simplification, not the basis for it.

c) Empirical verification: The cancellation was verified for one point: the r_3 geometry at 3.0 $\mathrm{L/min}$, re-run with the outlet at the physical PEEP value (5 $\mathrm{cmH_2O} \approx 490$ Pa) instead of 0 Pa. The front- and rear-face forces read -2140.9 and $+2140.13$ dyne ($\approx \mp 21{,}400$ μN), each dominated by the ≈ 490 Pa base pressure – three orders of magnitude above the expected signal. Their sum, -0.77 dyne ≈ 7.7 μN, agrees with the 7.19 μN obtained under the standard 0 Pa-gauge convention (Table I; $7\,\%$ difference, within run-to-run variation, Section IV-D), confirming Eq. (6): the base pressure cancels in the net force even though it dominates each face individually.

d) Wake correction: The rear-face suction is not resolved cleanly by the wall integration and contributes about $10\,\%$ of the total drag, estimated from the rear-face pressure valley. The net force is therefore taken as

$$F_{\mathrm{net}} = 1.1\, F_{\mathrm{front}}. \tag{7}$$

Forces are reported in micronewtons; the native CFD output in dyne is converted with 1 dyne $= 10$ μN.

D. Simulation for strain from the disc force

The structural response was solved in Autodesk Fusion 360 (Static Stress), with the cantilever modelled in Tough2000 photopolymer resin ($E = 2210$ MPa, $\nu = 0.4$, neck thickness $t = 1$ mm, printed by masked stereolithography). A fixed constraint was applied to the outer plate face ($r = 20$ mm) and the net aerodynamic force to the disc face – equivalent to the resultant acting at the centre of pressure by axisymmetry, avoiding stress singularities. A second-order (parabolic) mesh with absolute element sizing was used.

a) Analytical bending model: Treating the neck as a cantilever loaded near its tip, the bending moment at the root is $M = F\,\ell$ (ℓ: lever arm from disc centre to root), giving a root surface strain of

$$\varepsilon = \frac{\sigma}{E} = \frac{M\,c}{E\,I} = \frac{6\,F\,\ell}{E\,w\,t^2}, \tag{8}$$

with w the neck width, $c = t/2$, and $I = w\,t^3/12$. Strain scales as $1/t^2$ with thickness but only linearly with ℓ, so thinning the neck is the dominant sensitivity lever.

b) Linearity and scaling: Deflections are nanometric, so the response is linear-elastic and a single reference run at maximum flow suffices; strain at any other point follows by scaling,

$$\varepsilon_i = \varepsilon_{\mathrm{ref}}\,\frac{F_i}{F_{\mathrm{ref}}}. \tag{9}$$

A new FEA run is needed only if the geometry changes.

E. Signal model: strain to voltage

A strain gauge converts strain into a fractional resistance change $\Delta R/R = \mathrm{GF}\cdot\varepsilon$ [14], with GF the gauge factor. A single active gauge in a Wheatstone bridge (quarter-bridge) gives, for excitation V_{ex},

$$V_{out} = \frac{V_{ex}}{4}\,\mathrm{GF}\,\varepsilon. \tag{10}$$

The cantilever presents tension on one face and equal compression on the other; placing one gauge on each face in adjacent bridge arms (reading $+\varepsilon$ and $-\varepsilon$) doubles the output to

$$V_{out} = \frac{V_{ex}\,\mathrm{GF}}{2}\,\varepsilon. \tag{11}$$

This half-bridge doubles the quarter-bridge output (10) and, since both gauges share the same thermal environment, cancels common-mode drift – important given the resin substrate's poor thermal conductivity.

III. Results

The results follow the same sequence as the analysis. The three candidate geometries are first compared by the aerodynamic force extracted from CFD, which fixes the disc radius (Section III-A); the selected geometry is then carried into the FEA to obtain the root bending strain (Section III-B), and finally into the signal model, which determines whether the resulting bridge output is measurable over the target range (Section III-C).

A. CFD forces and disc-radius selection

The three candidate radii were compared by their net disc force, summarised in Table I and Fig. 2. At the top of the range (9.0 L/min) the baseline r_1 produces about 88 μN, the larger r_2 about 166 μN, and the smaller r_3 about 46 μN. The net force increases monotonically with the disc frontal area, so r_2 yields roughly 1.9 times the baseline force and about 3.6 times that of r_3. Because a larger force produces a proportionally larger bending strain and therefore a stronger output, r_2 gives the best response of the three while keeping $\beta \approx 0.71$ at the upper edge of the acceptable restriction range; r_3 keeps resistance lowest but its signal is too weak, and r_1 sits in between. The disc radius r_2 was therefore selected, and all subsequent analysis uses this geometry. Figure 3 shows the velocity field and the static-pressure distribution on the disc for the r_2 geometry at 9 L/min. The jet impinges on the upstream face and forms a central stagnation region of maximum pressure that decays towards the rim; integrating this distribution over the face gives the net axial load reported below.

TABLE I
NET DISC FORCE (μN) FOR THE THREE CANDIDATE RADII (OUTLET AT 0 PA GAUGE, NET FORCE = 1.1× IMPACT FACE)

Q (L/min)	r_1 = 3.5 mm	$r_2 = 4.2\,mm$	r_3 = 2.8 mm
0.2	0.30	**0.56**	0.14
0.4	0.76	**1.34**	0.34
0.6	1.23	**2.31**	0.59
0.8	1.84	**3.46**	0.90
1.0	2.54	**4.77**	1.26
1.5	4.70	**8.70**	2.36
2.0	7.30	**13.50**	3.73
2.5	10.30	**19.10**	5.34
3.0	13.80	**25.50**	7.19
3.5	17.70	**32.70**	9.28
4.0	22.00	**40.60**	11.60
4.5	26.70	**49.20**	14.10
5.0	31.90	**58.60**	16.80
5.5	37.40	**69.00**	19.80
6.0	43.30	**80.30**	22.90
6.5	49.70	**92.40**	26.20
7.0	56.50	**105.40**	29.80
7.5	63.80	**119.20**	33.60
8.0	71.50	**133.90**	37.50
8.5	79.80	**149.30**	41.70
9.0	88.40	**165.70**	46.10

For the selected geometry r_2 the net force grows from about 0.56 μN at 0.2 L/min to about 166 μN at 9.0 L/min, following the $F \propto Q^{1.7}$ law of (4), a gain consistent with the area dependence in (3). The impact-face force is recovered as the net value divided by the 1.1 wake factor of (7).

B. FEA strain

At the reference point ($F_{\mathrm{ref}} = 1.657 \times 10^{-4}$ N, i.e. 9.0 L/min), the normal strain along the flow axis at the root reaches $+5.659\times10^{-7}$ (about $+0.566$ $\mu\varepsilon$) on the tension face and -5.78×10^{-7} (about -0.578 $\mu\varepsilon$) on the compression face. The two values are nearly equal and opposite across the 1 mm thickness, which is the signature of pure bending and confirms that the chosen topology is correct.

The analytical estimate from (8) is about 0.72 $\mu\varepsilon$, and the FEA value is about 0.57 $\mu\varepsilon$; the two agree within about 21 % (ratio 0.79). The difference is attributed to the simplifying assumptions of a slender prismatic beam, whereas the real geometry includes the disc and the neck-to-plate transition, which add stiffness. The agreement is close enough to validate the model and to rule out unit errors. By (9), the strain at every other flow point is obtained by scaling the reference value with the force ratio; the resulting strain curve is listed in Table II and plotted in Fig. 4.

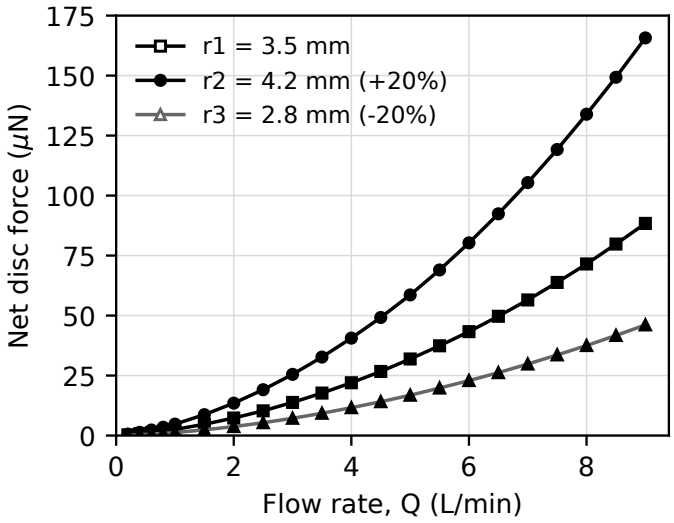

Fig. 2. Net disc force as a function of flow rate for the three evaluated disc radii. The generated force increases nonlinearly with flow rate due to the greater momentum transfer between the airflow and the sensing element. Increasing the disc radius increases the exposed area and enhances the flow-induced force, resulting in higher sensor sensitivity. The $r_2 = 4.2$ mm configuration ($+20\%$ relative to the baseline) produced the highest force response over the entire investigated flow range and was therefore selected as the final design due to its superior sensitivity. The baseline ($r_1 = 3.5$ mm) and reduced radius ($r_3 = 2.8$ mm) configurations exhibited lower force outputs due to their smaller interaction area with the flow.

TABLE II
FEA ROOT STRAIN AND FOIL HALF-BRIDGE OUTPUT FOR r_2 ($t = 1$ mm, GF $= 2$, $V_{ex} = 5$ V)

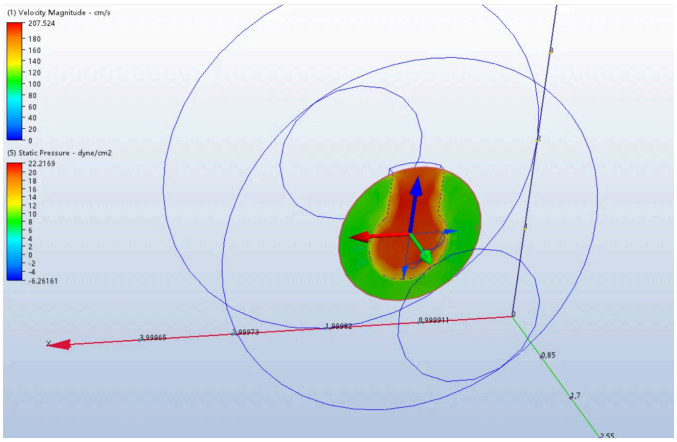

Fig. 3. CFD solution for the r_2 geometry at the upper bound of the neonatal range, 9 L/min. The blue streamlines trace the airflow around the impact disc and are coloured by velocity magnitude (top scale, cm/s), while the disc surface is coloured by static pressure (bottom scale, Pa; converted from the native Autodesk CFD output in dyne/cm^2, where 1 dyne/cm^2 $= 0.1$ Pa – the color-scale legend embedded in the image itself is still labelled in dyne/cm^2 and will be re-exported in Pa in a future revision). As the incoming jet strikes the upstream face, it decelerates and forms a central stagnation region where the static pressure reaches its maximum (≈ 2.2 Pa, red), decreasing towards the rim (≈ 0.6 Pa, green). Integrated over the face, this non-uniform pressure distribution yields the net axial load that deflects the cantilever and is transduced by the strain gauge.

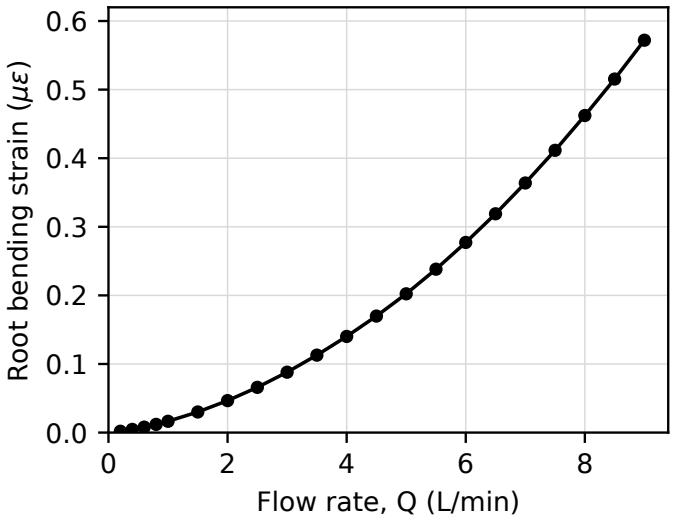

Fig. 4. FEA root bending strain versus flow rate for the r_2 geometry ($t = 1$ mm), obtained by linear scaling of the reference simulation. The predicted increase in root strain with flow rate highlights the greater mechanical sensitivity of r_2, which was selected due to its larger deformation response under the same flow conditions.

C. Signal viability

The transducer uses a metallic foil gauge (GF $= 2$), selected for its low cost, ready availability and robustness. With the half-bridge (11) at $V_{ex} = 5$ V the output reduces to $V_{out} = 5\,\varepsilon$ (μV per $\mu\varepsilon$); this linear strain-to-voltage transfer is shown in Fig. 5. Because the conversion is a constant factor, the foil output versus flow has the same $F \propto Q^{1.7}$ shape as the strain curve of Fig. 4, simply rescaled, and its values are listed in

the last column of Table II. The voltage-to-flow calibration is therefore non-linear.

The peak strain over the whole range is only about $0.57\ \mu\varepsilon$, comparable to the roughly $1\ \mu\varepsilon$ practical detection floor of metallic foil gauges. Even with the half-bridge, the foil output peaks at $2.86\ \mu\mathrm{V}$ and falls to about $10\ \mathrm{nV}$ at the lowest flow; below roughly $2.5\ \mathrm{L/min}$ it approaches the thermal noise floor of the bridge itself, a physical limit that no circuit architecture can overcome. The high-flow portion of the range is therefore the readable region for the present foil-based design, while the low-flow end is the limiting case, addressed in Section IV-D.

IV. Discussion

A. Design levers

With the gauge fixed as foil ($\mathrm{GF} = 2$), the available means to raise the signal are geometric and circuit-level. Geometrically, the neck thickness dominates: since $\varepsilon \propto 1/t^2$, reducing t from 1.0 to $0.5\ \mathrm{mm}$ would quadruple the strain (peak near $2.3\ \mu\varepsilon$), and $t = 0.3\ \mathrm{mm}$ would raise it to about $6.4\ \mu\varepsilon$, well above the foil detection floor. At circuit level, moving from the half-bridge to a full-bridge doubles the output again, and AC carrier excitation with synchronous demodulation, bandwidth limiting to the physiological band, oversampling and ratiometric measurement provide further, smaller gains. A complementary route is to replace the foil gauge with a semiconductor gauge, whose gauge factor is one to two orders of magnitude higher and would lift the output across the entire range, including the low-flow end that geometry alone cannot fully rescue; this was not adopted here on grounds of cost and availability. None of these options is applied to the present design, whose geometry is frozen and whose gauge is fixed as foil.

B. Conditioning chain

With the geometry frozen, the conditioning chain is fully analogue and discrete, and the microcontroller reads only the conditioned voltage at the end. The chain is shown in Fig. 6, and each stage is dictated by the nature of the signal: a sub-microvolt, near-DC voltage produced on a thermally poor resin substrate. The peak foil output is only about $2.86\ \mu\mathrm{V}$ (Fig. 5), so mapping it onto a useful ADC window of a few hundred millivolts requires a total gain near 10^5. The whole design follows from getting that gain without amplifying offset and drift along with the signal [15], [16].

Half-bridge. Two active gauges are placed on opposite faces of the neck, sensing equal and opposite strain. This doubles the sensitivity relative to a quarter-bridge (11) and, because both gauges share the same temperature, it cancels the common-mode thermal response to first order. A full bridge would double the output again but requires four matched gauges on a neck only a few millimetres wide, which the geometry does not allow; the half-bridge is the best compromise between sensitivity and the available area.

Instrumentation amplifier ($G_1 \approx 100$). The first stage must present a very high input impedance so as not to load the bridge, and a high common-mode rejection ratio so that the bridge common-mode voltage and supply noise are removed rather than amplified. A zero-drift (chopper-stabilized) instrumentation amplifier is used because the signal is essentially DC: at these frequencies the dominant error is the amplifier input offset and its drift, not broadband noise, and chopper devices reduce that offset to the nanovolt range [15], [16]. The first-stage gain is held to about 100 so that any residual bridge offset is not driven into saturation before it can be removed.

Offset cancellation. Even a $0.1\,\%$ mismatch between the two gauges produces a bridge offset of the order of millivolts, which at the full gain of 10^5 would saturate the chain long before the microvolt signal appeared. The offset is therefore nulled before the high-gain stage, either with a multi-turn trim potentiometer at the amplifier reference pin or with a DC servo that integrates the output and feeds the slow average back to the reference, high-pass filtering the chain so that only the dynamic (breathing) component is amplified. This is the single most critical requirement of the front-end.

Second-order low-pass filter ($f_c \approx 40$ Hz). The neonatal flow signal and its harmonics lie below a few tens of hertz, so the bandwidth is limited to about 40 Hz. Because broadband noise grows with the square root of bandwidth, restricting the band improves the signal-to-noise ratio, and the filter also serves as the anti-aliasing stage ahead of the ADC. A Sallen-Key topology is chosen because it realises a second-order response with a single op-amp and few passive components and has low sensitivity to component tolerances [17]; an equal-component unity-gain Butterworth alignment gives a maximally flat passband. A corner at 40 Hz passes the signal while attenuating mains interference at $50/60$ Hz and above.

Second gain and level shift (G_2). With the offset removed and the band limited, the remaining gain (about 10^3) is applied in a second stage, again with a zero-drift op-amp, and split from the first stage to keep each amplifier within its gain-bandwidth limit and stable. A level-shift network then moves the bipolar signal, which swings about zero on the $\pm$ rails, into the unipolar 0 to 3.3 V window of the ESP32 input.

Supply and grounding. The front-end runs on symmetric ($\pm$) rails so the bridge signal can swing about zero, while the ESP32 uses its own 3.3 V supply; the two share a single star ground to avoid ground loops, which at the microvolt level would otherwise inject more noise than the signal itself. Finally, because the force follows $F \propto Q^{1.7}$, the voltage-to-flow mapping is non-linear and is implemented as a calibration in firmware after digitisation.

C. Dead space and pressure drop

a) Dead space (disc and neck only): The physical volume displaced by the sensing element within the airway can be estimated from its two components inside the flow path: the impact disc and the cantilever neck. For the selected geometry ($r_2 = 4.2$ mm, disc thickness 1 mm), the disc volume is

$$V_{\mathrm{disc}} = \pi r_2^2 t_{\mathrm{disc}} \approx \pi (4.2\ \mathrm{mm})^2 (1\ \mathrm{mm}) \approx 55.4\ \mathrm{mm}^3. \quad (12)$$

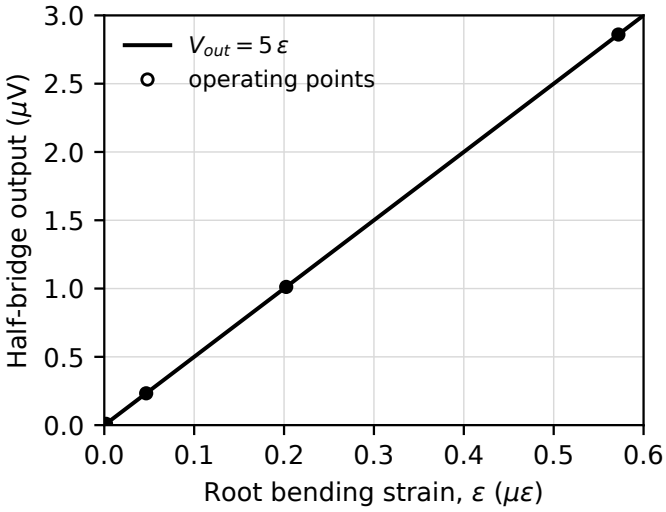

Fig. 5. Strain-to-voltage transfer characteristic of the foil half-bridge used for flow-induced deformation measurement. The bridge output voltage (μV) increases linearly with strain, providing the conversion factor between mechanical deformation and electrical signal.

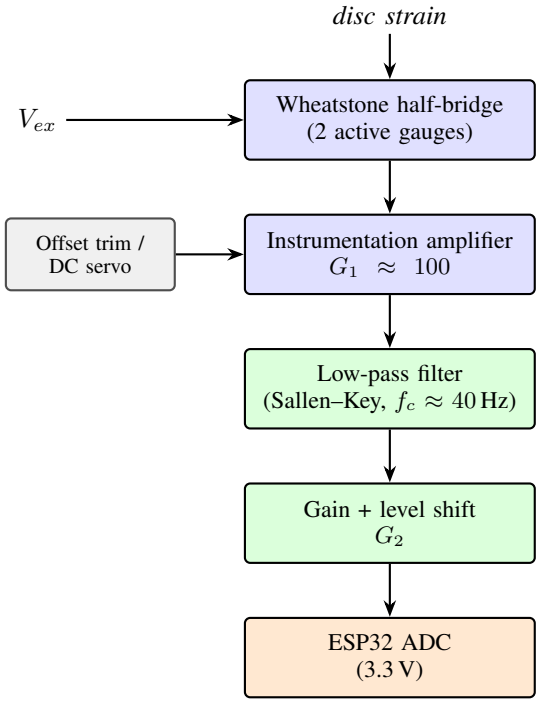

Fig. 6. Conditioning chain.

The cantilever neck, of width $w = 5.5$ mm, thickness $t = 1$ mm, and free length $\ell - r_2 \approx 7.56 - 4.2 = 3.36$ mm (from the disc rim to the root), adds

$$V_{\text{neck}} = w\,t\,(\ell - r_2) \approx (5.5)(1)(3.36)\ \text{mm}^3 \approx 18.5\ \text{mm}^3. \tag{13}$$

Together, $V_{\text{disc}} + V_{\text{neck}} \approx 73.9\ \text{mm}^3 \approx 0.074$ mL, well within the ≤ 1 mL dead-space target set for this sensor. This estimate, however, covers only the disc and neck; it excludes the volume of the outer mounting plate ($r = 20$ mm) and any housing structure within the airway, which were not analyzed for flow displacement in the present CFD study (only the force on the impact disc was extracted). The dead space of the complete assembly therefore remains to be confirmed once the full housing geometry is included.

b) Pressure drop: The pressure drop across the sensor was extracted directly from the CFD solution at one operating point: the r_3 geometry (the smallest of the three candidate radii, $\beta \approx 0.57$) at 3.0 L/min, using the same PEEP-outlet run reported in Section II-C for the base-pressure verification. The area-weighted average pressure at the inlet was 490.705 Pa, against an outlet condition fixed at 50 $\text{mmH}_2\text{O} \approx 490.33$ Pa (using 1 $\text{mmH}_2\text{O} \approx 9.80665$ Pa). The resulting pressure drop is

$$\Delta P = P_{\text{inlet}} - P_{\text{outlet}} \approx 490.705 - 490.33 \approx 0.37\ \text{Pa} \tag{14}$$

at this flow and geometry. This single point is far too limited to characterize the pressure-drop–flow relationship over the full 0.2–9.0 L/min range or to compare candidate radii, since ΔP is expected to scale with flow and with disc blockage β in the same manner as the axial force (Section II-C). Extracting the inlet average pressure at additional operating points, and ideally for the selected r_2 geometry used throughout the rest of this work, is needed to report a complete pressure-drop curve and to assess whether the added flow resistance of the disc is clinically acceptable for the intended application.

D. Limitations

1) **Low-flow sensitivity.** With the foil gauge (GF = 2) and the present 1 mm cantilever, peak strain over the whole range is only 0.57 $\mu\varepsilon$, near the practical detection floor of foil technology; below roughly 2.5 L/min the output approaches the bridge's own thermal noise floor, a physical limit no amplification recovers. Because the smallest patients are ventilated precisely at these low flows, this is the principal barrier to clinical usefulness.
2) **No physical validation.** The study is entirely computational; no prototype has been built or calibrated against a reference flowmeter, so the predicted forces, strains, and noise floor remain unconfirmed experimentally. Masked-stereolithography print tolerances – neck thickness, disc flatness, gauge placement and bonding – are not captured by the model.
3) **One-way fluid-structure coupling.** The aerodynamic force is transferred manually from CFD to FEA with no feedback of the deformed geometry on the flow;

justified by the nanometric, linear-elastic deflections, but the $10\,\%$ wake correction (Eq. (7)) is a fixed estimate rather than resolved independently at each flow, and a single reference FEA point anchors the linear force–strain scaling of Eq. (9) for the entire range.

4) **Convergence.** Autodesk CFD's automatic criterion halted runs before the configured 300-iteration budget (e.g. iteration 110 at $0.4\ \mathrm{L/min}$) while the y-velocity residual (-1.81) remained an order of magnitude above the other channels; whether this component was truly converged is unconfirmed.
5) **Mesh.** Only Autodesk CFD's automatic (autosize) meshing was used, at a single density; no mesh-independence study was performed, so under-resolution of the disc's stagnation region cannot be ruled out as a contributor to the forces in Table I.
6) **Flow directionality.** All nineteen operating points are unidirectional (inspiratory). The half-bridge can in principle sense a sign reversal for expiratory flow, but the aerodynamic force model and wake correction were neither derived nor verified for reversed flow, where the front and rear disc faces exchange roles.
7) **Steady state only.** The nineteen operating points are all steady, but neonatal ventilation is cyclic; the transient response of the disc–cantilever system and the $40\ \mathrm{Hz}$ conditioning bandwidth are not validated dynamically. The added flow resistance and dead space of the disc are only partially quantified (Section IV-C: a single pressure-drop point and a disc-and-neck-only dead-space estimate).

V. Conclusions

A sequential CFD-FEA-signal model of an impact-disc transducer on a thin cantilever, read by a strain gauge, identifies the feasibility constraints of this design as a candidate for an open-source, low-cost neonatal flow sensor. Over the clinical range of 0.2 to 9.0 L/min, the aerodynamic force reaches about 166 μN and produces a peak root strain of only about 0.57 $\mu\varepsilon$ in pure bending. Demonstrating that the base pressure cancels in the net force enabled clean, noise-free simulations, and the linear-elastic response allowed the whole range to be derived from a single reference run. A metallic foil gauge was adopted for cost, availability and robustness; with the present geometry, its predicted sensitivity at low flow is the principal limitation identified by the model, falling below the practical detection floor of foil technology precisely where the smallest patients are ventilated. Addressing this shortfall will require thinning the cantilever neck, moving to a full-bridge topology, or adopting a higher-gauge-factor transducer. As the analysis is entirely computational, the natural next step is a physical prototype, printed in the selected geometry and calibrated against a reference flowmeter over the target range, which would also expose the transient response and the thermal drift of the resin substrate to direct measurement. These results establish a computational foundation and the geometric and electronic constraints for that prototype and its experimental validation, rather than evidence that the sensor concept itself is already viable.

***Abstract*—Wearable inertial monitoring for amateur sport is largely restricted to commercial devices whose cost places them out of reach in lower-income settings. Cheap hardware closes part of that gap, but without a technician to position the sensor the device cannot assume a known mounting orientation. Functional sensor-to-segment calibration solves this in the biomechanics literature, at the price of supervised protocols with dedicated postures and offline processing. This work implements such a calibration entirely onboard an ankle-worn wearable built from retail components for about 21 US dollars, with no operator and no movement beyond walking. The vertical axis is recovered from the resting gravity vector and the mediolateral axis from the gyroscope component of highest variance during walking, when sagittal plane rotation dominates; the anteroposterior axis follows by the right-hand rule. Across sixteen mounting configurations, eight rotation angles crossed with two device faces, the assignment matched the mounting geometry and an offline recomputation in all sixteen, and the confidence ratio governing acceptance varied with geometry as predicted, from 1.26 to 21.83 when recomputed over the full recording. A stride detector on the identified axis reproduced a manual count exactly over six gait recordings spanning slow walking to running, 113 strides; under leave-one-out selection the held-out total deviated by at most three strides, 2.7 percent, with a worst case of 12.5 percent on a single recording. This is a single-participant proof of concept.**

I. Introduction

Regular physical activity lowers the risk of cardiovascular, metabolic and musculoskeletal disease, and is recommended by national and international public health bodies [1]. In Brazil, adherence is both low and unequally distributed. The 2019 National Health Survey found the odds of engaging in leisure-time physical activity roughly three times higher among adults in the highest per capita income bracket than among those in the lowest, with lower participation also among Black respondents and among women [2]. Activities that depend on equipment or on gym membership concentrate in the higher income brackets. Soccer is the exception, the only activity in the 2013 edition of the same survey more prevalent among lower income and among Black and mixed-race respondents, and the leading one among adults aged 18 to 29; outdoor walking, the most prevalent activity in the country, and street running likewise demand little or no infrastructure [3].

These activities are accessible as practice but not as measurement. Tracking cadence, intensity and progression over time requires instrumentation whose cost falls precisely on the population that most relies on low-barrier activities. The gap addressed here is not access to sport, but access to quantitative information about one's own practice. Commercial reference devices illustrate the distance: at prices consulted in July 2026, foot and ankle mounted inertial trackers were listed at 199 and 249 US dollars [4], [5], and entry-level team tracking systems at 320 US dollars [6].

Recent work shows that much of the accuracy penalty of inexpensive hardware can be recovered through signal processing and calibration rather than costlier components. Gascón *et al.* [7] report 97.8 percent accuracy in combined pass and kick detection from an insole-mounted microelectromechanical systems (MEMS) inertial measurement unit sampled at 50 Hz, using an adaptive threshold pipeline. Bernhart *et al.* [8] detect stride events during running from a chest-worn sensor. Chavarría-Fernández *et al.* [9] integrate a microcontroller-class inertial unit for real-time external load monitoring, framed explicitly in a Latin American resource context.

A requirement common to this body of work remains largely implicit: the sensor is assumed to sit in a known orientation relative to the body segment. An adjustable strap fastened by the user offers no guarantee that the sensor axes align with the anatomical axes of the limb, and a device that silently depends on correct placement will fail in exactly the unsupervised, low-resource setting that motivated building it cheaply in the first place.

The biomechanics literature addresses this through functional, or sensor-to-segment, calibration, in which anatomical axes are recovered from the sensor signals themselves rather than assumed from placement [10], [11]. These procedures are well established and accurate. They are also designed for supervised use: they prescribe dedicated calibration postures,

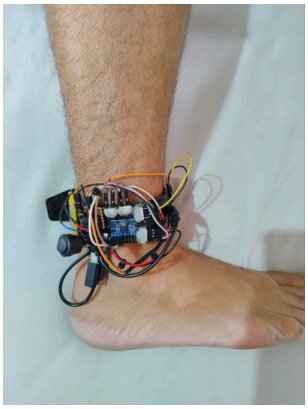

Fig. 1. Prototype strapped to the ankle over the lateral malleolus.

are executed under the guidance of an operator, and are computed offline on a workstation. Each of those assumptions is unavailable here, so the gap this paper addresses is one of implementation rather than of method: what is missing is not a way to recover anatomical axes, but a way to recover them on the device itself, without an operator, without dedicated postures, and within the computational budget of a microcontroller costing a few dollars.

The contributions are a functional ankle-worn prototype assembled from Brazilian retail components at a component cost of 105 Brazilian reais, about 21 US dollars; a fully onboard implementation of gait-based functional calibration, which assigns the vertical, mediolateral and anteroposterior axes to the sensor axes once at the start of each session, with no operator, no calibration posture beyond standing still and no movement beyond walking; an evaluation of that procedure across sixteen mounting configurations, obtained by combining eight strap rotation angles with two device faces, eight of them inverted; and a stride detector built on the identified mediolateral axis, evaluated against a manual reference count over six gait recordings spanning slow walking to running.

II. System Design

The system has two parts: a wearable device that acquires and stores data autonomously during the activity, and desktop tools that retrieve and analyze those data afterwards. This section describes the device.

A. Hardware

The microcontroller is an ESP32-C3 Super Mini, selected for its low cost, compact footprint, internal flash large enough for the recorded sessions, and a USB interface used for both programming and data retrieval. Its radios are not used. The inertial sensor is an MPU6050 module, a MEMS device combining a three-axis accelerometer and a three-axis gyroscope with an inter-integrated circuit (I2C) interface [12], chosen for its low unit cost and wide availability in Brazilian retail. It is configured for full-scale ranges of 16 g and 2000 degrees per second and sampled at 50 Hz. A buzzer and a push button on general-purpose input/output (GPIO) pins 3 and 10 provide

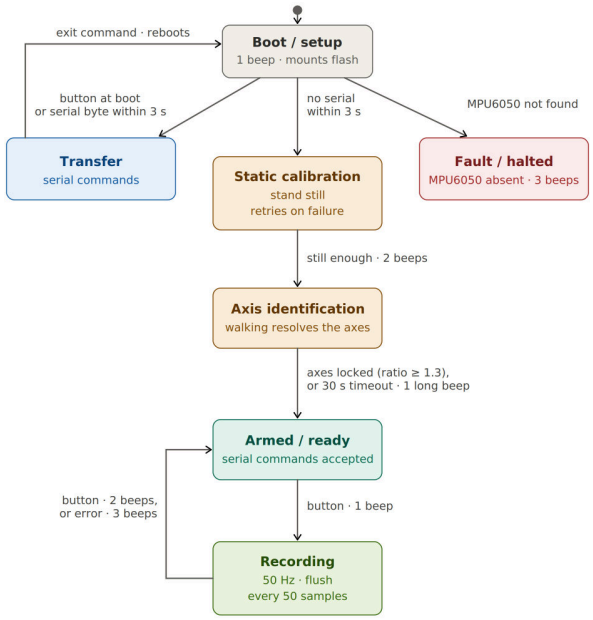

Fig. 2. Firmware state machine. Static calibration and axis identification are mandatory before recording is armed, and the buzzer signals each transition.

the entire user interface, and Fig. 2 shows the firmware state machine.

The assembly is mounted on a repurposed section of leather belt, adjustable by its buckle, and sits over the lateral malleolus, as Fig. 1 shows, the same region instrumented in external load work with runners [9]. Power comes from a single 3.7 V, 250 mAh lithium polymer cell, managed by a combined charger and boost converter module based on the 134N3P integrated circuit. Estimated from component datasheets, the microcontroller and sensor together draw about 48 mA during acquisition [12], [13], which places continuous recording autonomy on the order of five hours. The estimate excludes losses in the boost converter, so it is an upper bound on autonomy; direct measurement remains future work.

B. Recording Architecture

The sensor delivers acceleration and angular velocity to the microcontroller at 50 Hz. At startup the microcontroller runs the static calibration and the orientation identification of Section III, and from then on converts every sample to the body frame with gravity removed. Processed samples are written in binary to internal flash through a LittleFS file system, in sessions delimited with the push button. Each file begins with a fixed 64 byte header carrying the sampling rate, a timestamp, the inferred axis assignment and the resting gravity vector, followed by sample records of 32 bytes each, so a session grows by about 96 kB per minute. The metadata in the header makes each file self-contained, so the raw signal can be reconstructed during analysis without external logs.

The 50 Hz figure is the target of a fixed-rate scheduler, not the rate achieved. Writes to flash occasionally block the loop for longer than one sampling period, and the firmware then re-anchors the schedule rather than emitting the delayed samples

back to back. Measured over the recordings reported here, the achieved rate ranged from 47.8 to 49.5 Hz, with isolated gaps reaching 160 ms during running; each sample carries its own timestamp, so those gaps are visible to the analysis.

The acquisition path runs without external communication. Retrieval happens only after the session ends: the device is connected to a computer over the serial interface, and a script transfers the files and decodes them to comma-separated values (CSV).

C. Cost

At Brazilian retail prices consulted in June 2026, converted at the July 2026 rate of 5.07 reais per dollar, the same month as the commercial prices of Section I, the components total 105.00 reais, about 20.70 US dollars: 35.00 for the ESP32-C3 Super Mini, 25.00 for the lithium polymer cell, 20.00 for the MPU6050 module, 13.00 for buzzer, switch, button and wiring, and 12.00 for the charger and boost module. The strap is repurposed from a belt and is not counted.

The total places the prototype an order of magnitude below the commercial devices of Section I. It covers single-unit retail components only, so quantity sourcing would lower it while an industrialized enclosure and certification would raise it.

III. Automatic Orientation Identification

A strap fastened by the user gives no guarantee that the axes of the sensor align with the anatomical axes of the limb. Without that correspondence the measured components carry no mechanical meaning: there is no way to say which channel describes vertical motion, which rotation in the sagittal plane, and which motion along the direction of travel. The effect of sensor placement and displacement on wearable activity recognition is well documented [14], [15], and three families of response exist.

The first constrains placement, which most sport wearable work implicitly assumes. The second removes the dependence on orientation by transforming the raw signals into quantities invariant to it, discarding the orientation information itself [16], [17]. The third recovers the orientation, either continuously through attitude estimation or once through a functional sensor-to-segment calibration [10], [11].

The procedure described here belongs to the third family and follows its established structure. Carcreff *et al.* [11] recover the vertical axis from gravity in a standing posture, the mediolateral axis from the principal axis of angular velocity during gait, and the sign of that axis from a further seated posture; the first two steps are the ones adopted here. What differs is where the procedure runs. The published methods execute offline, from data recorded under a supervised protocol, whereas the implementation below runs in firmware on the microcontroller, unattended, and asks the wearer for nothing beyond standing still and then walking.

A. Static Calibration

The procedure requires the device to be at rest and averages each axis over one hundred consecutive samples, about two seconds. For the gyroscope, whose expected reading at rest is zero, the per-axis mean is the bias to subtract from subsequent samples. For the accelerometer, the mean is the gravity vector in the sensor frame, used both for gravity removal and for the axis assignment that follows. The same window corrects a scale error: the measured gravity magnitude deviated from the expected value by about 3 percent on the sensor used, so the firmware derives a scale factor forcing the resting magnitude to 9.807 m/s^2, compensating the tolerance of an inexpensive part in software.

Two quality checks accompany the calibration. The gyroscope standard deviation over the window must remain below 0.05 rad/s, about 2.9 degrees per second; above that the wearer moved and the bias estimate is untrustworthy, so the firmware silently discards the window and collects another until a still one is obtained, the beeps that end calibration being emitted only then. The acceleration magnitude is compared against the expected gravity with a tolerance of 0.5 m/s^2; a deviation beyond it points to a scale or mounting problem and is reported, but does not block the sequence, since the scale factor normalizes the magnitude in any case. Parameters are recomputed at every power-up and not persisted, which keeps the calibration representative of the conditions of use.

B. Axis Assignment

The vertical axis follows directly from the static calibration. Among the three sensor axes, the one carrying the largest component of the resting gravity vector is taken as vertical, and the sign of that component fixes its positive direction. This resolves one axis but leaves the other two ambiguous, since a static reading cannot distinguish rotation about the vertical.

Resolving the remaining two exploits a property of human gait: during walking, rotation of the lower limb concentrates in the sagittal plane, about the mediolateral axis of the ankle. That axis is therefore the one of largest angular velocity variance during walking, while the others remain comparatively quiet. This is the principle underlying the gait-based step of functional calibration [10], [11]; the contribution here is in reducing it to a form that a microcontroller can execute online during the session itself. After the static calibration the device enters a phase in which the user walks or swings the leg for a few seconds. During that phase the firmware accumulates angular velocity statistics only over samples with effective motion, identified by an angular velocity magnitude above a threshold of 30 degrees per second. Of the two candidate axes orthogonal to the known vertical, the one of larger variance is identified as mediolateral. The third axis, anteroposterior, follows by the right-hand rule, which also fixes a consistent triad. Continuous attitude estimation would also resolve the axes [18], but a stride detector needs the assignment, not the instantaneous attitude, and resolving it once costs one pair of accumulators per axis and a single comparison. Counted from the firmware sources, the identification holds 62 bytes of persistent state and the static calibration 44 more, so the procedure occupies 106 bytes of RAM, a constant number of operations per sample, and no filter state that could drift. For

scale, the complete firmware image occupies 330 kB of the 1.25 MB application partition and reserves 14.5 kB of the 320 kB of RAM at link time, so the procedure accounts for under 1 percent of an allocation that the linker reports for static memory and not for the heap and stack.

Two safeguards constrain the decision. The first is a confidence criterion: the mediolateral assignment is accepted only when the ratio between the largest and the second largest variance reaches 1.3, below which the difference is too small to trust and the firmware keeps accumulating samples. The second is a timeout of thirty seconds, counted from the first sample of the identification phase, which bounds that wait and forces an outcome. Section III-C describes the three outcomes and what each one writes to the session file.

The sequence is conveyed to the wearer by the buzzer alone, without a screen or a paired application: one beep at power-up to stand still, two beeps when calibration succeeds and walking should begin, one long beep when the assignment is locked and recording is armed.

C. Fallback Behavior

The identification phase ends in one of three ways, and the firmware records which one in the header of the session file. It locks on merit once at least one hundred samples above the motion threshold have accumulated, about two seconds of walking, and the variance ratio has reached 1.3; the session carries no flag. It locks on timeout with partial evidence when thirty seconds elapse with at least fifty such samples: the mediolateral axis is still assigned by largest variance, and the session is flagged as having uncertain orientation when the ratio at that moment is below 1.3. A ratio above 1.3 leaves the session unflagged, since the criterion the flag records is the confidence in the assignment and not the route by which the phase ended. It locks on timeout with no usable evidence when the wearer does not walk: the vertical axis is kept, since gravity alone determines it, the remaining two fall back to the sensor axes orthogonal to it taken in cyclic order, and the session is flagged. The flag occupies one bit of the 64 byte header, so the analysis can hold flagged sessions apart, and no file can lack an assignment, since the button that starts a recording stays inert until the phase ends.

Slipping of the strap is a separate case that none of the three covers. Calibration and identification run once, at power-up, and the firmware neither re-estimates the body frame afterwards nor monitors the device for movement on the leg, so a device that slips after the lock keeps reporting the frame identified at the start, with nothing in the data marking it stale.

D. Sign Ambiguity

Variance is signless, so selecting the mediolateral axis by largest variance determines which sensor axis lies along that direction but not which way it points. Rotating the device by 180 degrees on the strap makes the same forward leg swing produce angular velocity of opposite sign on the same axis, and nothing in the accumulated statistics distinguishes the two cases. The body frame is therefore determined only up to a sign on the mediolateral and anteroposterior axes. The consequences are bounded here, since every quantity used in this work is invariant to that sign: stride detection operates on the magnitude of the sagittal gyroscope component. The ambiguity would matter for a directional quantity, such as telling a forward from a backward kick.

A published solution exists. Carcreff *et al.* [11] resolve the sign with a seated posture with the leg extended, in which the direction of the measured acceleration disambiguates the axis. That step was deliberately not adopted, because it reintroduces what the implementation sets out to avoid: a prescribed posture, and therefore an operator or a screen to instruct it. Whether the sign can instead be recovered from the direction of travel during the identification walk is left as future work.

IV. Experimental Protocol

All data reported in this paper were collected from a single participant, an adult male, the first author of this work. That scope conditions how every result below should be read: the evaluation is a controlled study of the procedure across mounting configurations, not a study of its performance across bodies.

All recordings were made at 50 Hz with the device on the right ankle over the lateral malleolus. Static calibration was performed standing, in a posture close to that of the activity that followed, which keeps the resting gravity reference representative of the recording conditions.

A. Mounting Experiment

The mounting configuration was treated as a controlled variable with sixteen levels: eight rotation angles of the device on the strap crossed with the two faces on which it can be fastened.

Rotation is about the long axis of the shank: the strap remains closed and the device travels around the ankle. The reference of 0 degrees is the buckle positioned at the front of the leg, which places the device at the back of the leg. Angles increase in steps of 45 degrees in a single direction over a full turn: 0, 45, 90, 135, 180, 225, 270 and 315 degrees.

The two faces differ by turning the device over on the strap, which reverses the sign of the sensor axis that reads gravity. Eight of the sixteen configurations are inverted in this sense. The angular reference was set again after the device was turned over, so 0 degrees in the inverted set is not the same physical position as in the upright set, and angles are comparable only within a set. No attempt was made to align the sensor axes with the anatomical axes; the strap was simply fastened at the intended angle.

Each configuration was exercised over an identical route: a few steps forward, a 180-degree turn, a few steps back, a second 180-degree turn in the opposite direction, returning to the starting position and heading. The route provides the walking motion the identification requires, and the two turns add rotation about the vertical axis, which exercises the assignment under motion that is not gait. Two quantities were recorded per configuration: the axis the firmware assigned to each

anatomical direction, and the magnitude of the resting gravity vector. The number of steps was neither fixed nor counted, since these recordings exercise the orientation procedure rather than the detector.

B. Gait Recordings

A second set of six recordings, made in the canonical mounting, covers the range of locomotion in scope: one slow walk, two regular walks of different duration, one fast walk, one jog and one run. Together they span estimated stride periods from about 1.9 s at the slowest to about 0.7 s at the fastest, and total 113 strides. The labels record the pace the participant intended, not a measured one, and the fast walk turned out close in period to the shorter of the regular walks.

The reference for each recording is a manual count performed during execution, one stride per forward swing of the instrumented leg, so each swing corresponds to one detection. Total bilateral cadence follows by doubling, under an assumption of symmetry between legs. Each recording is delimited by a button press at its start and end, and the movement of reaching for the button is treated as part of the signal rather than trimmed away, since a detector intended for unsupervised use has to tolerate it.

C. Kick Recordings

Two further recordings, of ten and five maximum-force kicks, were made with the same device and mounting to probe the upper end of the acceleration range. They carry no stride reference and are used only in the discussion of sensor saturation in Section VI-B. Impacts were located as peaks of the acceleration magnitude and checked axis by axis against the full-scale limit on the raw signal, reconstructed by adding the resting gravity vector back to the recorded dynamic acceleration.

V. Results

A. Orientation Identification Across Mountings

Table I reports the assignment and the confidence ratio for each configuration.

The vertical axis was resolved as expected in all sixteen configurations. In every case the firmware assigned it to the sensor x-axis, with the sign tracking the face on which the device was mounted: positive when upright and negative when inverted.

The mediolateral assignment tracked the rotation of the device, as geometry requires: rotating it about the long axis of the leg exchanges the roles of the two sensor axes orthogonal to the vertical, so the axis nearest the mediolateral direction changes every 90 degrees. With no external motion reference, the assignment is checked against two expectations. It follows that alternation, in pairs within each set, and a post hoc recomputation of the variance on the two candidate axes, over the samples above the motion threshold, selected the same axis in all sixteen configurations. The results below report agreement with these two checks, not an angle measured against an anatomical reference.

TABLE I
Axis Assignment and Confidence Ratio Across the Sixteen Mountings

	Upright ($V = +X$)		Inverted ($V = -X$)	
Angle (deg)	Mediolat. axis	Confidence ratio	Mediolat. axis	Confidence ratio
0	$+Y$	6.14	$+Y$	3.38
45	$+Y$	1.30	$+Z$	21.83
90	$+Z$	18.94	$+Z$	1.52
135	$+Z$	**1.26**	$+Y$	8.06
180	$+Y$	7.39	$+Y$	1.50
225	$+Y$	1.54	$+Z$	10.84
270	$+Z$	13.32	$+Z$	2.03
315	$+Z$	2.12	$+Y$	9.24

Signs follow the right-hand convention and carry no anatomical meaning (Section III-D).

The confidence ratio is the more informative column, and its variation is itself a result. It ranged from 1.26 to 21.83, following the geometry of the mounting: when a sensor axis nearly coincides with the mediolateral direction the variance concentrates on it and the ratio is large, and when the mediolateral direction falls between two sensor axes the variance splits and the ratio approaches unity. The ratio therefore measures how well posed the assignment is, rather than acting as an arbitrary constant, which supports its use as an acceptance criterion.

Two observations qualify this. First, the two sets of eight configurations are offset from each other by about 45 degrees. This follows from the angular reference having been set again after the device was turned over (Section IV-A): the upright set shows high ratios at 0, 90, 180 and 270 degrees, the inverted set at 45, 135, 225 and 315 degrees. The two sets therefore do not sample the same physical angles, and the angle column is to be read as relative within each set. Second, one configuration fell below the acceptance threshold of 1.3, shown in bold in Table I, and a second sits exactly at it, yet neither was flagged as uncertain by the firmware. This follows the firmware logic rather than contradicting it. The two ratios are not the same quantity: Table I reports the ratio over the full recording, whereas the firmware evaluates it over the shorter identification window and, before the timeout, does not lock until that window ratio reaches 1.3. Both sessions locked well inside the timeout, as the timestamps below show, so the window ratio had reached the threshold, which the full recording, with its two turns and the handling at the edges, need not reproduce. The window value is not logged, so this account rests on the firmware logic; recording it at the instant of the lock would settle the point directly and is left as future work.

The session timestamps also constrain how each assignment was reached. They start with the identification phase, the instant from which the timeout is counted, and the button stays inert until the assignment locks, so the first recorded sample bounds the locking instant from above. In fifteen of the sixteen sessions it falls between 10.9 and 18.9 s, inside the 30 s bound, so those locked on merit, the outcome that leaves a session unflagged (Section III-C). The remaining one, at 45 degrees inverted, begins at 40.0 s, so a lock on merit followed by a

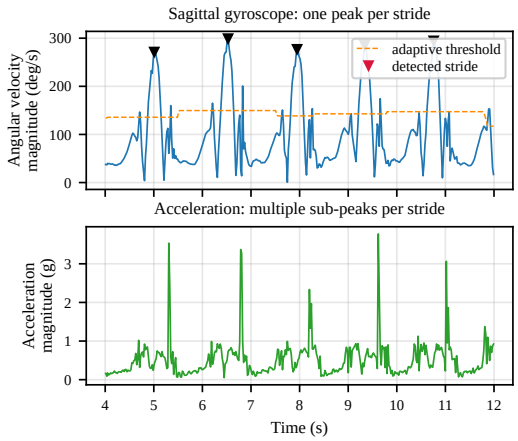

Fig. 3. Candidate input signals over the same walking segment. Triangles mark detected strides, the dashed line the adaptive threshold.

long wait before the button press cannot be told from a lock on timeout. Both routes assign the axis from the variance, and the recorded triad, $+Z$ and $+Y$ rather than the cyclic default $+Y$ and $-Z$, excludes a lock with no usable evidence.

The magnitude of the resting gravity vector was 9.807 m/s^2 in all sixteen configurations, to within 0.001. This confirms that the calibration completed in every mounting, but is not independent evidence of correct decoding, since the calibration derives a scale factor that forces precisely this magnitude.

B. Choice of Input Signal

Two candidate input signals were compared on the same recorded data. The first is the magnitude of the acceleration vector, the immediate candidate because it summarizes effort in a single scalar independent of sensor orientation. The second is the component of angular velocity in the sagittal plane, associated with rotation of the shank during the swing of the leg. Fig. 3 contrasts the two over the same walking segment.

The acceleration magnitude shows several sub-peaks per stride, corresponding to the successive phases of foot support: heel strike, midstance and push-off. These have no one-to-one correspondence with strides and lead to overcounting. The sagittal gyroscope component shows a single well-defined peak per stride, the forward swing of the instrumented leg, which permits direct counting. The choice is an empirical finding, not an inherited convention: no fixed threshold on acceleration magnitude resolved the sub-peaks in these recordings, which are comparable in amplitude to the peak itself and are genuine features of the signal rather than noise.

C. Stride Detection

The detector operates on the magnitude of the sagittal gyroscope component and combines three elements. The first is an adaptive threshold: a sample qualifies as a stride peak candidate only if it exceeds a fraction of the largest amplitude observed over a two second window centered on that sample, set to 0.5, which scales the threshold to the local intensity of the movement, following the adaptive threshold formulation of [7]. The second is a global amplitude floor: beyond the local threshold, a sample must also exceed a fraction of the largest peak of the entire recording, set to 0.3. This discards low-amplitude spurious peaks such as those generated by handling the device at the start and end of a session, which is why the edges of each recording could be left untrimmed. The third is an adaptive refractory period: after each detection, a minimum interval is imposed before the next, set to 0.6 of the stride period. That period is estimated automatically by autocorrelation of each recording [19], with the search restricted to lags between 0.30 and 3 s, which brackets the cadences in scope and keeps the zero-lag peak out of the estimate. When two candidates fall closer than the refractory interval, the smaller one is discarded.

Two of these elements look ahead in the signal: the local threshold reads a window centered on the sample, and the period is estimated over the whole recording. The detector as evaluated here is therefore not causal, consistent with running it after transfer but not during the activity. Moving it into the firmware, listed among the directions in Section VII, requires backward-looking equivalents of both, a trailing window and a period estimated from the intervals already detected, which would alter the operating point and has to be evaluated on its own terms.

The adaptive refractory period is what allows a single parameter set to operate from slow walking to running, specializing for the sagittal gyroscope signal at the ankle an idea established for inertial stride detection during running [8].

TABLE II
STRIDE COUNTS BY RECORDING, WITH PARAMETERS TUNED ON ALL SIX RECORDINGS AND UNDER LEAVE-ONE-OUT SELECTION

Recording	Period (s)	Manual count	Tuned count	Held-out count	Worst error strides (%)
Slow walk	1.90	17	17	17	0
Regular walk	1.42	16	16	16	0
Regular walk	1.16	23	23	23 to 24	1 (4.3)
Fast walk	1.14	16	16	16	0
Jog	0.76	24	24	21 to 24	3 (12.5)
Run	0.66	17	17	17 to 19	2 (11.8)
Total		113	113	110 to 116	3 (2.7)

Worst error is the largest deviation of the held-out count from the manual count; ranges follow from ties at zero training error.

Table II reports the detected and manual counts for each gait recording. With a single parameter set, the detector reproduces the manual count exactly in all six recordings. The range of cadence covered is wide: the estimated stride period in the table varies from 1.90 s in the slow walk to 0.66 s in the run, and the same configuration remains valid across that entire range.

The three parameters were selected over a grid of 36 combinations, and the values above are its optimum on the six recordings; the same grid is the one the leave-one-out selection of Section V-D searches. A wider sweep over 210 combinations locates this operating point on a plateau rather than a spike: 8 of the 210 reproduce the total exactly, 46 miss at most one stride of the total and 81 miss at most three.

The global amplitude floor was the element that brought the count to exact agreement, by suppressing the peaks produced by handling the device at the edges of each session.

This result measures the consistency of the method over the collected set, since the parameters were calibrated on the same recordings used to evaluate them. Section V-D separates tuning from evaluation.

D. Held-Out Evaluation

The counts of Table II come from parameters chosen on the same six recordings they were scored against. To separate tuning from evaluation, the selection was repeated in a leave-one-out scheme: for each recording, the three parameters were chosen on the remaining five over the same grid of 36 combinations of Section V-C, and applied to the recording held out.

Training error reaches zero in every fold, and at more than one grid point: between four and ten of the 36 combinations tie at zero on the five training recordings. Four of the 36 reproduce the manual count exactly in every one of the six recordings, a condition stricter than matching the total, and are among the tied optima of every fold, so a fold resolving the tie inside that set is exact on the held-out recording. The remaining tied combinations, present in three of the six folds, are what produce error.

Table II reports the bounds this leaves and the worst-case error per recording, in strides and in percent. The largest is three strides on the jog, 12.5 percent of its reference count. Summed across folds, the held-out total ranges from 110 to 116 against a reference of 113, an absolute error of at most three strides on the total and a percentage error of at most 2.7 percent.

Ranges are reported instead of single values because the tie among optimal training configurations is real, and any fixed convention would hide it. This is the figure to read for the method, and it remains restricted to one participant.

VI. Discussion and Limitations

A. Scope of the Claim

What was varied across sixteen levels is the mounting configuration, not the wearer, so the evidence supports invariance of the procedure to how the device is fastened, on the gait of one person, and not yet invariance across gaits. The distinction matters because the mechanism has an identifiable dependency. Identifying the mediolateral axis by largest angular velocity variance assumes that rotation of the lower limb concentrates in the sagittal plane during walking. This holds for typical gait, and the margin by which it holds is what the confidence ratio of 1.3 measures. A wearer with pronounced gait asymmetry, an altered gait from injury, or a markedly different limb geometry could reduce that margin. Whether the procedure then degrades gracefully or fails is an open question only multi-subject data can answer, and the timeout fallback exists because that failure mode was anticipated rather than observed.

B. Limitations

The sample is a single participant, the principal limitation: the work is a preliminary validation of a procedure, not a characterization of its performance across a population.

The exact agreement of Table II states internal consistency, since those parameters were chosen on those same recordings; the leave-one-out evaluation of Section V-D is bounded rather than exact and is the figure to read for what to expect elsewhere. Both are limited by the size of the set: six recordings leave each fold with five for tuning, which is why several parameter combinations tie at zero training error.

The orientation is identified once and not re-estimated, so the body frame becomes stale if the device shifts on the strap. The recordings bound the effect only loosely. Over the still intervals they contain, one second with peak angular rate below 7 degrees per second and mean acceleration magnitude within 0.2 m/s^2 of gravity, the measured direction departs from the gravity vector stored at calibration by 2 to 9 degrees, the larger values in the more vigorous recordings. A session in which the wearer only stood shows 2 to 5 degrees, so part of that spread is posture and noise rather than slip, and nothing in the data separates the two. Stride detection is unaffected, since a constant tilt offset does not reach the gyroscope, but any quantity derived from the direct-current (DC) level of gravity-removed acceleration would inherit it.

The invariance of stride detection to mounting is inferred rather than measured. The mounting experiment establishes that the axis assignment is recovered regardless of how the device is fastened, and the gait recordings establish that the detector is accurate on the identified axis in the canonical mounting. The step between the two is reasonable, since the detector consumes only the identified axis, but the mounting recordings carry no reference count against which detection could be scored. Repeating them with counted steps would close this gap at low cost.

The sign of the mediolateral and anteroposterior axes remains unresolved, as discussed in Section III-D.

Three quantities are estimated or counted statically rather than measured: autonomy follows from datasheet currents, execution time was not profiled, and the ratio the firmware evaluates over the identification window is not written to the session file, which leaves the account of Section V-A resting on the firmware logic rather than on a logged value. The last two ask for instrumenting the firmware, the first for a current measurement at the cell.

The accelerometer full-scale range of 16 g proved insufficient for the most intense event of the target sport, the instep kick [20]. Of the fifteen kicks performed in the recordings of Section IV-C, fourteen were located as distinct peaks, and twelve of those drove at least one axis against the limit, where the signal stops rising and flattens at about 15.5 g.

That plateau is a clipping artifact and not a measurement: the sensor clips at its hardware limit, and the static calibration then scales every sample by a fixed factor, close to 0.97 on the unit used, which yields the 15.5 g observed. Since that factor is recomputed at every power-up, the plateau differs

between sessions, 15.50 g in one recording and 15.56 g in the other, which is the signature clipping predicts. The true peak is therefore unknown. Widening the range would require a different part, since 16 g is the largest setting the MPU6050 offers [12]. Clipping is confined to the accelerometer: the gyroscope, set to 2000 degrees per second, peaked at 1330 on a single axis on the same kicks and at 641 across the gait recordings of Section IV-B, both compared against a full scale that is itself per axis, so for explosive events the angular velocity remains the valid quantity.

The validation reference is a manual count performed during execution, subject to human error at high cadence, and it carries no timing: a total per recording, not the instant of each stride. Accuracy is therefore a count error, which Table II reports, and not precision and sensitivity on individual events, since neither a true positive nor a false positive can be defined without a per-event reference, which a synchronized video would supply at low cost. Recordings were short, tens of strides each, so behavior over sessions of realistic duration remains untested.

VII. Conclusion

This paper presented, as a proof of concept, an ankle-worn inertial wearable assembled from retail components at about 21 US dollars, which recovers its own anatomical axes from the gait of the user: the vertical axis from the resting gravity vector, the mediolateral axis from the gyroscope component of largest variance during walking, and the anteroposterior axis by the right-hand rule. The principle is that of functional sensor-to-segment calibration, established in the biomechanics literature; the contribution is an implementation that runs entirely in firmware, requires no operator, no mounting instructions and no calibration posture beyond standing still, and completes once at the start of each session.

Evaluated across sixteen mounting configurations, including eight in which the device was inverted, the assignment matched both checks in every case, and the confidence ratio governing acceptance varied with mounting geometry in the manner geometry predicts. A stride detector built on the identified mediolateral axis, using an adaptive threshold with an adaptive refractory period, reproduced a manual reference count exactly over six gait recordings in the canonical mounting, spanning slow walking to running. Obtained from a single participant, these results establish feasibility within the computational budget of the target microcontroller, and not accuracy across wearers, across gait patterns, or over sessions of realistic duration.

Three directions follow. The first and most important is multi-subject data collection, recorded against a synchronized video so that detections can be scored event by event instead of against a manual total. It would turn invariance to mounting on one gait into invariance across gaits, and is a precondition for any performance claim. The second is resolving the sign ambiguity of the mediolateral and anteroposterior axes without a prescribed posture, plausibly from the direction of travel during the identification walk. The third is moving the detector into the firmware, so that stride counts become available during the activity rather than after transfer, which requires the causal reformulation of Section V-C.

***Abstract*—The project aimed to organize an experimental procedure for evaluating the functionality of electrodes for electromyography and muscle electrical stimulation. The methodology employed includes output-tracking agreement tests, as well as laboratory assays to detect the presence of visual electromagnetic noise. The model was developed to analyze the device's ability to transmit electrical impulses and capture the electrical potential of the muscle. The purpose was to provide a protocol to standardize the evaluation of electrode performance, contributing to the development and validation of more reliable devices.**

***Index Terms*—electrical stimulation, electrode, electromyography, experimental testing, performance evaluation, validation.**

I. Introduction

Surface electrodes are non-invasive devices that are applied to the patient's skin and are used to acquire electrical activity generated by motor units or to deliver electrical stimulation to the targeted muscle region [1].

The action potential is a rapid change in the membrane electrical potential of neurons and muscle cells, triggered by an adequate stimulus capable of activating these cells. It is responsible for initiating muscle contraction [2].

The summation of the action potentials recorded by a surface electrode over a muscle after its stimulation results in the compound muscle action potential (CMAP) [3].

The ABNT NBR IEC 60601 standard establishes general requirements for the basic safety and essential performance of medical electrical equipment. It defines criteria and tests for assessing device compliance, contributing to the safety of patients and healthcare professionals while ensuring proper device operation [4].

Fundação Instituto Nacional de Telecomunicações (FINATEL).

In the book Medical Instrumentation: Application and Design, Chapter 5 – Biopotential Electrodes, Webster and Nimunkar emphasize that electrode performance directly affects the quality of acquired biopotential signals. The authors highlight the importance of evaluating skin–electrode interface impedance, polarization, half-cell potential, and susceptibility to noise and artifacts to ensure reliable physiological signal acquisition [5].

In 1848, Emil du Bois-Reymond, considered the German founder of modern electrophysiology, demonstrated in his work Untersuchungen über thierische Elektricität that muscle contraction is accompanied by changes in muscle electrical activity, a phenomenon known as "negative variation," providing evidence that muscles and nerves generate electrical signals [6].

Surface electromyography is widely used for the assessment of skeletal muscle electrical activity through electrodes positioned on the patient's skin. It provides information regarding muscle control by the central and peripheral nervous systems. Its application has become increasingly relevant in several areas, such as obstetrics and neurorehabilitation [7].

Neuromuscular electrical stimulation produces contractions on the muscle surface, being responsible for increasing oxidative capacity and reducing inflammation [8].

Electrotherapy can be applied in the treatment of fractures, nerve fiber repair, soft tissue regeneration, treatment of peripheral nervous system injuries, cancer treatment, and may also influence cellular behavior [9], [10].

Electromagnetic interference can be emitted by equipment and can compromise the operation of electronic devices and electrical systems [11].

Based on this issue, the objective of this study was to develop a document containing test guidelines for the validation of devices with electromyographic signal acquisition for human muscle assessment and electrical stimulation, aiming to provide more accurate diagnosis and improved patient recovery.

II. Methodology

In order to evaluate the functional capability of the electrode, a survey was conducted on the different feasible tests for application in this device.

Experimental tests were developed for two types of electrodes, which differ only in shape and dimensions. That is, both present the same graphite- and silicone-based composition.

The main characteristics to be evaluated were:

- Conductivity: ability to conduct electrical current;
- Electromagnetic noise: unwanted signals that may impair device operation;
- Output-tracking agreement: changing the intensity of the electrical stimulator and analyzing the sensor response.

After evaluating these parameters, it is determined whether the electrode meets the necessary requirements for proper operation, that is, providing a preliminary assessment of its electrical performance under the evaluated experimental conditions.

III. Results and Discussion

The employed methodology resulted in the following steps for the analysis and evaluation of the device:

A. Electrical conductivity

The evaluation of electrical conductivity is essential to ensure that the electrical stimulator delivers the electrical signal through the electrode to the patient's muscle at the desired intensity, as previously programmed.

For this approach, an electrical stimulator, a 330 Ω resistor, and an oscilloscope were employed.

Figure 1 shows the adopted positioning.

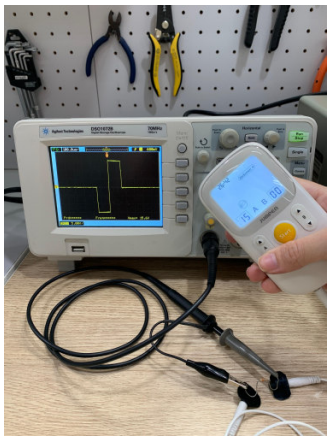

Fig. 1. Oscilloscope measurement. Source: Author (2025)

In the oscilloscope, the horizontal scale (time represented by each horizontal division of the oscilloscope grid) was set to 100.0 μs/div. Additionally, the vertical scale (voltage represented by each vertical division) was set to 5 V/div.

Subsequently, the oscilloscope probe was connected to the oscilloscope, with one clip connected to one terminal of the resistor and the other clip connected to the opposite terminal.

The electrical stimulator was connected to a pair of electrodes, one of which was under evaluation. Each terminal of the resistor was positioned on one of the electrodes.

The electrical stimulator was initially configured to reach its maximum voltage to be applied to the electrode.

For the individual evaluation of each device, a reference electrode with previously validated performance was used. The reference electrode was connected to one terminal of the electrical stimulator, while the electrode under evaluation was connected to the opposite terminal.

Furthermore, to assess electrical consistency across different regions of the electrode surface, meaning uniform current conduction throughout the electrode area, the Cartesian Plane proposed by René Descartes was used, in which each quadrant represented an area to be analyzed (Figures 2 and 3).

Fig. 2. Cartesian Plane markings for the smaller electrode. Source: Author (2025)

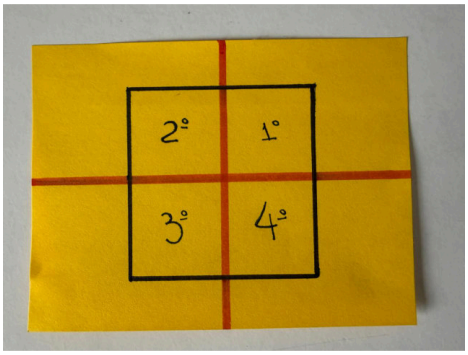

Fig. 3. Cartesian Plane markings for the larger electrode. Source: Author (2026)

The positioning employed for the analysis of homogeneous current distribution in the smaller electrode can be observed in Figures 4, 5, 6, and 7. The positioning for the larger electrode can be observed in Figures 8, 9, 10, and 11.

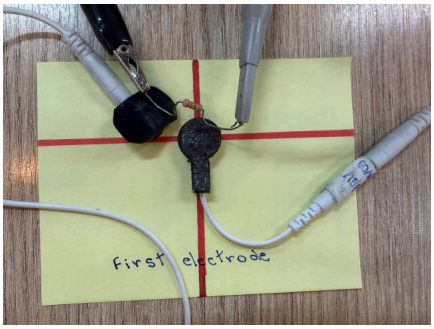

Fig. 4. Positioning in the first quadrant of the Cartesian Plane for the smaller electrode. Source: Author (2025)

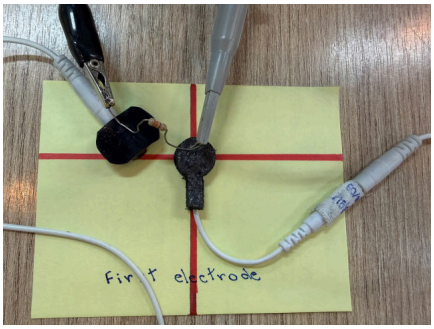

Fig. 5. Positioning in the second quadrant of the Cartesian Plane for the smaller electrode. Source: Author (2025)

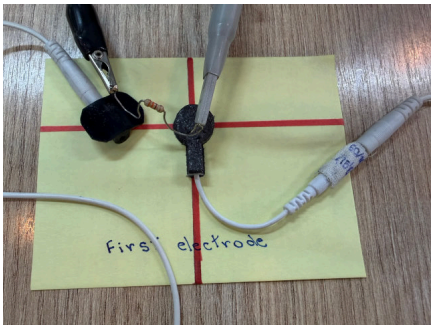

Fig. 6. Positioning in the third quadrant of the Cartesian Plane for the smaller electrode. Source: Author (2025)

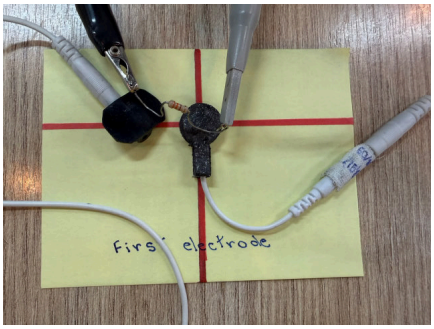

Fig. 7. Positioning in the fourth quadrant of the Cartesian Plane for the smaller electrode. Source: Author (2025)

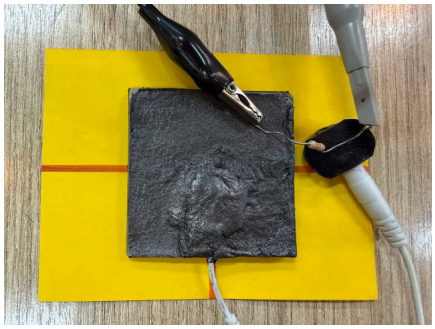

Fig. 8. Positioning in the first quadrant of the Cartesian Plane for the larger electrode. Source: Author (2026)

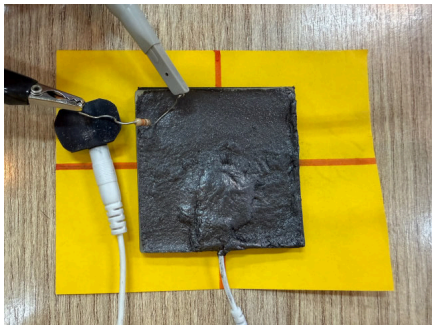

Fig. 9. Positioning in the second quadrant of the Cartesian Plane for the larger electrode. Source: Author (2026)

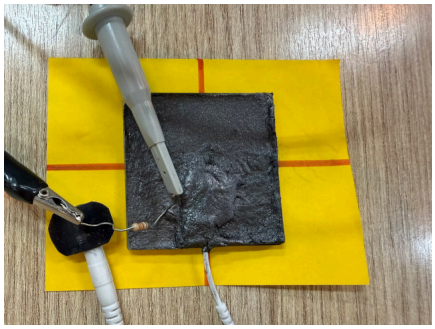

Fig. 10. Positioning in the third quadrant of the Cartesian Plane for the larger electrode. Source: Author (2026)

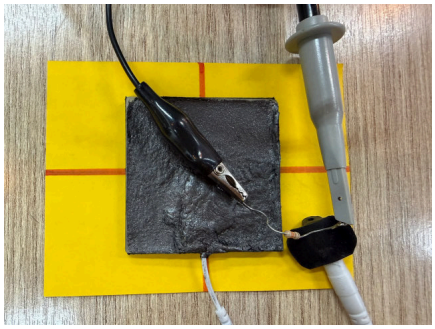

Fig. 11. Positioning in the fourth quadrant of the Cartesian Plane for the larger electrode. Source: Author (2026)

The results obtained for each quadrant were recorded in a table using the electronic spreadsheet software Microsoft Excel for subsequent evaluation and comparison with the gold standard observed in a previously approved electrode.

The obtained results can be seen in Table I, which showed the same measured voltage at the four tested positions under the evaluated conditions, both for the smaller and larger electrodes.

TABLE I
CURRENT HOMOGENEITY TEST.

Position:	**1**	**2**	**3**	**4**
Voltage (V):	14.8	14.8	14.8	14.8

Furthermore, when compared with the voltage value obtained from the analysis of a previously approved electrode, the results were the same. That is, when the electrical stimulator supplied its maximum applied voltage to the electrode, both the electrodes under evaluation and the gold standard presented a voltage of 14.8 V on the oscilloscope.

B. Visual Inspection for Electromagnetic noise

The visual inspection for electromagnetic noise test is necessary because it evaluates whether there is interference from unwanted signals that may affect the electromyography and electrical stimulation of the patient's muscle.

For this test, the same oscilloscope settings, components, and positioning proposed in the previous test (electrical conductivity) were used.

However, the objective was to verify the presence of visual noise in the waveform generated by the oscilloscope, performing a comparison with the image obtained from a previously approved electrode (Figure 12).

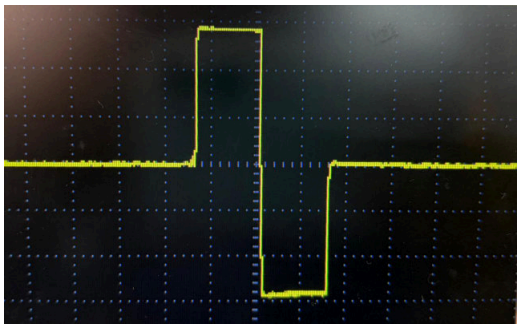

Fig. 12. Waveform without evident visual electromagnetic noise from a gold standard electrode. Source: Author (2025)

The analysis of the presence of electromagnetic noise was performed solely through visual comparison.

As can be observed in Figures 13 (smaller electrode) and 14 (larger electrode), the waveforms generated by the oscilloscope for both electrodes showed no evident electromagnetic noise upon visual inspection when compared with the waveform of the gold standard electrode.

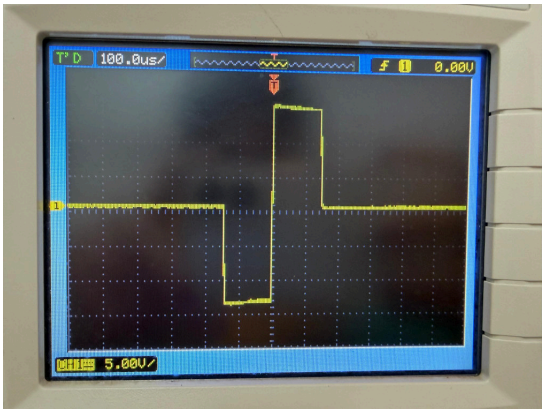

Fig. 13. Waveform without evident electromagnetic noise upon visual inspection from the smaller electrode. Source: Author (2025)

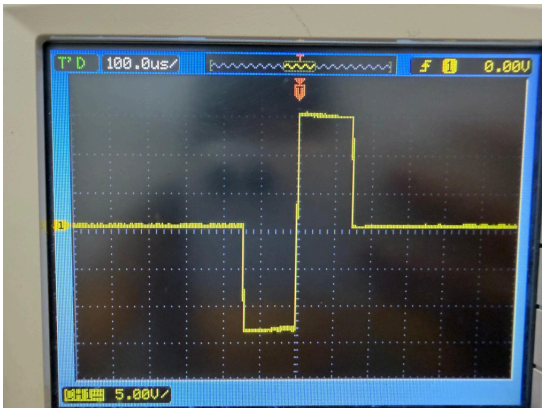

Fig. 14. Waveform without evident electromagnetic noise upon visual inspection from the larger electrode. Source: Author (2026)

C. Quantitative Noise and RMS Analysis

In order to provide a quantitative evaluation of the signal characteristics beyond visual waveform inspection, the Root Mean Square voltage (V_{RMS}) was selected as a key metric. This parameter accounts for the overall voltage magnitude, including baseline fluctuations, and provides a measure of the effective electrical energy delivered to the load under identical operating conditions.

To quantitatively evaluate signal magnitude, Root Mean Square voltage (V_{RMS}) values were extracted from the oscilloscope waveforms. The conventional reference electrode exhibited a V_{RMS} of 6.94 V, whereas the developed small and large electrodes yielded 6.87 V and 6.96 V, respectively, indicating comparable effective voltage levels across all tested geometries under identical experimental conditions.

The experimental setup utilized for the V_{RMS} quantitative measurement was identical to that previously described for the visual noise inspection test, maintaining the same oscilloscope settings, load resistor, probe connection, and component positioning.

Figures 15, 16, and 17 display the resulting oscilloscope trace captures for the conventional, small, and large electrodes,

respectively. In each waveform image, the measured V_{RMS} value is highlighted within a red outlined box for direct comparison.

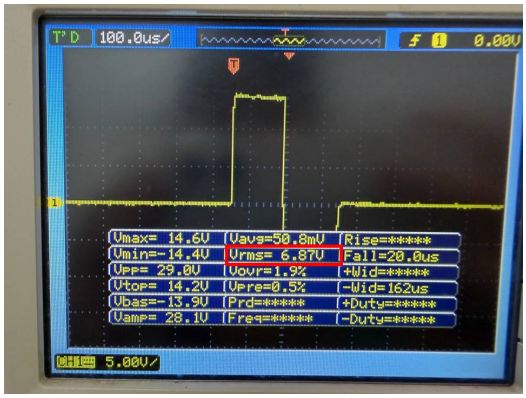

Fig. 16. Output voltage waveform from the smaller electrode. Source: Author (2026)

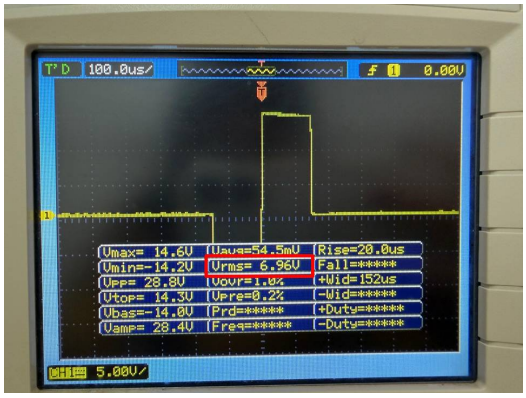

Fig. 17. Output voltage waveform from the larger electrode. Source: Author (2026)

D. Output-tracking agreement

The output-tracking agreement test ensures that, at different voltages, the electrode responds as expected. That is, for different parameters programmed in the electrical stimulator, the electrode must respond according to the applied settings and produce the corresponding electrical output.

For the experiment, the oscilloscope was configured in the same way as in both previous tests, and the positioning of the components for testing remained the same.

However, the only difference was the modification of the electrical stimulator parameter, in which all available voltage levels of the equipment used (modes 1 to 15) were applied in order to compare the results of each mode with those of a previously approved electrode and analyze whether the peak voltage value displayed on the oscilloscope was different for each mode.

The expected trend was that increasing the mode number would lead to an increase in the peak voltage measured by the oscilloscope.

All data obtained from the tests were recorded in spreadsheets using the Microsoft Excel spreadsheet software for subsequent analysis and comparison.

The voltage values obtained during the evaluation of the gold standard electrode are presented in Table II.

TABLE II
OUTPUT-TRACKING AGREEMENT TEST OF THE CONVENTIONAL ELECTRODE.

Mode:	**1**	**2**	**3**	**4**	**5**
Voltage (V):	1.2	2.2	3.2	4.2	5.2
Mode:	**6**	**7**	**8**	**9**	**10**
Voltage (V):	6.2	7.0	7.8	8.8	9.6
Mode:	**11**	**12**	**13**	**14**	**15**
Voltage (V):	10.6	11.8	12.6	13.6	14.6

The voltage values obtained from the smaller electrode are presented in Table III.

TABLE III
OUTPUT-TRACKING AGREEMENT TEST OF THE SMALLER ELECTRODE.

Mode:	**1**	**2**	**3**	**4**	**5**
Voltage (V):	1.2	2.2	3.2	4.2	5.2
Mode:	**6**	**7**	**8**	**9**	**10**
Voltage (V):	6.2	7.0	7.8	8.8	9.8
Mode:	**11**	**12**	**13**	**14**	**15**
Voltage (V):	10.6	11.8	12.6	13.6	14.6

The voltage values obtained from the larger electrode are presented in Table IV.

TABLE IV
OUTPUT-TRACKING AGREEMENT TEST OF THE LARGER ELECTRODE.

Mode:	**1**	**2**	**3**	**4**	**5**
Voltage (V):	1.0	2.2	3.0	4.0	5.0
Mode:	**6**	**7**	**8**	**9**	**10**
Voltage (V):	6.2	7.0	7.8	8.6	9.8
Mode:	**11**	**12**	**13**	**14**	**15**
Voltage (V):	10.8	11.8	12.6	13.6	14.8

The waveform images generated by the oscilloscope from the performed tests can be visualized in Figures 18 (gold

standard electrode), 19 (smaller electrode), and 20 (larger electrode).

The organization of the waveforms in each figure was based on the information order collected from the previously presented tables (Tables II, III, and IV).

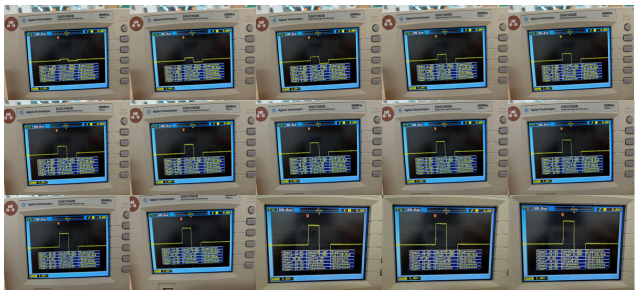

Fig. 18. Output-tracking agreement test waveforms from the gold standard electrode. Source: Author (2025)

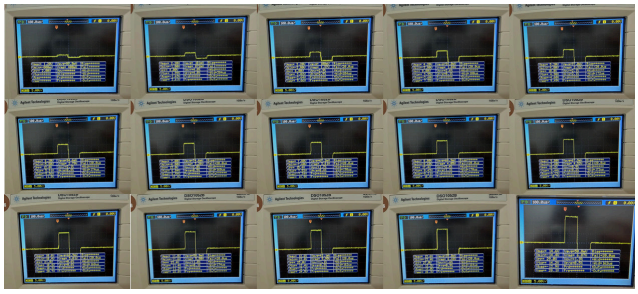

Fig. 19. Output-tracking agreement test waveforms from the smaller electrode. Source: Author (2025)

Fig. 20. Output-tracking agreement test waveforms from the larger electrode. Source: Author (2026)

It can be observed that the values recorded for the three analyzed electrodes showed only small variations, with differences of up to 200 mV. Therefore, it can be concluded that the tested electrodes exhibit output-tracking agreement comparable to those of a previously approved electrode.

E. Experimental Setup Specifications

To ensure test setup reproducibility, the bench evaluation was configured as a fixed resistive load circuit. Signal acquisition was performed using an Agilent Technologies DSO1072B Digital Storage Oscilloscope (70 MHz bandwidth, 1 GSa/s sampling rate) equipped with standard passive voltage probes.

Electrical stimulation was supplied by a portable Jumper TENS/EMS unit operating across 15 output intensity levels. The electrical pulses observed on the oscilloscope exhibited symmetrical or asymmetrical biphasic rectangular waveforms. The oscilloscope was configured with a horizontal time scale of 100.0 μs/div and a vertical voltage scale of 5 V/div for waveform acquisition.

The load circuit was constructed using axial carbon-film resistors with a $\pm 5\%$ tolerance (330 Ω and 510 Ω). The reference electrode consisted of a commercially available, pregelled, self-adhesive electrode. All physical contacts between the resistor leads and the electrode surfaces were maintained at fixed mechanical positions to minimize contact variability.

It is important to emphasize that this bench test setup evaluates voltage transfer exclusively within a simplified, fixed resistive circuit. The experimental design does not account for complex physiological and electrode–skin interface parameters, such as variations in skin impedance, delivered current density, electrode half-cell potential, or motion artifacts. Consequently, these measurements should be interpreted primarily as a preliminary electrical screening rather than as a comprehensive clinical validation.

F. Statistical Analysis

For the electrical conductivity tests, measurements were performed in quintuplicate for each electrode sample under the maximum output condition of the electrical stimulator. Three samples of each developed electrode geometry, as well as a previously approved commercial electrode, were evaluated. Subsequently, the data were analyzed using Microsoft Excel, and the mean values and standard deviations of the five measurements obtained for each test condition were calculated.

Additionally, two resistors with different resistance values, 330 Ω and 510 Ω, were used to evaluate the electrical performance of the electrodes under different load conditions. Each electrode was tested using both resistance values, following the same experimental setup and oscilloscope measurement procedure adopted in the electrical conductivity tests.

The voltage values obtained for the three types of electrodes—conventional, small, and large—were measured in quintuplicate. The results of the five measurements performed for each electrode type are presented in Tables V, VI and VII, respectively. The analysis of these results enabled the assessment of measurement consistency and the comparison of the electrical performance of the developed electrodes with that of the conventional electrode.

TABLE V
VOLTAGE MEASUREMENTS OF THE CONVENTIONAL ELECTRODE USING 330 Ω AND 510 Ω RESISTORS

Test	**330 Ω**	**510 Ω**
1	14.8	22.2
2	14.6	22.2
3	14.8	22.4
4	14.8	22.4
5	14.6	22.2

TABLE VI
VOLTAGE MEASUREMENTS OF SMALL ELECTRODES USING 330 Ω AND 510 Ω RESISTORS

For the output-tracking agreement analysis, three independent measurements were performed for each operating mode (Modes 1–15) using the conventional reference electrode, the small electrode, and the large electrode. For each operating mode, the mean voltage (μ), standard deviation (σ), and percentage relative error (RE%) with respect to the conventional reference electrode were calculated.

The relative error values were calculated using the original mean values before rounding.

The percentage relative error was calculated using the mean voltage of the conventional reference electrode as the reference value, according to:

$$\mathrm{RE}(\%) = \frac{\left|\mu_{\mathrm{electrode}} - \mu_{\mathrm{conventional}}\right|}{\mu_{\mathrm{conventional}}} \times 100 \qquad (1)$$

Where $\mu_{\mathrm{electrode}}$ represents the mean voltage measured for the small or large electrode, and $\mu_{\mathrm{conventional}}$ represents the mean voltage measured for the conventional reference electrode.

Table XIV presents the mean (μ), standard deviation (σ), and percentage relative error ($\mathrm{RE}\%$) for each operating mode.

TABLE XIV
STATISTICAL ANALYSIS OF OUTPUT VOLTAGE ACROSS 15 OPERATING MODES (MEAN ± STANDARD DEVIATION AND RELATIVE ERROR)

Mode	Conventional (V)	Small (V)	Error (%)	Large (V)	Error (%)
1	1.13 ± 0.12	1.13 ± 0.12	0.00%	1.13 ± 0.12	0.00%
2	2.20 ± 0.00	2.20 ± 0.00	0.00%	2.20 ± 0.00	0.00%
3	3.07 ± 0.12	3.13 ± 0.12	2.17%	3.07 ± 0.12	0.00%
4	4.13 ± 0.12	4.07 ± 0.12	1.61%	4.07 ± 0.12	1.61%
5	5.13 ± 0.12	5.13 ± 0.12	0.00%	5.13 ± 0.12	0.00%
6	6.20 ± 0.00	6.20 ± 0.00	0.00%	6.20 ± 0.00	0.00%
7	7.00 ± 0.00	7.00 ± 0.00	0.00%	7.00 ± 0.00	0.00%
8	7.80 ± 0.00	7.80 ± 0.00	0.00%	7.80 ± 0.00	0.00%
9	8.73 ± 0.12	8.67 ± 0.12	0.76%	8.60 ± 0.00	1.53%
10	9.67 ± 0.12	9.73 ± 0.12	0.69%	9.73 ± 0.12	0.69%
11	10.67 ± 0.12	10.67 ± 0.12	0.00%	10.73 ± 0.12	0.63%
12	11.80 ± 0.00	11.80 ± 0.00	0.00%	11.80 ± 0.00	0.00%
13	12.60 ± 0.00	12.60 ± 0.00	0.00%	12.60 ± 0.00	0.00%
14	13.60 ± 0.00	13.60 ± 0.00	0.00%	13.60 ± 0.00	0.00%
15	14.73 ± 0.12	14.73 ± 0.12	0.00%	14.73 ± 0.12	0.00%

The results demonstrated high measurement consistency for both developed electrode geometries, with a maximum standard deviation of 0.12 V. The relative error was 0.00%

for most operating modes, with maximum deviations of 2.17% for the small electrode in Mode 3 and 1.61% for the large electrode in Mode 4. These results indicate comparable output-voltage agreement between the developed and conventional electrodes under the evaluated conditions.

Based on these findings, the proposed procedure provided a preliminary assessment of the electrical performance of the developed electrodes. The electrodes demonstrated electrical behavior comparable to the conventional reference under the evaluated conditions. However, further testing with a larger number of devices is required to assess their safety, reliability, and applicability to electromyography and electrical stimulation.

IV. Conclusion

The development of the experimental procedure for the evaluation and validation of electrodes for human muscle electromyography and electrical stimulation enabled a preliminary assessment of the electrical performance of these devices.

The electrical conductivity test enabled the verification of the electrode's ability to conduct and transmit electrical signals from the electrical stimulator through the electrode.

The visual inspection for electromagnetic noise made it possible to verify that no evident undesirable noise was observed during the experimental conditions evaluated.

The output-tracking agreement experiment enabled the preliminary assessment of the electrode under different electrical stimulator settings, allowing its electrical response to be compared with that of the reference electrode.

The objective of this project was to develop a document compiling the essential tests required for the evaluation of electrodes used in human muscle electromyography and electrical stimulation.

Although the results demonstrate preliminary electrical functioning and the ability of the electrodes to conduct electrical signals, they are not sufficient to confirm that the devices are suitable or fully validated for electromyography or electrical stimulation applications. Furthermore, the experiments performed do not allow conclusions regarding patient safety, clinical efficacy, or suitability for use in humans. Following the completion of the test specification stage, future work will involve conducting tests on a larger number of devices and performing further evaluations to strengthen the validation of the proposed procedure for large-scale application. This may contribute to the future development of safer and more reliable electrodes for muscle assessment and electrical stimulation.

V. Future Work

Future studies will focus on expanding the experimental characterization of the developed electrodes by investigating their behavior under a broader range of operating and application conditions. Additional analyses will be performed to further investigate signal integrity, electrical stability, and the interaction between the electrodes and the application environment.

The study will also be extended to a larger number of devices to obtain a more representative assessment of the reproducibility of the results. Further investigations involving electromyographic signal acquisition and electrical stimulation will be conducted, together with evaluations related to device safety and performance. These additional studies will provide a more comprehensive basis for further evaluating the potential applicability of the developed electrodes in electromyography and electrical stimulation.

Acknowledgment

This work was supported by the Fundação Instituto Nacional de Telecomunicações (FINATEL), the Instituto Nacional de Telecomunicações (Inatel), and the eHealth - Innovation Center Laboratory, which diligently provided the resources necessary for the development of this project.

To Professor Filipe Bueno Vilela, Ph.D., for providing essential research contributions for the development of the artifact.

To Professor Luma Rissati Borges do Prado, for indicating the electrode testing method using the oscilloscope.

To Professor Elisa Rennó Carneiro Déster, M.Sc., for her valuable guidance and teachings in anatomy, physical therapy, and electrode application.

To the advisor, Professor Maysa Costa Alves, Ph.D., for all the support, ideas, and knowledge shared.

***Abstract*—Physiological monitoring for aviation human factors research is imperative due to human errors being the most prominent influences of aviation incidents and accidents. This paper presents the validation of a multimodal acquisition setup comprising a Daheng camera with Sony CMOS for pupillometry and a BITalino (r)evolution Board Kit with electrodes for electrodermal activity (EDA),), a.k.a. galvanic skin response (GSR), and electrocardiography (ECG) with heart rate variability (HRV) derivation, deployed in a flight simulator of a 737-800 during manual approach and touch-and-go landing (TGL) sequences. We enrolled 8 pilots (mean age 26.4, SD$\pm$7.7) and assessed pre/post-event changes comparing physiological responses across flight phases; measuring reliability using intraclass correlation coefficients (ICC), Bland–Altman analysis, standard error of measurement (SEM), and minimal detectable change (MDC); and Spearman correlations against Likert subjective self–evaluation ratings. ICC values were considered poor between the first pair of TGLs for each pilot, but large effect-sizes ($\eta_p^2 > 0.14$) were observed for skin conductance level (SCL), root mean square of successive RR-interval differences (RMSSD), and pupil/iris ratio. These results support the feasibility and physiological sensitivity of the setup, but test–retest reliability was not established for single-landing interpretation.**

***Index Terms*—pupillometry, EDA, GSR, ECG, HRV, flight simulator, method validation, aviation human factors, biosignals.**

I. Introduction

Considering the need for capturing pilots' autonomic and cognitive state changes during different phases of flight—particularly approach and landing, the most critical in terms of safety in conjunction with human factors [1], [2]—affordable and reliable means of measuring biosignals are required for research spreading. There are gaps for improvement, mainly in general aviation, where higher accident numbers also have prominent causal and contributing factors as human errors [3], [4]. Cognitive workload, attentional allocation, and autonomic arousal fluctuate markedly within intervals linked to each flight phase. Specifically, Instrument Landing System (ILS) final approach can be considered the most attentionally demanding flight phase [5].

Physiological measurement offers continuous, non-intrusive proxies for biosignals during pilots' states. Pupil diameter, modulated by the locus coeruleus-norepinephrine system, is a sensitive indicator of phasic arousal and mental effort [6]. Electrodermal activity (EDA), a.k.a. galvanic skin response (GSR), reflects sympathetic nervous system activation and is widely employed in stress and engagement/workload research [7]. Electrocardiography (ECG) and its derived heart rate variability (HRV) metrics—particularly Standard Deviation of the Normal-to-Normal Intervals (SDNN), Root Mean Square of Successive Differences (RMSSD), Low Frequency/High Frequency (LF/HF) ratio, and percentage of NN

intervals that differ by more than 50 milliseconds (pNN50)—provide indices of autonomic balance and have demonstrated sensitivity to pilot workload [8].

Considering the proliferation of lower-cost wearable biosignal platforms [9], the validation of their psychometric properties in simulation environments is welcome for literature representation and research use. Flight simulators may introduce electromagnetic interference, motion artifacts from control inputs and pilots' movement, lighting variability from screens and projectors, and temporal complexity from discrete task phases—all of which can interfere with signal integrity and measurement consistency.

This study helps address this gap by systematically evaluating the reliability and validity of a BITalino (r)evolution board (PLUX Biosignals, Portugal) for ECG and EDA/GSR acquisition, and a Daheng Venus vision camera for pupillometry, deployed in a Boeing 737NG Flight Training Device during manual touch-and-go landings (TGLs), mainly with student pilots.

The objectives are: (1) evaluate the reliability of pupillometric, EDA, ECG, and HRV measures across consecutive TGL trials within the same simulation session; (2) assess construct validity by comparing physiological responses between the approach phase and landing phase; (3) determine concurrent validity through correlation with subjective workload via Likert scale survey [10]; and (4) report signal quality metrics with artifact rates for each modality in the simulator environment.

II. Theoretical Background

Physiological validation with a standardized assessment protocol, particularly for wearables, ideally should be addressed in three levels: by signal, by parameter, and by event [11].

A. Pupillometry in Cognitive Research

Pupil diameter has been established as a sensitive index of phasic arousal and cognitive effort, driven by norepinephrine release from the locus coeruleus. Significant pupil dilation during higher workload contexts is expressively reported [12]. Measurement reliability across repeated trials with a fixed remote, non-corneal-reflection camera can also be formally validated. Pupil size is susceptible to ambient luminance changes in the cockpit, corneal reflection artifacts, and partial blink occlusion, which require robust preprocessing.

B. Electrodermal Activity (EDA) During Cognitive Tension

EDA (or GSR) decomposition into tonic (skin conductance level, SCL) and phasic (skin conductance response, SCR) components has improved discriminability in dynamic, movement-rich environments. Studies employing EDA sensors have demonstrated satisfactory results for pilot workload analysis during real flight tests [13], despite various limitations due to equipment and signals [14].

C. ECG and HRV During Cognitive Tension

A 2024 systematic review identified HRV as the most prevalent physiological modality in pilot mental workload studies (reported in 29 reviewed articles), with RMSSD, SDNN, and LF/HF ratio as the most consistently reported metrics [15]. Reliability of short-segment HRV is critically dependent on ectopic beat removal and artifact preprocessing. BITalino sensors have been evaluated against reference devices and are considered reliable tools for signal acquisition [16], supporting open-source processing.

III. Materials and Methods

A. Participants

Eight pilots (seven males, mean age 26.4, SD$\pm$7.7) were recruited as volunteers. Seven were students or low-experienced pilots (less than 300 flight-hours) and one commercial pilot with more than 1000 flight hours. Inclusion criteria: valid Brazilian medical certificate [17] (one private pilot's certificate was expired at the date of the test), at least 18 years of age, and being able to maintain attitude-power coordination and safely perform takeoffs and landings in a real airplane. All pilots had no familiarity with Boeing 737-800 procedures and handling. Exclusion criteria: no practical flying time or no medical certificate ever issued. All participants provided written informed consent. The study was approved by the UTFPR Ethics Committee [18], Protocol CEP_8289986.

B. Equipment and Data Acquisition

The flight simulator is a static Cabin Procedures Trainer of a Boeing 737-800X (New Generation), custom made with X-Plane 11 and FS-FlightControl 1.7.3 for external control. Post-flight data in CSV (comma—separated values) format were extracted, with timestamps of flight phases automatically recorded at approximately 1 Hz in the simulation management station. Time information was synchronized with an external notebook via Windows Network Time Protocol (NTP), with a tolerance below ± 1 second observed before every flight. An internal IP Dome camera captured the flight deck view (with audio) for every flight.

For ECG and EDA, a BITalino (r)Evolution Plugged Kit BLE/BT board (2021 version) with an ECG 3-lead electrode cable and an EDA 2-lead electrode cable was used, with Medix SF22 disposable electrodes. Performing the Einthoven Lead [19], the positive electrode was placed on the participant's left collarbone, the negative on the right collarbone, and the reference on the right side of the iliac crest. EDA electrodes were placed on the medial phalanges of the index and middle fingers of the non-dominant hand. Figure 1 contains the sensors/electrodes position indication. The board (battery supplied) was connected via Bluetooth to the external notebook using OpenSignals v2.2.7 at 100 Hz.

The camera for pupillometry is a Daheng Imaging VEN-042-121U3M/C monochrome camera (Sony IMX297 CMOS) with HN-P-1228-6M-C1/1.8 lens, mounted on the left side of the instrument panel at eye level, approximately 60 cm from the participant's face, connected via USB 3.0 and recorded using GalaxyViewer 3.2 (H.264 MP4, up to 99 fps). A custom illumination plate with 3$\times$ Epistar InfraRed LEDs (850 nm,

3 W, 120°), USB-powered, was front-mounted at eye level, 50 cm from the participant's face.

Camera and BITalino softwares live recorded signals in a Samsung SB20-FE notebook, Intel Core i5 10210U, 12 GB RAM, Windows 10 22H2. Absolute timestamps from synchronized clocks were used for multimodal alignment, as no shared hardware trigger was available (Fig. 1).

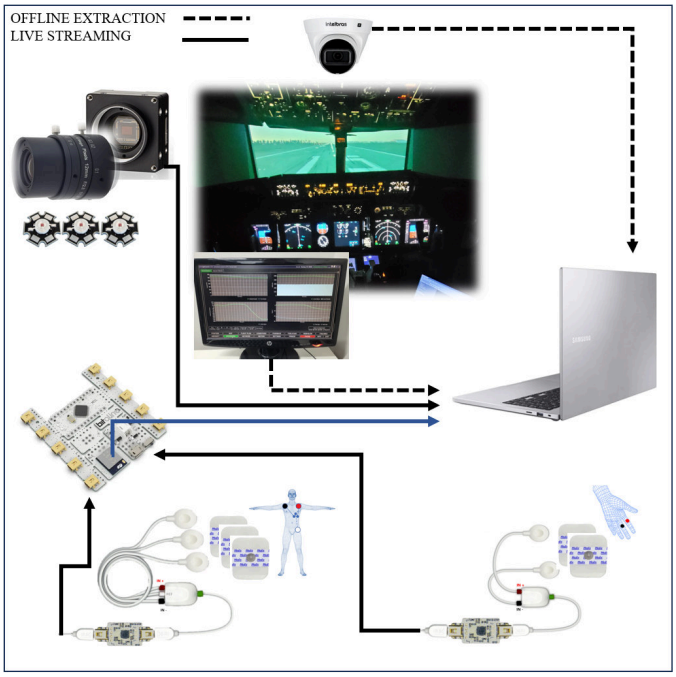

Fig. 1. Data transfer schematic diagram.

C. Experimental Protocol

Following the initial briefing and cabin familiarization, each participant performed consecutive manual TGL sequences (median 5, range 2–6) and a final landing at Curitiba airport, with Instrument Landing System (ILS) of Runway 15 under Visual Flight Rules (VFR), Visual Meteorological Conditions (VMC), and no wind. Scenario order or circuit was the same for all participants (departure, crosswind leg, downwind leg, base leg, final approach). Workload was manipulated and leveled by instructor inputs, considering the number and intensity of deviations/errors (altitude, speed, bank angles, etc) observed for each pilot performance. The final dataset comprised 37 verified TGL events across eight flights.

After the simulation session, participants completed a Likert scale form (based on NASA-TLX [20]) focusing on the hardest approach maneuver in retrospect, rating 10 questions across three dimensions: Cognitive Demand (CD), Perceived Performance (PP), and Emotional Response (ER), on a 0–5 scale. For CD, 2 questions about cognitive effort; for PP, 4 about self-performance and aircraft control; and for ER, 4 about perceived stress and fear. The overall "stimulus" score (0–100%) was computed expecting stronger biosignal responses for higher CD and ER grades, and smaller responses for PP.

D. Signal Preprocessing

1) ECG and HRV: ECG signal preprocessing was calibrated to millivolts, cleaned with Hampel-based artifact repair, detrended, and bandpass-filtered (0.5–40 Hz). R-peaks were detected from a differentiated, squared, and integrated ECG representation and refined on the filtered waveform. RR intervals outside physiological limits or deviating more than 20% from the local median were corrected by interpolation. Heart rate (HR) and RMSSD were estimated in 30-second moving windows, yielding second-by-second indices of chronotropic activation and short-term HRV.

2) EDA: EDA signal preprocessing was calibrated to microsiemens (μS) using the manufacturer transfer function, screened for rail saturation, and low-pass filtered at 2.5 Hz. The tonic component (SCL) was estimated with a 0.05 Hz low-pass filter; the phasic component was obtained as the residual and summarized by its root mean square. Event windows with excessive saturation were excluded from electrodermal inference.

3) Pupillometry: Videos preprocessing was done offline using a custom Python pipeline. The algorithm detects face and eye landmarks, selects the eye region with the best pupil evidence, and tracks this region over time with template-based updates and automatic re-detection when tracking confidence decreases. Inside the eye region of interest, contrast enhancement, Gaussian filtering, inverted thresholding, morphological filtering, and geometric validation are applied to segment the pupil. Frames affected by blinking, poor tracking, abrupt temporal changes, or weak pupil evidence are rejected. The pupil radius is normalized by the estimated iris radius, producing a relative pupil-to-iris percentage signal at 1 Hz. Event annotations were analyzed with pre-, during-, and post-event windows, generating per-event quality metrics, normalized pupil variation, and visual audit frames for methodological validation.

E. Event Windows, Quality Criteria, and Interpretation

Signals were resampled onto a common 1 Hz multimodal timeline. Each verified TGL was analyzed with a pre-event baseline window from -30 to -5 s and a post-event response window from 0 to $+30$ s. At least 20 valid baseline samples and 24 valid post-event samples were required. Valid event responses were averaged within each flight before inferential testing, ensuring that the unit of analysis was the flight rather than the individual landing.

Signal-quality limitations are noted explicitly as they materially affect interpretation. The RR correction fraction ranged from 25.4% to 56.4% across flights, indicating substantial ECG artifact burden in the simulator environment. Electrodermal saturation excluded two flights from EDA inference, whereas 1 Hz pupil availability remained comparatively high (86.1%–100.0%).

F. Statistical Analysis

The primary comparison was the pre/post-event change within each flight, expressed in native units and as normalized

percentage change ($\Delta\% = 100 \times (\text{post} - \text{pre})/\text{pre}$). Phase effects were summarized with paired tests, confidence intervals, and effect sizes, with false-discovery-rate (FDR) adjustment across the five primary metrics. TGL01 and TGL02 denote the first two valid events within each flight, selected a priori for test-retest reliability analysis.

Reliability: ICC(2,1) was computed [21], translated into Standard Error of Measurement (SEM) and Minimum Detectable Change at the 95% confidence level (MDC_{95}). SEM $= \text{SD} \times \sqrt{1 - \text{ICC}}$ and $\text{MDC}_{95} = 1.96 \times \text{SEM} \times \sqrt{2}$.

Bland–Altman analysis compared each flight-level post-event mean with its own pre-event baseline mean and summarized agreement through bias and 95% limits of agreement (LoA).

Likert scores were linearly transformed from the original 1-5 range to a 0-100 scale, averaged within each domain, and then averaged across domains to obtain an overall stimulus score. Because these scores were derived from ordinal responses and the sample size was small, questionnaire-physiology associations were tested at the item level using exact two-sided Spearman rank correlations with the mean pre/post physiological percentage change for each metric. Kendall tau-b was calculated as a sensitivity analysis for tied ranks, and false-discovery-rate correction (pFDR) was applied across the full family of questionnaire-physiology comparisons.

IV. Results

A. Physiological Effects: Pre/Post-TGL Comparison

The clearest group-level tendency was observed in the tonic electrodermal component. SCL increased by 0.91 μS on average, compatible with enhanced sympathetic arousal during landing-related perturbation. This tendency reached nominal significance ($p = 0.026$) but not FDR correction ($p_{\text{FDR}} = 0.129$), and should be interpreted as the strongest signal trend rather than as definitive isolated proof. HR increased modestly (0.53 bpm) and RMSSD tended to decrease (-3.07 ms), compatible with reduced vagal modulation under increased task demand. Phasic EDA changed very little at group level (< 0.001 μS), whereas the pupil-to-iris ratio increased slightly (0.94 percentage points), again in a physiologically plausible direction but with greater heterogeneity. Full results are shown in Table I.

TABLE I
Level of Pre/Post TGL Effects

Metric	n	Δ [95% CI]	F	p_{FDR}	η_p^2
Heart rate (bpm)	8	0.53 [−5.47, 6.53]	0.04	0.991	0.01
RMSSD (ms)	8	−3.07 [−7.41, 1.27]	2.80	0.346	0.29
SCL (μS)	6	0.91 [0.16, 1.65]	9.83	0.129	0.66
Phasic EDA (μS)	6	−0.00 [−0.12, 0.12]	0.00	0.991	0.00
Pupil/iris (%)	8	0.94 [−1.15, 3.03]	1.13	0.537	0.14

Pre: HR 98.79±9.17, RMSSD 59.60±6.51, SCL 15.84±4.25, Phasic EDA 0.34±0.17, Pupil 38.04±5.66. FDR adjusted.

The normalized pre/post distributions showed non-uniform responses across flights. The broadest interquartile spread was observed for Phasic EDA Root Mean Square/RMS (≈49.5 percentage points), indicating that landing-related physiology depends on pilot-specific regulation, procedural adaptation across repetitions, and measurement conditions (Fig. 2).

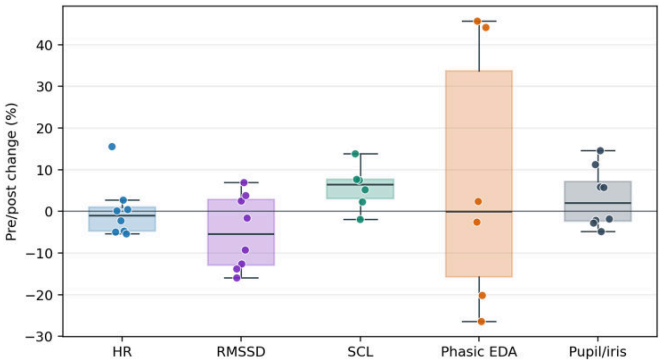

Fig. 2. Boxplots of percentage level change (pre to post-event) for each primary metric, illustrating interindividual variability.

B. Reliability Results

Reliability was weak when the first two valid events were treated as repeated measures. The highest ICC(2,1) was -0.01 for pupil-to-iris ratio, which falls in the poor range (< 0.40) [21]. Bland–Altman plots show broad event-to-event disagreement for several metrics, especially HR and RMSSD, whereas SCL displayed comparatively narrower limits (Fig. 3). These results do not negate physiological sensitivity, but indicate that the proposed setup should not be considered a reliable assessment of individual landing events, instead of a group-level analysis. Full reliability metrics are presented in Tables II and III.

TABLE II
First 2 TGLs Reliability Results – ICC(2,1), SEM, MDC_{95}

Metric	n	ICC(2,1) [95% CI]	SEM	MDC_{95}
Heart rate (bpm)	7	−0.08 [−0.77, 0.24]	12.72	35.25
RMSSD (ms)	7	−0.16 [−0.63, 0.15]	19.24	53.32
SCL (μS)	5	−0.11 [−1.16, 0.57]	1.20	3.32
Phasic EDA (μS)	5	−0.04 [−0.65, 0.47]	0.10	0.29
Pupil/iris (%)	7	−0.01 [−0.53, 0.49]	4.82	13.35

95% CI via bootstrap.

C. Likert Scale Correlations

Post-flight ratings indicated a moderate-to-high perceived challenge, with an overall stimulus score of 56.0 ± 16.3 on the 0-100 scale. Cognitive demand showed the highest average score (70.3), whereas emotional response was more heterogeneous across flights. No questionnaire-physiology association survived false-discovery-rate correction, but the most coherent nominal pattern involved RMSSD. Higher overall stimulus scores were associated with more negative RMSSD changes

TABLE III
BASELINE-REFERENCED BLAND–ALTMAN AGREEMENT

Metric	n	Bias	LoA low	LoA high
Heart rate (bpm)	8	0.53	−13.53	14.59
RMSSD (ms)	8	−3.07	−13.24	7.10
SCL (μS)	6	0.91	−0.48	2.30
Phasic EDA (μS)	6	−0.00	−0.23	0.23
Pupil/iris (%)	8	0.94	−3.95	5.83

LoA = bias $\pm$ 1.96 $\times$ SD_{diff}.

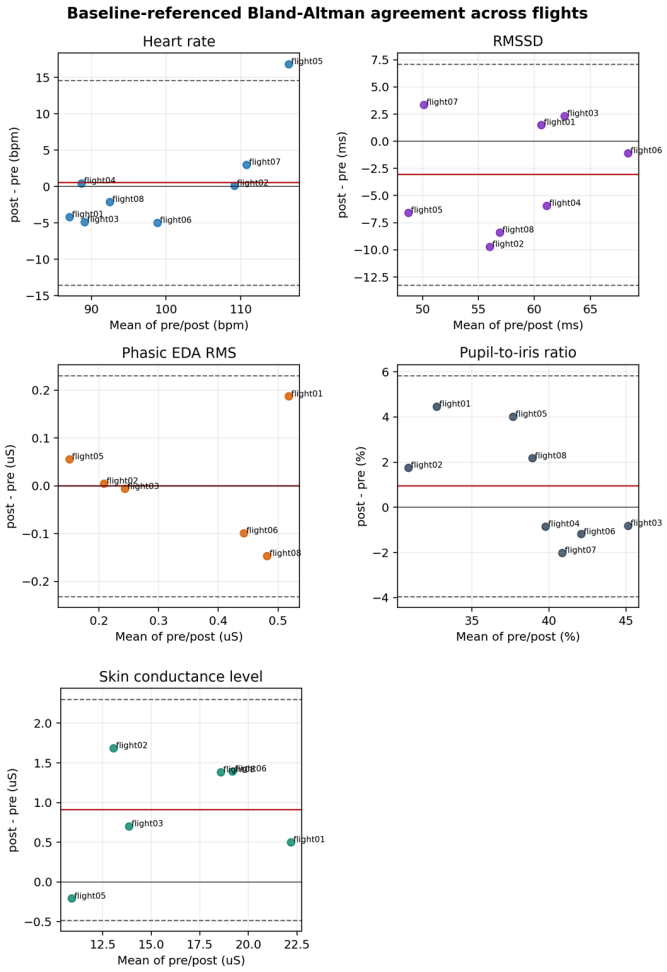

Fig. 3. Baseline-referenced Bland-Altman agreement for the primary physiological outcomes.

(rho=-0.81, exact p=0.022, pFDR=0.278; tau-b=-0.64), with similar trends for perceived performance difficulty (rho=-0.78) and cognitive demand (rho=-0.69). Electrodermal trends were directionally plausible but imprecise, with the strongest nominal EDA association observed between emotional response and SCL (rho = 0.75, n = 6). Correlations with physiological metrics are presented in Table IV. The strongest nominal trend for each flight, with RMSSD versus stimulus score, are presented in Fig. 4.

TABLE IV
SPEARMAN CORRELATIONS BETWEEN METRICS AND LIKERT FORMS

Metric	n	ρ	p-value	p_{FDR}	Kendall τ-B
Heart rate (bpm)	8	0.38	0.360	0.654	0.29
RMSSD (ms)	8	−0.81	0.022	0.278	−0.64
SCL (μS)	6	0.54	0.297	0.654	0.33
Phasic EDA (μS)	6	−0.26	0.658	0.823	−0.20
Pupil/iris (%)	8	0.14	0.752	0.836	0.00

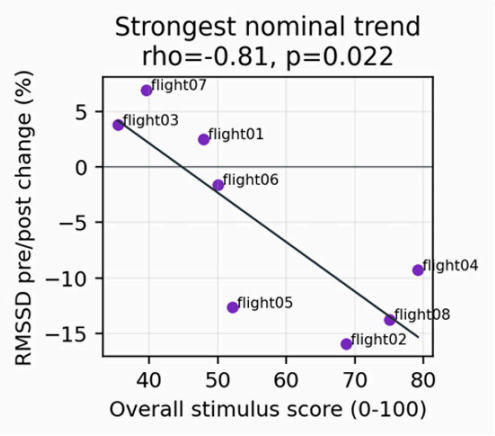

Fig. 4. Baseline-referenced scatter plot for RMSSD and Likert score.

V. DISCUSSION

A. General Validation

Quality control is still required before claiming standalone validation. The clearest support for the study hypotheses comes from the combination of directional plausibility and multimodal consistency rather than from a single overwhelmingly significant marker. Tonic EDA behaved most consistently with the expected autonomic activation, whereas HR, RMSSD, and pupil responses added complementary but more variable information. This pattern is physiologically credible for a simulator setting in which the landing task is repeated, partially anticipated, and not identical across trials. Similar physiological responses are expected to be observed in full-motion simulators or real flights in more challenging situations for experienced pilots.

The large between-flight spread is also scientifically informative: physiological response amplitude depends not only on the characteristics of each final approach, but also on pilot-specific regulation, strategy, familiarity across repetitions, and measurement conditions. The present findings are therefore better framed as evidence that the instrumentation can reveal meaningful physiological modulation than as proof of a single universal physiological signature.

The Likert scale findings suggest partial convergent validity rather than definitive concurrent validation. Flights perceived as more demanding tended to exhibit larger reductions in RMSSD, which is physiologically consistent with reduced vagal modulation under higher workload or stress. However, the estimates remained imprecise after correction for multiple

testing, and the retrospective questionnaire referred to the most difficult flight approach only. This scale mismatch probably attenuated the observed associations and should be resolved in future acquisitions by pairing each subjective rating with a single objectively defined landing event.

B. Instrumentation and Signal Quality

The BITalino platform demonstrated acceptable signal quality in the flight deck environment, without perceivable Bluetooth connection dropouts. Signal instabilities occurred during TGLs, attributed to electrode cable movement during pilots' motion when seeking the runway and alternating focus between panel and external view. Higher hand hidrosis and subsequent electrode detachment or signal saturation were observed during yoke input motion. Higher artifact rates during final approach and landing phases should be considered in future arrangements.

Pupillometry presented a challenge due to head movements around flight deck and the static camera frame limitation. Despite that, no illumination losses were observed due to stable ambient light. The absence of active gaze tracking meant that pupil size estimates could be confounded—a limitation addressable by integrating a wearable eye-tracking system (e.g., Tobii Glasses) in future work.

C. Limitations

The main limitations arise from data quality and synchronization. High RR correction fractions reduce confidence in short-window HRV [22], and electrodermal saturation in two flights shows that sensor range remains a practical bottleneck. Clock-based synchronization was sufficient for 30-second event windows, but would not support claims about sub-second onset latency.

Additional limitations include: *Sample size*—a larger, more experienced cohort would aid generalizability. *Single simulator model*—results may not generalize to other aircraft types or fidelity levels. *Retrospective Likert survey*—memory decay may affect ratings; in-sequence collection after each TGL is recommended. *No gold-standard comparison*—no clinical-grade ECG or laboratory-grade eye-tracker was used simultaneously. *Hand hidrosis*—EDA signal saturation or dropout from sweat accumulation on electrodes. *Pilot motion*—all biosignals are affected by cockpit movement, especially during runway sighting.

VI. Conclusion

This study provides the first systematic validation analysis of a combined BITalino ECG/EDA and fixed Daheng camera pupillometry setup in a commercial airliner flight simulator. The methodology established here—phase-aligned signal segmentation, Hampel-based ECG artifact correction, tonic/phasic EDA decomposition, normalized pupil-to-iris tracking, and ICC/Bland–Altman reliability analysis—provides a replicable framework for psychophysiological signals research in simulations, supporting the use of the described setup, with attention to the limitations identified, for within-pilot workload monitoring during approach and landing operations. The method cannot assure validation of operational fatigue or safety monitoring.

Future work should address: (1) replication in actual flight operations with lightweight, certified wearable devices; (2) integration of gaze tracking; (3) machine learning classification of workload states using the validated multimodal feature set; and (4) multi-session reliability across training events.

***Abstract*—Polysomnography is the reference method for assessing sleep bruxism, but it is costly and requires specialized facilities. This paper presents the development and experimental characterization of a low-cost instrumentation system for acquiring mechanical signals associated with temporomandibular joint (TMJ) activity using a piezoelectric disk as the primary transducer. The system includes an analog signal-conditioning circuit and digital filtering. Signals were acquired from volunteers performing controlled clenching and grinding sequences. Time-domain analysis showed differences in the waveforms associated with the evaluated events, while spectral analysis revealed differences in their frequency distributions. The results demonstrate the system's ability to acquire mechanical signals associated with controlled mandibular events under laboratory conditions. The proposed system has potential for integration into a future portable device for the assessment and monitoring of sleep bruxism. Clinical validation and overnight recordings were beyond the scope of this study.**

***Index Terms*—Sleep bruxism, piezoelectric sensor, biomedical instrumentation, signal conditioning, temporomandibular joint.**

I. Introduction

Sleep bruxism is the involuntary grinding or clenching of teeth during sleep, a condition that affects a significant portion of the population [1]. Prevalence estimates vary, ranging from 22% to 30% in adults, but in clinical observations with children and adolescents, the numbers have frequently exceeded 40%, consistent with previous epidemiological reports [2]. Patients are often unaware of the condition, since the episodes occur during sleep without causing arousal [3]. In practice, the clinical burden is not limited to tooth wear. Temporomandibular joint pain, morning headaches, and masseter muscle hypertrophy are frequently observed in patients referred to clinical services, often as secondary findings during routine dental or neurological examinations [1].

The gold standard for the definitive diagnosis of sleep bruxism is polysomnography, an examination that monitors multiple physiological variables during sleep, including electromyography of the masseter muscles, electroencephalography, electro-oculography, airflow, and oxygen saturation [4]. However, access to this examination within the public healthcare system is severely restricted. Access to polysomnography within the Brazilian public healthcare system is limited: only 50 sleep centers are accredited by the Brazilian Unified Health System (SUS), with 10 states lacking any mapped diagnostic facilities for sleep disorders [5].

Even when accessible, polysomnography presents technical limitations. Surface electromyography is sensitive to movement artifacts, incorrect electrode placement, and electrical noise from the environment. Studies have shown that configurations relying exclusively on electromyographic signals, without the simultaneous support of audio and video channels, are considered unreliable for the accurate scoring of sleep bruxism events [6].

The limitations of polysomnography and surface EMG motivated the investigation of an alternative transduction principle. Previous studies have compared piezoelectric and surface electromyography sensing approaches for physiological and muscle activity monitoring, highlighting differences in characteristics such as response time, durability, and reusability [12].

This paper details the development of a piezoelectric-based instrumentation system designed to prioritize portability, electrical robustness, and low component cost for the acquisition of mechanical signals associated with mandibular clenching and grinding events characteristic of bruxism.

II. Background Literature

A. Sleep Bruxism

In clinical practice, sleep bruxism manifests in two distinct patterns of mandibular activity [7]. Clenching consists of isometric contraction of the masticatory muscles without dental sliding. Grinding, in turn, involves isotonic movements with lateral or protrusive mandibular sliding. During grinding episodes, mandibular movements often exceed the canine edge-to-edge position, accompanied by elevated masseter muscle activity [8]. These movements account for the characteristic tooth wear and mechanical overload on the temporomandibular joint. Both clenching and grinding are mechanical events. They involve force application, temporomandibular joint deformation, and tissue vibration. The physical quantity directly associated with these events is mechanical deformation, not the preceding electrical activity measured by electromyography.

This distinction guides the choice of transduction principle for the acquisition of mechanical events associated with bruxism. Surface electromyography measures muscle activity indirectly through electrical potentials detected at the skin surface. The technique is sensitive to movement artifacts, electromagnetic interference, and contamination by electrical signals from other muscles or even from the electrocardiogram, whose rhythmic activity may overlap with the signal of interest in the thoracic and cervical regions. The piezoelectric sensor, in turn, responds directly to the mechanical deformation caused by both clenching and grinding. It captures the physical quantity of interest without the interferences that affect conventional electromyographic methods [9].

B. Piezoelectricity

Piezoelectric materials generate an electrical potential difference when mechanically deformed, a property first described by the Curie brothers in 1880 [10]. The same materials also deform when subjected to an electric field. This bidirectional conversion between mechanical and electrical energy makes them suitable for detecting forces, pressures, vibrations, and displacements.

Piezoelectric transducers are well suited for biomedical instrumentation, especially for surface applications. Their dynamic response allows direct transduction of mechanical vibrations without requiring external excitation simplifying the conditioning circuit and reducing power consumption. These transducers also exhibit low drift compared to resistive or capacitive alternatives, which is advantageous for long-term monitoring [9]. Piezoelectric materials range from natural crystals like quartz to ceramics such as PZT and polymers including PVDF. Polymer-based devices, such as PVDF, offer mechanical flexibility and compact form factors.

Each type presents different trade-offs in terms of sensitivity, flexibility, and cost, influencing its suitability for a given application [10]. Polymer-based transducers offer high sensitivity and a broad linear range, capable of detecting sub-Newton forces [9].

III. Methodology

This section describes the components and procedures adopted for the instrumentation of the mechanical signal acquisition system for the temporomandibular joint, covering from the piezoelectric transducer to analog conditioning, digitization, and digital filtering.

A. System Overview

The proposed system, named Morpheus, is illustrated in Fig. 1. The hardware acquisition unit is the focus of the present article, including the analog signal conditioning and data acquisition stages.

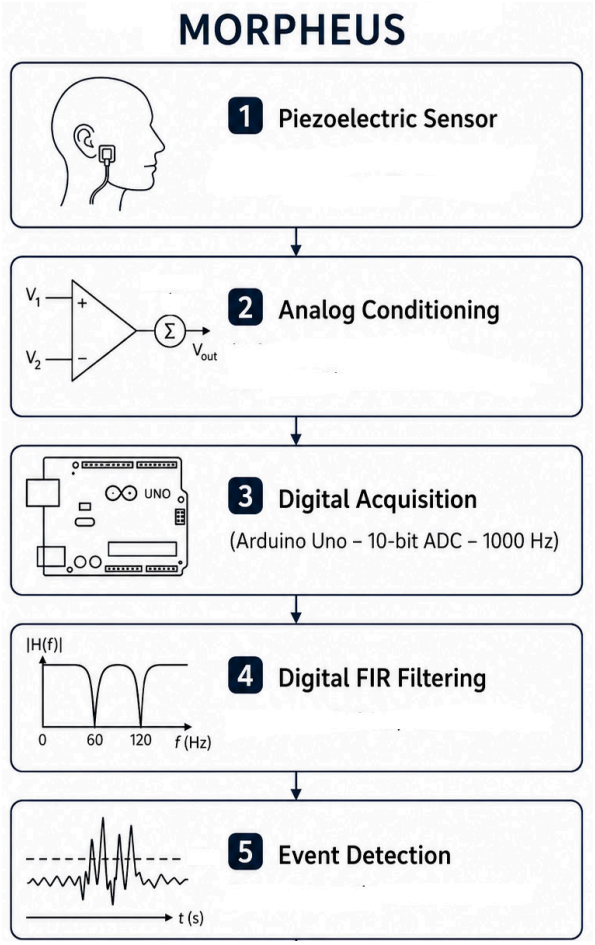

Fig. 1. Architecture of the instrumentation system.

B. Piezoelectric Transducer

The sensing element is a 27 mm piezoelectric disk with a brass substrate and ceramic coating, resonant at 4.5 kHz. Before placement, the transducer was wrapped with adhesive tape and then positioned over the temporomandibular joint, on the lateral region of the face, to capture mechanical deformations resulting from mandibular movements during clenching and grinding. The sensor output consists of millivolt-level signals with bipolar polarity. Since the microcontroller's analog-to-digital converter accepts a 0 to 5 V input range with 4.9 mV

resolution, a conditioning circuit was designed to shift and amplify the signal to the appropriate range.

C. Analog Conditioning Circuit

The conditioning circuit was designed in two stages: an initial amplifier and a summing amplifier with DC level shifting to offset the signal reference.

The mechanical deformation sensed by the piezoelectric transducer depends on the attachment method, including contact pressure, alignment, and fixation technique, which may affect the signal amplitude and morphology for the same mechanical event. To account for such variability, the conditioning circuit was designed to provide signal amplification, while the determination of the optimal gain and detection thresholds was left for a later stage.

The first stage of signal conditioning is presented in Fig. 2.

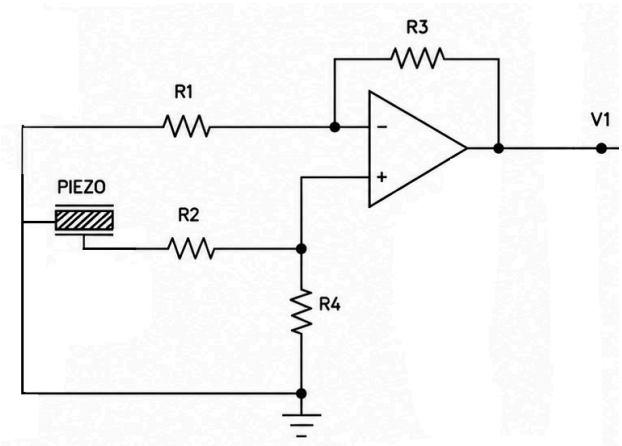

Fig. 2. Piezoelectric transducer amplifier configuration.

The potential difference generated by the piezoelectric sensor directly represents the relative mechanical deformation, making a single transducer sufficient for signal acquisition. Therefore, an additional input for establishing a signal reference is not required.

Applying Kirchhoff's current law at the amplifier input nodes yields the following relationship between the output voltage V_1 and the voltages at the sensor terminals V_{piezo}:

$$V_1 = \frac{R_4 \cdot (R_3 + R_1)}{R_1 \cdot (R_2 + R_4)} \cdot V_{piezo} \tag{1}$$

The second stage, presented in Fig. 3.

In addition to amplifying the signal, adds a DC voltage to the amplified signal, shifting its reference. Since the microcontroller's analog-to-digital converter operates in a range between 0 and 5 V, the added DC voltage must be 2.5 V, so that both positive and negative variations of the biological signal can be acquired by the microcontroller. The output equation of the summing amplifier is given by:

$$V_{out} = -\frac{R_f}{R5} \cdot V_1 - \frac{R_f}{R_6} \cdot V_2 \tag{2}$$

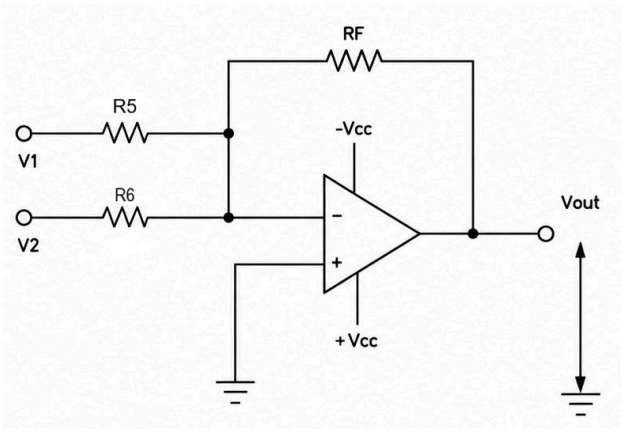

Fig. 3. Summing circuit for DC level shifting.

The signal from the initial amplifier is applied to one of the inputs of the inverting summing amplifier. Thus, the circuit output voltage can be obtained by combining the contribution of the amplified piezoelectric signal with the second input of the summing amplifier. Substituting the expression for V_1, given by Equation (1), into Equation (2), we obtain:

$$V_{out} = -\frac{R_f R_4 (R_3 + R_1)}{R_5 R_1 (R_2 + R_4)} V_{piezo} - \frac{R_f}{R_6} V_2 \tag{3}$$

Since V_2 is the DC voltage used to add a reference level to the conditioned signal, the ratio between resistors R_f and R_6 must be adjusted to $1/2$, so as to position the reference at the midpoint of the circuit's operating range. As the configuration used is an inverting summing amplifier, the contribution of V_2 undergoes polarity inversion at the output. Therefore, to produce a positive offset of $2.5\,\mathrm{V}$ at the output, the input V_2 is connected to a $-5\,\mathrm{V}$ reference.

Considering the condition

$$\frac{R_f}{R_6} = \frac{1}{2}, \tag{4}$$

Equation 3 can be rewritten as

$$V_{out} = -\frac{R_f R_4 (R_3 + R_1)}{R_5 R_1 (R_2 + R_4)} V_{piezo} - \frac{1}{2} V_2. \tag{5}$$

Since $V_2 = -5\,\mathrm{V}$, we obtain

$$V_{out} = -\frac{R_f R_4 (R_3 + R_1)}{R_5 R_1 (R_2 + R_4)} V_{piezo} + 2.5. \tag{6}$$

Therefore, the signal from the piezoelectric sensor is amplified and inverted, while a DC level of $2.5\,\mathrm{V}$ is added to the output, ensuring that the signal remains centered within the desired operating range.

D. Acquisition and Digitization

For digitization of the conditioned signal, the Arduino Uno microcontroller was used, which features the following relevant characteristics:

- 10-bit analog-to-digital converter (resolution of approximately 4.9 mV)
- 5 V reference voltage

As a starting point for selecting the resistors and sampling rate, information reported in the literature on electromyographic signals will be used. These signals exhibit amplitudes on the order of $10^{-3}\,\mathrm{V}$, reaching values close to $5\,\mathrm{mV}$, and frequencies between 5 and 500 Hz [12]. These parameters will be adjusted as the experimental analyses progress.

The digital value read by the ADC, V_r, is converted back to actual voltage and reference using the following expression:

$$V_p = -\left(V_r \cdot \frac{5}{1024} - 2.5\right) \tag{7}$$

E. Participants and Data Collection Protocol

Data were collected from four volunteers to evaluate the proposed signal acquisition and conditioning system. All participants and, where applicable, their legal guardians agreed to participate voluntarily in the data collection. For the minor participant, participation was authorized by the legal guardian, and the participant provided assent. P1 was a 23-year-old male who used an orthodontic appliance; P2 was a 17-year-old female without an orthodontic appliance; P3 was a 23-year-old male without an orthodontic appliance; and P4 was a 24-year-old female who used an orthodontic appliance.

The recordings were performed in a controlled environment. The participants were instructed to perform clenching, teeth grinding, and temporomandibular joint rest. Each event lasted approximately 1 to 3 s. A total of 210 clenching events and 210 grinding events were recorded. P1 contributed 60 events from each class, while P2, P3, and P4 contributed 50 events from each class. The recordings from P1 and P2 were used for training, and those from P3 and P4 were used for validation.

The data were collected on three different dates. The sensor was repositioned after every 10 acquisitions, resulting in repeated sensor placements during the recordings. This procedure introduced changes in the sensor position across the collected events while maintaining the same acquisition protocol. The signals obtained from the different recordings showed the main characteristics described in the subsequent time- and frequency-domain analyses.

IV. Results

This section presents and discusses the results obtained during the development of the proposed instrumentation system. The presentation follows the same sequence adopted in the methodology, beginning with the definition and implementation of the signal conditioning circuit, followed by frequency-domain analysis, evaluation of noise effects and filtering performance, time-domain analysis of the acquired signals, and finally the initial systematic statistical treatment of the data, including variability analyses and signal-to-noise ratio.

The results presented focus on demonstrating the functionality of the signal acquisition and conditioning hardware, with examples of the temporal and spectral signals obtained. Classification was not performed, since the scope of this study is the development and initial characterization of the circuit, which can be integrated into a new device for monitoring.

A. Conditioning Circuit

For the first stage, resistance values were experimentally selected to provide adequate gain without saturation, resulting in $R_1 = 50\,\Omega$, $R_2 = 50\,\Omega$, $R_3 = 100\,\Omega$, $R_4 = 200\,\Omega$. Thus, Equation (1) reduces to:

$$V_1 = 2.4 \cdot V_{piezo} \tag{8}$$

In the second stage, resistors R_2 and R_f were initially implemented using potentiometers for gain adjustment during bench tests. After calibration and validation tests, the final values of $R_5 = 1\,k\Omega$, $R_6 = 20\,k\Omega$, and $R_f = 10\,k\Omega$ were defined, with $V_1 = V_o$ and $V_2 = -5\,V$. The ratio $R_2/R_f = 2$ was maintained to ensure the application of an offset of approximately 2.5 V, while simultaneously providing the necessary amplification to fit the signal within the acquisition system's operating range.

Thus, combining Equations (8) and (2), the final equation of the conditioning circuit is obtained:

$$V_{out} = -24 \cdot V_{piezo} + 2.5 \tag{9}$$

The circuit was assembled on a breadboard, allowing the necessary adjustments and tests to ensure the correct operation of the signal conditioning system. After defining the components and testing the circuit, its implementation was transferred to the printed circuit board shown in Figure 4.

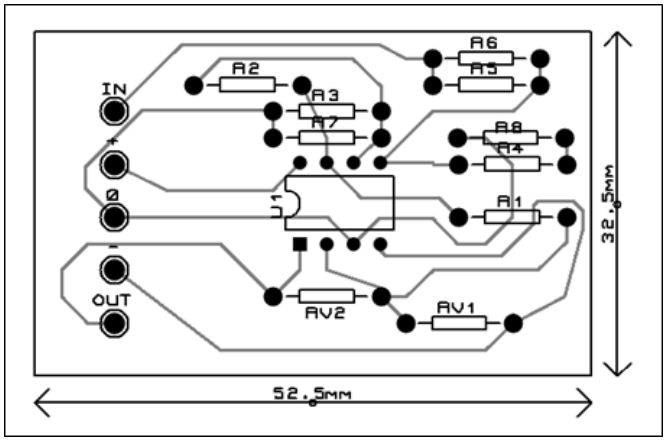

Fig. 4. Printed circuit board developed for the signal conditioning system.

The total gain of 24× was selected considering the 10-bit ADC resolution (approximately 4.9 mV per digital step) and the amplitude of the piezoelectric signals observed during the preliminary acquisitions. The 2.5 V DC offset allows the conditioned signal to vary around the midpoint of the ADC input range, providing an effective signal range of approximately ± 2.5 V around the reference level. The gain was therefore selected to increase the amplitude of the acquired signals while keeping the conditioned output within the 0–5 V ADC range.

B. Frequency-Domain Analysis

After data collection using the using a bench symmetrical power supply, spectral analysis of the signals corresponding to clenching and grinding movements was performed. For this purpose, the normalized Fast Fourier Transform (FFT) was applied to the acquired signals.

Figure 5 presents the normalized spectra of both movements. Clenching events concentrate most of their spectral energy below 20 Hz. Grinding events show a broader spectral distribution with a pronounced peak near 35 Hz.

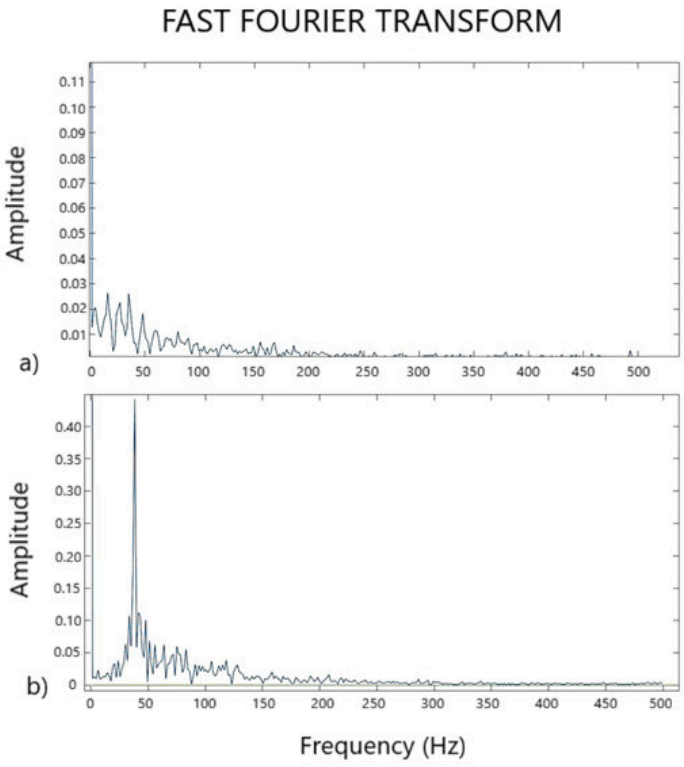

Fig. 5. Normalized spectra of clenching and grinding events obtained with a bench symmetrical power supply.

During the development of the portable version of the device, the circuit power supply was replaced by a symmetrical supply built from cell phone chargers. Although this solution allowed for greater system portability, the presence of interferences that hindered visual analysis of the acquired signals was observed.

To investigate this behavior, the frequency spectra of the same clenching event were compared using two power supply configurations: a bench symmetrical power supply (Figure 6) and a power supply based on cell phone chargers (Figure 7).

When comparing the spectra, the emergence of additional components near 60 Hz and 120 Hz is observed when using the portable power supply. Since the analysis of the characteristic movements indicated that most of the useful signal information lies below 45 Hz. These components are attributed to power supply noise.

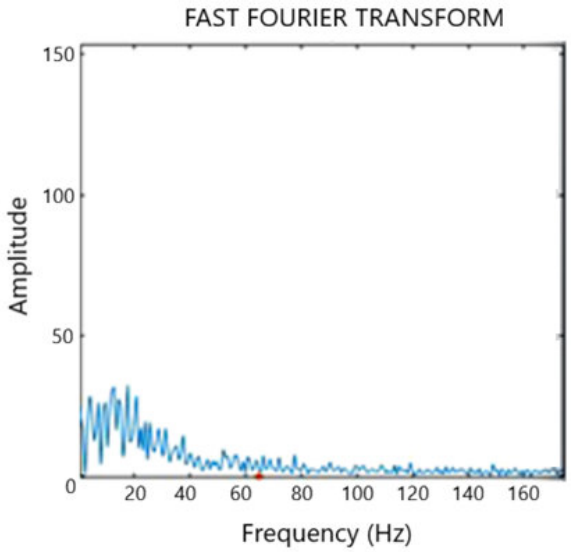

Fig. 6. Frequency spectrum of the clenching event using a bench symmetrical power supply.

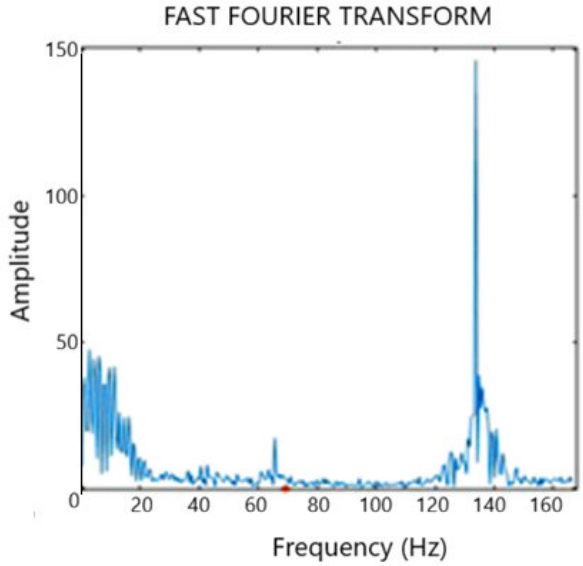

Fig. 7. Frequency spectrum of the clenching event using a power supply based on cell phone chargers.

A digital FIR low-pass filter was implemented to attenuate the noise components while preserving the movement-related frequencies. The filter was designed in MATLAB software using the designfilt() function, with a passband frequency of 50 Hz, stopband frequency of 57 Hz, maximum passband ripple of 1 dB, and minimum stopband attenuation of 60 dB.

After defining the parameters, the FIR filter coefficients were obtained, whose impulse response is shown in Figure 8. The obtained coefficients were then employed in digital signal filtering through the convolution operation.

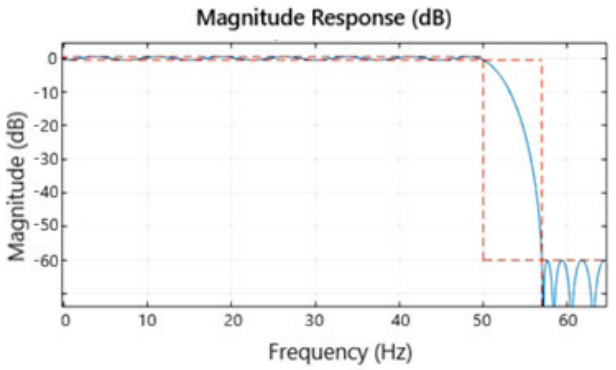

Fig. 8. Impulse response of the designed FIR filter.

C. Time-Domain Signal Analysis

Figure 9 presents a typical clenching event recorded by the system. A temporal pattern characterized by a negative amplitude rise associated with mandibular closure and a positive peak associated with relaxation of the masticatory musculature is observed. The noisy signal between these two moments is the vibration during tooth clenching.

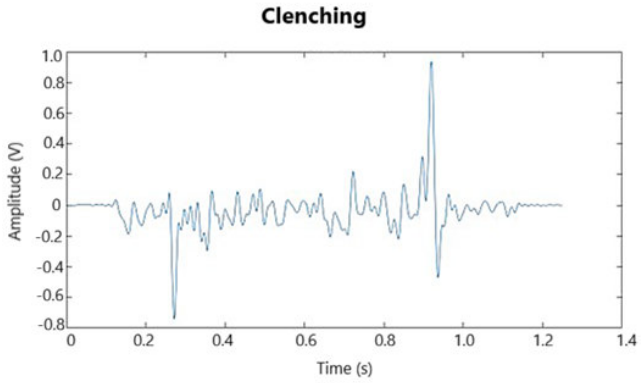

Fig. 9. Temporal signal corresponding to a clenching event.

Figure 10 presents a grinding event. Multiple successive oscillations appear, associated with lateral mandibular sliding.

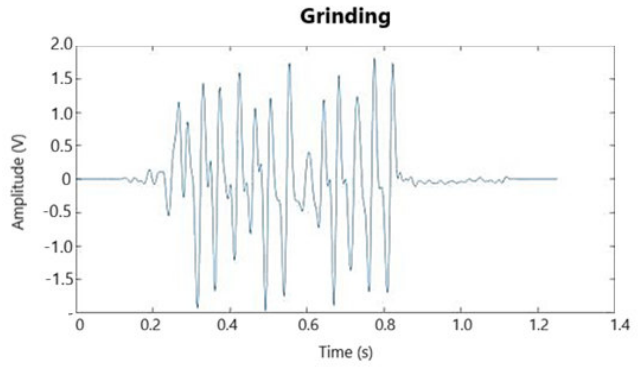

Fig. 10. Temporal signal corresponding to a grinding event.

This pattern differs from clenching due to the continuous displacement involved in grinding, rather than a single closing-opening cycle. Using the same dataset, previous work [11] reported that these signal features enabled automatic classification by neural networks.

D. Signal Quality and Variability

To quantitatively characterize signal quality, the signal-to-noise ratio (SNR) was calculated for each acquisition after DC-offset removal, using a 100-sample noise reference. The reference noise presented an RMS value of 0.0424.

Grinding events presented an SNR of 27.03 $\pm$ 2.75 dB and a CV of 10.16%. Clenching events presented an SNR of 12.97 $\pm$ 7.29 dB and a CV of 56.18%. Thus, grinding signals exhibited higher SNR and lower variability than clenching signals.

The greater variability observed for clenching may be related to differences in event intensity, sensor coupling conditions (e.g., contact pressure, positioning, and attachment), and the intrinsic characteristics of the clenching signal. Unlike grinding, which presents a more continuous oscillatory pattern, clenching signals may contain low-amplitude mechanical components in addition to the main compression and relaxation phases highlighted in Fig. 9, contributing to greater amplitude variability across acquisitions.

E. Cost Estimate

An estimate of the component-level hardware cost for a single bench prototype was performed based on retail prices from national suppliers in the first half of 2026. The 27 mm piezoelectric disk costs between R$ 0.79 and R$ 3.00; the LM358 operational amplifier costs between R$ 1.11 and R$ 2.20; and the Arduino Uno R3 development board costs approximately R$ 120.00. Including the printed circuit board, resistors, connectors, and power supply, the estimated bill of materials (BOM) for the laboratory prototype is approximately R$ 150.00 per unit [13]–[15].

For context, this value represents less than 2% of the retail price of a portable polysomnography system available on the Brazilian market, which costs R$ 14,700.00 [16]. Although this direct price comparison does not account for regulatory certification, large-scale manufacturing overhead, or the additional physiological sensors present in a full PSG (EEG, ECG, EMG, airflow, oximetry), it suggests that the proposed piezoelectric front-end could potentially be integrated into a low-cost, dedicated bruxism screening device at a fraction of the cost of multi-parameter PSG systems.

V. Conclusion

This paper described the design and benchtop characterization of a piezoelectric instrumentation system for TMJ signal acquisition. The conditioning system and digital filter captured signals with distinct features for clenching and grinding events under controlled conditions. The results validated the device's functionality under controlled laboratory conditions.

Although the piezoelectric sensor employed has characteristics that may offer practical advantages over surface electromyography, such as a simpler signal conditioning circuit and the use of a single sensing element, no direct experimental comparison between the two approaches was performed in this study. The results indicate that the piezoelectric approach can acquire and characterize mechanical events associated with clenching and grinding, supporting further investigation of its use in bruxism related monitoring applications.

The clinical validation, including comparison with polysomnography, is beyond the scope of this work, which focuses on hardware development and initial characterization. Future studies with larger samples and in real sleep environments are required to establish the sensitivity, specificity, and diagnostic accuracy of the system. The estimated hardware production cost aligns with the primary objective of developing a low-cost platform. The software cost will be estimated.

The current results are constrained by limitations that will be addressed in future work. The sample size precludes statistical generalization. Data were collected in a laboratory setting with participants awake; performance during sleep, including the effects of head movement and pillow contact, remains unevaluated.

Future work should prioritize:

A systematic metrological characterization of the acquisition system using a calibrated mechanical reference, including calibration and quantification linearity, and frequency response;

- A battery-powered, wireless revision to reduce conducted noise and improve wearability;
- A controlled evaluation of sensor attachment methods and geometries to assess their impact on signal consistency across different facial anatomies;
- Expanded data collection involving a larger number of participants and overnight recordings to evaluate the behavior of the acquired signals under natural sleep conditions;
- A clinical study with simultaneous PSG, surface EMG of the masseter muscle, and sensor recordings to compare the acquired mechanical signals with clinically scored sleep bruxism events. Such a study would provide the basis for subsequent evaluation of diagnostic performance using sensitivity, specificity, and ROC analysis.

***Abstract*—Non-contact capacitive sensing (NCC) has emerged as a promising approach for unobtrusive human movement monitoring in healthcare and healthcare-related contexts. Unlike contact-based sensors, NCC technologies can detect movement, proximity, posture, gesture, gait, physiological signals, and body-related activity without requiring direct skin contact, which may improve comfort and support remote or continuous monitoring. This scoping review organized the literature on NCC technologies applied to human movement monitoring. A total of 452 records were imported from six scientific databases, and 72 qualified studies were included after screening and eligibility assessment. The studies were analyzed according to application domain, sensing configuration, data acquisition strategy, signal processing method, artificial intelligence and machine learning approaches, reported advantages, limitations, and open research questions.**

***Index Terms*—non-contact capacitive sensing, scoping review, human movement monitoring, healthcare, biomedical engineering, signal processing, machine learning, Parkinson's disease.**

I. Introduction

Over the past two decades, sensing technologies have become increasingly present in devices attached to, worn on, or placed near the human body. In particular, wearable, flexible, and stretchable sensors have been explored for human activity recognition, body signal monitoring, and health-related applications. In this context, capacitive sensors have received growing attention because they may offer low power consumption, fast response time, simple structure, great linearity, and the possibility of integration into wearable and unobtrusive systems [1].

Movement sensing plays an integral role in several aspects of daily life, spanning from academic research to healthcare institutions. Its applications range from monitoring periodic physical activities and human activity recognition to aiding in rehabilitation, clinical assessment, and long-term follow-up of patients. Particularly within the realm of health technology, movement sensing serves as a valuable technique for understanding human movement and its implications across diverse applications, including motor assessment, gait analysis, gesture recognition, and patient monitoring [2], [3].

In recent years, the rapid advancement of diagnostic, prognostic, assistive, and human-machine interaction technologies has emphasized the need for sensors capable of accurately detecting human movement in a comfortable and reliable way. This need is evident in both industrial and academic contexts, fueling demand for precise, low-cost, scalable, and non-contact sensing technologies. Consequently, there has been a growing interest in alternatives to traditional inertial and contact-based sensing methods, such as capacitive and electric field sensing, which constitute the primary focus of this study [3].

A non-contact capacitive (NCC) sensor belongs to a category of capacitive or electric potential sensing technologies capable of remotely detecting disturbances in electric fields surrounding the sensor when affected by nearby bodies, ob-

jects, or body segments. These technologies can detect changes associated with proximity, displacement, posture, gesture, and motion without requiring direct skin contact [2], [3]. NCCs have been explored across various domains, including human movement recognition, gesture recognition, physiological monitoring, gait analysis, activity recognition, and patient monitoring [3]–[5].

Specifically focusing on motion and gesture recognition, several sensor technologies have been employed to track position, displacement, or movement patterns over time. Inertial sensors, for example, are extensively used in wearable devices and research applications. However, unlike inertial sensors, which include accelerometers and gyroscopes, NCC sensors do not require direct physical contact with the body to operate. This characteristic may improve comfort, reduce preparation time, avoid skin irritation, and enable unobtrusive monitoring, especially in healthcare applications involving older adults, patients with sensitive skin, or individuals with motor disorders [6], [7].

Despite these advantages, NCC systems still face important technical and methodological challenges. Their performance can be affected by environmental noise, proximity to the target, low coupling capacitance, interference from nearby objects, motion artifacts, and variations in body position. These limitations highlight the need for robust signal processing strategies, noise reduction methods, and systematic benchmarking against established technologies such as inertial sensors, gyroscopes, optical motion capture systems, camera-based systems, and clinical assessment scales [5], [6].

Related works have addressed specific NCC applications in Parkinson's disease, hand motor task assessment, postural tremor analysis, human motion recognition, physiological monitoring, and the physical and material aspects of capacitive sensor design [6], [7]. However, the literature remains heterogeneous regarding sensor architecture, acquisition settings, target applications, comparison methods, performance metrics, and the use of artificial intelligence and machine learning for signal processing. Although AI and machine learning approaches have been increasingly applied to capacitive and electric field sensing data, their effectiveness varies according to the task, dataset, feature extraction procedure, and validation strategy [3].

This study was structured as a scoping review of the literature. This approach is appropriate for organizing a broad and heterogeneous research field, identifying trends, classifying evidence, and highlighting methodological and technological gaps. In this scoping review, 452 records were imported from ACM Digital Library, IEEE Digital Library, ISI Web of Science, ScienceDirect, Scopus, and Springer Link.

This scoping review provides a comprehensive examination of non-contact capacitive sensing and its application to human movement monitoring in healthcare and healthcare-related contexts. It investigates sensor systems, target applications, signal processing techniques, artificial intelligence and machine learning approaches, advantages, limitations, validation strategies, and open research questions. By expanding the number of analyzed studies and organizing the evidence through an analytical taxonomy, this work aims to support future research on NCC-based systems for rehabilitation, gait analysis, tremor assessment, fall detection, remote patient care, and diseases that affect movement, such as Parkinson's disease.

II. Materials and Methods

This study was conducted as a scoping review of the literature on non-contact capacitive sensing technologies applied to human movement monitoring in healthcare and healthcare-related contexts. The review process was guided by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews (PRISMA-ScR) [9]. The scoping review approach was adopted because the literature in this field is heterogeneous in terms of sensor architecture, acquisition protocol, target application, signal processing strategy, validation method, and performance metrics.

The review was guided by the following research questions: RQ1) What healthcare and healthcare-related applications have employed non-contact capacitive sensing for human movement monitoring? RQ2) Which sensing configurations and data acquisition strategies have been proposed? RQ3) Which signal processing techniques have been adopted? RQ4) Which artificial intelligence or machine learning approaches have been used? RQ5) What advantages, limitations, and open research questions remain in this field?

The scope of the review was structured according to the Population–Concept–Context (PCC) framework. The population comprised human subjects and human movement monitoring systems. The concept was non-contact capacitive sensing, including capacitive proximity, electric field, and electrostatic sensing approaches. The context included healthcare and healthcare-related applications, such as rehabilitation, motor assessment, physiological monitoring, assistive technologies, and human movement analysis.

The methodological workflow comprised four main stages: planning, database search, screening and eligibility assessment, and data extraction and synthesis. Differently from a conventional systematic review focused on estimating a pooled effect, this scoping review aimed to identify, classify, and analyze the main technological and methodological trends related to non-contact capacitive sensing for movement monitoring.

The selection process was conducted in sequential stages, including duplicate removal, title and abstract screening, eligibility assessment, and final inclusion. The records were organized in a spreadsheet and screened according to the inclusion and exclusion criteria. Five reviewers participated in the title and abstract screening stage, and two to three reviewers assessed the studies selected for full-text reading and eligibility confirmation. Disagreements or uncertain cases were resolved through discussion among the authors, considering the relevance of each study to non-contact capacitive sensing and human movement monitoring.

Figure 1 presents the PRISMA-ScR flow diagram of the identification, screening, eligibility, and inclusion process adopted in this scoping review.

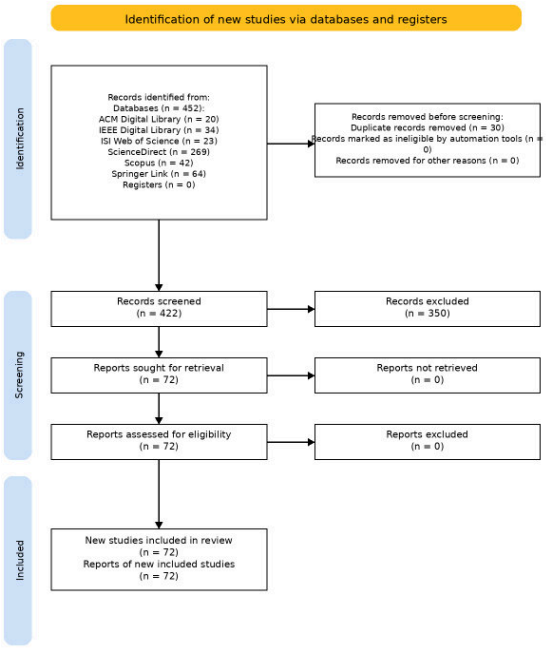

Fig. 1. PRISMA-ScR flow diagram of the identification, screening, eligibility, and inclusion process adopted in this scoping review.

A. Search Methods

The search strategy was developed based on terms commonly used in the literature on capacitive sensors, capacitive proximity sensing, electric potential sensing, electrostatic sensing, and human movement monitoring [1]–[3]. Searches were conducted in six scientific databases: ACM Digital Library, IEEE Digital Library, ISI Web of Science, ScienceDirect, Scopus, and Springer Link. The records were imported into Parsifal on November 14, 2025.

The search terms combined expressions related to the sensing technology and the target application. The general search strategy included the following terms: “capacitive”, “sensor”, “sensing”, “non-contact”, “non contact”, “noncontact”, “motion”, “movement”, “gesture”, “gait”, “human activity”, “rehabilitation”, and “healthcare”. Boolean operators and database-specific filters were adapted according to the search resources available in each database, as summarized in Table I.

A total of 452 records were imported from the selected databases. Titles and abstracts were screened to verify whether each study was related to non-contact capacitive sensing, electric field sensing, capacitive proximity sensing, or closely related approaches applied to movement detection, activity recognition, gesture recognition, gait analysis, physiological monitoring, rehabilitation, or healthcare-related monitoring. After duplicate removal, screening, and eligibility assessment, 72 qualified studies were included in the final review.

TABLE I
DETAILED SEARCH STRATEGY

Database Source	**Search Details**		
	Records[a]	***Specific Filters***	***Search Strategy***
ACM Digital Library	20	Conference and journal papers; English language	capacitive sensing AND movement OR gesture OR human activity
IEEE Digital Library	34	Conference and journal papers; English language	capacitive sensor OR capacitive sensing AND non-contact OR noncontact AND motion OR gait OR gesture
ISI Web of Science	23	Article and proceedings paper; English language	capacitive sensing AND non-contact OR noncontact AND movement OR healthcare
Science Direct	269	Research articles; English language	capacitive sensor OR capacitive sensing AND motion OR movement OR rehabilitation OR healthcare
Scopus	42	Title, abstract, and keywords; article and conference paper; English language	capacitive AND sensor OR sensing AND non-contact OR non-contact AND motion OR gesture
Springer Link	64	Conference paper, book chapter, and article; English language	capacitive sensing AND non-contact OR noncontact AND motion OR movement OR healthcare

[a]Total imported records: 452.

B. Eligibility Criteria

Studies were included when they met all the following criteria: (i) addressed non-contact capacitive sensing, capacitive proximity sensing, electric potential sensing, electrostatic sensing, or closely related capacitive approaches; (ii) involved movement detection, gesture recognition, gait analysis, activity recognition, physiological monitoring, rehabilitation, or healthcare-related monitoring; (iii) were published as full papers in journals, conference proceedings, or book chapters; and (iv) were written in English.

Studies were excluded when they were unrelated to capacitive or electric field sensing, focused exclusively on conventional contact-based sensors without relevance to non-contact capacitive approaches, were abstracts, editorials, posters, protocols, or incomplete records, were duplicates, or did not provide sufficient methodological information for analysis.

C. Data Extraction and Analysis

Data extraction was conducted using a standardized protocol adapted from the previous version of the review and refined to support a scoping review perspective. For each included study, information was collected regarding bibliographic data, sensor type, sensing principle, application domain, target movement or physiological variable, acquisition setup, population or experimental object, number of participants when reported, reference system, validation strategy, validation across individuals, acquisition environment, signal processing methods,

artificial intelligence or machine learning approaches, advantages, limitations, and open research questions.

To characterize the level of experimental and clinical evidence, the extraction also considered whether studies reported sample size, acquisition environment, reference system, validation across individuals, and population type. This assessment was used descriptively and was not applied as an exclusion criterion.

The extraction process resulted in a consolidated spreadsheet used to organize and compare the selected studies. The extracted variables were defined to capture the diversity of the field, including studies on hand movement detection [4], physiological signal monitoring [5], Parkinson-related motor assessment [6], [7], locomotion and gait analysis [10]–[14], hand gesture recognition with machine learning [15], [16], and textile-based capacitive sensing for pose tracking [17].

D. Data Synthesis and Analytical Taxonomy

The included studies were synthesized through descriptive and analytical mapping. The analysis did not aim to calculate a pooled effect size, but to classify the evidence and identify research trends, methodological patterns, and open challenges. The studies were grouped according to their main application domains, including gesture recognition, gait and locomotion analysis, physiological monitoring, Parkinson-related assessment, activity recognition, and wearable or textile sensing.

An analytical taxonomy was defined to organize the evidence according to: (i) sensor type and sensing configuration; (ii) application context; (iii) target movement or physiological variable; (iv) data acquisition setup; (v) signal processing strategy; (vi) artificial intelligence or machine learning method; (vii) validation protocol; and (viii) reported advantages, limitations, and research opportunities.

III. Results and Discussion

The scoping review resulted in the organization of the selected literature according to application domain, sensing configuration, data acquisition strategy, processing method, use of artificial intelligence or machine learning, reported advantages, limitations, and open research questions. A total of 72 qualified studies were included in the final review. Tables II and III present a condensed synthesis of selected representative studies. The corresponding supplementary extraction matrix, including sample size, population, acquisition environment, reference systems, validation strategies, cross-subject validation, AI/ML methods, limitations, and descriptive evidence level, is openly available on Zenodo [29]. Although the final review included 72 qualified studies, the complete extraction matrix is not reproduced in the article due to space limitations. The full set of studies was used to define the application domains discussed in this section, while the tables highlight studies with sufficient methodological detail to support comparative synthesis. The complete extraction matrix was also used to support the descriptive synthesis of sample size, reference systems, validation strategies, validation across individuals, and acquisition environments when reported.

A. Overview of the Included Studies

The analyzed studies show that non-contact capacitive sensing is not restricted to a single type of movement monitoring application. Instead, the technology has been explored across different domains, including Parkinson's disease assessment, gait and locomotion analysis, gesture recognition, human-computer interaction, textile-based monitoring, eye and facial movement tracking, physiological monitoring, and indoor presence detection.

B. Emerging Application Domains

The first domain involves Parkinson's disease and motor assessment, where NCC systems were used to detect hand movements, assess hand motor tasks, and analyze postural tremor [4], [6], [7]. In the mapped literature, the studies identified for Parkinson-related movement assessment using NCC are concentrated in works associated with GPCA/IFB and NIATS/UFU. This concentration emphasizes both the innovative character of the technology in this clinical context and the need for broader validation by other research groups, with larger samples, standardized protocols, and comparison with clinical reference measures.

Figure 2 illustrates the relevance of NCC systems for Parkinson-related hand motor assessment.

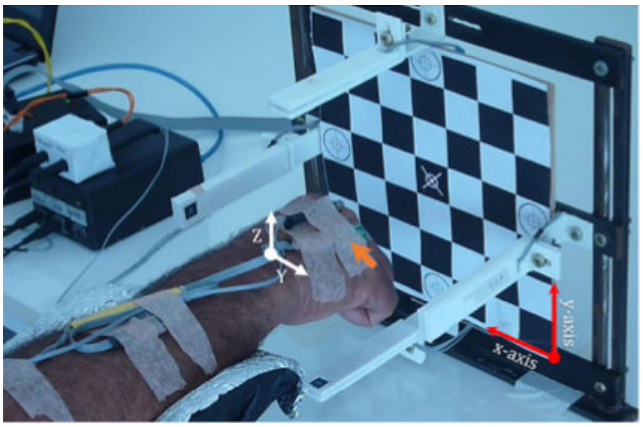

Fig. 2. Example of a non-contact capacitive sensing setup for hand motor assessment in Parkinson-related applications. The system illustrates the use of NCC sensors for detecting hand and wrist movements without direct skin contact. Adapted from [6].

The second domain includes gait, locomotion, and assistive devices. In this group, capacitive sensing was applied to locomotion mode recognition, gait phase detection, gait phase estimation, and temporal gait parameter estimation [10]–[14].

The third domain comprises gesture recognition and human-computer interaction. Studies in this category explored capacitive sensor arrays, textile capacitive sensors, distance-informed features, and machine learning classifiers to recognize hand gestures and support interaction with digital systems [15], [16], [24], [27], [28].

The fourth domain is related to wearable and textile-based body monitoring. Textile capacitive sensing was used

for upper-body pose tracking and body-integrated breathing monitoring [17], [19].

The fifth domain includes eye, blink, and facial movement monitoring. In this group, flexible electrostatic interfaces, capacitive skin glass, and carbon nanotube-paper composites were used for eye tracking, eye expression decoding, wearable eye movement monitoring, and blink detection [18], [20], [21].

The sixth domain includes physiological monitoring and indoor presence detection. Studies in this group used electric potential sensors, displacement current sensors, capacitively coupled electrode arrays, low-noise amplifiers, and OpenCapSense-based systems for ECG, respiration, EEG, EMG, bio-activity detection, in-bed ECG monitoring, and indoor presence detection [5], [22], [23], [25], [26].

C. Data Acquisition and Processing Strategies

The acquisition setups varied substantially among the included studies. Some systems used custom capacitive sensors and analog front-end circuits, while others used commercially available capacitive-to-digital converters, flexible electrodes, textile electrodes, printed sensors, or integrated amplifiers. Sampling frequencies also varied according to the application, ranging from low-frequency monitoring in wearable and indoor sensing systems to higher sampling rates in motor assessment, gait analysis, and physiological signal acquisition.

This heterogeneity limits direct performance comparison across studies, since sensor configurations, acquisition protocols, populations, reference systems, processing methods, and reported metrics vary substantially among application domains.

The most common data processing strategies included filtering, moving average smoothing, signal envelope extraction, nonlinear detrending, feature extraction, threshold-based detection, frequency-domain analysis, and classification. In studies involving gait and locomotion, sliding windows and feature-based classifiers were frequently used [10]–[12]. In studies involving tremor and motor assessment, methods such as moving average filtering, nonlinear detrending, empirical mode decomposition, and Hilbert spectrum analysis were used to characterize signal behavior [6], [7]. In physiological monitoring, filtering, amplification, signal conditioning, and waveform extraction were essential due to the weak coupling between the body and the sensing electrode [5], [25], [26].

D. Use of Artificial Intelligence and Machine Learning

Artificial intelligence and machine learning were not uniformly adopted across the included studies. Several papers did not report AI or machine learning methods, especially those focused on hardware design, sensing principles, or signal acquisition. However, when AI/ML was used, it played an important role in classification, feature interpretation, personalization, and movement recognition.

Machine learning methods identified in the analyzed papers included QDA, LDA, GMM, ECOC-SVM, KNN, SVM classifiers, decision trees, deep neural networks, LSTM models, explainable AI approaches, and personalized classifiers [10]–[12], [15]–[17], [21], [22], [24], [27]. Gesture recognition studies were the most strongly associated with AI/ML, especially because gesture patterns depend on user behavior, sensor placement, and signal variability. Gait and locomotion studies also used classifiers to distinguish locomotion modes and gait phases, indicating the relevance of machine learning for assistive devices and rehabilitation technologies.

Despite these advances, the review indicates that many studies still rely on small datasets, controlled experiments, or subject-specific calibration. Therefore, open questions remain regarding model generalization, cross-user validation, explainability, real-time performance, and the availability of standardized datasets for NCC-based movement monitoring.

E. Limitations of the Review

This scoping review has some limitations. The search was restricted to six scientific databases and to studies written in English. Grey literature, patents, theses, and technical reports were not included. In addition, no formal critical appraisal of methodological quality was conducted, since the objective was to map applications, methods, and research gaps rather than estimate intervention effects. Finally, the synthesis tables present selected representative studies rather than the complete set of 72 included papers, due to space restrictions in the conference format.

IV. Conclusion

This scoping review organized the literature on non-contact capacitive sensing for human movement monitoring in healthcare and healthcare-related contexts. From 452 imported records, 72 qualified studies were included and analyzed according to application domain, sensing configuration, data acquisition strategy, signal processing method, use of artificial intelligence or machine learning, reported advantages, limitations, and open research questions. The results show that NCC technologies are applied across multiple domains, including Parkinson's disease assessment, gait and locomotion analysis, gesture recognition, human-computer interaction, textile-based monitoring, eye and facial movement tracking, physiological monitoring, and indoor presence detection. Across the analyzed studies, signal processing and artificial intelligence appear as central components for extracting movement-related information from capacitive signals, especially through filtering, signal envelope extraction, feature extraction, frequency-domain analysis, and classification methods.

The review also revealed that research on Parkinson's disease assessment using non-contact capacitive sensing is currently concentrated within a limited number of studies associated with GPCA/IFB and NIATS/UFU, emphasizing both the novelty of this application and the need for broader validation by the scientific community. Despite the potential of NCC technologies for accessible, comfortable, and scalable monitoring, the field still faces challenges related to environmental noise, body position, sensor distance, low coupling capacitance, motion artifacts, electrode placement,

limited benchmarking, and reduced validation in real healthcare environments. Future research should focus on standardized acquisition protocols, larger and more diverse datasets, comparison with reference systems, interpretable machine learning, and long-term usability studies for rehabilitation, remote monitoring, and assistive healthcare systems.

***Abstract*—Conventional thermal therapy monitoring often relies on high-cost modalities like MRI or is limited to 2D ultrasound planes, which may overlook critical off-plane hotspots. This work presents the implementation of an automated theranostic platform designed for 3D volumetric hyperthermia monitoring. The system integrates an open-architecture ultrasound scanner (ArtUs EXT-1H) with a custom-built mechanical scanning module and a 927 kHz high-intensity focused ultrasound (HIFU) transducer. By applying the Thermal Strain Imaging (TSI) method and the Lucas-Kanade optical flow algorithm to raw radiofrequency (RF) data, the platform reconstructed the induced thermal field across a 1.62° angular sweep on a paraffin-gel phantom. Experimental results demonstrated a localized heating pattern consistent with the focal geometry, reaching a maximum temperature of 41.6 °C. The volumetric mapping allowed for the visualization of discrete thermal slices, providing a new path to analyze a discret thermal map volume. This establishes a robust framework for non-invasive therapeutic monitoring in public health settings.**

Keywords—3D Ultrasound, HIFU, Hyperthermia, Volumetric Reconstruction, Thermal Strain Imaging, Theranostics.

I. INTRODUÇÃO

O agravamento global na incidência do câncer consolidou a doença como um dos principais desafios de saúde pública contemporânea [1], [2]. Projeções do Global Cancer Observatory (GCO) indicam um incremento nos diagnósticos de 60,2% em homens e 48,5% em mulheres até 2045 [3]. No cenário brasileiro, o INCA estima a ocorrência de aproximadamente 781 mil novos casos anuais para o triênio 2026-2028, sendo o câncer de mama a neoplasia mais frequente na população feminina (excluindo o de pele não melanoma) [4], [5], com previsão de alta de 40% na mortalidade específica até 2050 [6]. A gravidade deste quadro é acentuada em regiões de menor renda, onde disparidades de infraestrutura fazem com que cerca de 40% das detecções ocorram em estágios avançados, reduzindo drasticamente as chances de sobrevida relativa [7], [8].

Detectado o câncer, o protocolo clínico convencional envolve etapas que variam de biópsias a tratamentos agressivos como cirurgia e quimioterapia [9]. Como uma alternativa minimamente invasiva, a terapia por hipertermia utiliza o Ultrassom Focalizado de Alta Intensidade (HIFU) para elevar a temperatura do tecido alvo a aproximadamente 43 °C, sensibilizando as células tumorais e potencializando a eficácia de tratamentos adjacentes [10]. A tecnologia HIFU permite a destruição tumoral precisa com preservação de tecidos sadios, tornando o pós-operatório menos complexo [11], [12]. No entanto, a segurança e a eficácia desta modalidade dependem estritamente da deposição correta da dose térmica no volume planejado [12].

Atualmente, o monitoramento térmico padrão-ouro baseia-se na Ressonância Magnética (MRI), cujo alto custo e complexidade de infraestrutura limitam sua adoção, especialmente em países de média e baixa renda [13]. A termometria baseada em ultrassom via Imagem de Deformação Térmica (Thermal Strain Imaging - TSI) surge como uma alternativa acessível e não invasiva [14]. Entretanto, o monitoramento por ultrassom convencional é majoritariamente restrito a planos bidimensionais (2D). Essa limitação impede a captura da distribuição espacial total do calor, podendo ignorar pontos de aquecimento (hot spots) situados fora do plano de imagem, o que compromete a avaliação precisa dos mapas térmicos [15].

Visando superar essa lacuna, o Grupo de Inovação em Instrumentação Médica e Ultrassom (GIIMUS) tem atuado no desenvolvimento de scanners automatizados para reconstrução 3D [16], [17]. O presente trabalho apresenta a transição tecnológica dessas plataformas para uma

configuração dedicada à hipertermia volumétrica. O sistema proposto integra o tratamento por HIFU à reconstrução tridimensional de mapas térmicos a partir de varreduras angulares automatizadas. Esta abordagem visa avaliar a viabilidade de mapear a distribuição espacial de calor em três dimensões, estabelecendo uma prova de conceito para o monitoramento térmico volumétrico.

II. Material e Métodos

A. Instrumentação da Plataforma Teranóstica

A plataforma experimental (Fig. 1a e Fig. 1b) é estruturada em torno de uma cuba de acoplamento acústico contendo um motor DC controlado por uma ponte-H para a execução da varredura rotacional. O sistema é gerenciado por um microcontrolador responsável por automatizar a rotação e emitir sinais de *trigger* para a sincronização temporal entre os módulos. O subsistema de imageamento utiliza um scanner de arquitetura aberta ArtUs EXT-1H (Telemed Ultrasound) integrado a um transdutor linear L12-5N40-A4 de campo de visão de 36,8 mm. As aquisições ocorrem a uma taxa de 60 FPS em modo *Standard*. A sincronização entre o manipulador e o disparo do ultrassom é feita via hardware pela porta ScanStart Input, com conversão de nível lógico para 3,3 V para proteção do equipamento [17].

O sistema de hipertermia consiste em um transdutor de HIFU monoelemento focalizado (raio de concavidade de 88,89 mm e frequência central de 927 kHz [17]). A caracterização focal, calculada pelo método *Full Width at Half Maximum* (FWHM), identificou uma região focal acústica de 10 mm de profundidade por 2 mm de lateralidade e elevação (Fig. 2). Para a validação, utilizou-se um mimetizador de tecido (phantom) de parafina-gel (98 mm de diâmetro e 180 mm de altura), produzido conforme formulação do GIIMUS [18] (Fig. 1c).

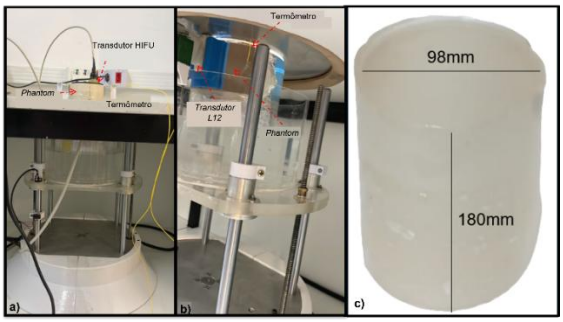

Fig. 1. **Montagem do sistema experimental. (a)** Vista frontal da plataforma mecânica; **(b)** detalhe do acoplamento acústico e transdutores; e **(c)** phantom de parafina-gel.

B. Etapa Experimental e Protocolo de Hipertermia

O protocolo iniciou-se com a aquisição de um frame de referência (pré-aquecimento) com o sistema submerso em água. Para a indução térmica, o gerador de funções foi configurado para uma saída senoidal de 2 Vpp a 927 kHz, elevada para aproximadamente 20 Vpp após amplificação para alimentar a cerâmica piezoelétrica. Essa tensão elétrica foi mantida constante para parametrizar indiretamente a deposição de energia acústica e assegurar a reprodutibilidade entre os ciclos. O período de aquecimento foi de 90 segundos.

Imediatamente após o aquecimento, realizou-se a coleta dos dados de RF pelo scanner ArtUs e a rotação automatizada do phantom em 0,54°. O sistema foi então freado, respeitando-se um intervalo de 2 minutos para resfriamento antes de reiniciar o ciclo, chegando à temperatura *baseline* inicial. Este procedimento (aquisição, aquecimento e rotação) foi repetido para 4 pontos angulares, totalizando uma varredura volumétrica discreta de 1,62°.

A varredura angular foi delimitada em 1,62° (quatro fatias discretas com passo de 0.54º) em conformidade com a extensão espacial do foco do transdutor de HIFU (2 mm de largura em elevação). Em aberturas angulares superiores a esse intervalo, a ausência de deposição acústica direta resultou em variações térmicas residuais (causadas apenas por difusão) insuficientes para induzir deformação térmica mensurável. Consequentemente, as alterações de fase no sinal de RF ficaram abaixo do limite de sensibilidade do algoritmo de Lucas-Kanade, restringindo a detecção de aquecimento a esse volume focalizado.

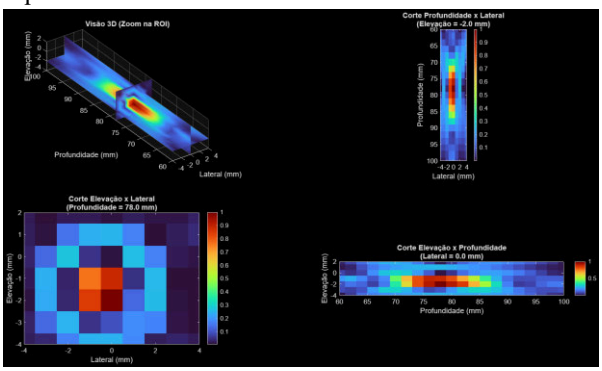

Fig. 2. **Mapeamento do campo acústico do transdutor de HIFU.** Visão 3D e fatias ortogonais 2D (profundidade, elevação e lateral) na região focal. A escala de cores indica a intensidade normalizada.

C. Processamento de Sinal e Reconstrução 3D

Os dados de RF pré e pós-aquecimento foram processados em ambiente MATLAB utilizando o método de TSI [14]. O algoritmo (Fig. 3) realiza o pré-processamento para seleção da região de interesse (ROI) e remoção de ruídos de fundo. O rastreio de microdeslocamentos axiais foi executado pelo algoritmo de fluxo óptico de Lucas–Kanade 2D [19]seguido pelo cálculo do gradiente de deformação (*strain*).

Após a suavização espacial do *strain*, realizou-se um ajuste linear (*fit*) utilizando a temperatura de referência obtida por um termômetro de fibra óptica inserido no *phantom*, determinando-se a constante de sensibilidade (K) do cálculo do TSI. Por fim, as fatias térmicas foram espacialmente coregistradas para a reconstrução do volume 3D discreto da temperatura.

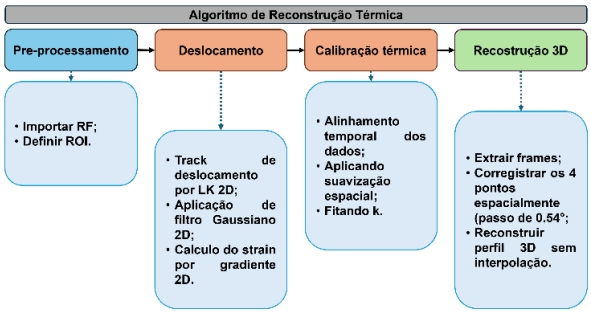

Fig. 3. **Fluxograma do algoritmo de reconstrução térmica.** Principais etapas do processamento dos dados de radiofrequência (RF), englobando o cálculo de deslocamento, calibração e montagem volumétrica 3D.

III. Resultados

Os resultados demonstraram um padrão de aquecimento espacialmente condizente com a geometria acústica do transdutor de HIFU, registrando uma temperatura máxima estimada de 41,6 °C no foco. A estimativa obtida via TSI apresentou concordância com a medição pontual da fibra óptica utilizada na etapa de calibração. Na caracterização volumétrica, a integração das quatro fatias angulares (varredura total de 1,62°) permitiu mapear o perfil térmico e identificar a presença de regiões aquecidas fora do plano principal de imagem (Fig. 4). A opção por uma visualização discreta sem interpolação preservou a resolução espacial nativa dos sinais de RF, evitando a suavização digital dos gradientes térmicos e delimitando o volume efetivo em que a variação de temperatura superou o limiar de detecção do algoritmo.

IV. Conclusão

Este trabalho apresentou uma prova de conceito para uma plataforma teranóstica de arquitetura aberta, demonstrando a viabilidade do mapeamento térmico 3D por ultrassom durante a aplicação de HIFU. A reconstrução volumétrica discreta permitiu a identificação de regiões aquecidas fora do plano principal de imagem, registrando uma variação térmica máxima de 41,6 °C. Contudo, o estudo possui limitações: a varredura esteve restrita a 1,62º (4 fatias) devido à dimensão focal do transdutor (2 mm) e ao limite de sensibilidade do algoritmo TSI para variações puramente difusivas; o ensaio utilizou um phantom sintético homogêneo (sem perfusão sanguínea ou atenuação biológica complexa); e a estimativa dependeu de um único ponto de calibração via fibra óptica, o que limita a validação quantitativa independente do erro térmico no volume. Como trabalhos futuros, pretende-se empregar arranjos independentes de múltiplos sensores de temperatura para mapeamento quantitativo do erro 3D, implementar algoritmos de compensação de movimento e realizar validações em tecidos biológicos, visando ao desenvolvimento contínuo de sistemas acessíveis de monitoramento por hipertermia.

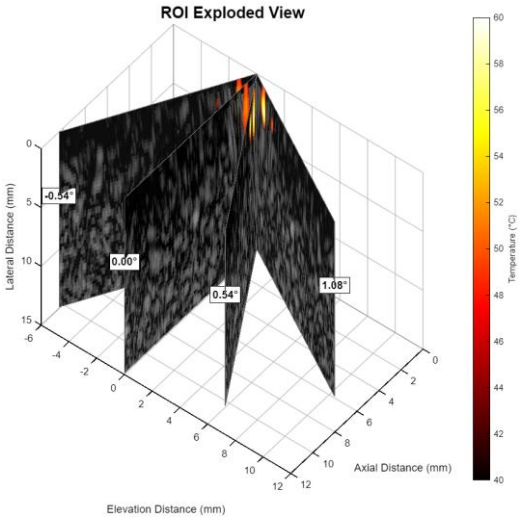

Fig. 4. **Mapeamento espacial 3D da temperatura induzida por HIFU.** A visualização explodida da região de interesse destaca as quatro fatias angulares discretas obtidas na varredura de 1,62°, preservando a resolução nativa do algoritmo TSI.

***Abstract*—This work presents the fabrication and electrical characterization of multilayer gelatin-based phantoms designed to reproduce the passive electrical properties of the epidermis, dermis, and hypodermis, and to evaluate the sensitivity of tetrapolar electrode geometry to subsurface impedance changes. A temperature-resistivity calibration was first performed, comparing agar- and gelatin-based formulations; agar exhibited excessive intrinsic conductivity and a limited resistivity range, whereas gelatin provided both adequate mechanical stability and the target resistivity values needed for multilayer fabrication. Using an empirical regression relating temperature, NaCl concentration, and conductivity, three phantoms (P1, P2, P3) were built with identical epidermis and hypodermis resistivities but distinct dermis resistivities, allowing isolated evaluation of subsurface sensitivity. Electrical Impedance Spectroscopy (200 Hz–100 kHz) was performed on each phantom using five tetrapolar electrode configurations (three linear, two coplanar), and the resulting spectra were analyzed with Relative Difference (RD) and Bland–Altman statistics. Coplanar arrangements showed moderate, stable sensitivity to the middle layer variations, with impedance differences that gradually converged at higher frequencies. Among the linear configurations, Linear Arrangement 1 was the most sensitive, with relative differences exceeding 100% at low frequencies for the phantom with the greatest resistivity change, while Linear Arrangements 2 and 3 produced smaller but more consistent responses across the spectrum. Bland–Altman analysis confirmed that the observed differences were systematic rather than random, verifying that electrode geometry governs current distribution and sensing depth. The results demonstrate the potential of the proposed phantoms as a controlled experimental platform for assessing electrode configurations and electrical variations in subsurface skin layers, with educational applications using biological phantoms.**

***Index Terms*—Multilayer measurement, customized skin phantoms, EIS, electrode geometries**

I. Introduction

The skin, the largest organ of the human body, acts as a protective barrier against physical, chemical, and biological agents while maintaining essential homeostatic functions [1] [2]. It is composed of three main layers, namely the epidermis, dermis, and subcutaneous tissue, each exhibiting distinct structural and electrical characteristics [3]. Owing to its continuous exposure to harmful agents associated with skin cancer [3], considerable efforts have focused on developing minimally invasive techniques for early diagnosis, reducing unnecessary biopsies and improving clinical decision-making [4] [5] [6] [7] [8].

Electrical Impedance Spectroscopy (EIS) has emerged as a promising non-invasive technique for differentiating healthy and malignant skin tissues by exploiting changes in their passive electrical properties [9] [10] [11]. Variations in cell morphology, membrane integrity, and tissue composition modify tissue conductivity and capacitance. These alterations produce measurable changes in the impedance spectrum and have been associated with lesions such as Basal Cell Carcinoma (BCC), Squamous Cell Carcinoma (SCC), and melanoma. [9] [12] [11] [13]

The multilayered structure of the skin strongly influences the measured impedance response. Since each layer presents different passive electrical properties, the measured spectrum results from the combined contribution of the epidermis, dermis, hypodermis, and embedded anatomical structures [14] [15] [13]. Moreover, the sensitivity of EIS depends on the distribution of the injected alternating current which is governed by electrode geometry, inter-electrode spacing, measurement configuration, and excitation frequency. [16] [17] [18] [12].

Direct investigation of these factors in vivo is limited by biological variability, ethical constraints, and the difficulty of reproducing controlled experimental conditions [19] [13] [20]. Consequently, biological phantoms have become an important alternative for evaluating bioimpedance systems under reproducible conditions [21] [22] [23] [24]. By reproducing the passive electrical properties of biological tissues, multilayer phantoms enable systematic investigations of current distribution, electrode sensitivity, and impedance variations while providing a low-cost platform for instrumentation development and experimental validation [16].

Commercial EIS systems, such as Nevisense®, have demonstrated promising clinical performance for melanoma detection [25]. However, their high cost and proprietary electrode configurations limit their use in research and educational environments, restricting experimental reproducibility and the development of new measurement methodologies [19]. Therefore, low cost multilayer skin phantoms can provide a controlled and accessible tool for teaching EIS, testing electrode configurations, and studying electrical variations in skin layers. These models may support the development of measurement

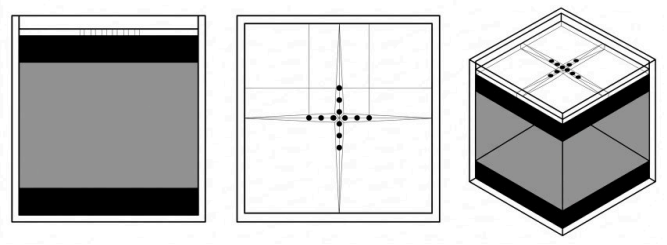

Fig. 1. Side, top, and isometric elevational views of the gelatin phantom. The visualization highlights the multilayered matrix and the corresponding perforated cover, prior to the final positioning and fixation of the measuring electrodes.

methods that may contribute to future diagnostic applications, including cancer detection.

This work investigates the sensitivity of a three layered gelatin skin phantom to variations in tetrapolar electrode geometry using Electrical Impedance Spectroscopy. The study focuses on controlled changes in dermis resistivity and does not evaluate cancer detection.

II. Materials and Methods

A. Creation of the Phantoms

Three multilayer skin phantoms were fabricated using three layers representing the epidermis, dermis, and hypodermis. The layers has thicknesses of 12.15 mm, 56.70 mm, and 12.15 mm, respectively, corresponding to 15%, 70%, and 15% of the 81 mm phantom depth. Each layer was prepared using distilled water and commercial gelatin with documented physicochemical specifications, while controlled amounts of sodium chloride (NaCl) were added to obtain the target electrical conductivity of each skin mimicking layer [26], [27]. The gelatin label indicates a pH of 5.2 in a 1% solution, moisture below 12%, ash below 2%, nitrogen below 15%, and a particle size of 30 mesh. The electrical properties were determined experimentally through the calibration procedure described below.

The phantom geometry was designed to approximate a homogeneous, isotropic, and semi-infinite medium only in the region adjacent to the electrode array where the electric field is established during the measurements. Each phantom was prepared in a cubic acrylic mold with internal dimensions of 81x81×8 mm and stored for 8 hours before measurements. A cover with twelve circular holes held 1.6 mm diameter polished stainless steel electrodes (AISI 308L) in a cross arrangement. The center to center spacing was 5 mm, with a maximum interelectrode distance of 25 mm. The cover weighes 40 g, resulting in a contact pressure of approximately 16 kPa.

B. Conductivity Temperature Calibration

Because the electrical properties of gelatin-based materials are temperature-dependent, controlled cooling ramps were performed prior to phantom fabrication to characterize the relationship between temperature, NaCl concentration, and electrical conductivity. One gelatin-agar and three gelatin-only

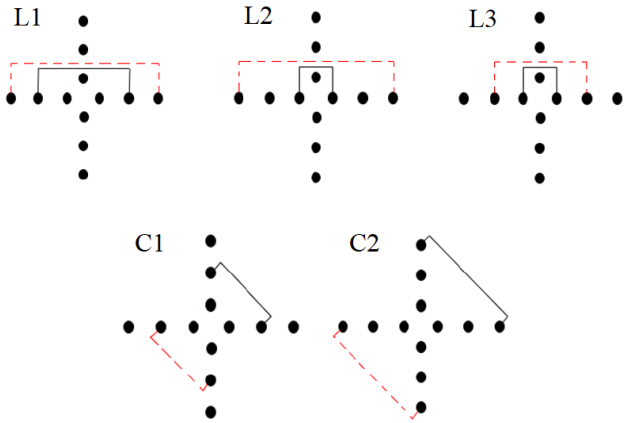

Fig. 2. The five different configurations for linear and coplanar interelectrode arrays. The dotted lines correspond to the current electrodes and the solid lines to the voltage electrodes respectively.

formulations were evaluated for their temperature-dependent electrical behavior and mechanical stability. The resulting calibration curves were used to estimate resistivity at the target measurement temperature (10°C) and to guide formulation selection for multilayer phantom fabrication [27].

TABLE I
Temperature-dependent resistivity of the evaluated phantom formulations.

T(°C)	A(Ω·m)	B(Ω·m)	C(Ω·m)	D(Ω·m)
60.0	19.75	4.74	7.39	13.33
57.5	19.75	5.24	7.64	13.50
55.0	21.20	5.30	7.86	13.88
52.5	21.55	5.54	8.08	14.03
50.0	22.16	5.74	8.40	14.77
47.5	22.94	5.92	8.64	15.15
45.0	23.57	6.15	8.97	15.76
42.5	24.00	6.37	9.25	16.32
40.0	25.33	6.89	9.55	16.92
37.7	25.66	7.04	9.79	17.61
35.0	26.53	7.18	10.40	18.35
32.5	27.27	7.44	10.76	18.98
30.0	28.89	7.88	11.39	19.95

A: 4 g agar and 96 mL water; **B**: 8 g gelatin and 92 mL water; **C**: 6 g gelatin and 94 mL water; **D**: 3 g gelatin and 97 mL water. Resistivity values are expressed in Ω·m.

The formulation containing 3 g of gelatin and 97 mL of water was selected as the epidermis-equivalent layer. Based on the temperature–resistivity calibration, the resistivity at the measurement temperature (10 °C) was estimated using Eqs. (1)–(3), yielding an extrapolated value of approximately 23.84 Ωm. This value was adopted as the reference resistivity for the epidermis-equivalent phantom, while the target resistivities for the remaining layers were determined according to the relative ratios reported in the literature.

$$\rho(T) = -0.2227\,T + 26.0690 \tag{1}$$

$$\rho(10) = -0.2227(10) + 26.0690 = 23.84\ \Omega\text{m} \quad (2)$$

$$\rho_{epi} = 23.84\ \Omega\text{m} \quad (3)$$

Rather than reproducing the absolute resistivity values reported for human skin, the multilayer phantom was designed to preserve the relative electrical contrasts among the epidermis, dermis, and hypodermis described in the literature [28], [29], [13]. Consequently, the target resistivities of the remaining layers were obtained by scaling the resistivity of the epidermis-equivalent formulation according to the relative ratios reported for biological skin tissues.

For the middle layer (dermis):

$$\rho_{der} = \rho_{epi}\left(\frac{20}{100}\right) = 23.84\left(\frac{20}{100}\right) = 4.77\ \Omega\text{m} \quad (4)$$

For the bottom layer (hypodermis):

$$\rho_{hyp} = \rho_{epi}\left(\frac{40}{100}\right) = 23.84\left(\frac{40}{100}\right) = 9.54\ \Omega\text{m} \quad (5)$$

TABLE II
TARGET ELECTRICAL PROPERTIES ADOPTED FOR THE MULTILAYER SKIN PHANTOM BASED ON RELATIVE RESISTIVITY SCALING.

Layer	Relative Ratio	Resistivity (Ωm)	Conductivity (S/m)
Epidermis	1.00	23.84	0.0419
Dermis	0.20	4.77	0.2096
Hypodermis	0.40	9.54	0.1048

Once the target apparent resistivities had been defined, two additional gelatin formulations consisting of 3 g of gelatin and 97 mL of water were prepared by incorporating different amounts of sodium chloride (NaCl), namely 0.010 g and 0.020 g. Similar to the previous experiments, both formulations were subjected to a descending temperature ramp from 60°C to 30°C, while conductivity measurements were acquired at regular intervals. These data were used to establish an empirical relationship among temperature, NaCl concentration, and electrical conductivity, enabling the estimation of the amount of salt required to achieve a target resistivity at a specified temperature. The resulting conductivity profiles are presented in Table II.

Controlled additions of NaCl were subsequently used to adjust the conductivity of each layer, resulting in target resistivities of 23.84 Ωm, 4.77 Ωm, and 9.54 Ωm for the top, middle, and bottom layers, respectively. To address this issue, an empirical multiple regression model was developed using gelatin formulations containing different sodium chloride concentrations and conductivity measurements acquired over a range of temperatures. Since the phantoms are fully solidified at the measurement temperature of 10°C, direct conductivity measurements at this stage are difficult to perform. Therefore, the model was employed to estimate both the amount of NaCl required to achieve a target electrical resistivity and the expected resistivity of the phantom at 10°C. The resulting relationship is given by:

TABLE III
TEMPERATURE-DEPENDENT ELECTRICAL PROPERTIES OF GELATIN PHANTOMS WITH DIFFERENT NACL CONCENTRATIONS.

T (°C)	A		B	
	σ (S/m)	ρ (Ω·m)	σ (S/m)	ρ (Ω·m)

30.0	0.0801	12.48	0.1602	6.24

A: Gelatin phantom prepared with 3 g gelatin, 97 mL distilled water, and 0.010 g NaCl. **B**: Gelatin phantom prepared with 3 g gelatin, 97 mL distilled water, and 0.020 g NaCl.

$$\sigma(T, m_{\text{NaCl}}) = 0.03908 + 2.87\times10^{-4}T + 8.3845\, m_{\text{NaCl}}, \quad (6)$$

where σ is the electrical conductivity (S/m), T is the temperature (°C), and m_{NaCl} is the mass of sodium chloride added to the formulation (g).

Since all impedance measurements were carried out at 10°C, Eq. (6) simplifies to

$$m_{\text{NaCl}} = \frac{\dfrac{1}{\rho_{\text{obj}}} - 0.04195}{8.3845}. \quad (7)$$

C. Measurements and Data Collection

Three different phantoms (P1, P2, and P3) were independently constructed to investigate the influence of the middle layer resistivity on the measured impedance. The top and bottom layers were kept unchanged across all phantoms, while only the middle layer resistivity was varied to represent different electrical conditions.

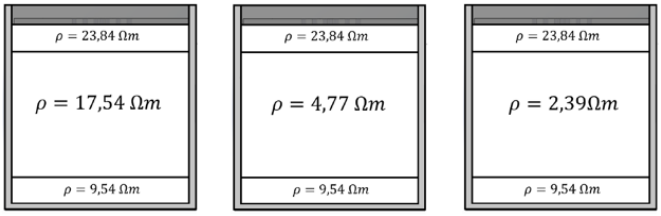

Fig. 3. Phantoms P1, P2, and P3 with the respective resistivity values of each layer.

EIS measurements were done by using the EmStat4R potentiostat (PalmSens BV) operating in a tetrapolar configuration.

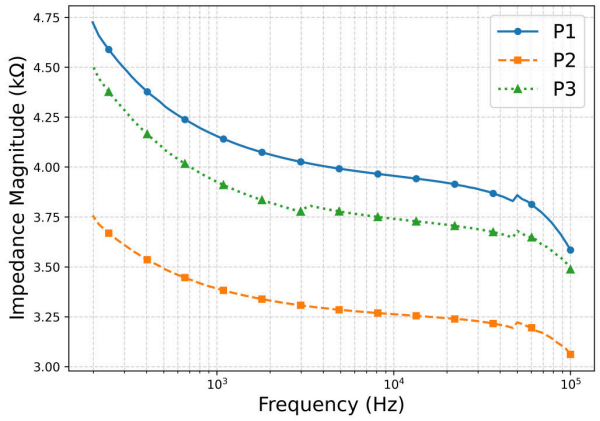

Fig. 4. Impedance magnitude ($|Z|$) spectra of Phantoms P1, P2, and P3 obtained using the Coplanar Arrangement 1 electrode configuration over the frequency range from 200 Hz to 100 kHz. The figure illustrates the influence of variations in the resistivity of the middle layer on the surface impedance response of the multilayer phantom..

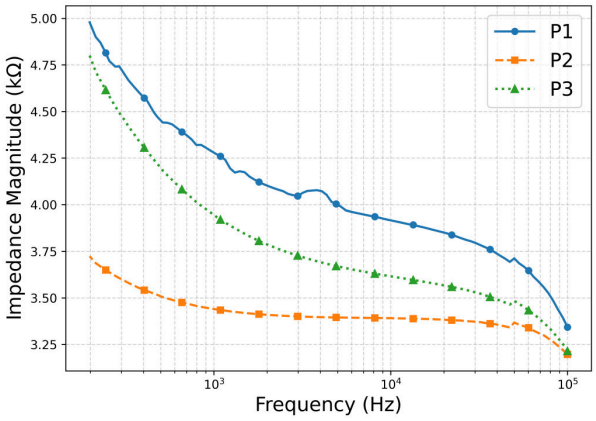

Fig. 5. Impedance magnitude ($|Z|$) spectra of Phantoms P1, P2, and P3 obtained using the Coplanar Arrangement 2 electrode configuration over the frequency range from 200 Hz to 100 kHz. The figure illustrates the influence of variations in the resistivity of the middle layer on the surface impedance response of the multilayer phantom.

Impedance magnitude and phase were measured from 0.2 to 100 kHz, recording. Each phantom was measured using the five electrode configurations, resulting in fifteen experimental datasets. In addition, each layer was individually characterized before depositing the subsequent layer to validate its electrical properties.

The sensitivity of each electrode configuration to middle layer resistivity variations was evaluated by comparing the impedance spectra of the three phantoms. Relative Difference (%RD) and Bland–Altman analyses were employed to quantify the differences between the reference phantom (P2) and the modified phantoms (P1 and P3), following the methodology described in [30].

III. Results

Figures 4–8 present the impedance magnitude ($|Z|$) and real impedance (Z') spectra obtained using the three linear and two coplanar electrode configurations. For each configuration, the responses of Phantoms P1, P2, and P3 are presented over the frequency range from 200 Hz to 100 kHz, enabling a direct comparison of the sensitivity of each electrode configuration to the variations introduced in the middle layer resistivity.

As observed in Figures 4 and 5, the Coplanar Arrangement 1 and Coplanar Arrangement 2 electrode configurations exhibited higher impedance magnitude and real impedance values for Phantoms P1 and P3 than for Phantom P2 over most of the analyzed frequency range. These differences remained nearly constant throughout the spectrum, with Phantom P1 consistently exhibiting slightly higher values than Phantom P3. However, the responses of the three phantoms gradually converged as the frequency increased, becoming more similar at frequencies above 100 kHz.

For the Linear Arrangement 1 electrode configuration, a nearly constant difference of less than 1000 Ω was observed between Phantoms P1 and P2 over the entire frequency range for both the impedance magnitude and the real impedance.

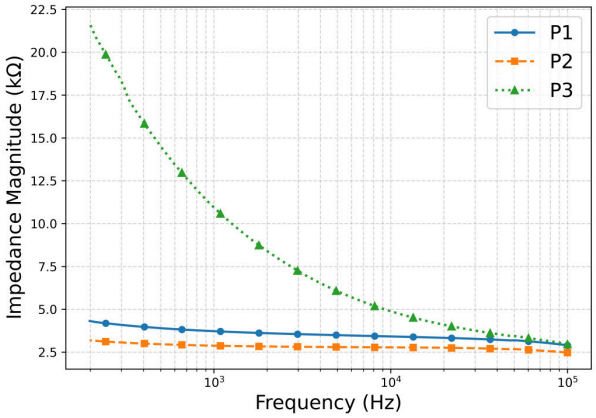

Fig. 6. Impedance magnitude ($|Z|$) spectra of Phantoms P1, P2, and P3 obtained using the Linear Arrangement 1 electrode configuration over the frequency range from 200 Hz to 100 kHz. The figure illustrates the influence of variations in the resistivity of the middle layer on the surface impedance response of the multilayer phantom.

In contrast, Phantom P3 exhibited a markedly different behavior, with impedance magnitude and real impedance values approximately five to ten times higher than those of Phantoms P1 and P2 at low frequencies. As the frequency increased, both parameters decreased progressively, converging toward the responses of P1 and P2 at approximately 100 kHz.

For the Linear Arrangement 2 electrode configuration, higher impedance magnitude and real impedance values were observed for Phantom P1 at the lower end of the frequency spectrum (200 Hz). In contrast, Phantoms P2 and P3 exhibited similar responses, maintaining an approximately constant separation throughout most of the analyzed frequency range despite the gradual decrease in impedance with increasing frequency. As the frequency approached the upper limit of the investigated spectrum, the responses of all three phantoms converged rapidly toward lower impedance values.

For the Linear Arrangement 3 electrode configuration, a

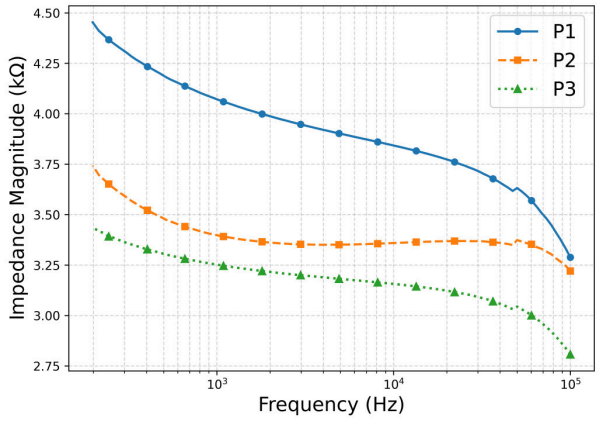

Fig. 7. Impedance magnitude ($|Z|$) spectra of Phantoms P1, P2, and P3 obtained using the Linear Arrangement 2 electrode configuration over the frequency range from 200 Hz to 100 kHz. The figure illustrates the influence of variations in the resistivity of the middle layer on the surface impedance response of the multilayer phantom.

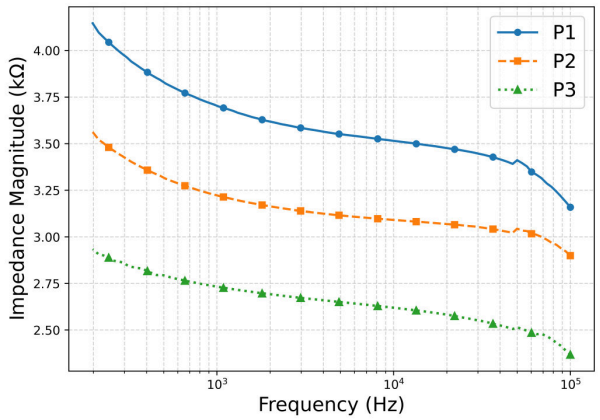

Fig. 8. Impedance magnitude ($|Z|$) spectra of Phantoms P1, P2, and P3 obtained using the Linear Arrangement 3 electrode configuration over the frequency range from 200 Hz to 100 kHz.The figure illustrates the influence of variations in the resistivity of the middle layer on the surface impedance response of the multilayer phantom.

nearly constant separation between the responses of the three phantoms was observed over the entire analyzed frequency range. Both the impedance magnitude and the real impedance exhibited a gradual decrease from 200 Hz to 100 kHz, with the three spectra following approximately parallel trends and maintaining a similar difference throughout the spectrum.

Since the top layer resistivity was identical in all three phantoms, these results suggest that the Linear Arrangement 3 configuration is predominantly sensitive to variations in the electrical properties of the deeper layers. The nearly uniform separation between the spectra indicates that changes in middle layer resistivity produce a proportional variation in the measured impedance over the investigated frequency range.

To complement the analysis of the impedance spectra, a statistical evaluation was subsequently performed using the relative difference (%RD) and Bland–Altman analysis. These methods allowed an objective quantification of the differences between the reference phantom (P2) and Phantoms P1 and P3, as well as an assessment of the agreement between the impedance measurements obtained with each electrode configuration [30].

A. Statistical Analysis

Figures 9–13 present the Relative Difference (%RD) and Bland–Altman plots for the five electrode configurations evaluated. %RD was calculated using P2 as the reference according to:

$$\%\mathrm{RD} = \frac{|Z_i - Z_{\mathrm{P2}}|}{Z_{\mathrm{P2}}} \times 100, \tag{8}$$

where Z_i represents the impedance magnitude of P1 or P3 at each frequency.

The Bland–Altman analysis was used to characterize the distribution and bias of both reference (P2) and modified resistivity phantoms. The absolute impedance difference was calculated as $\Delta Z (= |Z_i - Z_{P2}|)$ in order to avoid interpretation based only on the reference magnitude.

Values above 100% indicate that the absolute impedance difference exceeded the P2 reference value. Because the calculation uses the reference impedance as the denominator, then small reference values produce large %RD values. Therefore, %RD is better interpreted together with the absolute impedance difference.

The Relative Difference plots show the percentage variation in impedance magnitude as a function of frequency for the P1–P2 and P3–P2 comparisons. This analysis identifies the frequency intervals in which changes in middle layer resistivity produced the largest deviations from the reference phantom, as well as the regions where the electrical response remained comparatively stable.

The Bland–Altman plots present the impedance differences as a function of the mean values, allowing the bias and distribution of the differences evaluated for each electrode configuration. Together, these analyses quantify the sensitivity of each electrode arrangement to changes in the middle layer resistivity in the multilayer phantoms [30].

It is important to emphasize that, in the context of the present study, the objective of the %RD analysis is not to minimize the relative difference, but to evaluate the sensitivity of each electrode configuration to changes middle layer resistivity. Consequently, a %RD value close to zero indicates that the electrode configuration is relatively insensitive to the modifications introduced in the inner layer. Conversely, a high and consistent %RD indicates that the configuration is capable of detecting changes in resistivity of the middle layer from surface impedance measurements. Likewise, a stable %RD over the analyzed frequency range indicates a consistent response of the electrode configuration to variations in the electrical properties of the middle layer.

Unlike the relative difference analysis, which quantifies the sensitivity of each electrode configuration to changes in resistivity of the middle layer. The Bland–Altman analysis evaluates the distribution and consistency of these differences over the analyzed frequency range. It is better to emphasize

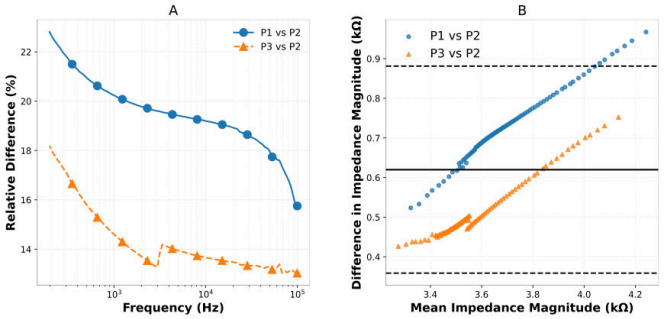

Fig. 9. (A) %RD in impedance magnitude for the P1–P2 and P3–P2 comparisons obtained with the Coplanar Arrangement 1 electrode configuration. (B) Bland–Altman analysis of the corresponding measurements, with a mean bias of 619.83 Ω and limits of agreement defined as ±1.96 SD.

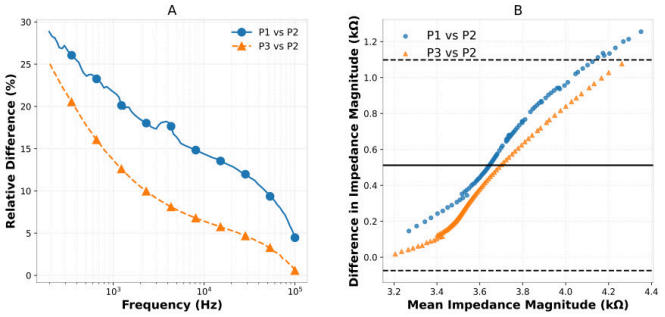

Fig. 10. (A) %RD in impedance magnitude for the P1–P2 and P3–P2 comparisons obtained with the Coplanar Arrangement 2 electrode configuration. (B) Bland–Altman analysis of the corresponding measurements, with a mean bias of 511.89 Ω and limits of agreement defined as ±1.96 SD.

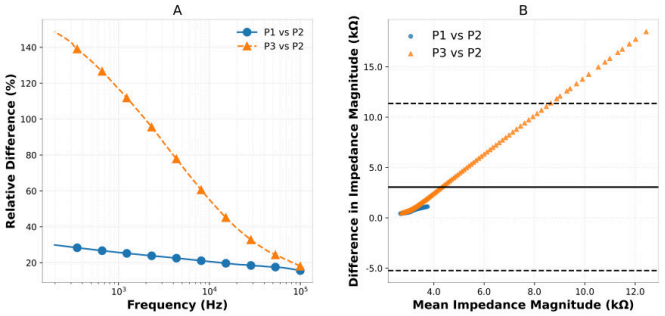

Fig. 11. (A) %RD in impedance magnitude for the P1–P2 and P3–P2 comparisons obtained with the Linear Arrangement 1. (B) Bland–Altman analysis of the corresponding measurements, with a mean bias of 3062.96 Ω and limits of agreement defined as ±1.96 SD.

that the objective here was not intended to obtain a bias close to zero, since the phantoms were intentionally prepared with different resistivities for the middle layers. Therefore, a consistent bias with a compact distribution of the differences indicates a stable response to the introduced changes in resistivity of the middle layers.

For the Coplanar Arrangement 1 electrode configuration, the Relative Difference (%RD) between Phantoms P1 and P2 decreased from approximately 22% at 200 Hz to 15% at 100 kHz. Similarly, the comparison between Phantoms P3 and P2 exhibited a gradual decrease from approximately 18% to 13% over the same frequency range. The smooth reduction in %RD with increasing frequency indicates that the impedance responses of the three phantoms became progressively more similar at higher frequencies while maintaining a consistent separation throughout the spectrum.

The corresponding Bland–Altman plot shows two well-defined ascending clusters associated with the P1–P2 and P3–P2 comparisons, with differences ranging from approximately 400 Ω to more than 1000 Ω. The calculated bias of 619.83 Ω indicates a systematic difference between the reference phantom (P2) and the modified phantoms. Furthermore, the compact distribution of the data around each trend suggests that these differences remain consistent over the analyzed frequency range, demonstrating that the Coplanar Arrangement 1 configuration is capable of reliably distinguishing variations in middle layer resistivity.

For the Coplanar Arrangement 2 electrode configuration, a behavior similar to that observed for Coplanar Arrangement 1 was obtained. The Bland–Altman analysis yielded a bias of 511.89 Ω, indicating a systematic difference between the reference phantom (P2) and the modified phantoms. The data points formed two closely spaced ascending clusters, with differences ranging from approximately 0 Ω to 1200 Ω, demonstrating a consistent trend over the analyzed frequency range.

The %RD also exhibited a gradual decrease with increasing frequency for both the P1–P2 and P3–P2 comparisons. As the frequency approached the upper limit of the analyzed spectrum, the relative differences tended to decrease toward zero, indicating that the electrical responses of the three phantoms became progressively more similar above 100 kHz.

For the Linear Arrangement 1 electrode configuration, the %RD between Phantoms P1 and P2 remained relatively low and nearly constant, decreasing slightly from approximately 30% to 20% over the analyzed frequency range. In contrast, the P3–P2 comparison exhibited a pronounced descending trend, with the %RD decreasing from approximately 140% at 200 Hz to values close to 20% at 100 kHz, where it converged toward the P1–P2 comparison.

The corresponding Bland–Altman plot clearly distinguishes the two phantom comparisons. The P1–P2 data points form a compact cluster below the bias, concentrated at lower mean impedance values and characterized by relatively small differences. In contrast, the P3–P2 comparison follows a marked ascending trend, with the differences increasing from approximately 0 Ω to values exceeding 15 kΩ. The calculated bias of 3062.96 Ω, together with the wide separation between the two clusters, indicates that the Linear Arrangement 1 configuration is highly sensitive to the modifications introduced in the middle layer resistivity, particularly for Phantom P3.

For the Linear Arrangement 2 electrode configuration, the %RD between Phantoms P1 and P2 remained relatively low, decreasing from approximately 17% to 2% over the analyzed frequency range. An even smaller relative difference was

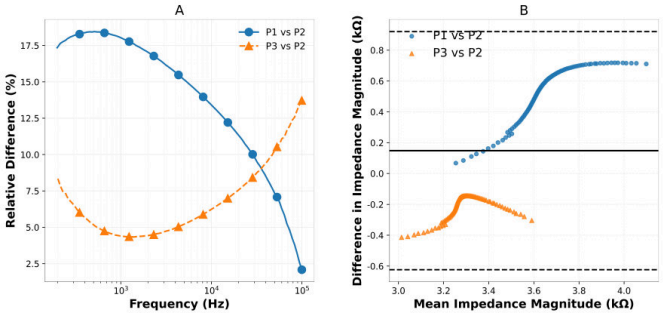

Fig. 12. (A) %RD in impedance magnitude for the P1–P2 and P3–P2 comparisons obtained with the Linear Arrangement 2. (B) Bland–Altman analysis of the corresponding measurements, with a mean bias of 148.28 Ω and limits of agreement defined as ±1.96 SD.

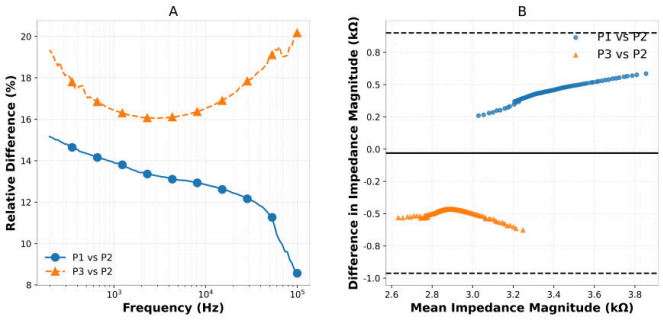

Fig. 13. (A) %RD in impedance magnitude for the P1–P2 and P3–P2 comparisons obtained with the Linear Arrangement 3. (B) Bland–Altman analysis of the corresponding measurements, with a mean bias of -30.95 Ω and limits of agreement defined as ±1.96 SD.

observed for the P3–P2 comparison, varying between approximately 8% and 14%. These results indicate that the Linear Arrangement 2 configuration exhibits a limited sensitivity to the variations in middle layer resistivity, particularly for the P3–P2 comparison.

The corresponding Bland–Altman plot shows a clear separation between the two phantom comparisons. The P3–P2 data are predominantly distributed below the zero-difference line and, consequently, below the calculated bias of 148.28 Ω, reflecting the lower impedance of Phantom P3 resulting from its higher middle layer conductivity. In contrast, the P1–P2 comparison is located almost entirely above the bias and is concentrated over mean impedance values ranging from approximately 3200 Ω to 4000 Ω. The distinct distribution of both clusters indicates that the Linear Arrangement 2 configuration consistently differentiates between increases and decreases in the middle layer resistivity with respect to the reference phantom.

For the Linear Arrangement 3 electrode configuration, the relative difference remained below 20% throughout the analyzed frequency range. The P1–P2 comparison exhibited a gradual decrease, tending toward zero at higher frequencies, whereas the P3–P2 comparison showed the opposite behavior, with the relative difference increasing above approximately 10 kHz. This divergence between the two comparisons at higher frequencies indicates that the Linear Arrangement 3 configuration is capable of distinguishing changes in middle layer resistivity, particularly in the upper portion of the analyzed spectrum.

The corresponding Bland–Altman plot yielded a bias of -30.95 Ω. Although the overall bias was close to zero, this result reflects the compensation between the positive differences observed for the P1–P2 comparison and the negative differences associated with the P3–P2 comparison, rather than the absence of systematic differences. The P1–P2 data form a nearly constant positive cluster, with differences ranging from approximately 250 Ω to 600 Ω, whereas the P3–P2 comparison remains consistently below the zero-difference line, with negative differences spanning approximately 150 Ω. The clear separation between the two clusters demonstrates that the Linear Arrangement 3 configuration consistently discriminates between increases and decreases in middle layer resistivity relative to the reference phantom.

IV. Discussion and Conclusions

The calibration procedure revealed substantial differences between agar and gelatin based formulations. Agar exhibited high intrinsic conductivity, which limited the attainable resistivity range, particularly for epidermis-mimicking layers. Increasing the agar concentration improved mechanical strength but further increased conductivity. In contrast, gelatin based formulations simultaneously provided adequate mechanical stability and the target resistivity range, making them suitable for multilayer phantom fabrication.

The experimental results demonstrated that electrode geometry strongly affects the impedance response of multilayer structures. Although all configurations distinguished the three phantoms, the magnitude and frequency dependence of the measured differences varied considerably. These variations indicate that the electrode arrangement modifies the current distribution and consequently the contribution of each layer to the measured impedance.

The coplanar configurations exhibited moderate sensitivity and progressive convergence of the impedance spectra with increasing frequency. In contrast, the linear arrangements showed markedly different performances. Linear Arrangement 1 produced the highest sensitivity to middle layer resistivity variations, exhibiting relative differences exceeding 100% at low frequencies. Linear Arrangements 2 and 3 displayed lower sensitivities but more stable responses across the analyzed spectrum.

The combined use of relative difference (%RD) and Bland-Altman analysis provided complementary information regarding the performance of each electrode configuration. The %RD quantified the sensitivity to changes in middle layer resistivity, whereas Bland-Altman analysis demonstrated that the observed differences were systematic and reproducible rather than arising from random variability.

The use of tissue mimicking phantoms limits direct extrapolation to biological tissue. Electrode skin contact, tissue heterogeneity, hydration, temperature fluctuations, and motion

were not evaluated. Complementary in vivo measurements using different electrode types were reported separately in [19]. The present study evaluated a defined set of electrode configurations without numerical simulations or geometry optimization.

From a physical perspective, the observed behavior can be attributed to the current density distribution imposed by each tetrapolar geometry. Small modifications in electrode spacing and arrangement produced substantial changes in sensing depth and sensitivity to subsurface electrical properties.

Overall, the proposed multilayer phantoms provided a controlled platform for assessing electrode configurations and variations in the electrical properties of subsurface mimicking skin layers. The methodology enables controlled modifications of individual layers for superficial bioimpedance measurements.

***Abstract*— Therapeutic ultrasound is a widely utilized modality in physical therapy, yet its safety in the presence of metallic orthopedic implants remains a subject of clinical debate. This study evaluates the thermal response of multilayer phantoms simulating fat, muscle, and bone tissues when subjected to 1 MHz continuous ultrasound at 1.0 W/cm² for 180 seconds. The methodology integrated experimental infrared thermography with numerical modelling using COMSOL® Multiphysics to analyze heat distribution across three groups: a control group (no plate), a stainless steel 316L plate group, and a titanium Ti-6Al-7Nb plate group. Results indicated that the control group exhibited the highest overall heating, reaching 56.31°C. Stainless steel plate demonstrated the lowest surface bone mean temperature (23.98°C), representing a minimal rise of approximately 1°C, while the titanium plate promoted a slightly surface bone mean temperature elevation (25.05°C).The COMSOL® simulation corroborated the experimental findings, highlighting how acoustic impedance mismatch and material properties influence energy redistribution. The study concludes that implant material significantly dictates thermal safety profiles, with stainless steel providing a more conservative thermal behavior under the tested conditions. Limitations are also considered.**

Keywords— therapeutic ultrasound, orthopedic implants, thermal effects, COMSOL® simulation, titanium, stainless steel.

I. Introduction

Therapeutic ultrasound (TUS) is extensively applied in clinical rehabilitation to promote tissue healing and pain relief through thermal and non-thermal mechanisms [1], [2]. However, the interaction between ultrasonic waves and metallic orthopedic implants introduces complexities regarding energy absorption and reflection at the tissue-implant interface. High acoustic impedance mismatches between metal and biological tissue can lead to localized hot spots, potentially causing thermal injury to peri-implant tissues [3].

To address these concerns, this research employs multilayer phantoms that mimic the acoustic and thermal properties of human tissue layers. A hybrid approach was adopted, combining experimental measurements via high-resolution thermography with computational modelling in COMSOL® Multiphysics. This dual methodology allows for a comprehensive visualization of the internal thermal fields that are otherwise inaccessible during experimental procedures.

This study specifically shows the thermal behavior of stainless steel (316L) and titanium alloy (Ti-6Al-7Nb) implants (Fig. 1). By establishing a clear thermal hierarchy between these materials and a control group, this work aims to provide evidence-based guidance for the safe application of ultrasound in patients with internal fixation devices.

.

II. Theoretical Foundations

The propagation of ultrasonic waves through heterogeneous media is governed by the acoustic impedance (Z) of each layer, which is the product of the material density (ρ) and the speed of sound (c) within that medium (eq. 1).

$$Z = \rho \times c \qquad (1)$$

When the wave encounters an interface between two media with impedances Z_1 and Z_2, a portion of the energy is reflected, according to the reflection coefficient R (eq. 2):

$$R = \left(\frac{Z_2 - Z_1}{Z_2 + Z_1}\right)^2 \qquad (2)$$

As the wave travels through a medium, its initial intensity ($I0$) decreases as a function of distance ($I(x)$) and attenuation coefficient α (eq. 3):

$$I = I_0 e^{-2\alpha x} \qquad (3)$$

III. Literature Review

The biophysical effects of ultrasound are well documented, with absorption being the primary driver of thermal elevation in protein-rich tissues like muscle and bone [1], [2]. Previous studies by Huang et al. [8] and Sun et al. [9] using simple models and hydrogel phantoms demonstrated that metallic inserts significantly alter the peak temperature location. Zawislak *et al*. [12] investigated titanium implants, suggesting that heating occurs, but may remain within safe limits under low-intensity protocols. However, data from different alloys in a multilayer physiological context remains scarce, needing advanced simulation tools to validate experimental trends.

Previous research also supports the use of phantoms as reliable tissue-mimicking materials for imaging and therapy studies [10]. The structural properties of these materials are essential for reproducing the acoustic and thermal conditions in vivo [3], [4], 6].

IV. Materials and Methods

A multilayer phantom was constructed using tissue-mimicking materials (TMM) to represent the human limb structure. The layers were measured precisely to ensure consistency across all experimental trials. The phantom configuration was based on previously established methodologies [9], [10]. The orthopedic plates in this study were manufactured by Depuy Synthes-Johnson®.

Three experimental configurations were considered: one composed of fat, muscle, and bone phantoms (control), another composed of the aforementioned layers with a TAN alloy plate (Titanium-1 Aluminum-6 Niobium-7) added between the muscle and bone layers, and another similar to the previous one with a stainless-steel plate (316L) (Fig.1).

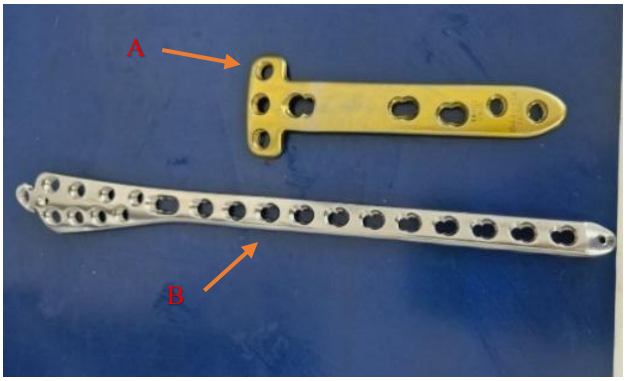

Fig. 1. A: Titanium plate; B: Stainless Steel
Source: the author.

For each experimental set-up, 30 repetitions were performed. The initial temperatures of the phantoms and plates were equal to the room temperature, which ranged between 23 and 24°C (as shown in Tables 1, 2, and 3). Thermography was obtained from the upper face of each of the layers.

The authors wish to thank the Brazilian agencies CNPQ, CAPES and FAPERJ for the financial support.

The following dimensions were used:

- Fat layer: 13.26 mm
- Muscle layer: 12.10 mm
- Bone layer: 1.27 mm
- Titanium plate (Ti-6Al-7Nb): 3.24 mm
- Stainless steel plate (316L): 4.15 mm

Therapeutic ultrasound (SONOPULSE III, IBRAMED, BRAZIL) was applied using a device at a frequency of 1 MHz with a spatial-average temporal-average intensity (I_{sata}) of 1.0 W/cm² in continuous mode for 180°s. The transducer was positioned perpendicularly to the phantom surface using a coupling gel (Fig 2). Each configuration receives 30 sessions of 180 s. The time between the sessions was 30 minutes.

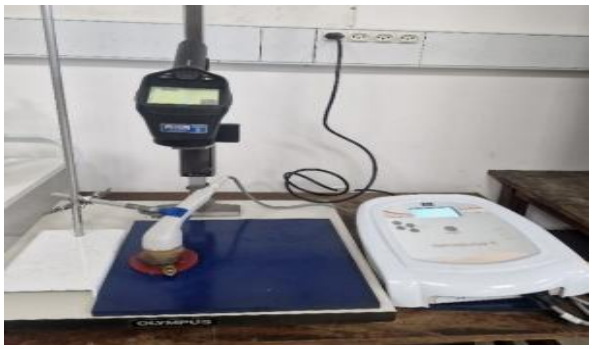

Fig. 2. Experimental Setup.
Source: the author.

Experimental data were captured using a FLIR® E40 infrared camera with 60 Hz (Fig.3). Acquisition rate, thermal range from -20°C to 650°C, sensitivity of 0.07°C, and emissivity adjusted to 0.98.

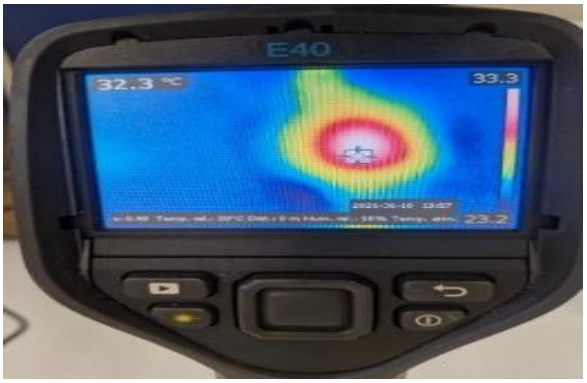

Fig. 3. FLIR® E40 infrared camera.

In parallel, a 3D numerical model was developed in COMSOL® Multiphysics. In this simulation Helmholtz' and the Penne's bioheat equations are used to model the acoustic and heat propagations in a medium composed of fat/muscle/metal/bone (Fig. 4). The simulation presents a heat distribution map derived from ultrasonic absorption.

For the acoustic model, the radiation zone was defined using a Dirichlet condition in the area labeled "Transducer." The region outside each PML was assigned a free boundary or Neumann condition. For the Penne's model, a Dirichlet condition with a constant temperature of 24°C was applied, assumed as the lab. temperature. A λ/8 mesh was defined for

the acoustic case, assuming a 1 MHz frequency. The same mesh was used for the heating model. Acoustic parameters obtained from the COMSOL Library. Radiation pattern as the real experimental case.

V. Result

A. Descriptive Statistics

The thermal response of the multilayer phantoms was recorded at the end of the 180-second ultrasound applications (1 MHz, 1.0 W/cm²). Tables 1, 2 and 3 summarize the mean (M), standard deviation (SD), and coefficient of variation (CV) for each experimental group. Figs 5, 6 and 7 show the temperatures reached for each layer in the respective experiment.

TABLE I. DESCRIPTIVE STATISTICS FOR THE CONTROL GROUP.

Interface	Mean [°C] +SD [°C]	CV [%]
Fat (G)	29.02 ± 1.18	4.05
Muscle (MU)	37.16 ± 2.98	8.02
Bone (O)	56.31 ± 5.84	10.36
Room (S)	23.84 ± 0.40	1.68

TABLE II. DESCRIPTIVE STATISTICS FOR THE TITANIUM PLATE GROUP (TP).

Interface	Mean [°C] ± SD [°C]	CV [%]
Plate (P)	25.46 ± 1.08	4.24
Fat (G)	30.10 ± 1.13	3.75
Muscle (MU)	30.53 ± 1.70	5.57
Bone (O)	25.05 ± 0.92	3.67
Room (S)	23.67 ± 0.26	1.10

TABLE III. DESCRIPTIVE STATISTICS FOR THE STAINLESS-STEEL PLATE GROUP (SP).

Interface	Mean [°C] ± SD [°C]	CV [%]
Plate (P)	24.55 ± 2.25	9.16
Fat (G)	27.41 ± 2.40	8.87
Muscle (MU)	28.39 ± 2.32	8.17
Bone (O)	23.98 ± 2.34	9.76
Room (S)	23.12 ± 1.96	8.48

B. Thermal Dynamics Analysis

The temperature rise (ΔT) was significantly higher in the Control Group, where the bone layer reached a critical mean of 56.31°C. In contrast, the presence of metallic plates acted as a thermal heatsink. For the Titanium Group (PT), the bone temperature remained at 25.05°C, representing a minimal rise relative to the initial state. The Stainless-Steel Group (SP) showed the lowest bone temperature at 23.98°C.

C. Inferential Analysis

A Student's T-test was performed to compare bone temperatures between the control group and each of the two groups with metallic implants. The difference between the Control Group and each of implanted groups (TP and SP) was statistically significant ($p < 0.001$).

Regarding the use of the t-test, what is clinically relevant is to determine whether there is a statistical difference between the normal physiological condition (without implant) and the condition with implant. Therefore, the comparison between the set-ups with implants was removed,

and the t-test was maintained for the aforementioned conditions.

D. COMSOL® Simulation Results

The numerical data from COMSOL® Multiphysics corroborated the experimental findings. In the Control Group simulation (Fig.8), the bone surface reached 56 °C at 180 s. For the Titanium Plate (Fig.9), the simulation showed a bone surface temperature of approximately 26.5°C with a rise of 2.5°C. The Steel Plate simulation (Fig.10) showed a similar pattern but with a slightly lower rise (ΔT 1°C) in the metal itself, while keeping the bone surface at 24°C.

The interface profiles in the simulation revealed a gradient where the transducer/fat interface reached 32.5°C, decreasing through the muscle (31°C) to the bone (25°C).

VI. Discussion

A. Thermal Behavior Interpretation

The most significant finding is the "heat sink" effect provided by the metallic implants. In the Control Group, the acoustic energy is highly absorbed by the bone phantom due to its high absorption coefficient, leading to potentially necrotic temperatures (> 50°C). However, the metallic plates, possessing high thermal conductivity (k), rapidly redistribute the absorbed energy. The acoustic impedance mismatch (Z) at the muscle-metal interface also causes a portion of the wave to reflect, reducing the direct energy deposition on the bone.

B. Material Comparison

Stainless-steel (SP) and Titanium (TP) exhibited distinct thermal profiles. Although Titanium is often preferred for its biocompatibility, the Stainless-Steel plate resulted in a lower bone temperature (23.98°C vs 25.05°C). This is attributed to the higher thermal diffusivity of the steel alloy used, which allowed for faster heat dissipation into the surrounding soft tissue phantoms, as evidenced by the higher CV values in the SP group, indicating more dynamic thermal fluctuations.

C. Interface Analysis

The temperature distribution across interfaces was non-uniform. In the TP group, the muscle reached 30.53°C, which was higher than the bone (25.05°C). This suggests that the metal-bone interface is protected by the plate's ability to conduct heat laterally and back toward the muscle layer. The COMSOL® profiles confirmed this, showing that the highest thermal stress occurs at the fat/muscle and muscle/metal boundaries rather than the bone itself.

D. Clinical Implications

The results *in vitro* seem to challenge the traditional contraindication of therapeutic ultrasound over metallic implants. Under the parameters of 1 MHz and 1.0 W/cm², the bone temperature remained far below the threshold for thermal damage (45°C). The presence of the implant actually protected the bone from the excessive heating observed in the control group. However, the increased temperature in the muscle and fat layers (reaching ~30°C) suggests that clinicians should monitor soft tissue sensitivity rather than bone pain.

E. COMSOL® Validation

The good degree of correlation between the experimental average values and the COMSOL® numerical curves validates the multilayer phantom model. The simulation's ability to predict the ~1°C rise for Titanium(Fig. 11) and the ~3°C rise for Steel (Fig. 12) confirms that the physical properties (density, specific heat, and conductivity) assigned to the materials accurately represent the experimental reality. While the Control Group exhibited a continuous linear rise, the implanted groups reached a thermal plateau, suggesting efficient heat dissipation through the metallic medium.

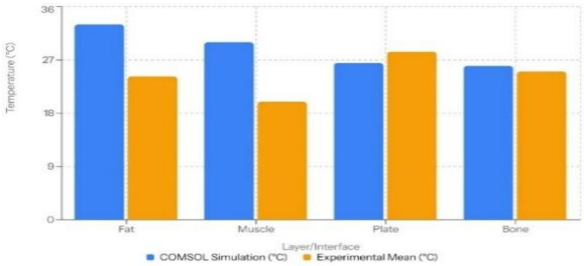

Fig. 11. Titanium Plate COMSOL® Simulation x Experimental Mean.
Source: the author.

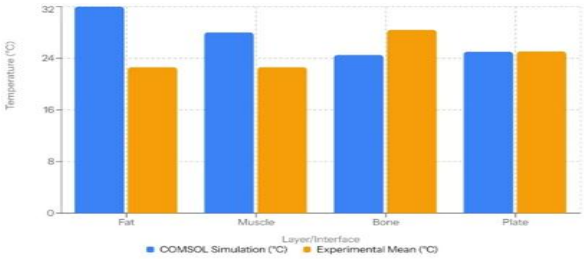

Fig. 12. Stainless Steel Plate: COMSOL® Simulation x Experimental Mean.
Source: the author.

At this point, it is important to note that the objective of the experiments was to simulate conditions close to the real case. Thus, the phantom thicknesses are similar to the real case, and the implants are of the same type and size as those used in practice. Therefore, the behaviour of the implants is expected to approximate the real case. In the simulation, however, the implants have the same size and thickness, which allowed us to observe that the heating at the metal-bone interface was much lower than at the muscle-bone interface in the control case.

VII. Conclusion

This study evaluated the thermal effects of therapeutic ultrasound on phantoms with orthopedic implants. The main findings are:

1. Safety Hierarchy: The Control Group reached dangerous temperatures (56.31°C), while Titanium (25.05°C) and Stainless-Steel (23.98°C) remained safe.

2. Heat Sink Effect: Metallic plates effectively protect bone tissue by dissipating thermal energy and reflecting acoustic waves.

3. Material Performance: Stainless steel provided a slightly higher cooling effect for the bone layer compared to titanium under the tested conditions. Maybe because it is a larger piece.

4. Clinical Recommendation: The results suggest that therapeutic ultrasound at 1.0 W/cm² appears safe for patients with internal fixators, provided the transducer is moved continuously to avoid soft tissue hotspots. Complementary experiments *in vivo* are needed.

Limitations include the use of static phantoms without blood perfusion. Future research should incorporate vascular cooling simulations and evaluate pulsed ultrasound modes to further refine safety protocols. Smaller implant sizes can have a different behavior and should be tested to see if the temperature has similar comportment.

Conflict of Interest

The authors declare that there are no conflicts of interest.

***Abstract*— Mastitis is the primary disease affecting dairy cows, causing significant economic losses due to reduced production and a decline in the quality of milk intended for human consumption. Among conventional therapies, antibiotics are widely recommended but can foster the emergence of resistant strains. This study aimed to develop and evaluate a universal photobiomodulation (PBM) prototype for coupling with commercial milking equipment. The device was designed using modeling software and fabricated via 3D printing; it was then deployed on a farm with Jersey cows, which were mechanically milked twice daily. Over three consecutive weeks, the front teats of each cow were subjected to PBM through an energy density (ED) of 2.76 J/cm². Milk samples were collected weekly before, during, and after the intervention for quality analysis. The results demonstrated that the prototype was incorporated into the milking system without compromising the seal, enabling safe PBM application without altering milk quality parameters.**

Keywords— Cow, mechanical milking, photobiomodulation, prevention.

I. Introduction

Photobiomodulation (PBM) is a non-invasive technique that uses red or near-infrared light to stimulate healing, alleviate pain, and reduce inflammatory processes. In veterinary medicine, PBM has been applied in various fields, including rehabilitation, sports medicine, and general practice [1]. In dairy animals, studies report its use for the treatment and prevention of teat hyperkeratosis [2] and mastitis [3–7].

Among the most significant diseases in dairy farming, mastitis directly compromises productivity, milk quality, and farm profitability. Beyond the economic losses associated with reduced production and the disposal of contaminated milk, the disease poses a public health risk due to antibiotic residues and potential pathogens in the final product. Therefore, mastitis control and prevention are essential to ensuring the sustainability, competitiveness, and food safety of the dairy supply chain [8,9].

Subclinical mastitis, which is highly prevalent in dairy herds, represents the most concerning form of the disease; it presents no visible clinical signs and manifests only through changes in milk composition, making its monitoring and control indispensable [10,11].

Despite the availability of portable PBM equipment, one of the major challenges is adapting it to veterinary routines, particularly for large animals, to prevent mammary gland diseases [12]. This is because the devices must be used for extended periods, multiple times a day, in alignment with farm milking schedules, which often leads to premature equipment fatigue.

Given this context, this study aimed to develop a PBM prototype adaptable to commercial milking equipment, enabling its daily use on dairy farms.

II. Material and Methods

A. Device setup

To develop a PBM prototype compatible with commercially available mechanical milking systems, Computer-Aided Design (CAD) software (v. 2025, Autodesk Inc., Mill Valley, CA, USA) was used for 2D and 3D design. The optoelectronic system was fabricated using a 3D printer (Replicator Z18, MakerBot Print, China) and black polylactic acid (PLA) filament.

B. Device and PBM beam parameters

Four flanges were produced based on the 3D-printed PBM optical system. The device has a diameter of 9 cm and a height of 2.4 cm. Near-infrared (940 nm) LEDs (5 mm diameter package, GaAlAs, L-51AEIR1BC, China) were installed on each flange, totaling 50 units geometrically distributed over a circular active area of 39 cm² (Fig. 1a and b).

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

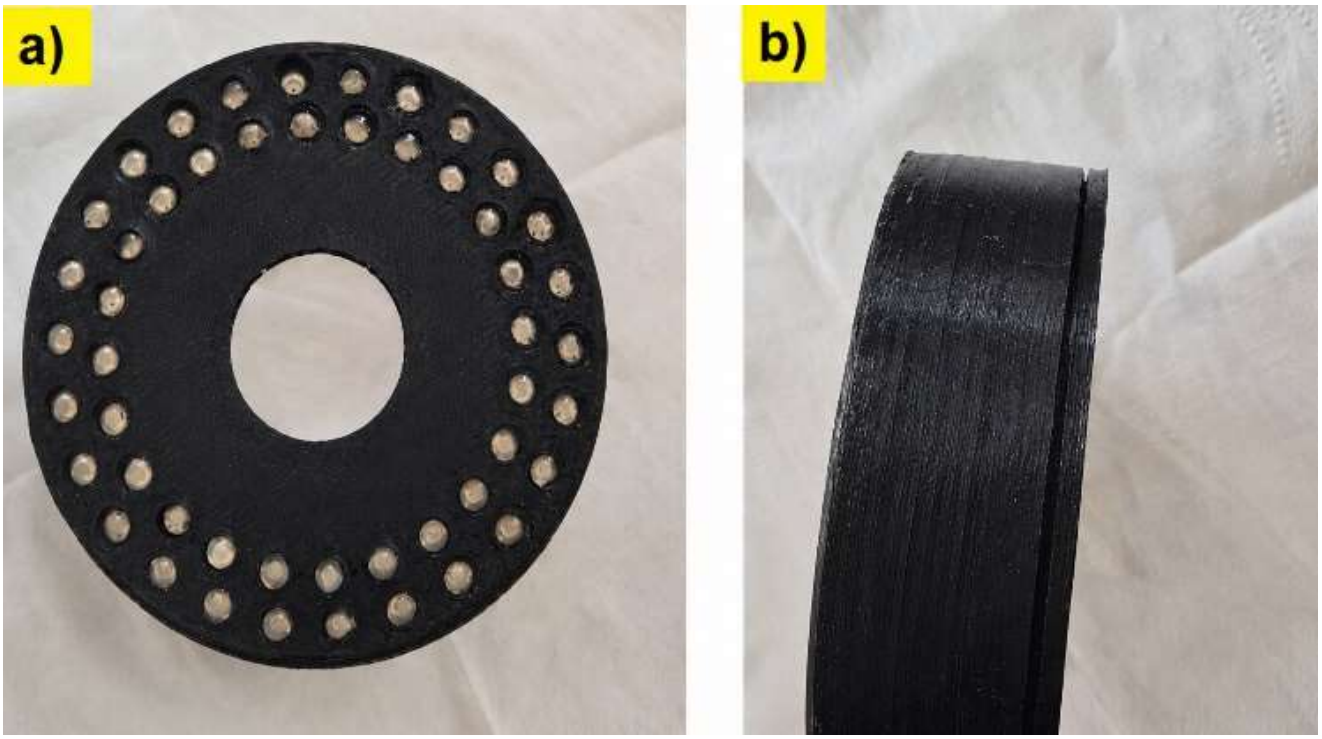

Fig. 1: PBM prototype developed using a 3D printer; front (a) and side (b) views with the near-infrared LEDs.

Each LED-equipped flange emitted a total optical power of 0.9 W, resulting in a power density of 23 mW/cm². The total incident optical energy, considering the four LED flanges (Fig. 2 – a), which are to be individually coupled (Fig. 2 – b) to each of the animal's four teats, corresponds to a radiant energy per session of approximately 650 J.

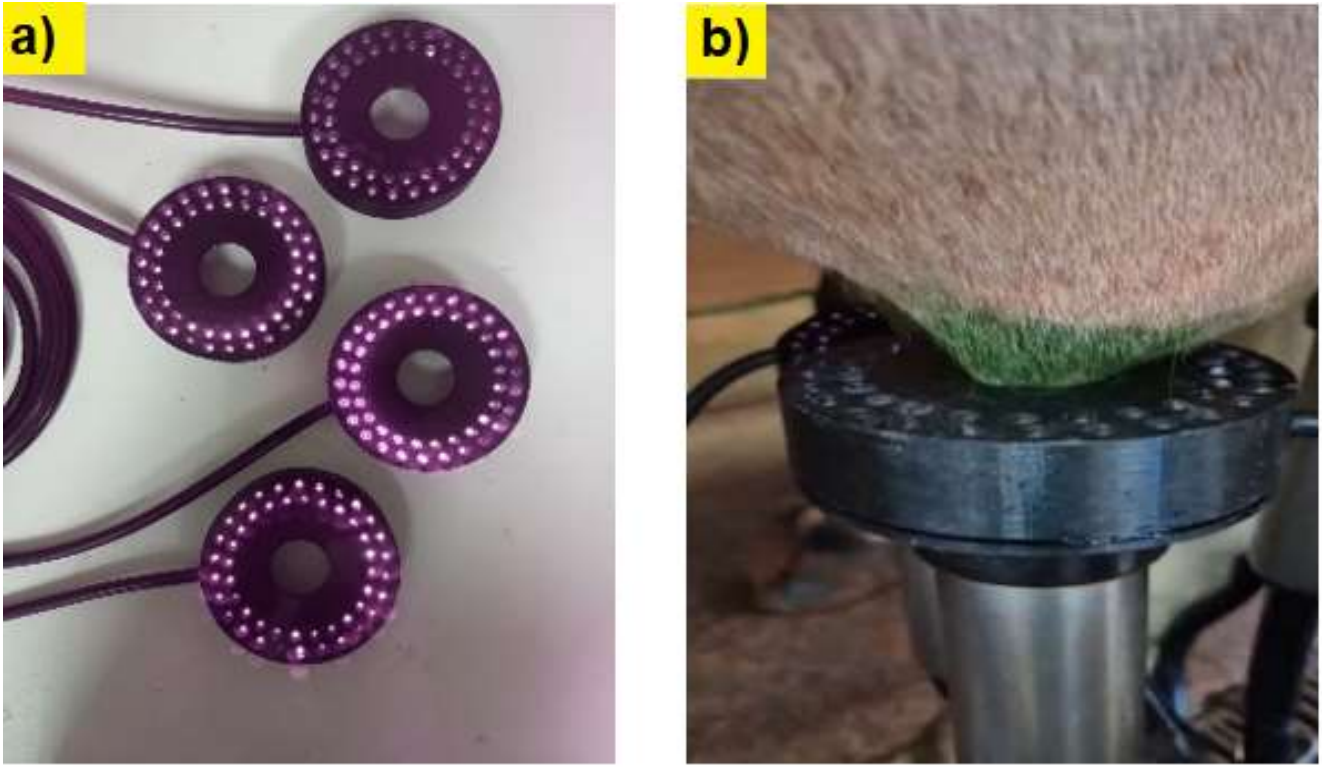

Fig. 2: Prototype assembled with LEDs (a) and coupled to the mechanical milking equipment (b) in operation.

C. Experimental setup

Jersey cows healthy (n=4) and without mastitis (n=14 functional teats), were mechanically milked twice daily at the Universidade Estadual de Londrina (UEL) Teaching-Farm, received PBM following project ethical approval (CEUA No. 031.2023).

The milking system used at UEL Farm is a compact system (mod. P100, DeLaval Ltda., Jaguariúna-SP, Brazil) with an in-line parlor, allowing for the simultaneous milking of two animals. Vacuum calibrations and the replacement of silicone parts are carried out every six months, in accordance with the manufacturer's recommendations.

System cleaning and sanitization take place twice daily, following these steps:

- Pre-milking: closed-circuit cleaning for 10 minutes using a commercial sanitizing product diluted in 40 L of water at 70°C, followed by two rinses with water at ambient temperature.
- Post-milking: closed-circuit cleaning for 10 minutes using an alkaline detergent diluted in 40 L of water at 70°C, followed by two 5-minute rinses with water at ambient temperature.

Additionally, a more intensive cleaning process is performed once a week during the post-milking phase. In this step, a commercial acid detergent is used prior to the alkaline detergent, followed by two 5-minute rinses with water heated to 70°C, after which the farm's standard routine is resumed.

The protocol spanned three consecutive weeks, including every milking session during that period. The optoelectronic PBM system was integrated into the milking equipment; PBM was applied only to the front teats of each cow, while the rear teats served as internal controls.

To evaluate milk quality, three time points were compared: before the intervention (time zero / control – Pre), during the intervention (three consecutive weeks, without interruption), and after the intervention (two weeks without the optical system in use (Post)). An ED of 2.76 J/cm² was evaluated during every milking session throughout the three weeks, as shown in Table 1.

TABLE 1: EXPERIMENTAL PBM PROTOCOL CONDUCTED ON THE COWS MILKED.

Stage	Experimental stage setup
Pre-PBM	Milk samples *(n=14)* were collected from each teat of every animal for initial monitoring.
During-PBM	PBM was applied for 2 min in each session and three consecutive weeks during every milking session (twice daily, following the farm's routine) at an ED of 2.76 J/cm². Milk samples *(n=34)* were collected weekly from each teat of every animal for monitoring.
Post-PBM	The cows went two consecutive weeks without PBM light stimulation while being milked according to the farm's routine; milk samples were collected weekly for assessment. Milk samples *(n=28)* were collected from each teat of every animal for the final monitoring stage.

D. Milk laboratory analysis

Milk samples were collected weekly after cleaning the teats, and before milking (n=76*)*. The samples were collected from each cow's teat, stored in sterile vials, refrigerated for 24 hours, and packed in isothermal boxes with recyclable ice and shipped to the official laboratory of the Ministério da Agricultura e Pecuária (MAPA) in Curitiba-PR, Brazil.

Milk samples were analyzed for content/composition (protein, fat, lactose, total solids, % w/w), Somatic Cell Count (SCC, mil/mL), and Total Bacterial Count (TBC, 10^3 CFU/mL).

E. Milk statistical analysis

Milk data were analyzed using GraphPad Instat software (v. 3.0; GraphPad Software Inc., San Diego, CA, USA). Differences in milk parameters measured before (Pre-PBM), during (During-PBM), and after (Post-PBM) PBM were analyzed using a one-way repeated-measures ANOVA with Dunnett's multiple-comparison test, with Pre-PBM values as the control. Statistical significance was set at $p < 0.05$.

III. Results and Discussion

No signals of discomfort, restlessness, irritability, or burns were observed on the teats during or after the protocol, indicating that the device is potentially safe and may be applied even in dairy animals, which corroborates previous studies [4,6,7,12] demonstrating the PBM potential in veterinary medicine, particularly in dairy cows.

Paudyal *et al.* (2026) [13] highlight in their review that PBM presents a ‘therapeutic window’ between 600 and 1100 nm (red and near-infrared). The authors emphasize that optical dosage must account for penetration depth and animal size; specifically, cattle require higher energy levels than smaller animals, underscoring the need to make specific adjustments to commercial devices for veterinary use.

Adapting equipment originally developed for human use to large-animal use presents a significant challenge. Key barriers include the need to adjust optical dosages, compatibility issues between different types of optical fibers, and limitations regarding applicator probes, which often fail to meet the demands of veterinary routines involving production animals. In many cases, these difficulties render the technique impractical, underscoring the need to develop specialized devices that are suitable for daily use and focused on disease prevention [5, 6, 12].

In previous studies evaluating the application of PBM in dairy cows [5, 6, 12], adapted equipment exhibited several limitations, such as poor durability under continuous handling, ineffective sealing in humid environments, and an inability to accommodate teats with anatomical malformations or greater thickness; additionally, vacuum loss during milking frequently caused the device to fall to the ground. These issues were overcome in the present study, as the photonic device, externally attached to universal-type milking equipment, proved compatible with any commercially available system. It

did not compromise the vacuum and ensured animal comfort during milking, making it an efficient and safe solution.

Regarding the optical dosages applied, Moreira *et al.* (2022, 2024) [5, 6] tested energy levels of 2.5 and 5 J/cm², while Valongo *et al.* (2024) [12] evaluated a dose of 10 J/cm² in dairy cows. In the present study, a similar ED was applied; these dosages had been previously investigated in other studies, with no reports of side effects during short-term application periods. Unlike those studies, the applications here were performed twice daily for 3 consecutive weeks, totaling 42 sessions per optical dosage, allowing evaluation of safety and efficacy under a prolonged-use regimen.

Favaretto *et al.* (2024) [14], in a study on clinical mastitis in cows, applied laser at wavelengths of 808 nm (1.4 W) and 637 nm (1 W), corresponding to power densities of 1.4 and 1 W/cm², respectively, with irradiation of 2 minutes per wavelength for 5 consecutive days. The authors demonstrated that the combination of these options was safe and effective as an adjuvant therapy to antibiotic therapy. Complementarily, Lage *et al.* (2014) [2] used a red-infrared LED device applied three times a week for six weeks and observed that, although it did not reverse the hyperkeratosis lesions of the cows' teats, it caused the incidence of subclinical mastitis (SCC > 250 mil cells/mL). Overall, these results suggest that even relatively low doses of LED can modulate inflammatory processes and prevent the progression of teat lesions, highlighting the potential of PBM for mammary gland health.

Regarding the assessment of milk quality, the results showed that PBM applied using 940 nm infrared LEDs at an ED of 2.76 J/cm² resulted in no statistically significant differences ($p > 0.05$) in milk quality between treated and control teats regarding protein, fat, and lactose content, total solids, SCC, and TBC. Thus, milk quality was maintained throughout and remained within current national regulatory standards for human consumption [15, 16], as illustrated in Figure 3.

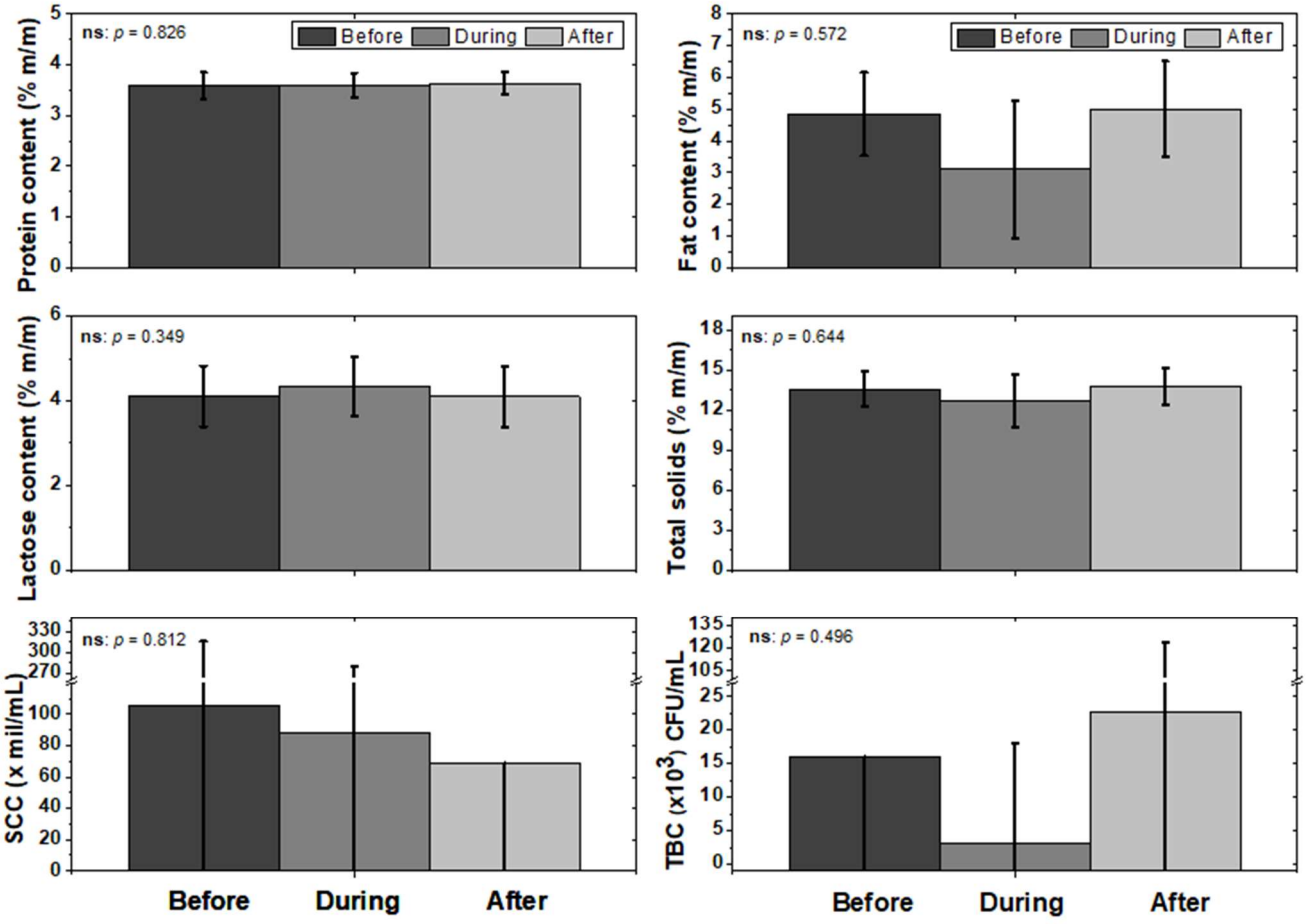

Fig. 3: Evaluation before, during and after PBM of milk quality with daily application of an energy density of 2.76 J/cm². The PBM device was applied twice daily for 21 consecutive days, for a total of 42 sessions. Data expressed as Mean and Standard Deviation (SD) values. ns: non-significant.

These findings reaffirm that PBM can be safely employed without compromising the quality of milk intended for human consumption, corroborating evidence from previous studies [5, 6, 12-14].

The cows included in this preliminary study were healthy, with no cases of clinical or subclinical mastitis, and produced milk within the parameters recommended for human consumption. The use of the PBM device, both during and after PBM, did not cause teat lesions that could predispose the animals to subclinical mastitis in the event of aseptic failure, as described in other studies [8,10,11].

The data presented reinforce that PBM is a sustainability-aligned strategy that can reduce antibiotic reliance and promote animal welfare, thereby contributing to mastitis

prevention in dairy cows. However, further studies are needed, considering different milking practices, incorporating optimized protocols with longer application periods, and including larger sample sizes aiming to consolidate and expand the applicability of this technology.

IV – CONCLUSION

A universal 3D-printed PBM device compatible with commercial milking systems was successfully developed and validated. The prototype maintained vacuum integrity during routine milking, resisted daily sanitation procedures, and enabled safe PBM application without affecting milk quality. These findings support the feasibility of integrating PBM into routine dairy farming as a practical strategy for mastitis prevention.

***Abstract*— Continuous monitoring of physiological parameters in neonatal patients requires technological solutions that combine mobility, connectivity, and low cost. This study presents the development and evaluation of a proof-of-concept for a wearable, wireless, multiparameter system. The prototype integrates pulse oximetry (MAX30102) and body temperature (AHT25) sensors into an architecture based on ESP32 microcontrollers, which handle the acquisition, processing, and transmission of physiological data. Data are displayed locally on a screen and sent to the ThingSpeak® platform for remote monitoring. Testing demonstrated the integrated operation of the data acquisition, processing, visualization, and transmission modules, as well as the execution of alert routines implemented in the firmware. Additionally, the system operated for approximately 2.6 h. The results confirm the technical feasibility proposed and its potential for future applications in neonatal monitoring.**

Keywords*— Edge Computing, ESP32, Neonatal Monitoring, Internet of Things.

I. INTRODUCTION

This study presents the open architecture and benchtop evaluation of a low-cost, wireless multiparametric wearable prototype aimed at continuous data acquisition, serving as a preliminary step toward supporting non-invasive neonatal monitoring. [2,3].

In Brazilian hospital context, devices predominantly used to monitor newborns' vital signs are bedside multiparametric monitors [2]. Although accurate, such systems pose significant operational limitations when applied in the reality of neonatology [4]. An example is pulse oximetry, where most devices and peripheral sensors were originally designed to meet the ergonomic parameters and tissue characteristics of adult patients [4,5]. This morphological incompatibility can hinder proper sensor placement on newborns' limbs, especially in premature and low-birth-weight infants, compromising the quality of the photoplethysmographic (PPG) signal and increasing susceptibility to motion artifacts and inconsistent readings [4,5].

Additionally, hospital-grade sensors placed on the fingers are typically ineffective at mitigating motion artifacts from active infants [4]. Due to reflexes and spontaneous limb movements, these rigid devices easily detach, triggering recurrent false alarms that cause alarm fatigue among nursing staff or, more seriously, the actual interruption of monitoring [6]. In parallel, the large volume of cables required to connect the sensors can restrict the newborn's mobility and hinder care procedures in neonatal units [3]. This limitation can also act as a barrier to performing the Kangaroo Method and skin-to-skin contact between parents and children [7,8]. Outside the intensive care ecosystem, the vulnerability scenario is exacerbated by the lack of wireless, low-cost home monitoring systems adapted to neonatal anatomy [2,9].

Various approaches in the literature propose developing wireless architectures to mitigate the impact of cables on neonatal monitoring. Recent studies have investigated the use of wearable sensors and remote monitoring systems in both hospital settings and at-home follow-up of newborns [5,6,10]. However, many of these solutions focus on the acquisition and transmission of physiological signals. At the same time, integration with multiparametric monitoring, local alert processing, real-time wireless communication, and remote follow-up support remains limited.

To address this gap, this work aims to develop and evaluate a proof-of-concept for a wireless multiparametric system adapted to neonatal anatomy. In this way, it seeks to expand the capacity for continuous monitoring and to promote the early identification of predefined, potentially critical conditions in both hospital and home environments.

II. METHODOLOGY

From a methodological perspective, this work was structured around identifying project requirements based on the specialized literature.

The system's electronic architecture was centered on the ESP32-S3 Touch LCD 1.69 board, which features a dual-core microcontroller (MCU), integrated Wi-Fi and Bluetooth connectivity, and a 1.69-inch LCD screen (240x280 pixels) with a touchscreen interface (ST7789V2 driver) [11]. The touchscreen enabled the system to be organized into multiple navigation screens, facilitating switching between parameter viewing and real-time data monitoring, as shown in Fig. 1. Additionally, bench tests were conducted in a controlled environment to evaluate the prototype's functional

performance indicators.

Fig. 1. Displays of the ser interface into multiple navigation screens accessible via touchscreen.

A. Specification of Requirements

The first phase of development consisted of mapping the system's functional and non-functional requirements, based on international recommendations for neonatal care proposed by the World Health Organization (WHO) [12] and on evidence from recent literature on neonatal monitoring and wireless wearable devices [2,9,10].

Among the functional requirements established for the system, the capacity for synchronous acquisition of the PPG signal to estimate peripheral oxygen saturation (SpO2) and heart rate (HR), as well as continuous monitoring of body temperature (T), was highlighted. Associated with crying detection and the local triggering of humanized audible alerts, the system utilizes a miniature, square-shaped magnetic micro-speaker (mod. 1609, China) with an impedance of 8 Ω and a maximum power of 1 W [13].

As a non-functional requirement, it was established that the system should operate without wired connections between the newborn and external equipment during use, employing wireless communication for physiological data transmission and alert generation, thereby potentially supporting patient mobility and reducing limitations associated with conventional monitoring systems.

The mechanical requirements were also designed to minimize newborn handling and to reduce the presence of rigid or excessively heavy elements that might restrict mobility. In this way, the design sought to potentially reduce the risk of injuries resulting from mechanical pressure, friction, or improper sensor positioning, in line with the principles of neuroprotective care and the preservation of neonatal skin integrity [2,9,10,14].

B. Hardware Architecture and Selection of Components

The processing core is centered on the ESP32-S3 Touch LCD 1.69 platform (Espressif Systems Co. Ltd., Shanghai, China) [11], selected for its embedded processing capabilities, integrated graphical interface, and wireless connectivity. The system architecture is complemented by independent peripheral modules based on the ESP32-C3 Super Mini microcontroller (Espressif Systems Co. Ltd., Shanghai, China) [15], responsible for physiological signal acquisition and wireless communication with the central unit.

For the acquisition of the monitored physiological parameters, two high-sensitivity digital sensors were integrated, interconnected to the MCU via the I2C (Inter-Integrated Circuit) communication bus:

Oximetry and PPG Module: A CJMCU development module based on the MAX30102 sensor (Analog Devices Inc., Wilmington, USA) was used. It incorporates light-emitting LEDs in the red (660 nm) and infrared (880 nm) wavelengths, along with a high-sensitivity photodetector, an 18-bit analog-to-digital converter (ADC), and integrated ambient-light interference-rejection mechanisms [16].

Thermometry Module: For measuring neonatal body temperature, the AHT25 digital sensor (Aosong Electronics Co., Ltd./ASAIR, Guangzhou, China) was used, selected for its high resolution and accuracy in physiological monitoring applications, as well as its compatibility with low-power embedded systems [17].

The electrical power supply circuit, shown in Fig. 2, uses 3.7 V, 600 mAh lithium-ion batteries integrated with the TP4056 integrated circuit (Nanjing Top Power ASIC Corp., Nanjing, China) [18] to manage charging. The power, regulated at 3.3 V, is distributed independently among the three functional peripheral modules, based on the ESP32-C3-Super Mini MCU (Espressif Systems Co. Ltd., Shanghai, China) [15]. The first module performs the acquisition of SpO_2 and HR via the MAX30102 PPG sensor (Analog Devices Inc., Wilmington, USA) [16]; the second monitors temperature with the AHT25 digital sensor [17]; and the third comprises the acoustic system with the MAX4466 microphone (Maxim Integrated, San Jose, USA) [19] and the DFPlayer Mini player (DFRobot, Shanghai, China) [20], associated with the speaker [13]. Data collected by these nodes is transmitted via the ESP-NOW protocol to an ESP32-S3 Touch LCD central concentrator [11], which is responsible for real-time processing, local display, sending data to the cloud, and remote activation of the DFPlayer's audible alerts.

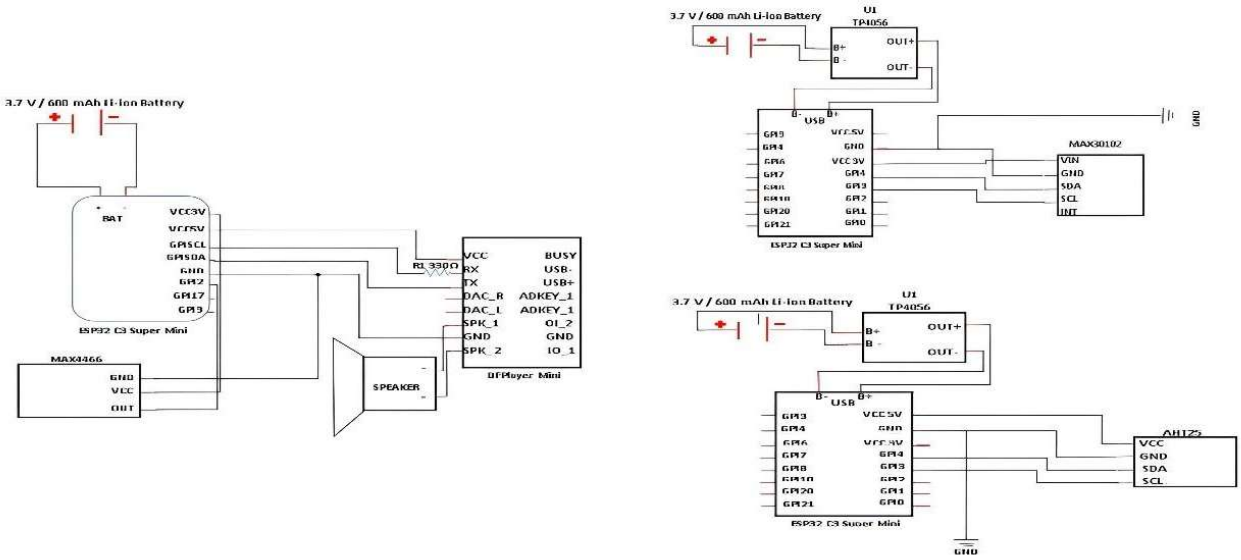

Fig. 2. Schematic diagram of the circuit for power supply and energy management of the neonatal multiparametric device.

C. Firmware, Edge Processing, and IoT Protocol

The ESP32-S3 firmware was developed in C++ and structured on FreeRTOS. Wireless communication between the peripheral nodes (ESP32-C3) and the central unit (ESP32-S3) uses the proprietary ESP-NOW protocol—a communication technology operating at the data link layer (MAC) without a router, enabling rapid packet transmission without burdening traditional connections. This technology was selected for its low transmission latency. The system performs continuous local sampling and applies a digital moving average filter to attenuate noise and transient fluctuations during signal acquisition, aiming to yield more consistent SpO_2 and HR results.

The calculation of SpO_2 is based on the ratio-of-ratios method, widely used in pulse oximetry systems to estimate arterial oxygen saturation from differential light absorption at red and infrared wavelengths.

Locally processed data are transmitted via Wi-Fi to the ThingSpeak® platform using HTTP requests, sending telemetry at 15-second intervals. This architecture enables cloud storage and remote monitoring of physiological variables, thereby characterizing an Internet of Things (IoT) application for continuous monitoring of neonatal parameters [21].

D. Demonstration and Bench Test Protocol

The prototype's operation was initially tested on a bench. The evaluation of thermal readings was performed by coupling the AHT25 sensor to a temperature reference system, enabling analysis of the sensor's behavior over the range of 34.0 to 42.0 °C.

To evaluate the robustness of wireless communication and the software architecture, a continuous physiological data transmission test to the monitoring platform was conducted via Wi-Fi. These tests aimed to analyze communication stability, data integrity and system behavior over long operating periods. The data recorded on the ThingSpeak® platform were used to analyze the temporal behavior of the monitored variables, thereby verifying the system's operational stability and the consistency of measurements during experimental testing.

III. RESULTS AND DISCUSSION

A. Device

Based on the established methodological workflow, the prototype is presented in Fig. 3a. It illustrates the oximetry (MAX30102) and temperature (AHT25) sensors integrated into bands made of elastic strap and Velcro fasteners for personalized contact with the neonatal limb and skin. Fig. 3b shows the encapsulated modules operating independently and wirelessly, communicating directly with the central unit, which is equipped with an LCD for data visualization.

Fig. 3. Functional prototype of the developed system in two views: (a) sensors exposed in the bands; (b) encapsulated modules and central unit.

Fig. 4 presents the system algorithm's flowchart, illustrating its continuous operating cycle. Initially, the SpO_2, HR, T sensors, and the dedicated microphone for cry detection are read. Next, the raw data are filtered and signal-averaged to attenuate noise, followed by local calculation and processing of biometric variables. After updating the display, the algorithm executes a conditional structure to check the neonatal behavioral state ("*Is the baby crying?*"). If affirmative, the system activates the audio to reproduce white noise or the mother's pre-recorded voice. Simultaneously with sending data to the cloud via the ThingSpeak® platform, the system evaluates whether parameters are outside normal limits. If anomalies are detected, an audible alert is emitted, categorized by thermal zones based on WHO guidelines [12]: 37.5 °C for feverish state, 38.0 °C for established fever, and 40.0 °C as a critical level of attention, then returning to the beginning of the cycle for a new evaluation of vital signs.

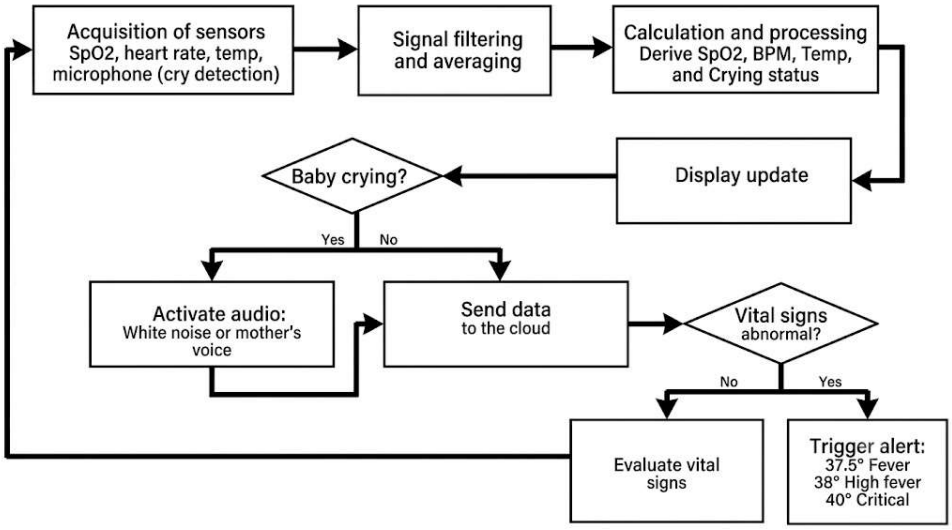

Fig. 4. Flowchart of the system architecture for neonatal multiparametric monitoring. Diagram adjusted using the Nano Gemini® AI-tool.

B. Functional Bench Tests

The prototype underwent functional bench testing to evaluate the functionality of the sensors, embedded processing routines, alert mechanisms, and wireless communication, as well as to evaluate system performance through oximetry indicators (%SpO_2), heart rate (BPM), body temperature (°C), wireless communication stability, and energy autonomy.

The developed prototype had an approximate weight of 32 g, including the battery, MCU, sensors, and the 1.69" ESP-S3 LCD. The system architecture was organized into functional modules responsible for physiological signal acquisition, data processing, power management, user interface, and remote communication. The sensors were distributed in specific modules as described below:

- Pulse Module: Oximetry module consisting of the MAX30102 sensor and a compact housing developed by additive manufacturing (3D printing) using white PLA (Polylactic Acid) filament. The housing was designed to mechanically accommodate the sensor, facilitate its positioning within the monitoring region, and provide greater

stability during PPG signal acquisition. The use of 3D printing enabled the fabrication of a structure with customized dimensions that meet project requirements, allowing geometric adjustments and adaptations during prototype development and tailoring the device to the specific needs identified for neonatal monitoring.

- Temperature Module: Thermal monitoring module featuring the AHT25 digital sensor in its original housing, designed to be positioned in future tests in the neonatal axillary region so that the metal sensing capsule remains in direct contact with the skin for data acquisition.

Benchtop limitations: tests were limited to simulated adult resting-state parameters (65–75 BPM and standard SpO2 values). These preliminary evaluations do not establish measurement accuracy in neonatal physiological ranges (120–160 BPM), nor do they account for motion artifacts, skin temperature variations, low peripheral perfusion, or long-term biocompatibility.

C. Evaluation of Performance Indicators

The evaluation phase aimed to validate the prototype's functionality and its capacity to acquire, process, and transmit physiological parameters through bench tests, assessing communication between electronic modules, the system's operational stability, and data transmission to the remote monitoring platform.

- Operational Stability of the System: The evaluation of the system occurred by monitoring the history of requests sent to ThingSpeak®, allowing the acquisition, processing, and transmission of data from the sensors integrated into the prototype. Each test lasted 60 minutes, with sampling every 15 seconds, enabling analysis of the operation of the distributed architecture comprising ESP32-C3-based acquisition modules and an ESP32-S3-based central unit, as well as communication between devices and the transmission of information to the monitoring platform.

- Oxygen Saturation (% SpO_2): The oximetry module based on the MAX30102 sensor was evaluated on the bench using an electronic patient simulator capable of simulating physiological signals compatible with HR and SpO_2 parameters. The procedure validated the LEDs' physical activation and the photodiode's ability to capture the reflection of the optical signal generated by the simulator. At the same time, the programming interface was used to verify the raw data reading. As shown in Fig. 5, the system continuously acquired and transmitted information to the central unit throughout the 60-minute trial, operating stably and without communication bus failures.

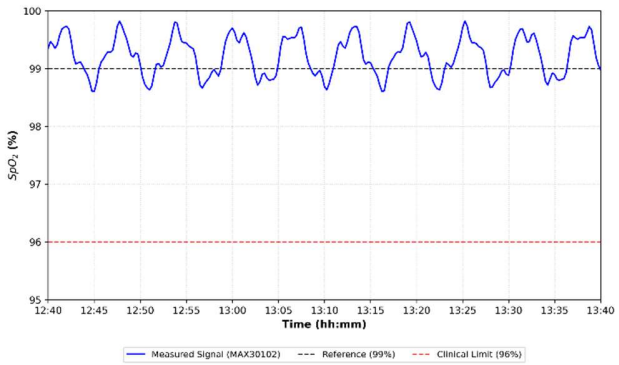

Fig. 5. SpO_2 (%) data obtained with the MAX30102 sensor. *Note:* Benchtop validation was performed using adult/resting-state simulation parameters (65–75 BPM) to evaluate baseline signal acquisition stability

- Heart Rate (BPM): Bench tests evaluate the acquisition of PPG signals, from which the firmware algorithm calculates HR by identifying pulse peaks. It should be noted that during these initial benchtop tests, simulation parameters were set to adult resting-state heart rates (65–75 BPM) to evaluate basic signal processing and transmission stability before clinical trials in neonatal ranges (120–160 BPM). As presented in Fig. 6, the module operated continuously during the 60-minute test, maintaining stable readings in the range of 65 to 75 BPM, corresponding to the condition simulated during the tests.

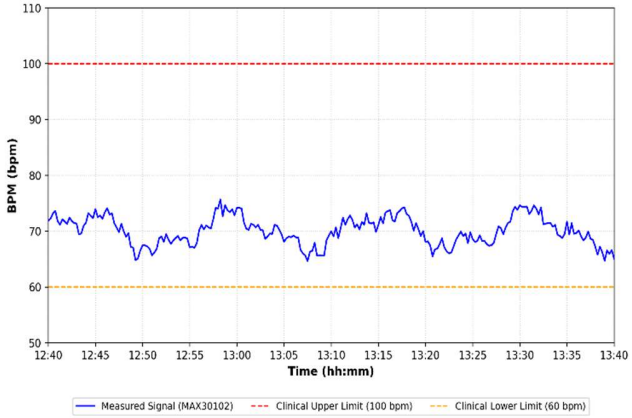

Fig. 6. HR (BPM) logs obtained by the MAX30102 sensor.

- Body Temperature: Fig. 7 presents the temperature data obtained by the AHT25 sensor. The curve records the initial room temperature reading at 20 °C before the start of the test. To evaluate the system's dynamic response, the sensor was subjected to an abrupt thermal variation that simulated the target temperature. The component required 0.45 s to register the thermal transition and stabilize the reading at around 36.5 °C, with residual oscillations of less than ±0.2 °C. Under the conditions evaluated, these results enabled observation of the sensor response and the alert routine's processing time in response to the applied thermal variation.

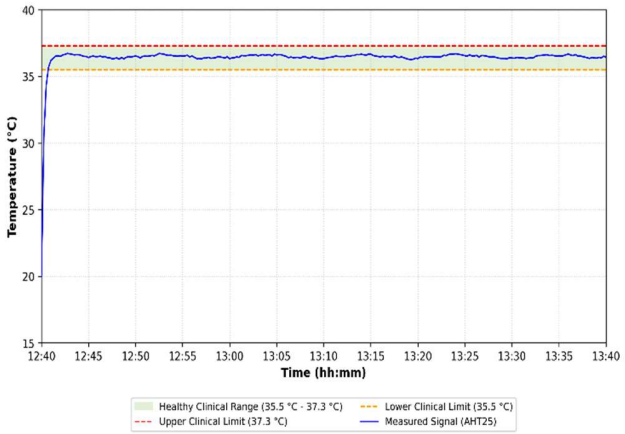

Fig. 7. Reading and thermal stability (°C) of the AHT25 sensor during functional system validation.

- Network Reliability and IoT Data Integrity: During the tests, the data acquired and validated by the acquisition modules were transmitted to the ThingSpeak® platform and made available for remote monitoring. The system employs a verification step to detect blood pulsation using the MAX30102 sensor's infrared (IR) signal before transmitting data. Consequently, only readings deemed valid, obtained when stable blood pulsation is detected over the sensor, are transmitted via ESP-NOW, reducing the risk of inconsistent records and improving remote monitoring reliability. Bench tests indicated proper reception of the transmitted information, contributing to the reliability of remote monitoring.

- Energy Efficiency and Autonomy: The prototype was powered by a lithium polymer (LiPo) battery with a nominal capacity of 600 mAh. During system operation, the acquisition, processing, and data transmission modules functioned continuously, demonstrating the technical feasibility of operation with a portable power supply. However, the resulting runtime is insufficient to support prolonged use of the prototype for the intended application. was verified using a digital oscilloscope (mod. TDS 2024C, Tektronix, Inc., Beaverton, OR, USA), with an average demand of 230 mA when the MAX30102 oximetry sensor was active and periodic data transmission via the wireless network was enabled. Communication periods account for the system's main energy demand due to the integrated radio's activity. Based on these electrical parameters, the module's nominal continuous-discharge autonomy is approximately 2.6 hours.

- Alert Latency and Evaluation of Intervention Logic: To evaluate the system speed, a critical anomaly was simulated through abrupt temperature variation and crying identification. The algorithm processed the variables and triggered the alert in 1.8 s after detecting the events. This response time demonstrates the system's ability to trigger an alert shortly after event detection; future studies should evaluate its potential contribution to reducing this time under the monitored conditions.

- Local Alert System Operation: During the tests, the system identified situations where sensor signals were absent and automatically executed the alert routine implemented in the firmware. Under this condition, the sound reproduction module was activated to emit the preconfigured voice message, providing a local response from the device.

Bench tests validated the MCU firmware interrupt routine for triggering the audible temperature alert via the micro-speaker. Local activation occurred immediately upon detecting the critical threshold, set to 37.5-40.0 °C during programming, and operated autonomously on the embedded unit without relying on external processing or cloud communication. The integrity of the audio signal was verified through logical monitoring of the MCU output pins and direct acoustic validation in the test environment, confirming correct execution of the alert code.

Future studies in neonatal patients may evaluate system performance under different motion and usage conditions. Additionally, the literature highlights the clinical relevance of continuous body temperature monitoring, especially in premature newborns, who are more susceptible to thermal disturbances due to immaturity of thermoregulatory mechanisms [9,22].

D. Kangaroo Method and Neonatal Care

Using a wireless architecture based on ESP32 MCUs eliminates the need for cables to transmit physiological data between system modules throughout the monitoring period, reducing limitations associated with the use of conventional wired connections; furthermore, the ESP32 family modules used in this project hold ANATEL (Agência Nacional de Telecomunicações) national regulatory certification [23] regarding radiofrequency and telecommunications requirements. However, this certification does not equate to approval of the system as a medical device. Consequently, any future application in a hospital setting would require additional evaluations concerning safety, performance, electromagnetic compatibility, and applicable regulatory requirements. In the literature, the Kangaroo Method is recognized as an important strategy for the care of low-birth-weight infants, based on skin-to-skin contact between the baby and their caregivers [7,8]. In this context, wireless monitoring solutions have been investigated as alternatives to reduce physical interference during neonatal care and evaluate the integration of continuous monitoring and humanized care [3,9,10].

Thus, the proposed system features characteristics consistent with current trends in wireless neonatal monitoring reported in the literature, enabling remote acquisition of physiological parameters without requiring permanent physical connections between device modules.

E. Comparative Cost and Functionality Analysis

Table I presents a comparison among the proposed system, hospital neonatal monitoring equipment and a commercial home care monitor. The developed system presents a lower estimated material cost than the final retail value of the other devices, which included certification and commercialization costs. In addition, the prototype integrates

SpO_2, HR, and T monitoring into a single platform, combining wireless connectivity, open cloud storage, and easily replaceable components.

TABLE I. COMPARATIVE COST AND FUNCTIONALITY ANALYSIS

Category	Hospital Monitor (Masimo/Philips)	Owlet Dream Sock	Proposed System
Cost (BRL / R$)	15,000 – 40,000	1,600 – 4,000	350 – 500
Measured Parameters	SpO_2, HR, Temperature	SpO_2, HR	SpO_2, HR, Temperature
Connectivity	Wired	*Bluetooth*	Wi-Fi
Response	Local Alarm	Smartphone Alerts	Audible Alarm, Mobile Alert
Data Storage	Restricted	Company	ThingSpeak®
Maintenance	Specialized Service	Device Replacement	Commercial Off-the-Shelf Components
Weight (g)	1,360 - 5,900	25 - 30	20 - 32
Battery Life (h)	3 - 4	8 – 16	2.6
Dimension (H x W x L) (cm)	22.9 x 10.2 x 16.5	4.1 x 2.3 x 0.8-15.5	4 x 2.8 x 2.2

Hospital multiparametric monitors used in neonatal units, such as the Masimo Rad-97 (Masimo Corporation, Irvine, CA, USA) [24] and the Philips IntelliVue MX450 (Philips Healthcare, Amsterdam, Netherlands) [25], integrate several physiological parameters into a single monitoring platform, including SpO_2, heart rate, temperature, and other vital signs. However, these solutions generally incur higher acquisition and maintenance costs than devices designed for home use or research prototypes. On the other hand, wearable devices intended for residential monitoring, such as the Owlet Dream Sock (Owlet Technologies Inc., Lehi, UT, USA) [26], employ optical sensors for physiological monitoring and utilize proprietary platforms for data storage and visualization. In comparison, the proposed system uses a wireless communication architecture and an open platform for remote monitoring, combined with low-cost, easily replaceable components, as presented in Table I.

One feature of the prototype is the reproduction of pre-recorded audio messages when certain conditions configured in the system are met. Unlike conventional audible alarms widely used in monitoring systems, this functionality was conceived to provide an alternative signaling method for caregivers. The literature highlights that frequent exposure to alarms can pose a challenge in neonatal environments, contributing to the phenomenon known as alarm fatigue [6]. In this context, the implemented feature offers a complementary approach to user interaction. In future versions, its potential use in a hospital setting could be evaluated, including its relationship to more humanized approaches to neonatal monitoring.

Data from the prototype were sent to the ThingSpeak® platform for storage and visualization. Although the platform has its own access control mechanisms, a specific assessment of the system's overall cybersecurity, including data protection during transmission, storage, and processing, was not conducted in this study phase, and will be analyzed in future versions.

Thus, future evaluations should consider various movement and positioning conditions, as well as aspects related to cleaning and contamination control, material biocompatibility, and device safety, before any clinical application.

Although the battery life was preliminarily estimated at around 2.6 h, which limits prolonged home monitoring or support for the Kangaroo Method, future research will focus on firmware optimization to reduce the system's duty cycle (active time). Since the prototype already uses the ESP-NOW protocol for low-latency direct communication, the intention is to implement the ESP32-C3's Deep Sleep low-power mode between sampling intervals. This approach will allow powering down the radio and peripherals almost instantaneously after data packet transmission, drastically reducing average current and extending operational autonomy to levels that could significantly extend the prototype's operational autonomy.

Additionally, further development of the prototype will require obtaining applicable ethical and regulatory approvals in future stages involving neonates. This includes comparative clinical studies against gold-standard reference equipment and quantitative agreement analyses (e.g., Bland–Altman plots, mean absolute error, root mean square error) between prototype measurements and those from certified devices, aiming to evaluate the performance of monitoring algorithms under various physiological conditions. Finally, transitioning from an experimental prototype to a product intended for clinical application evidently requires additional development steps, including electrical and thermal safety testing, mechanical risk assessment, human factors and usability evaluation, electromagnetic compatibility testing, and compliance with relevant regulatory requirements.

Comprehensive evaluations regarding electrical safety, thermal dissipation, mechanical choking hazards from small enclosure components, infection control protocols, and telemetry data encryption (cybersecurity over HTTP to ThingSpeak®) remain to be addressed in future clinical-grade iterations.

IV. CONCLUSION

The system for wireless multiparametric monitoring developed in this study demonstrated the technical feasibility of integrating sensors into a wearable architecture. The results showed proper functioning of the acquisition, processing, visualization, and remote transmission of physiological data, utilizing low-cost components and an open monitoring platform.

Wireless communication eliminated the need for cables to transmit data between devices, potentially providing greater flexibility during newborn care. Additionally, the system correctly executed the local processing and alert routines implemented in the firmware.

It should be emphasized that the results obtained

correspond to a proof-of-concept evaluated exclusively under benchtop conditions. The open, low-cost architecture represents the main contribution of this work; extensive clinical validation, quantitative accuracy assessment, risk analysis, and regulatory approval are mandatory prior to any healthcare or home application.

ACKNOWLEDGEMENTS

The authors thank the Federal University of Technology – Paraná (UTFPR) for making resources available for the project development, and the Araucária Foundation (FA) and the Superintendency of Science, Technology and Higher Education (SETI) for the conference grant awarded to H. C. C.

***Abstract*— The objective of this study was to develop a computational tool to prioritize preventive maintenance of endoscopes based on their technical evaluation. A predictive model was developed to estimate equipment failure risk based on the Random Forest Regressor algorithm. Two partial indicators were defined: P_1. Global relevance score, which aggregates operational variables related to equipment usage and maintenance conditions and, P_2. Weighted failure risk, which considers different types of recorded failures and their respective criticality weights. From these indicators, a global indicator called Integrated Risk was developed, representing the technical condition of the equipment. A qualitative scale with three categories was defined: good, attention and critical technical conditions, representing operational criticality levels of the medical devices. The model was applied to a sample of 39 video-gastroscopes from the Endoscopy Department of Hospital Beneficência Portuguesa in São Paulo, Brazil. Results were distributed as follows: six devices in good condition, 17 in attention condition, and 16 in critical condition. These preliminary results suggest that the proposed approach may support technical prioritization processes and preventive maintenance planning in hospital engineering management.**

Keywords—Random Forest regressor, health technology assessment, preventive maintenance.

I. INTRODUCTION

The management of hospital medical equipment is a fundamental component of healthcare administration, ensuring availability, traceability, and proper maintenance of technological resources. In the endoscopy sector, characterized by intensive use of high-cost and complex equipment, the adoption of computerized management systems contributes to process optimization, risk reduction, and improved patient safety. In this context, programs aimed at organizing and monitoring the equipment lifecycle represent strategic tools to support decision-making, promoting operational efficiency and sustainability in hospital practice.

The objective of this work was to develop and preliminarily evaluate a computational tool to support preventive maintenance prioritization of endoscopes based on operational and maintenance indicators derived from a previously developed mathematical model [1]. The Random Forest Regressor was explored as a predictive approximation approach to estimate equipment criticality from historical operational variables [2, 3]. This algorithm operates through the combination of multiple decision trees trained from random samples of the dataset. The goal was to provide a criterion to support prioritization of preventive maintenance, considering operational history and characteristics specific to each type of endoscope. The analyzed dataset included a sample of 39 video gastroscopes from the endoscopy sector of Hospital Beneficência Portuguesa in São Paulo, Brazil.

II. METHODOLOGY

The proposed framework combines a deterministic technical risk formulation with a machine learning predictive stage. Initially, the integrated risk indicator was mathematically constructed from operational and maintenance variables using predefined weighting factors. Subsequently, the Random Forest Regressor was trained to learn nonlinear relationships between the operational variables and the integrated risk score. Therefore, the machine learning stage acts as a predictive approximation model capable of estimating equipment criticality patterns from historical operational behavior.

Two partial indicators and one final criticality indicator were defined:

P_1. *Global relevance score*, which brings together operational variables related to the use and maintenance conditions of the equipment.

P_2. *Weighted failure risk*, which considers the different types of failures recorded and their respective criticality weights.

These two indicators were combined to form the Integrated Risk, representing a consolidated measure of the technical condition and criticality of the equipment.

Integrated Risk Indicator. Defined as the target variable (Y) of the predictive model. The Random Forest Regressor is trained using independent variables (X) related to operational and historical characteristics. During the training process, the algorithm learns the patterns present in historical data and the relationship between these variables and the previously calculated integrated risk.

A. Random Forest Regressor Algorithm

The operation of the Random Forest Regressor (RFR) is based on three key principles: bootstrap aggregation (bagging), which generates random training subsets to reduce variance; random feature selection, which increases diversity among individual trees; and prediction aggregation, where the final

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

output is obtained by averaging the predictions of all trees [2, 3]. As we said, in this study the RFR was used to estimate an integrated risk score associated with the criticality of medical equipment based on technical and operational variables. The resulting risk score enables the classification of equipment into priority levels, supporting preventive maintenance planning, technical interventions, and replacement decision-making processes.

The RFR model was developed in Python using the Scikit-learn library to predict the target variable based on the selected operational and technical indicators. Data preprocessing and analysis were performed with the support of the Pandas and NumPy libraries, while visualization of the results was carried out using Matplotlib and Seaborn. The model was configured with 200 decision trees and no restriction on tree depth, allowing the algorithm to fully capture complex nonlinear relationships within the dataset. To ensure reproducibility, a fixed random seed (random_state = 42) was adopted.

B. Mathematical Model

Five variables were selected with associated relevance weights (ρ_i) (Table I). These variables were considered representative of the technical and operational characteristics of the equipment. The variables considered most relevant were corrective maintenance and days out of service, given that they represent how many failures the equipment presented and how many days the equipment was out of use, respectively.

TABLE I. TECHNICAL VARIABLES

Variavel (x_i)	Weight (p)
x_1 Corrective maintenance (C)	1.0
x_2 Days out of service (D)	1.0
x_3 Preventive maintenance (P)	0.8
x_4 Equipment age (I)	0.7
x_5 Type of failure (F)	

It is important to emphasize that the variable x_2 is defined from the ranges of days the equipment is out of operation. Each range has an associated value as shown in Table II.

TABLE II. INTERVALS FOR VARIABLE X_2. DAYS OUT OF SERVICE

Days interval	Relevance(p)
[0, 30]	0,2
[31, 90]	0,7
[> 91]	1,0

*Global relevance score (Gr***)**. This partial indicator is defined by (1).

$$Gr = \sum_{i=1}^{4} \rho_i \, x_i \quad (1)$$

Weighted Failure Risk (Fr). This partial indicator is formed from the failures that the gastroscope presented. The failures were classified into five main types, and the rest into "other failures" (Table III). 1) Control buttons, are used to operate and control the different functions of the device. 2) Leaks, are usually caused by microcracks or damage to the external sheath, allowing fluids to enter the interior of the device. If not detected in time, they can lead to electronic failures, internal corrosion, and accelerated deterioration of the device. 3) Control knobs, are used to maneuver the distal tip of the insertion tube during a procedure. They provide fine control of angulation, which is essential for proper visualization, targeted examination, biopsy, and therapeutic interventions. 4) Images, related to the image quality display at the monitor. 5) Perforations, refer to tears or holes in the insertion tube, bending section, or internal channels. These defects can cause several serious failures: loss of insufflation, mechanical instability or infection risk, among others. Each type of failure has a specific value (M_5) according to the degree of relevance. This variable is basically formed by the sum of the failures with their respective weights.

TABLE III. TYPE OF FAILURE

x_5	Q_5	M_5
1	Control buttons (CB)	0.25
2	Leaks (L)	0.5
3	Control knobs (CK)	0.75
4	Images (I)	1.0
5	Perforations (P)	1.0
6	*Other failures* (OF)	0.5

The Fr indicator is defined by the mathematical function (2) formed by the failures presented in each piece of equipment, with the weighting factor corresponding to each failure.

$$Fr = \sum_{j=1}^{6} \rho_j \, x_5 \quad (2)$$

Where, ρ_j is the value of each type of failure, j = {1, ..., 6}

Integrated Risk (RI). The construction of this indicator aims to more accurately represent the actual criticality, that is, the technical condition of the equipment, considering not only its failures but also its other operational characteristics. The Integrated Risk (RI) is represented by a mathematical function that incorporates the two partial indicators previously described, along with their respective relevance factors, as shown in (3).

$$R_I = (0.6)\ Gr_k + (0.4)\ Fr_k \quad (3)$$

Where: k = {1, ..., 39}

C. Application of the Random Forest Regressor Algorithm

After constructing the partial indicators and calculating the Integrated Risk, defined as the target variable (Y) of the model, the predictive modeling stage begins using the Random Forest Regressor algorithm, as illustrated in Fig. 1. The independent variables (X) (Table 1) were used for the algorithm training. Additionally, other variable was included: equipment label. This variable originally categorical, was converted into a numerical format using label encoding, allowing its use in the model without introducing any hierarchical relationship among categories.

Qualitative Scale. A qualitative scale was defined to facilitate the interpretation of the results generated by the predictive model. This scale allows the numerical value of the integrated risk to be interpreted in terms of the technical and operational condition of the equipment. To this end, three main evaluation categories were established: good condition,

attention, and critical, which represent different levels of operational criticality identified from the risk score calculated by the model (Table IV).

TABLE IV. QUALITATIVE SCALE FOR THE NUMERICAL VALUE OF RI

R_I Interval	Technical condition
[0.0, 0.3]	Good
[0.31, 0.6]	Attention
[0.61, 1.0]	Critical

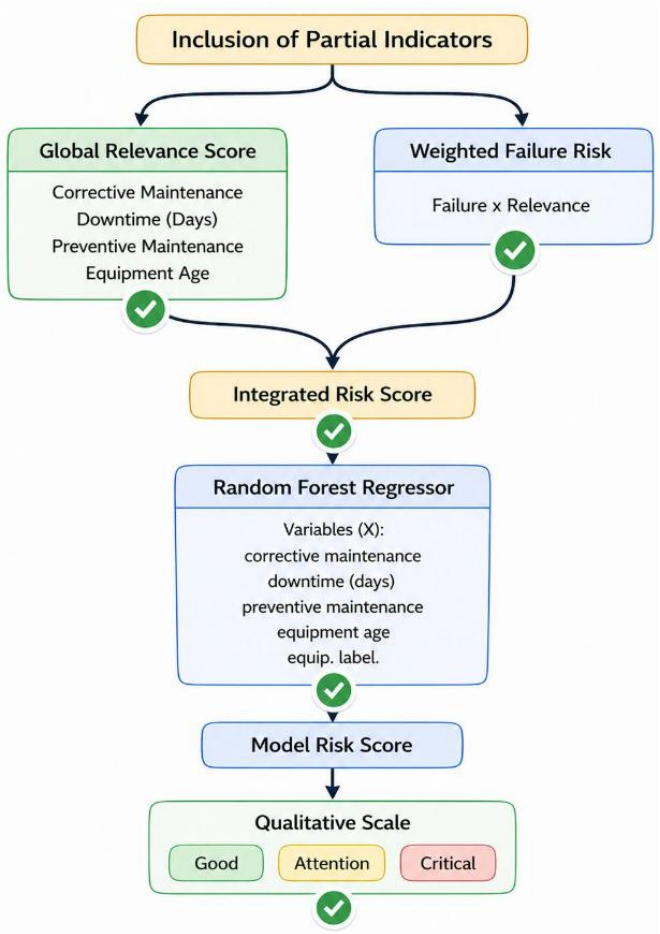

Fig. 1. Algorithm flowchart

D. Statistical Validation of the Predictive Model

The dataset was divided into training and testing subsets, where 75% of the observations were used for model training and 25% were reserved for independent performance evaluation. Due to the limited sample size (n = 39), k-fold cross-validation was additionally considered to reduce overfitting effects and improve the robustness of model evaluation. Model performance was evaluated using the coefficient of determination (R^2), mean absolute error (MAE), and root mean square error (RMSE). Feature importance analysis was also performed to identify the variables with the greatest influence on the estimated integrated risk.

III. RESULTS

The model was applied for technical evaluation to a sample of 39 videogastroscopes: 36 standard gastroscopes and 3 ultrasound gastroscopes (US). The results were distributed as follows:

Good technical condition. Six video-gastroscopes were classified in this condition (Table V). They presented low values of downtime, as well as absence or low occurrence of corrective maintenance and, in some cases, records of preventive maintenance. These factors contributed to lower integrated risk scores in the model. Observe equipment G5 and G6 presented the highest risk values within this group. This behavior can be explained primarily by downtime and the occurrence of failures. For example, G5 registered just one failure, while G6 presented two occurrences. In contrast, the remaining equipment showed no downtime or recorded failures.

TABLE V. RESULTS OF THE INTEGRATED RISK SCORE OF 39 GASTROSCOPES

Video gastroscope	Integrated risk	Qualitative status
G1	0.03	
G2	0.10	
G3	0.15	Good
G4	0.16	
G5	0.25	
G6	0.25	
G7	0.37	
G8	0.37	
G9	0.37	
G10	0.37	
G11	0.37	
G12	0.42	
G13	0.44	
G14	0.45	
G15	0.46	Attention
G16	0,49	
G17	0.49	
G18	0.49	
G19	0.49	
G20	0.49	
G21	0.49	
G22	0.49	
G23+US	0.58	
G24	0.60	
G25	0.61	
G26	0.64	
G27	0.66	
G28	0.66	
G29	0.68	
G30	0.71	
G31	0.72	
G32	0.72	Critical
G33	0.72	
G34	0.75	
G35	0.76	
G36	0.78	
G37	0.79	
G38+US	0.82	
G39+US	0.89	

Attention technical condition. There were classified 17 video-gastroscopes in this condition. They presented intermediate Integrate Risk (RI) scores [0.37, 0.58] (Table V). In general, these devices showed an absence of preventive maintenance and/or the presence of corrective maintenance. Observed that equipment G23 exhibited the highest RI score (RI = 0.58) within this group. This may reflect occurrence of corrective maintenance has a significant influence on the increase of the risk score in this classification condition.

Critical condition. 16 Video-gastroscopes were classified in this category. They presented the highest RI scores (Table V). The RI is mainly associated with the combination of prolonged periods of downtime and a higher occurrence of corrective maintenance. For example, equipment G39 exhibited the highest risk score in the sample (RI = 0.89). This result is primarily associated with a high value of the corrective maintenance variable.

A. Statistical Validation of the Predictive Model

We analyzed the dataset using a Random Forest Regressor (RFR) with Integrated Risk (RI) as the target variable. The model performance is shown in Table VI. Observe that R^2 indicates that approximately 75.2% of the variance in the RI score was explained by the selected predictors. Five-fold cross-validation produced a mean R^2=0.630, suggesting moderate generalization capability despite the limited sample size.

TABLE VI. MODEL PERFORMANCE

Metric	Value
R^2 (Test Set)	0.752
MAE	0.108
RMSE	0.142
Mean Cross-Validation R^2 (5-fold)	0.630

Feature importance analysis revealed that days out of service was the most influential predictor of the Integrated Risk score (Table VII). This indicates that prolonged equipment downtime has the strongest impact on the estimated technical criticality of video-gastroscopes. Failure type and corrective maintenance history also contributed substantially to the model predictions, while preventive maintenance showed a moderate influence. In contrast, equipment age exhibited a relatively low contribution, suggesting that operational performance indicators may provide more relevant information regarding equipment criticality than chronological age alone. These findings support the use of reliability and maintenance-related variables as primary criteria for prioritizing preventive maintenance interventions.

TABLE VII. FEATURE IMPORTANCE

Variable	Importance
Days Out of Service	0.574
Failure Type	0.144
Corrective Maintenance	0.138
Preventive Maintenance	0.123
Equipment Age	0.021

To further evaluate the predictive performance of the RFR, an Observed versus Predicted plot was generated (Fig. 2). Observe a strong agreement between the actual and estimated Integrated Risk values, with most observations distributed near the identity line. That is, RFR successfully captured the relationship between operational variables and equipment criticality. Although a moderate dispersion was observed for some high-risk cases, no evident systematic prediction bias was identified. These findings are consistent with the obtained performance metrics (R^2 = 0.752, MAE = 0.108, RMSE = 0.142) and support the applicability of the model as a preliminary decision-support tool for maintenance prioritization. Nevertheless, further validation with larger datasets is required to assess the robustness and generalizability of the proposed methodology.

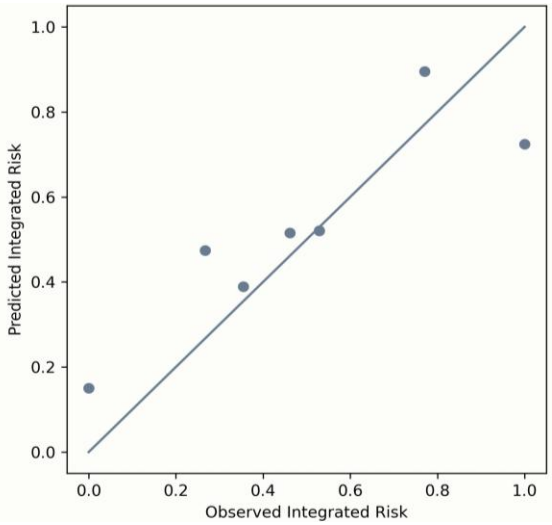

Fig. 2. Observed versus Predicted plot

IV. DISCUSSION

Compared with traditional maintenance prioritization approaches based exclusively on equipment age or corrective maintenance frequency, the proposed framework integrates multiple operational dimensions into a unified risk representation. This multidimensional approach allows identification of equipment presenting hidden operational vulnerability even when isolated indicators remain within acceptable ranges.

Although the Random Forest model demonstrated the ability to reproduce patterns associated with operational criticality, it is important to recognize that the integrated risk score itself was constructed from predefined engineering criteria. Therefore, the predictive model should not be interpreted as an autonomous diagnostic system, but rather as a computational mechanism capable of approximating complex maintenance relationships and supporting prioritization processes. In addition, the strong influence of corrective maintenance and downtime observed in the results suggests that operational instability may play a more relevant role in equipment criticality than age alone. This finding may contribute to maintenance planning strategies focused on reliability and availability indicators.

From a biomedical engineering perspective, the proposed framework may contribute to the evolution of intelligent hospital maintenance systems aligned with Industry 4.0 principles [4]. The integration of predictive maintenance models with hospital management platforms, and digital equipment lifecycle management may improve operational efficiency and reduce equipment downtime.

A. Limitations of the Study

This study presents some limitations that should be considered when interpreting the results. First, the dataset was obtained from a single hospital institution and included a reduced sample size (39 video-gastroscopes). This limitation may affect the generalizability and robustness of the predictive model and increase the risk of overfitting.

Second, the weighting coefficients used in the mathematical formulation were partially based on expert-defined relevance assumptions. Although these coefficients were designed to represent technical criticality, different institutional contexts may require coefficient recalibration.

Finally, the study should be considered exploratory due to the reduced sample size. Future multicenter studies involving larger datasets and different categories of endoscopic equipment are necessary to validate the external generalizability of the proposed framework.

V. CONCLUSIONS

The proposed computational tool demonstrated the potential to assist the prioritization of preventive maintenance actions for endoscopic equipment by integrating operational and maintenance-related variables into a unified risk indicator.

The results suggest that corrective maintenance history and prolonged downtime are strongly associated with increased integrated risk scores, while preventive maintenance may contribute to mitigating equipment criticality. Therefore, the current framework should be interpreted as an exploratory predictive support tool rather than a definitive maintenance decision system.

Future work should incorporate artificial intelligence techniques to improve transparency and interpretability, as well as, multicenter datasets and external validation procedures to improve robustness, scalability, and integration with intelligent hospital technology management systems. The proposed model could be incorporated into real-time maintenance ecosystems capable of continuously updating equipment criticality according to operational behavior and technical intervention history.

ACKNOWLEDGMENT

The authors of this work would like to thank Eng. Mike V Baroni for authorizing the use of the data presented in his undergraduate work, since without this valuable information, the development of the present study would not have been possible.

***Abstract*— Healthcare decision-making often requires balancing clinical performance, economic constraints, and practical implementation requirements. When selecting a technology from among several alternatives, decision-makers must consider not only cost-effectiveness but also factors such as resource requirements, portability, environmental robustness, and ease of use. This study proposes a scenario-based multi-criteria decision analysis framework to support the selection of sensing technologies for human milk analysis. The framework was motivated by the need for a low-cost, portable device capable of measuring fat and protein concentrations in human milk samples. Three candidate sensing technologies were evaluated across three healthcare settings: a Primary Healthcare Unit, a Human Milk Bank, and a High-Complexity Tertiary Hospital. Technology-specific performance scores were combined with scenario-specific criterion weights using a normalized weighted-sum model. Results indicate that the relative suitability of the candidate technologies within the proposed framework depends on the operational conditions and clinical priorities of the intended healthcare setting.**

***Keywords*— human milk, MCDA, sensors.**

I. Introduction

Healthcare decision-making is a complex process that requires balancing clinical effectiveness, economic constraints, operational feasibility, and technological availability. Such decisions occur at multiple levels of healthcare systems, ranging from the routine selection of diagnostic tools by healthcare professionals [1] to public policy formulation and health technology incorporation [2], [3]. In particular, data science tools provide a promising means of supporting healthcare professionals in daily decision-making by enabling the analysis of the large volumes of patient data available in hospital settings [1]. Given the importance of multi-criteria decision-making for population health and welfare, evidence-based health technology assessment (HTA) procedures have increasingly been adopted by government health agencies worldwide [2], [3]. Researchers have also proposed incorporating HTA approaches into the early stages of medical device development, including the prototyping phase [4].

When selecting a new medical device from among several candidate technologies, clinical performance remains a fundamental requirement. However, practical factors such as affordability, portability, ease of use, interoperability, and the characteristics of a country's healthcare infrastructure [5] frequently determine whether a technology can be successfully implemented in real-world settings. Consequently, the adoption of biomedical devices increasingly requires structured decision-support approaches capable of simultaneously considering multiple, often conflicting evaluation criteria that extend beyond conventional cost-effectiveness considerations [6].

This challenge has become particularly evident with the rapid expansion of portable sensing technologies for point-of-care testing. Advances in biosensors, microelectronics, optical systems, and embedded computing have enabled the development of compact, low-cost diagnostic devices capable of generating clinically relevant information outside conventional laboratory environments. These technologies

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

are especially attractive in low- and middle-income countries, where geographical barriers, financial constraints, and limited specialized infrastructure frequently restrict access to laboratory-based diagnostic services. Ewen et al. [7] conducted a survey in six low- and middle-income countries—Fiji, Indonesia, Kyrgyzstan, Mali, Peru, and Vietnam—to investigate the availability and affordability of devices for self-monitoring blood glucose. In some of these countries, the availability of glucose meters for diabetes management was as low as 0% in public healthcare facilities and 31% in private pharmacies, while prices ranged from the equivalent of 1.5 to 10.9 days' wages. Xu et al. [8] described the potential scalability of low-cost, reusable wireless skin sensors designed to transmit newborn physiological data to smartphones. Such technologies may contribute to reducing mortality among preterm newborns in low-income countries.

In recent years, our research group has been involved in the development of low-cost sensors, with a particular focus on healthcare systems in low-income countries. One notable example is the Preemie-Test device, which uses optical sensing techniques to estimate gestational age [9] and assess pulmonary maturity [10] immediately after birth. The device provides clinically relevant information in settings where advanced diagnostic resources may not be readily available. Our current research investigates the effects of global warming on maternal and child health. In this context, the nutritional composition of human milk represents an important indicator of maternal and infant health. A recent systematic review [11] suggests a declining trend in milk fat and protein concentrations among mammals exposed to heat stress. We therefore aim to design or select, from among candidate technologies, an appropriate low-cost, portable sensing device capable of measuring fat and protein concentrations in human milk.

The present study addresses this practical need by proposing a scenario-based multi-criteria decision-support framework for evaluating and selecting sensing technologies capable of measuring specific macronutrients in human milk. The framework combines technology-specific performance scores with scenario-dependent weighting to support sensor selection across healthcare settings with different operational and clinical requirements.

The remainder of this paper is organized as follows. Section 2 introduces the proposed multi-criteria decision-support framework, including the evaluation criteria, performance-scoring scale (PSS), scenario-specific weighting strategy (W), and normalized weighted-sum procedure. Section 3 presents the healthcare scenarios and section 4 describes the candidate sensing technologies evaluated in this particular study. Section 5 presents and discusses the comparative results for each clinical scenario. Finally, Section 6 summarizes the main contributions, limitations, and directions for future research.

II. Proposed Framework

A. Multi-Criteria Evaluation Procedure

The proposed framework aims to classify quantitatively the candidate sensing technologies according to a performance-scoring scale (PSS), which characterizes the degree of compliance to technical criteria, and a set of weights (W) that specify the importance of each criteria to a specific healthcare scenario.

PSS and W were combined using a normalized weighted-sum model. The final weighted score S was calculated as:

$$S_{ts} = \frac{\sum_{i=1}^{10}(P_{ti} \times W_{is})}{\sum_{i=1}^{10} W_{is}} \quad (1)$$

In the above, P represents PSS, W the weight, t is the index of the sensor technologies, s is the index of the healthcare scenarios and i is the index of the i-th criterion. Therefore, P_{ti} represents the PSS assigned for technology t according to criteria i and W_{is} represents the weight assigned to criteria i in the s-th application scenario. It is expected that the development team will analyze the candidate sensing techniques and assign P and W values, allowing thus the calculation of the final scores given to each candidate technology. Higher values of the score indicator S_{ts} represent greater overall suitability of the sensing technology for the corresponding healthcare scenario.

B. Study Design

The proposed framework was applied to the comparative evaluation of candidate sensing technologies for human milk analysis. The framework was designed to compare the candidate technologies using a consistent evaluation structure while accounting for the operational and clinical requirements of different healthcare settings. Three technologies were selected based on previously reported applications in the assessment of milk properties. For each scenario, each sensing technology was evaluated according to 10 evaluation criteria, each of which have one of 4 performance scores (degree of technology compliance to the criteria) and one of 5 weights (degree of criteria importance for that scenario).

C. Development Team

Our study was conducted by an interdisciplinary team composed of 8 researchers, 3 of them senior or young university professors and 5 undergraduate students. One of them is a medical student and 4 are electrical engineering undergraduate students. The medical team was responsible for the definition of the clinical scenarios and performance criteria, while the engineering team was responsible for the technical analysis of the candidate sensor technologies.

The team worked in a collaborative way in order to avoid biased decisions as much as possible. However, it is advisable to keep in mind that the setting of PSS and W values in this way is not completely free of tendencies. This is a matter of future investigations in our work, *i.e.* to develop systematic data-based procedures to quantify technical relevance and scenario-specific agreement. In the current stage, the framework has been used for definition of which sensor technologies should be considered for in-depth study, actual development and testing.

D. Development of Evaluation Criteria

The set of 10 evaluation criteria was established to represent the main clinical, analytical, operational, safety, and implementation-related dimensions involved in the adoption of sensing technologies in healthcare practice. The criteria took in consideration clinical relevance, accuracy and reliability, usability, response time, cost, environmental robustness, user safety, sample handling practicality, integration with health information systems, and portability.

Each sensing technology was evaluated using a four-level PSS ranging from 0 to 3. A score of 0 indicated unacceptable performance, 1 indicated limited performance associated with substantial implementation constraints, 2 indicated acceptable performance with manageable limitations, and 3 indicated optimal or near-optimal performance for the intended application. Criterion-specific scoring descriptors were defined before the evaluation to improve transparency, consistency, reproducibility, and avoid biased conclusions, as summarized in Table 1. In particular, the Response Time criterion was defined as the total time from milk sample preparation to result availability.

TABLE I. TEN CRITERION-SPECIFIC DESCRIPTORS FOR THE INTRINSIC PSS.

Criterion/PSS	**0**	**1**	**2**	**3**
1. Clinical relevance	No relevant application to the intended clinical purpose	Indirect relevance; limited potential to support decision-making	Supports decision-making in selected situations	Directly and consistently supports decision-making for the intended application
2. Accuracy and reliability	Inconsistent results or unacceptable agreement with reference methods	High variability or frequent disagreement with reference methods	Acceptable agreement with limited variability	High agreement and consistent reproducibility
3. Usability	Impractical; requires highly specialized expertise	Complex procedure or extensive formal training	Moderate operational complexity; brief training required	Intuitive procedure requiring little or no formal training
4. Response time	>24 h or unsuitable for the intended application	>60 min to 24 h	5–60 min	<5 min or real-time results
5. Cost	Economically unfeasible	High acquisition or operational cost; restricted to specialized centers	Moderate cost; feasible in structured services	Low cost; suitable for large-scale implementation
6. Environmental robustness	Highly unstable outside strictly controlled conditions	Frequent interference; strict environmental control required	Minor interference under usual clinical conditions	Stable under common environmental variations
7. User safety	High biological, electrical, chemical, thermal, or occupational risk	Moderate risk; rigorous protective measures required	Low risk; manageable using standard protective measures	Minimal risk; appropriate protective features incorporated
8. Sample handling practicality	Infeasible or highly complex	Multiple preparation steps or specialized equipment required	Simple collection with limited preparation	Direct or nearly direct analysis with minimal preparation
9. Integration with health information systems	No digital record or output	Manual transcription required	Non-automated digital export	Automatic integration with electronic health records or laboratory systems
10. Portability	Fixed equipment or dependent on permanent infrastructure	Difficult to transport; substantial peripheral equipment required	Moderately portable; some auxiliary equipment required	Lightweight, compact, and self-contained

E. Scenario-Based Weighting Strategy

The relative importance of each evaluation criterion varied according to the operational conditions of each healthcare setting. Therefore, a scenario-specific weight was assigned to each criterion, as described in Table 2.

Weights W were assigned using a five-level relevance scale, in which 1 indicated low importance, 2 limited importance, 3 moderate importance, 4 high importance, and 5 critical importance for the adoption of that technology in that healthcare scenario. The weights represented the expected contribution of each criterion to implementation feasibility and clinical usefulness within the corresponding healthcare environment.

TABLE 2. SCENARIO-SPECIFIC WEIGHTS ASSIGNED TO THE EVALUATION CRITERIA

Evaluation criterion	Primary Healthcare Unit	Human Milk Bank	High-Complexity Tertiary Hospital
1. Clinical relevance	5	5	5
2. Accuracy and reliability	4	5	5
3. Usability	5	3	2
4. Response time	5	4	3
5. Cost	5	3	2
6. Environmental robustness	5	4	1
7. User safety	4	5	4
8. Sample handling practicality	5	4	3
9. Integration with health information systems	3	4	5
10. Portability	3	1	1

III. Clinical Scenarios

To demonstrate the proposed framework, three representative healthcare scenarios within the Brazilian public healthcare system were considered: a Primary Healthcare Unit, a Human Milk Bank, and a High-Complexity Tertiary Hospital. These scenarios were selected because they differ substantially in their operational conditions, resource availability, technological infrastructure, workforce expertise, and clinical priorities. Nevertheless, the proposed methodology is not restricted to the Brazilian Unified Health System (*Sistema Único de Saúde*, SUS) and may be adapted to private hospital networks, research institutions, and other healthcare systems requiring structured support for health technology adoption.

A. Primary Healthcare Unit (PHU)

The PHU scenario represents public primary care facilities characterized by high patient volumes, limited financial resources, heterogeneous technological infrastructure, and limited time for healthcare professionals to undergo training or perform complex procedures. Although these facilities provide adequate infrastructure for patient care, temperature and humidity are not usually subject to rigorous control.

In this setting, successful technology adoption depends primarily on clinical usefulness, affordability, operational simplicity, rapid availability of results, environmental robustness, and straightforward sample handling. Accuracy, reliability and user safety also remain important, while digital integration and portability may provide additional implementation benefits.

B. Human Milk Bank (HMB)

The HMB scenario represents specialized facilities responsible for the collection, processing, quality control, storage, and distribution of human milk, particularly for preterm infants and other high-risk newborns. These facilities employ trained personnel, follow established biosafety protocols, and have basic laboratory infrastructure. Environmental conditions are generally more controlled than those in primary care facilities, although less rigorously than in high-complexity hospitals.

Technology adoption in this scenario is primarily guided by the clinical relevance, analytical reliability, and safety of the results because the generated information may directly influence decisions regarding milk processing, quality

control, and distribution. Traceability, sample handling practicality, and timely result availability are also important, whereas portability is less relevant because the equipment is expected to remain within the facility.

C. High-Complexity Tertiary Hospital (HCTH)

The High-Complexity Tertiary Hospital scenario represents university hospitals and referral centers equipped with advanced technological infrastructure, integrated electronic health record systems, climate-controlled environments, specialized personnel, and technical support.

In this setting, technology adoption prioritizes clinical impact, analytical performance, and digital integration. Financial and operational constraints are less restrictive than in the other scenarios, while environmental variability is minimized through infrastructure-based controls. Consequently, greater operational complexity and higher costs may be acceptable when associated with improved clinical or analytical performance. Portability and environmental robustness are comparatively less critical because the equipment can remain in a fixed, controlled environment.

IV. Candidate Technologies

A. Technology #1

Islam et al. [12] describe a 4-electrode cylindrical sensor, as illustrated in Fig. 1, which is filled with milk samples. In this figure, A, B, C, and D represent terminals connected to metallic surfaces. If a voltage is applied between terminals A and D, while grounding terminals B and C, then the cross-conductance per unit thickness (S/m), G_1, can be indirectly measured with a simple inverting operational amplifier circuit. Now, if a voltage is applied between terminals B and C while grounding terminals A and D, the cross-conductance per unit thickness G_2 can be calculated, enabling the calculation of the conductivity of the medium:

$$\sigma = \frac{\pi(G_1+G_2)}{2Lln(2)} \quad (2))$$

where L is the level of liquid inside the cylindrical device. The idea is to prepare multiple milk samples, each having a certain amount of a given element and observe the variations upon the electric quantities. The authors observe these variations under different milk contamination conditions. However, this sensor has a good potential for testing milk samples with different fat and protein contents**.**

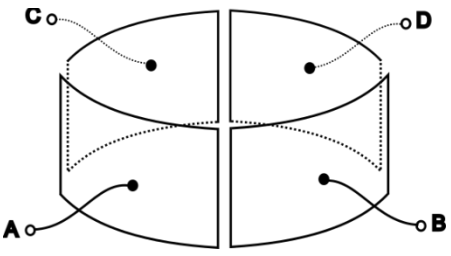

Fig.1 -A simplified illustration of the sensor described in [12]. Milk samples fill the space between the metal sheets.

B. Technology #2

Sheng et al. [13] describe an optical sensor device based on the capture of the transmitted light, after interacting with a milk sample stored within a cuvette, as illustrated in Fig. 2. One of the key aspects of this sensor device is the fact that it is based on a multi-wavelength analysis. The light source is a broadband infrared (IR) light emitting diode (LED) and the photodetector is a multi-spectral sensor capable of detecting six wavelengths: 610, 680, 730, 760, 810, and 860 nm. Such a feature allows the device to detect different absorbance signatures, so it can simultaneously detect fat and protein concentrations. Another key aspect of this technology is the post-processing of the measured signals with the Gradient-Boosted Regression Tree (GBRT) machine learning algorithm. So, an external laptop is required in addition to the elements shown in Fig. 2.

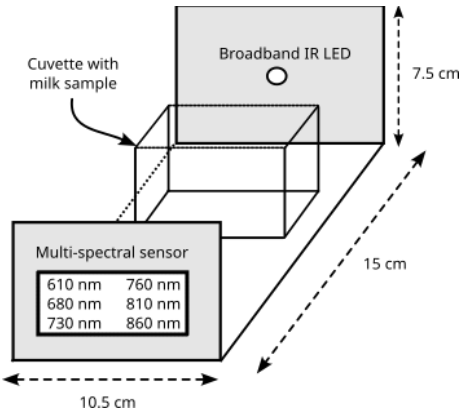

Fig.2 - A simplified illustration of the sensor described in [13].

C. Technology #3

Chakraborty and Biswas [14] describe a sensing technology which, in its first version [15], was designed to identify adulteration in commercial milk. In both versions of this technology, the impedance of a rectangular metallic probe is measured after it is immersed in milk. More specifically, authors found out that, after exciting the metallic probe with low-frequency current (500 Hz), the impedance phase varies as a function of milk fat percentage. The mechanism behind the sensing technology illustrated in Fig. 3 is chemical: a lipase layer is immobilized at the copper surface of the metallic probe. The contact of milk samples with the external lipase molecules triggers an hydrolysis process which, in turn, produces ions, affecting thus the probe impedance. Furthermore, the sensitivity of this device is potentialized with an increase of the surface area for the diffusion of ions. This is achieved after a treatment of the original copper surface with polymethyl methacrylate (PMMA), which makes it porous.

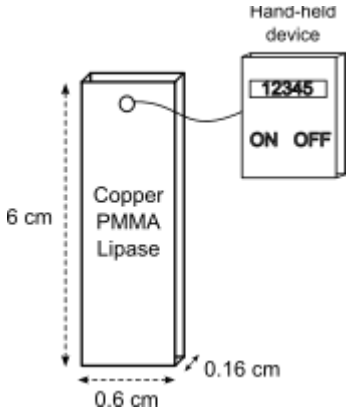

Fig.3 -A simplified illustration of the sensor described in [14].

V. Results and Discussion

Each candidate sensing technology was evaluated against the ten predefined criteria using the four-level ordinal scale described in Section 4.2. The resulting performance scores are presented in Table 3. To understand the comparative analysis, we must take into account the fact that not all information were clearly stated or declared in papers [12]-[14]. For instance, although all authors claim that their devices are cost-effective, only reference [14] brings the actual production cost (0.2 USD). In this situation, one can either make certain inferences or remove this criterion from the comparative analysis.

TABLE 3. PSS ASSIGNED TO THE CANDIDATE SENSING TECHNOLOGIES.

Evaluation criterion	Tec hnology 1 [12]	Tech nology 2 [13]	Tec hnology 3 [14]
1. Clinical relevance	1	3	2
2. Accuracy and reliability	1	2	2
3. Usability	3	2	2
4. Response time	3	3	2
5. Cost	3	2	3
6. Environmental robustness	2	1	1
7. User safety	2	2	2
8. Sample handling practicality	3	3	2
9. Integration with health information systems	1	1	1
10. Portability	3	2	2

Technology 1 [12] achieved the highest possible scores for usability, response time, cost, sample handling practicality, and portability. These scores reflected its simple operation, rapid measurement times, low estimated cost, limited sample preparation requirements, and compact configuration. However, it received lower scores for clinical relevance and accuracy and reliability because this technology was originally conceived for measuring adulteration of commercial milk. Therefore, the sensor was tested for detection of water in excess or even the presence of contaminants such as urea, rather than fat - one of our target milk nutrients. Its integration with health information systems was also limited because automatic data transfer was not demonstrated.

Technology 2 [13] received the highest clinical relevance score because it was designed to quantitatively estimate fat and protein concentrations, which directly corresponded to the intended application. It also achieved favorable scores for accuracy and reliability, usability, response time, and sample handling practicality. Nevertheless, its performance was limited by greater environmental sensitivity, dependence on calibration and computational processing, and limited portability. Automatic integration with health information systems was not demonstrated.

Technology 3 [14] showed moderate performance in clinical relevance, accuracy and reliability, usability, response time, sample handling practicality, and portability. Its categorical assessment of milk fat may provide clinically useful information in selected applications, although it does not quantify protein concentration and does not generate continuous quantitative measurements. The requirement to heat the sample before measurement reduced its environmental robustness and sample handling practicality. The absence of demonstrated digital data transfer resulted in the lowest score for integration with health information systems.

Overall, the three technologies exhibited distinct performance profiles. Technology 1 presented the most favorable operational, economic, and portability characteristics. Technology 2 demonstrated the strongest clinical relevance and a more comprehensive analytical capability. Technology 3 combined a favorable cost profile with moderate clinical and operational performance but was limited by sample heating requirements and the absence of protein measurement.

The suitability of each candidate technology across the application scenario is summarized in Table 4. The results came from the application of Eq. 2 combined with the scenario-specific weights and the PSS values described in Tables 2 and 3. It is interesting to note that there is no universal technology that simultaneously addresses the performance requirements from all application scenarios. For instance, Technology 1 seems to be the most suitable for the PHU scenario but not for the HMB and tertiary hospitals.

TABLE 4. FINAL WEIGHTED SCORES AND RANKINGS OF THE CANDIDATE SENSING TECHNOLOGIES ACROSS THE THREE HEALTHCARE SCENARIOS.

Technology	**PHU score**	**Rank**	**HMB score**	**Rank**	**Tertiary hospital score**	**Rank**
Technology 1 [12]	2.244	1st	2.026	2nd	1.906	2nd

Technology 2 [13]	2.195	2nd	2.132	1st	2.188	1st
Technology 3 [14]	1.976	3rd	1.868	3rd	1.875	3rd

The proposed methodology has certain limitations that should be addressed in a future work. One important limitation is the absence of an assessment of the bias introduced by human subjectivity when the PSS values are assigned (see Table 3). Different evaluators may fill this table differently and, consequently, the final scores of the candidate technologies can be affected. In a future study, we will recruit a set of independent evaluators, generating thus a dataset of PSS values which will, in turn, allow us to perform a statistical analysis. This will allow us to know the impact of small PSS variations from one evaluator to another around the same technology on the final scores assigned to the candidate technologies. The statistical analysis will also allow us to know if two technologies receiving close scores are statistically tied or not.

VI. Conclusion

This study proposed a scenario-based MCDA framework to support the selection of sensing technologies for human milk analysis across healthcare settings with different operational and clinical priorities. The application of the proposed framework showed that the relative suitability of the candidate technologies varied according to the intended healthcare setting.

The findings suggest that selecting a sensing technology solely on the basis of analytical performance or acquisition cost may overlook relevant implementation requirements. Operational simplicity, affordability, rapid response, and sample handling practicality were particularly influential in the PHU scenario. Conversely, clinical relevance, accuracy and reliability, and compatibility with specialized workflows had greater importance in the HMB and High-Complexity Tertiary Hospital scenarios.

The proposed framework provides a transparent and structured approach for comparing candidate technologies across distinct healthcare environments. It may also be adapted to other biomedical devices, clinical applications, and healthcare systems by modifying the evaluation criteria, scoring descriptors, and scenario-specific weights according to the intended context of use.

Nevertheless, the findings should be interpreted in light of the study's limitations. The performance assessment was based on technical evidence reported in the original studies rather than on direct experimental comparison of the technologies using human milk samples. Some relevant characteristics were therefore inferred from the reported operational configurations, and none of the candidate technologies had been comprehensively validated for the intended clinical application. In addition, the performance scores and scenario-specific weights were established through judgment and consensus within the study team and may vary according to institutional priorities, available resources, and stakeholder perspectives.

Future studies should experimentally evaluate the candidate technologies using human milk samples under representative operational conditions, incorporate the perspectives of healthcare professionals and other stakeholders, and perform sensitivity analyses to determine whether variations in performance scores and criterion weights alter the final rankings. These steps may strengthen the robustness and practical applicability of the framework and support evidence-based decisions during the development and adoption of sensing technologies in healthcare.

***Abstract*—Skin lesions pose a significant challenge to the public health system, especially in the case of skin diseases such as Hansen disease, where a delayed diagnosis can lead to serious complications. Given this issue, this study proposes a new approach titled "A Multimodal Framework for Hansen's Disease Monitoring Using Lesion Detection Segmentation Quantitative Feature Extraction and LLM-Based Clinical Reasoning", grounded in a hybrid architecture that integrates lesion detection using YOLOv8, segmentation with the Segment Anything Model (SAM), and feature extraction, followed by clinical interpretation using large language models. The study used the public CO2Wounds-V2 dataset with 764 RGB images from 96 patients with Hansen disease, while the LLMs used were Qwen2.5 and Gemma2. As a result, this study achieved satisfactory detection results with Precision above 90%. This was followed by segmentation, where a Precision above 80% was achieved. Thus, the results obtained were quite satisfactory for CAD systems associated with a multimodal methodology for monitoring skin lesions and supporting clinical medical decisions.**

***Index Terms*—Hansen's disease, detection, segmentation, prediagnosis, large language models (LLMs), artificial intelligence, healthcare, computer-aided diagnosis (CAD), skin lesion analysis.**

I. Introduction

The human skin is one of the most important organs in the human body, as it performs its function exceptionally well, protecting the body against bacterial attacks and dehydration [1]. When a skin injury occurs, the body's defense system triggers several processes to restore the organism's protection. However, wounds in human adults undergo repair processes that lead to scar formation. Nevertheless, in some cases, the natural healing process does not occur properly, giving rise to what are known as chronic wounds [1], [2].

Chronic wounds can be defined as a disruption in the continuity of body tissue. These types of conditions affect approximately 5% of adults in Western countries and impose significant burdens on healthcare systems, as they require prolonged hospitalizations and extensive procedures, with a high recurrence rate [3].

Among the conditions associated with the development of chronic wounds, Hansen disease stands out as a chronic infectious disease caused by *Mycobacterium leprae*, which primarily affects the skin and peripheral nerves and can spread to other organs, causing neurological damage and permanent sequelae that compromise tissue function, leading to the development of skin lesions that are difficult to heal [3], [4]. Transmission occurs through close and prolonged contact between infected individuals and susceptible persons [3]. According to the World Health Organization, Brazil ranks second worldwide in reported Hansen disease cases, with 22,129 new cases recorded in 2024, representing a significant public health concern; if Hansen disease is not properly detected and treated, it can result in serious disabilities, impairing the patient's quality of life due to the social stigma associated with the disease [4], [5].

In this context, early detection of Hansen disease is essential to ensure prompt treatment, clinical follow-up, and the prevention of permanent sequelae [6]. In this regard, with the aim of leveraging technology to improve medical diagnosis, the Federal Council of Medicine published Resolution CFM No. 2,454/2026, which regulates the use of Artificial Intelligence in medical practice in Brazil. This regulation establishes guidelines for the development and application of AI-based systems in healthcare, encompassing diagnosis, prognosis, prevention, and disease management [21].

Consequently, this study address deep learning methods by applying techniques for the detection, segmentation, and progressive quantification of Hansen disease lesions. Recent segmentation models based on foundation models, such as the Segment Anything Model (SAM), enable the monitoring of disease progression and provide a basis for planning and evaluating the applicability of medical treatment [16].

In the context of generalized segmentation in medical imag-

ing, the ability to delineate regions of interest without the need for manual annotation has improved significantly [15].

In addition to the detection and segmentation stages, there remains a gap in the automated clinical interpretation of quantitative features extracted from lesions. In this context, large language models are increasingly being recognized as valuable tools for clinical decision support [12].

Large Language Models (LLMs) are advanced systems based on transformer architecture, capable of processing and integrating large volumes of information, thereby enabling contextualized analysis of clinical data [14]. Recent studies indicate that LLMs have the potential to support clinical decision-making (CDM), particularly in the interpretation of complex data and in the generation of structured recommendations [13].

For this study, the publicly available CO2Wounds-V2 dataset was used. The dataset comprises 764 RGB images from 96 patients diagnosed with Hansen disease, captured using smartphone cameras under varying lighting conditions and image resolutions. Of these, 607 images contain bounding box annotations, which were used during the model training and validation stages. The remaining images, lacking bounding box annotations, were used exclusively for inference, in order to assess the method's performance on unannotated data and evaluate its applicability in clinical contexts.

Accordingly, this study aims to compare different LLMs based on features extracted from lesion images providing a comprehensive perspective on automated detection, segmentation, and LLM-based analysis to support the clinical characterization of Hansen disease lesions, thereby contributing to the monitoring of disease progression in resource-limited settings.

II. RELATED WORK

Traditionally, the diagnosis of infections in dermatological wounds has relied heavily on the assessment of clinical characteristics and reported symptoms. As noted by [20], conventional techniques, such as swabs and biopsies, present critical limitations, as they are invasive and time-consuming, leading to a growing demand for solutions that offer faster and more accurate diagnosis.

In this context, with the advancement of Artificial Intelligence (AI), several studies have proposed methods based on machine learning (ML) and deep learning (DL) for the detection and segmentation of dermatological lesions in medical images. Works such as the SDA-Detection Melanoma framework proposed by Rodrigues et al. [8] demonstrate that convolutional neural networks, including architectures such as U-Net and YOLO, achieve high performance in the identification and segmentation of skin lesions, with reported metrics exceeding 96% accuracy.

The study in [23] focused on skin cancer, where a new approach was developed for the detection, segmentation, and classification of melanomas in dermatoscopic images. The proposed pre-diagnosis using generative AI achieved 99% accuracy, outperforming some models in the literature. Meanwhile, the classification phase relied on an integrated pipeline for feature extraction and selection of the best combination for classifying the melanoma region, achieving an accuracy of 86.0

The study by [24] evaluates a segmentation tool using machine learning methods to aid in the early diagnosis of skin cancer through the semantic segmentation of dermatoscopic images. The results showed average Dice loss values of 0.0971 during training and 0.1724 during validation, indicating good accuracy in image segmentation.

Other studies have made significant contributions to the segmentation of skin lesions, such as the one by [25], in which a computer-aided medical pre-diagnosis system was developed. By combining computer vision techniques with active contour models, the new method contributes to clinical diagnosis, demonstrating good performance even in images with high levels of noise.

Furthermore, Rayed et al. [18] review the advances and challenges of deep learning-based medical image segmentation, highlighting issues such as the scarcity of annotated data, limited model generalization, and sensitivity to variations in clinical images.

Studies applied to other diseases, such as the work presented in [9], demonstrate the potential of advanced computational methods for segmenting tumor regions in magnetic resonance images, achieving high performance rates. Similarly, the work presented in [10] demonstrates the effectiveness of segmentation techniques in computed tomography, with metrics exceeding 99% in controlled settings.

While these studies address different clinical contexts, they share challenges similar to those encountered in the analysis of dermatological lesions, underscoring the need for robust methods focused on detection, segmentation, and quantification in real-world scenarios. In the context of chronic wounds, the study by [11] demonstrates the potential of the YOLO family of architectures for the automatic detection of regions of interest and the prediction of lesion classes and bounding boxes.

Despite these advances, there remains a gap between precise visual segmentation methods and approaches capable of performing structured clinical interpretation of features extracted from medical images. In this context, Large Language Models (LLMs) have emerged as promising tools for supporting the interpretation of medical data and aiding clinical decision-making.

Accordingly, this study proposes the integration of computer vision techniques for lesion segmentation with LLM-based models for medical data analysis, as a diagnostic support technology. Specifically, it employs YOLO-based detection and segmentation architectures to identify Hansen disease lesions, with the aim of supporting clinical interpretation and monitoring disease progression.

III. MATERIALS AND METHODS

A. Dataset

The dataset used in this study was CO2Wounds-V2 [19], comprising 764 RGB images of chronic wounds from 96

patients diagnosed with Hansen disease. The images were captured in a clinical setting using smartphone cameras and varied in terms of lighting, resolution, capture angle, and acquisition conditions.

Among the available images, 607 contain bounding box annotations, which were used during the training and validation stages of the detection model. The remaining unannotated images were used exclusively for inference, allowing for the evaluation of the model's performance in scenarios closer to real clinical practice, where labeled data is scarce. Prior to training, a preprocessing and data cleaning pipeline was conducted, encompassing image integrity checks, format standardization, and partitioning into training, validation, and test subsets.

B. YOLO

YOLOv8 (You Only Look Once, version 8) represents one of the most recent advancements in object detection within the YOLO family of frameworks. Its architecture is organized into four main components: the Backbone, responsible for extracting visual features at multiple scales; the Neck, responsible for fusing and aggregating these features; the Detection Head, responsible for predicting bounding boxes and classifying regions of interest; and the Segmentation Head, an additional module that enables the generation of instance segmentation masks directly from the model.

The model was trained on the 607 annotated images from the CO2Wounds-V2 dataset, partitioned into training, validation, and test subsets. The bounding boxes predicted by the model serve as input for the subsequent segmentation stage, integrating the proposed pipeline in a sequential and automated manner.

C. Segmentation

The purpose of this segmentation step is to precisely delineate the boundaries of Hansen disease lesions identified during the detection stage, thereby enabling the extraction of quantitative features for clinical analysis. To this end, the Segment Anything Model (SAM) [15], developed by Meta AI, was adopted due to its versatility and ability to integrate with other systems. SAM was designed to segment objects of interest in images based on user-provided prompts, which can take the form of a single point, a set of points, a bounding box, or text, and returns a corresponding segmentation mask [16].

In the proposed pipeline, the bounding boxes generated by YOLO during the detection stage were used directly as input prompts for SAM, obtaining segmentation masks as output. This integration enables fully automated segmentation without manual intervention, an approach that proved well-suited to the characteristics of the CO2Wounds-V2 dataset.

D. Large Language Models (LLMs)

Large Language Models (LLMs) are advanced AI systems based on the Transformer architecture, capable of generating and processing human language through probabilistic modeling of sequential tokens. These models are typically trained via self-supervised learning, which enables them to develop broad language comprehension and generalization capabilities, and are increasingly being adapted for clinical tasks. In this study, LLMs were employed to interpret quantitative features extracted from segmented lesions and generate structured clinical descriptions, functioning as clinical decision support tools. To this end, the features of each lesion were organized and standardized prior to being provided as input to the models, which produced structured outputs classifying the lesions and indicating the presence of signs of infection.

IV. Methodology

This section describes the methodological workflow of the proposed approach, as illustrated in Figure 1. It is organized into sequential steps that constitute the complete pipeline, from dataset acquisition and image preprocessing to clinical decision support.

Step 1: Detecting the Lesion Region with YOLO

In the first stage, the YOLOv8 model was employed to automatically detect regions of interest through the prediction of bounding boxes around Hansen disease lesions. The dataset was partitioned into 70% for training, 20% for validation, and 10% for testing. The resulting model returns the detected region along with the corresponding confidence score for each identified lesion, as illustrated in Figure 2.

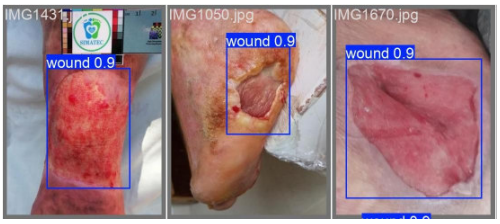

Fig. 2. Predicted detection results.

Step 2: Segmentation with SAM

Following lesion detection, the Segment Anything Model (SAM) was applied to delineate the identified regions. The bounding boxes generated by YOLOv8 were provided directly as input prompts to SAM, enabling more precise mask generation of the wound contours, reducing background interference, and improving the quality of the representation of the affected region, as shown in Figure 3.

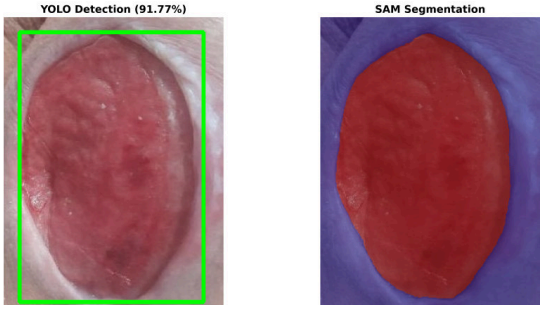

Fig. 3. YOLO Detection and Segmentation with SAM.

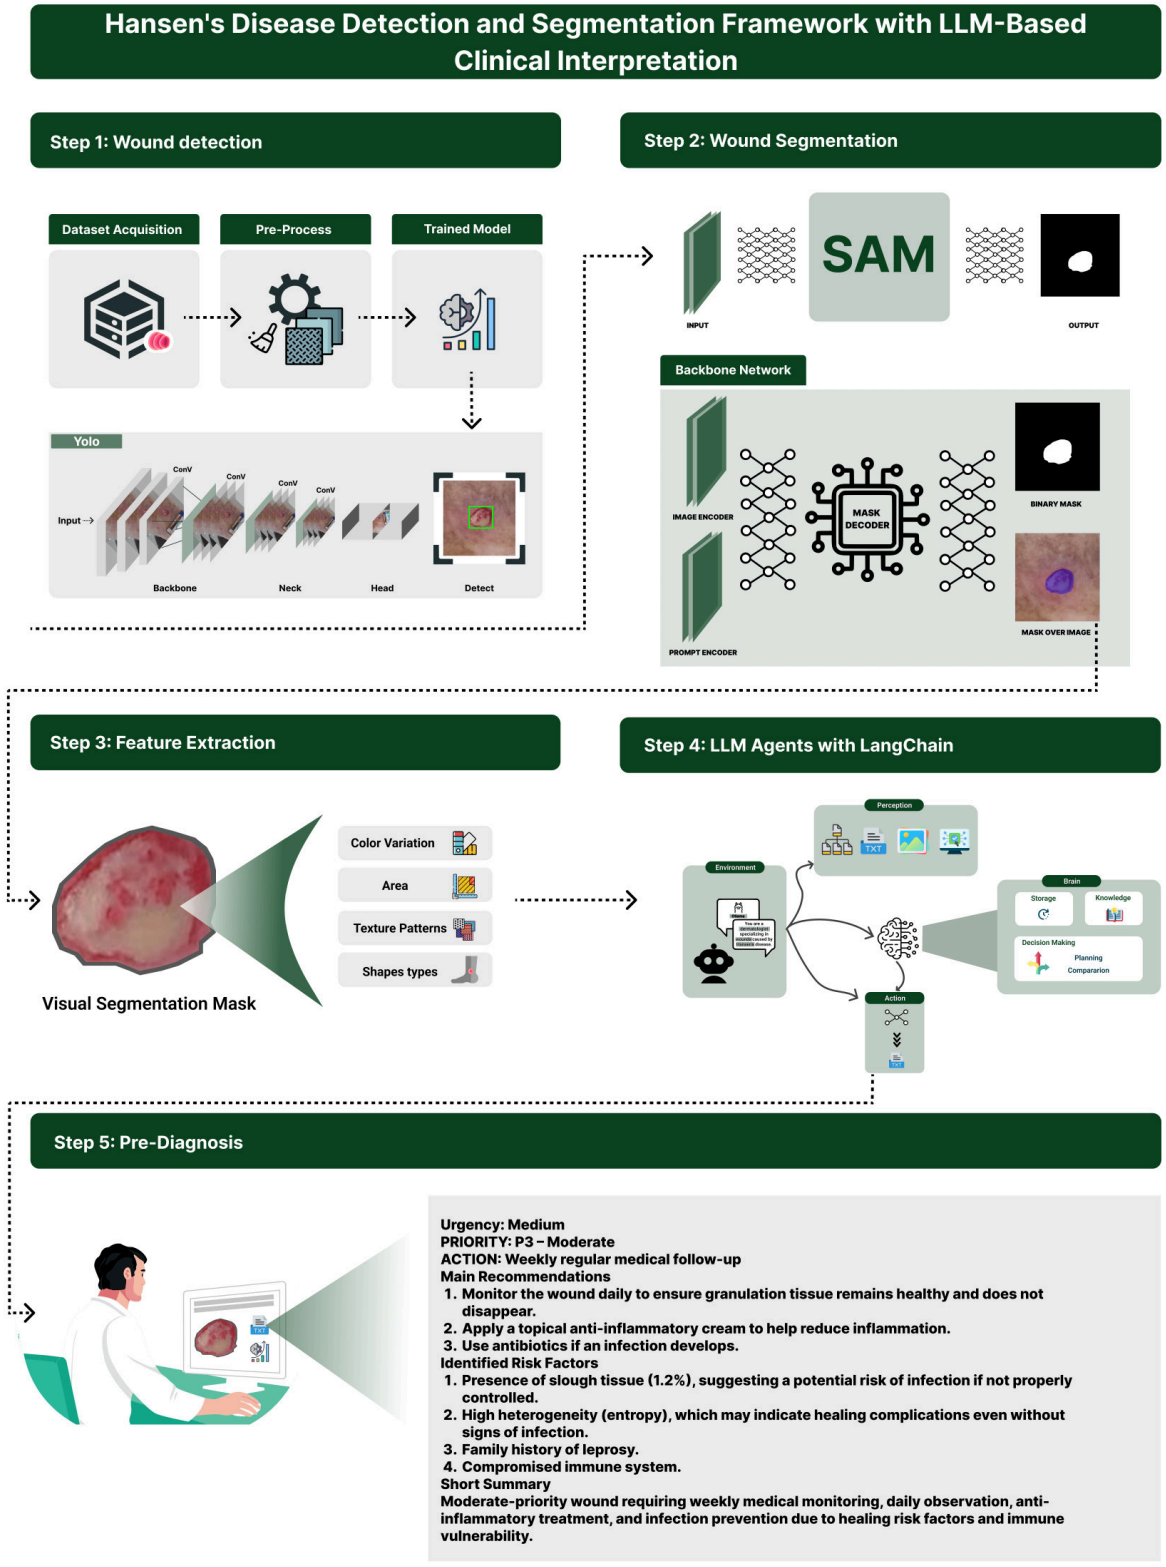

Fig. 1. Proposed methodology divided into five steps: Step1. Wound Detection; Step2. Wound Segmentation; Step3. Feature Extraction; Step4. LLM Agents with LangChain; Step5.Results Consolidation.

Step 3: Extraction of Visual and Geometric Features

After segmentation using SAM and the mask obtained from the process, the next step involved feature extraction from the lesion area, where visual and geometric features were extracted. Some of the features considered relate to size and shape, such as area and perimeter, as well as properties associated with color variation and texture patterns present in the segmented region. This information allows for a quantitative description of the wound, transforming visual aspects into structured data suitable for computational analysis.

Step 4: Analysis Using Language Models

In this step, several natural language models were used to interpret the features that had been extracted, organized into a structured format, and provided to the models. Among the models used were Qwen2.5 and gemma2:2b.

The features extracted from the lesion include the area, perimeter, color distribution, and texture, which were converted into a structured textual format that was also provided as input to the language models. Thus, this quantitative information served as the basis for the LLMs' inference process, enabling the models to correlate visual patterns and possible stages of the lesion with signs of progression and relevant clinical indicators.

The evaluation method adopted for the language models (LLMs) in this study, given the absence of external clinical validation, was based on an internal evaluation strategy relying on inter-model consensus. The two LLMs mentioned above were run locally via Ollama without relying on external infrastructure and were queried independently for each wound.

The diagnoses were compared using agreement metrics, including: classification consensus rate, standard deviation of the severity score, and agreement in the diagnosis of infection. This approach is justified by three main reasons: (i) the exploratory nature of the study, whose objective is to demonstrate the technical feasibility of the YOLO + SAM + LLMs pipeline for the automated analysis of chronic wounds caused by leprosy, rather than to replace clinical judgment; (ii) the lack, to date, of public benchmarks with structured clinical annotations for CO2Wounds-V2, whose test set is deliberately provided without labels; and (iii) the fact that LLMs are fed exclusively quantitative features derived from segmentation, such as color in the RGB, HSV and LAB, the RYKW tissue composition map, LBP and HOG texture descriptors, and geometric attributes such as circularity, solidity, and compactness, thereby eliminating any bias introduced by the raw image and making the analysis reproducible and auditable.

This stage sought to explore the interpretive capacity of the models in the integrated analysis of structured data and to provide clinical contexts, where a comparative analysis of the convergences and divergences among the responses generated by the agents was conducted. This comparison made it possible to assess the consistency of the generated hypotheses, identify patterns of agreement among the models, evaluate the risk of hallucination associated with them, and enable a more accurate and unified diagnosis.

Step 5: Clinical decision support

Finally, based on the diagnostic outputs generated by the LLMs, an interpretive report was produced to support clinical decision-making. The system provides risk stratification and identifies potential indicators of lesion progression. This study does not aim to replace medical evaluation, but rather to serve as a complementary tool supporting healthcare professionals in their decision-making process, offering an AI-based second opinion grounded in computer vision and natural language processing techniques.

V. Results and Discussion

This section presents the results obtained from the proposed YOLO+SAM pipeline applied to the CO2Wounds-V2 dataset, along with an analysis of the implications and limitations of the study and the performance of the LLM-based clinical interpretation stage.

A. Detection

The YOLOv8 model achieved strong detection performance, with a precision of 90.07% and an mAP@50 of 83.44%, indicating robust generalization on the detection task. The recall of 75.63% demonstrates a satisfactory capacity to identify regions of interest within the dataset. Although the primary focus of the evaluation lies on segmentation performance, these results highlight the feasibility of employing detection models in hybrid pipelines, where YOLOv8 serves as a reliable preliminary stage for wound segmentation and downstream analysis.

B. Segmentation

Table I presents a comparison between existing methods for Hansen disease lesion segmentation reported in the literature and the models evaluated in this study on the CO2Wounds dataset. The analysis was conducted using metrics widely used in the literature, including Precision, Recall, F1-score, and IoU.

TABLE I
COMPARISON OF SEGMENTATION METHODS ON THE CO2WOUNDS-V2 DATASET.

Citation	Method	Task	Prec. Value	Rec. Value	F1 Value	IoU Value	Source
This work	YOLO+SAM	Seg.	**80.30%**	74.70%	70.70%	57.80%	This work
[11]	COD2Net	Seg.	84.50%	81.90%	**80.30%**	82.50%	SOTA
[11]	VGG16	Seg.	68.70%	53.90%	50.60%	—	Paper
[11]	SegNet	Seg.	68.40%	51.50%	46.40%	—	Paper
[11]	MobileNetV2	Seg.	65.90%	70.70%	54.10%	—	Paper
[11]	U-Net	Seg.	82.70%	66.70%	64.30%	—	Paper

Among the segmentation methods reported in the literature, COD2Net achieves the highest performance, with an F1-score of 80.30% and an IoU ranging from 80.00% to 85.00%, and was considered state-of-the-art (SOTA) in the original study. Among the remaining architectures, U-Net attains the most competitive performance, with an F1-score of 64.30%, outperforming VGG16, SegNet, and MobileNetV2.

In summary, the proposed YOLO+SAM pipeline demonstrated high precision (80.30%), indicating a strong ability to avoid false positives. The recall of 74.70%, while satisfactory

in absolute terms, was comparatively lower than that of methods focused purely on segmentation, which may account for a higher rate of false negatives; consequently, the F1-score (70.70%) and IoU (57.80%) remained below the SOTA benchmark.

The results indicate that methods dedicated exclusively to segmentation, such as COD2Net, still achieve a better overall balance between precision and recall, whereas the YOLO+SAM pipeline exhibits greater metric variability, which may suggest sensitivity to heterogeneous characteristics across lesion images.

The detection-based strategy employed in this study YOLOv8 demonstrates strong capacity to locate wound regions, which can be leveraged in clinical settings where rapid identification of the lesion site is a priority, particularly in resource-limited environments with restricted access to specialized healthcare services.

Furthermore, the lower IoU achieved by the YOLO+SAM pipeline suggests that incorporating mask refinement strategies or fine-tuning the segmentation components could yield meaningful improvements in overall performance.

From a practical standpoint, the choice among the methods described in the literature will depend on the target application scenario. In clinical settings where minimizing false positives is a priority, approaches with higher precision are preferable. Conversely, for longitudinal monitoring applications, higher recall may be prioritized to avoid missing clinically relevant findings.

C. Robustness Under Varied Acquisition Conditions

Regarding the pipeline's robustness under the various conditions under which the images were acquired and used for model training, it is important to note that the CO2Wounds-V2 dataset subjects the pipeline to heterogeneous image acquisition conditions. The images were collected over approximately one year and nine months using smartphone cameras, resulting in variations in lighting, angle, focal length, and resolution across samples.

Challenges such as uneven lighting and indistinct lesion margins are common in the dataset, where the detection model achieved satisfactory results in detecting skin lesions caused by leprosy. However, it is important to note that the size of the dataset does not adequately represent the clinical variance observed across different populations—such as skin tones, lighting conditions, and disease stages—which can pose a challenge for the pipeline.

D. Evaluation of Large Language Models (LLMs)

The language models were evaluated using the Ollama framework, deployed in a local environment to ensure standardized execution and controlled experimental conditions, including variables such as temperature and maximum token limits. The Qwen2.5 and Gemma2:2b models were assessed, both integrated into the proposed multimodal pipeline.

The evaluation of these models was based on two main criteria: (i) structural agreement with the internally generated consensus, and (ii) textual similarity between the produced descriptions. It is important to emphasize that the consensus used as reference was derived from the system itself, through inferences performed on a separate batch of images; therefore, this evaluation focuses on assessing internal consistency and structural stability, rather than serving as external clinical validation.

Table II presents the results obtained. In summary, the Qwen2.5 model demonstrated greater structural agreement with the internal consensus (Exact Match = 100.00%), whereas Gemma2:2b achieved an average agreement of 76.30%. In terms of textual similarity, both models performed comparably (F1 = 33.00%), indicating substantial lexical variation in the generated clinical descriptions. The low BLEU scores ($<$2.00%) further suggest that differences between the models occur primarily at the level of textual formulation, while the underlying diagnostic structure remains consistent.

TABLE II
QUANTITATIVE COMPARISON OF LLMS RUNNING ON OLLAMA.

Model	Exact Match Value	F1 Value	BLEU Value	Time (ms) Value
gemma2:2b	76.00%	33.00%	2.00%	76185.5
Qwen2.5	**100.00%**	34.00%	2.00%	97724.2

It can also be observed that there was a significant difference in computational cost. Gemma2:2b had a shorter average inference time (approximately 76 s) compared to Qwen2.5 (approximately 98 s). These results indicate a trade-off between greater structural alignment with the internal consensus and higher computational cost, and that depending on where the model is being run, the time tends to be shorter or longer.

VI. CONCLUSION

The proposed study is intended to serve as an auxiliary tool to support clinical decision-making, and not as a standalone diagnostic mechanism, in accordance with Federal Council of Medicine (CFM) Resolution No. 2,454/2026, which regulates the use of Artificial Intelligence in medical practice in Brazil.

The development of the model focused on the detection and segmentation of chronic leprosy wounds yielded interesting results, given the accuracy (80.3%) achieved by the proposed architecture. The integration of LLMs demonstrated the feasibility of building multimodal decision support systems, in which discrepancies between models can be used as an additional indicator of clinical uncertainty.

Furthermore, the choice of model must therefore balance structural performance, computational cost, operational stability, and the application context. The absence of external clinical validation is thus recognized as a limitation of this study, and future work should incorporate specialized clinical annotation to enable assessment of agreement with the human gold standard; the framework requires further study before any clinical application.

Despite the promising results, the study has some limitations related to the size and diversity of the dataset; the

CO2Wounds-V2 dataset contains 764 images from 96 patients, which does not adequately represent the clinical variability observed across different populations, skin tones, lighting conditions, and disease stages. Furthermore, the images were captured by smartphones under various conditions, which may introduce noise and uncontrolled variations in the training of the models.

As future work, we propose (i) to fine-tune the models to address the specific nature of the miscarriage, (ii) to reconstruct the wound in 3D, (iii) to track its development over time, (iv) to include larger multimodal datasets, and (v) to apply clinical RAG.

***Abstract*— To address the limitations of high error rates and radiation exposure associated with traditional visual estimation and fluoroscopy in femoral derotational osteotomies (FDO), this study proposes a novel, non-ionizing angular measurement method using structured-light 3D scanning. Utilizing a 3D-printed femur model with predefined pin channels (0° to 35°) and custom-designed 2.5 mm polylactic acid (PLA) cylindrical tracking markers, 40 trial scans were captured using an Artec Eva 3D scanner. The digitized point clouds were reconstructed in Artec Studio, and the axial angular differences were mathematically calculated in Blender 4.2. Bland-Altman analysis against the reference computer-aided design (CAD) model revealed a minor systematic measurement bias of -1.13° ± 2.66°, with 95% limits of agreement ranging from -6.34° to 4.08°. These results demonstrate the feasibility of this benchtop 3D scanning workflow, providing a radiation-free alternative whose repeatability and clinical translation warrant further investigation.**

Keywords—3D scanner, osteotomy, angular measurement.

I. INTRODUCTION

Proper alignment of the lower limbs is fundamental to minimizing muscular work and joint wear during locomotion. Within this scope, three fundamental concepts are distinguished:

Femoral version: Normal and static rotational variation of a specific bone. It is formally defined as the angular difference between the axis of the femoral neck and the transcondylar axis of the knee[1] [2].

Rotation: The result of the dynamic interaction between bones, joints, and muscles.

Bone torsion: Static structural deformation of a bone around its longitudinal axis.

Under normal conditions, the femur exhibits anteversion (the femoral head is rotated anteriorly relative to the condylar axis). At birth, this angle ranges between 25° and 50° and progressively decreases with growth, stabilizing between 10° and 15° around 16 years of age.

Evaluation in the frontal plane distinguishes critical parameters:

Anatomical axis: A straight line from the piriform fossa to the center of the knee.

Mechanical axis: A straight line from the center of the femoral head to the center of the knee.

Neck-shaft angle (cervicodiaphyseal angle): Formed between the axis of the femoral neck and the anatomical axis, with a normal value between 125° and 131°.

A. Femoral Torsional Deformity

Torsional anomalies are clinically defined when femoral version values deviate significantly from the mean (by more than 2 standard deviations).

Types of deformity:

Excessive femoral anteversion (internal torsion): This is the most frequent presentation in pediatric consultations; it causes patellofemoral instability, anterior knee pain, and femoroacetabular impingement.

Femoral retroversion (external torsion): A condition always considered abnormal. It can be physiological (bilateral, symmetrical, and generally self-limiting) or pathological (congenital, or acquired due to conditions such as Perthes disease, cerebral palsy, or poliomyelitis). It is based on clinical history, gait analysis, and the Staheli rotational profile, which measures parameters such as the foot progression angle and hip rotations.

Excessive anteversion is compensated for by an in-toeing gait. Retroversion is compensated for by an out-toeing gait.

For high-precision diagnosis, cross-sectional imaging is utilized (Computed Tomography [CT] and Magnetic Resonance Imaging [MRI]), which are considered the gold standard. MRI is notable for avoiding ionizing radiation and allowing the evaluation of soft tissues and cartilage. Furthermore, image processing software such as OsiriX facilitates digital angle measurement by superimposing axial slices of the femoral neck and condyles.

B. Femoral Derotational Osteotomy (FDO)

When anteversion deformities (>25°–30°) persist beyond 8 years of age, cause frequent falls, or impair daily function, surgical treatment is indicated: femoral derotational

osteotomy (FDO). Its objective is to restore anteversion to a physiological value of approximately 15°.

Distal osteotomies prevent misalignment because they are performed along the mechanical axis, whereas proximal osteotomies are performed transverse to the anatomical axis to avoid unwanted translation of the bone.

C. *Intraoperative Measurement Methods and New Technologies*

The main challenge of FDO is the precise measurement of rotational degrees in the operating room. Traditionally, surgeons have relied on visual estimation and two-dimensional fluoroscopy, methodologies that exhibit a high margin of error.

To overcome these limitations, several intraoperative technological alternatives have been developed:

Computer-Assisted Navigation Systems and Sensors: Computer-assisted freehand tracking using C-arm imaging or electromagnetic sensors coupled to Kirschner wires (K-wires), enabling real-time monitoring of the derotation angle.

Mobile Devices (Smartphones): The use of internal gyroscopic sensors or dedicated applications (such as Navi-Gator) to photographically record the angulation of the pins, proving to be accessible options that are more precise than purely visual estimation.

Robotics and Augmented Reality: Systems such as Skywalker or robot-assisted navigation technologies with augmented reality allow the alignment of 3D preoperative planning with the patient's anatomy in real time, enhancing surgical safety.

Hybrid Operating Rooms: Facilities that combine CT/MRI and real-time 3D reconstruction to guide surgical procedures, optimizing precision but carrying the disadvantages of high cost and radiation exposure.

3D Scanning and Digitization: Based on the principle of stereoscopic triangulation, structured-light scanners are emerging as fast and precise tools for documenting exposed surfaces and instruments in the operating room without resorting to postoperative radiation.

In this work, an analysis performed on a 3D-printed bone model using structured-light-based 3D scanning technology and its contrast with reference values will be presented.

Objective: To propose an innovative angular measurement method using 3D scanning that can be implemented in future surgical practice.

II. Materials and Methods

A. *Artec EVA*

Artec Eva is a high-quality professional 3D scanner used in a wide variety of fields. This is a non-contact scanner that operates on structured-light technology; it is portable, lightweight, and does not emit any harmful radiation.

The scanner projects normal visible light stripe patterns onto the object, and their deformation is captured by three cameras: two cameras on different edges of the scanner and one positioned in the middle, surrounded by flash LEDs to receive texture information. During scanning, Artec Eva captures up to 16 3D frames per second and transfers them to Artec Studio, its proprietary software. The latter creates a texture atlas, and the user receives a color-textured 3D mesh composed of triangles. The final output generated in Artec Studio is a commonly used 3D data format, such as stereolithography (.stl) [3].

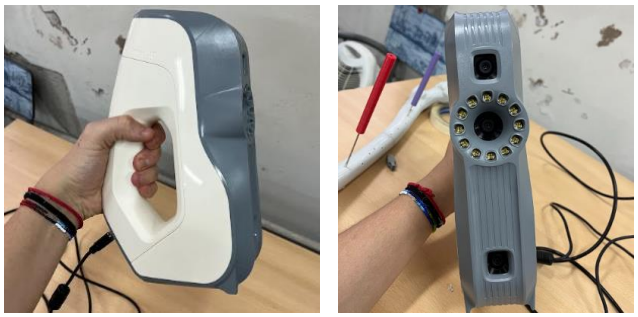

Figure 1. Artec EVA scanner.

Artec Eva has been implemented in various medical fields, such as orthotics and prosthetics for the head and neck region [4], injury documentation during autopsies [5], and facial and body scanning [6]. Furthermore, it has demonstrated superior accuracy in facial scanning applications due to being a mobile rather than a stationary system [3].

B. *3D Printing in the Medical Industry*

3D printing is the process of forming a solid object from a computer-generated digital model. While various technologies exist for manufacturing a three-dimensional object, the fundamental concept lies in the successive addition of layers of material until the final product is obtained.

Acquisition of a three-dimensional model of the object: This can be achieved either through 3D scanning or computer-aided design, typically using CAD software such as SolidWorks, Blender, among others.

Preparation of the model in the appropriate format: Generally STL, where its geometric information is stored.

Transformation of the model file into a format the printer understands: Usually G-code.

Finally, certain printing parameters are specified, and fabrication begins.

C. *Computer-Aided Design*

Blender® software version 4.2 was used for the computer-aided design of all three-dimensional elements in this project: the cylindrical markers and the necessary adaptations to the femoral bones. Additionally, this software offers useful tools to obtain angular measurements with any desired precision.

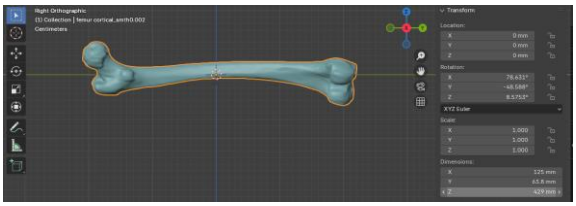

Figure 2. Femur view in Blender ® workspace.

The process begins with the selection of a femur file in STL format, downloaded freely and at no cost from the online platform "GrabCAD". It is imported into Blender, and its characteristics are analyzed. As shown in Figure 2, it has a length of 429 mm and exhibits normal anatomical features. In order to place the pins through the bone, three groups of intersections are planned that differ from each other by 20 and

30 degrees from the axial view of the femur. To achieve this, cylinders of 2.5 mm in diameter are created. From the axial view, these cylinders are parallel, pass through the bone, and are guided by a plane to ensure they remain parallel to one another. Subsequently, using Blender's Boolean operations, a "difference" function is performed between the bone and the cylinders, resulting in holes that pass completely through the bone.

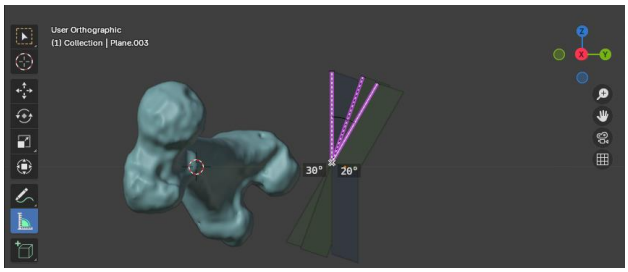

Figure 3. Planes for boolean operations in Blender ®.

According to various authors, the scanner faces certain difficulties when scanning shiny and transparent objects. This gave rise to the idea of implementing colored cylindrical markers to be placed around the pins. These markers are designed to be small enough not to hinder surgical techniques, while facilitating the spatial localization of the pins (which are metallic) in the 3D space. They are manufactured from PLA.

Although the markers are non-invasive, the pins themselves are inserted into the patient's bones, placing them within centimeters of surrounding tissues. Consequently, the markers are also in close proximity. For this reason, we aimed to design the markers with the highest possible precision, taking into account the dimensions of the pins, to ensure they remain securely fixed without risking displacement or falling off while the surgeon moves the patient. Since 2.5 mm diameter pins are used, the markers are designed with an internal diameter of 2.5 mm, an external diameter of 10 mm, and a height of 100 mm.

D. Printing and Scanning

An Ender 3 fused deposition modeling (FDM) printer with a printing precision of 0.1 mm was employed. The fabrication material was PLA filament: white for the femoral bones, and red, lilac, and green for the markers.

Forty random measurements were planned (20 for each bone). Color coding was used on the holes to visually identify which exact angular difference corresponded to each pair of pins.

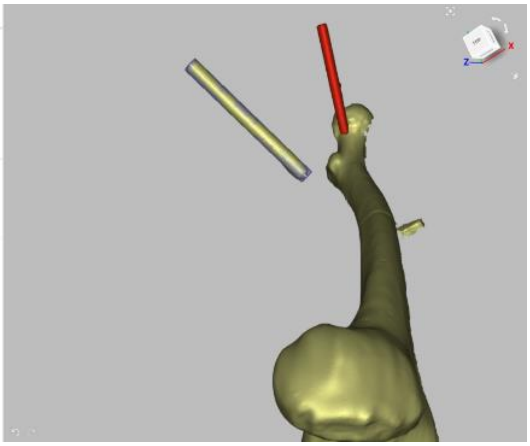

Figure 4. Fussion in Artec Studio. Marker reconstruction.

Each measurement consisted of two scanning sessions from multiple perspectives to achieve a better reconstruction. Processing in Artec Studio involved:

Eraser: Manual selection and removal of noise and the base to isolate the object of interest.

Alignment: Automatic or manual alignment of the point clouds from both sessions by selecting spatial correspondence points.

Fusion: Application of fast mesh simplification and smoothing.

Object Construction: Creation of perfect cylinders over the reconstructed surface of the markers to precisely identify their axis and longitudinal direction.

Translation and Rotation: Reorientation of the femur to align its longitudinal axis with the X-axis, ensuring that the axial measurement plane coincides exactly with the coordinate plane (Y,Z).

E. Angular Measurement and Analysis

The processed scans were imported into Blender. To measure the angular difference in the axial plane without being affected by potential sagittal or coronal tilts, face normal visualization was enabled for the virtual cylinders constructed in Artec Studio. The length of these normal lines was extended until they intersected in the axial plane. Three exact mathematical vertices were created (one on each normal vector and one at the intersection of both normal lines). The "measurement tools" extension was used to automatically register the angle generated by the three vertices with a precision of two decimal places.

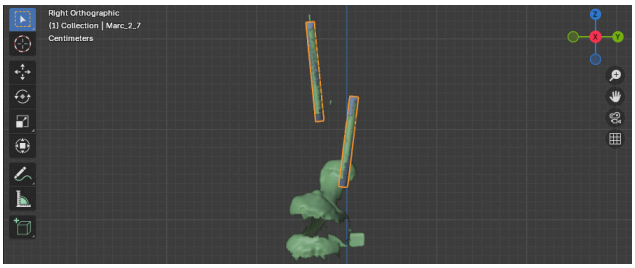

Figure 5. Angle measurement in Blender ®.

An initial descriptive analysis (mean, median, variance, standard deviation, maximum, and minimum) was defined for each angular control group (0°, 10°, 20°, 25°, 30°, and 35°). Data normality was planned to be verified using the Shapiro-Wilk test and histograms. The Bland-Altman statistical methodology was selected to compare the 3D-measured values against the exact theoretical values of the computer model, evaluate precision, identify bias, and calculate the limits of agreement with a significance level α=0.05.

III. Results and Discussion

The markers printed with an internal diameter of approximately 3 mm did not remain securely attached to the pins, whereas those with the same diameter as the pins 2.5 mm, provided a snug fit and remained securely fixed. It is crucial for these markers to remain stationary and for the diameter to be appropriate so that the pins do not easily shift, which would introduce errors in the spatial localization of the markers. Therefore, it is considered essential to know the precise dimensions of the pins to design custom-fit markers.

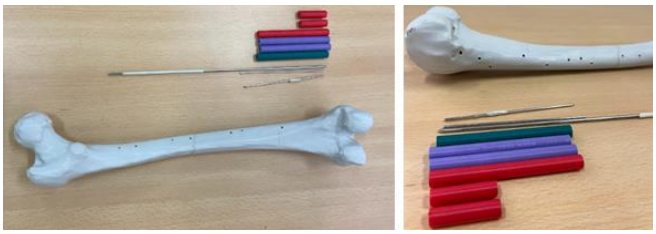

Figure 6. 3D printed femur with markers and wires.

The frequency distribution in Figure 7 shows the distribution of reconstructed angular values across the six target angles alongside their respective Gaussian fits. While the distributions confirm unimodal behavior across trials, the shift in the central tendency relative to nominal references highlights the magnitude-dependent variation summarized in Table 1.

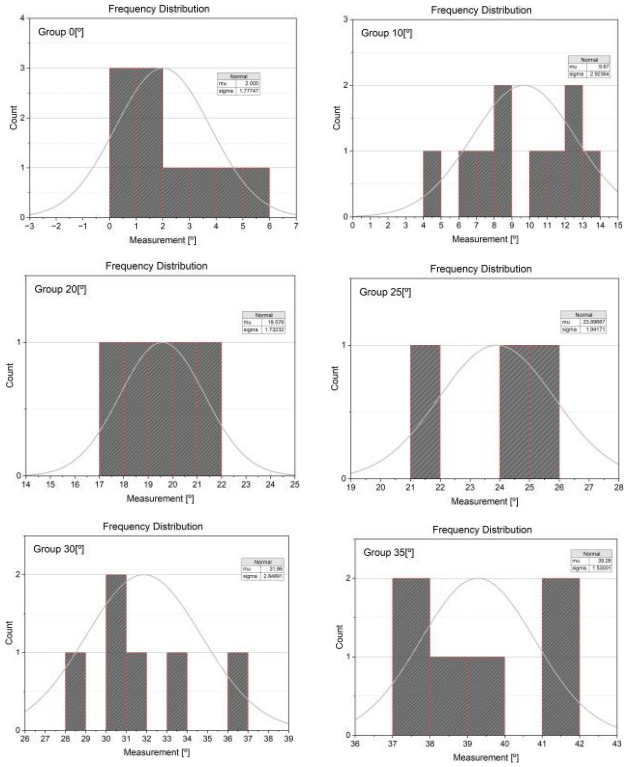

Figure 7. Data distribution histogram with normal curve distribution.

TABLE I. STATISTICS IN GROUPS.

Group	*Mean [°]*	*SD [°]*	*Max Value [°]*	*Min Value [°]*	*MAE [°]*	*RMSE [°]*
0°	2.01	1.78	5.46	0	2.00	2.62
10°	9.67	2.92	13.47	4.28	2.33	2.71
20°	19.58	1.73	21.58	17.09	1.32	1.61
25°	23.90	1.94	25.15	21.66	1.20	1.93
30°	31.86	2.85	36.73	28.89	1.33	1.79
35°	38.78	1.31	41.05	37.59	3.78	3.96

Bland-Altman Plot

To graphically compare the differences between the measured and exact values, the Bland-Altman statistical technique was used. Additionally, this technique helps observe the precision of the measurements obtained with the 3D scanner. First, it was necessary to confirm that the differences between the measured and reference values followed a normal distribution; thus, the Shapiro-Wilk test was applied to them. The hypothesis being tested is whether the differences between the exact and measured values follow a normal distribution; therefore, the null hypothesis H_0 is that they are normally distributed, and the alternative hypothesis H_1 is that they do not follow a normal distribution. The red line represents the bias (the mean of the differences), which has a value of -1.13º. This demonstrates a discrepancy between the measured and exact values. Specifically, the 3D scanning method measures the value as 1.13º less than it actually should be implying a bias that must be taken into account when evaluating the validity of this measurement method. The green and blue lines represent the lower and upper limits of agreement, respectively. These are defined as the mean difference ±1.96 times the standard deviation of the differences. The upper limit (blue line) has a value of 4.08º and the lower limit (green line) is -6.34º. These limits indicate the interval within which 95% of the differences fall, an assertion supported by their normal distribution.

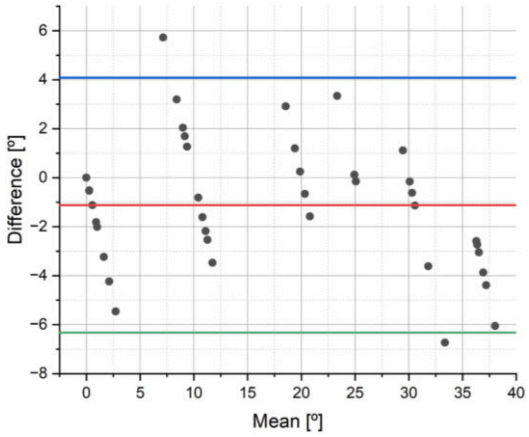

Figure 8. Bland Altman plot.

The progression of the elapsed time across consecutive trials is illustrated in Figure 9, showing a steep reduction from an initial duration exceeding 27 min to a plateau between 7 and 10 min after the 20th trial. This steep downward trend reflects a pronounced learning curve, suggesting that operating speed, manual point-cloud processing in Artec Studio, and vertex-based alignment in Blender are heavily operator-dependent.

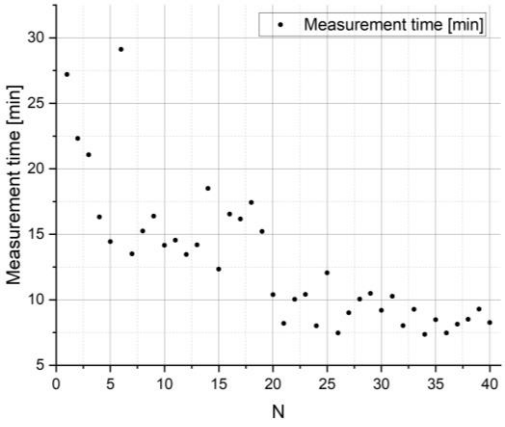

Figure 9. Measurement time.

IV. CONCLUSION

The Artec Eva 3D scanner allows for high precision and accurate marker reconstruction, we succeeded in measuring

the angles between two pins. The Artec Studio and Blender® software were fundamental to performing all measurements. In orthopedic and traumatological applications, the 3D scanner is potentially superior to other technologies due to its portability, ease of use, structured-light operating mode (which is harmless to patients), and excellent resolution, allowing for color-rich, highly textured 3D scans.

The overall measurement duration decreased by approximately 3.5-fold between the initial and concluding trials, demonstrating a clear learning effect throughout the 40 scans. Therefore, the progressive decrease in processing time—along with the variability observed in the angular errors—suggests that operator proficiency across both software environments is a critical variable that directly conditions the reliability and reproducibility of the method, reinforcing the need for standardized multi-observer protocols.

The mean difference between the proposed 3D scanning method and the exact values of the computer model is -1.13º ±2.66º. Comparing the data reported in [7] with the results obtained in this study, we consider the 3D scanning method to be more accurate than visual estimation, and it even yields better standard deviations than the differences measured using the osteotomy template method. However, it does not achieve the high level of precision obtained when using the iPhone 4 gyroscope. Furthermore, the 3D scanning method proposed in this project presents a standard deviation of differences very close to that reported in [8], with values of 2.77º and 2.66º, respectively. This is highly encouraging, especially when compared to a study that implemented measurements based on MRI and CT scans.

For future work, the test using the Artec EVA inside the surgery room in order to obtain real measurements is being analyzed. The aims to evaluate will be: easiness of use during the surgical practice, workflow using the measurement software, reliability of the values in relation with the test results. Although the mean bias of -1.13° reflects low systematic deviation, the limits of agreement (-6.34° to 4.08°) represent a dispersion span exceeding 10°. In the context of femoral derotational osteotomies, where clinical correction margins are typically aimed within ±3° to ±5°, this benchtop variability must be narrowed through automated alignment algorithms before intraoperative application can be pursued.

***Abstract*—This paper introduces DFChat, an open-source tool designed to facilitate interactive Exploratory Data Analysis (EDA) over Pandas DataFrames using Large Language Models (LLMs). By integrating Retrieval-Augmented Generation (RAG) and rule-based post-processing, DFChat allows users to ask questions about datasets in natural language and receive insights through text, statistics, and visualizations. A comparative study was conducted using five healthcare datasets and evaluated against two LLM-based tools (Data Formulator and PandasAI) using four statistical measures (Kendall's τ, Spearman's ρ, Kendall's W, and ICC). Results show that DFChat outperforms the compared tools, providing more accurate, complete, and interpretable responses.**

***Index Terms*—large language model, exploratory data analysis, retrieval-augmented generation, natural language**

I. Introduction

Open health datasets play a crucial role in scientific and technological advancement and in public health by facilitating scientific collaboration, enriching research, and expanding analytical capacity to support decision-making [1]. Exploratory Data Analysis (EDA) is a fundamental step in achieving these benefits, responsible for uncovering patterns, identifying anomalies, and providing initial insights [2]. Usually, it is a time-consuming task that requires technical knowledge of programming, as well as proficiency in libraries for data exploration and visualization [3].

We thank the National Council of Technological and Scientific Development (CNPq), Brazil, grant #405352/2021-2.

In recent years, advances in natural language have opened new possibilities for interaction between humans and computational systems with the emergence of Large Language Models (LLMs). These models can interpret and generate natural language with a high degree of fluency and contextual understanding [4], making them ideal candidates to serve as intelligent interfaces between users and data analysis tools.

In this work, we extend and evaluate an approach that builds on the interaction capabilities of LLMs to guide users through the EDA process [5]. The approach enhances LLM effectiveness through Retrieval-Augmented Generation (RAG), which automatically enriches the context with metadata and statistics extracted from the dataset. During each interaction, DFChat dynamically analyzes the response generated by the LLM, returning descriptive summaries, visualizations, and insights in natural language.

The approach presents advances in the use of generative artificial intelligence to boost data analysis by enabling LLMs to execute EDA tasks directly on Pandas DataFrames. Through a benchmark of five real-world health datasets and a multi-criteria evaluation conducted by experts, DFChat consistently outperformed two baseline tools (Data Formulator [6] and PandasAI[1]) in terms of Relatedness, Error presence, Clarity, and Coverage. These findings were supported by statistical correlation and agreement measures, which indicated high

[1]https://github.com/sinaptik-ai/pandas-ai

consistency among annotators. Additionally, we discuss the challenges, limitations, and potential future directions for enhancing the integration between LLMs and DataFrames.

II. Related work

The integration of LLMs into data science pipelines has become increasingly popular, particularly in automating code generation using natural language. This trend has given rise to a variety of systems designed to address the gap between natural language interaction and specialized data manipulation [7], [8]. In this context, the following papers are related work on various applications of LLMs in tasks such as data transformation, standardization, and visualization.

Wang, Thompson and Lee [6] propose the Data Formulator, an approach for creating visualizations through a paradigm called concept binding, which separates the visualization intent (expressed in natural language or examples) from the technical steps of data transformation. The tool utilizes an AI agent to automate these transformations, enabling users to create complex visualizations without requiring technical programming skills. A study with participants demonstrated that the system facilitates the creation of graphs that would typically require structured manipulations with libraries such as Pandas.

Fan et al. [9] propose DataChat, a conversational agent for searching and exploring scientific datasets. The system utilizes knowledge graphs to represent relationships between publications, terms, and institutions, in conjunction with the GPT-3.5-turbo model, which converts questions into Cypher queries for a Neo4j database. This structure enables users to ask questions and receive visual or textual queries as responses.

Jaisinghani and Aggarwal [10] conducted a study to evaluate two LLMs, Llama3 and BambooLLM, applied to five business intelligence tasks in the AdventureWorks dataset. The study investigated the ability of the model to answer analytical questions and generate relevant visualizations using an architecture with PandasAI and Chainlit, while evaluating metrics from both models against predefined expected responses. The results show that Llama3 offers greater efficiency and a lower error rate in tasks that combine structured and interpretive elements. However, the work does not propose any new approach for extracting responses; only a comparative study with LLMs from the literature is carried out.

Finally, Qi, Miao and Wang [11] developed CleanAgent, a framework that combines LLM-based agents with the ``Dataprep.Clean'' library to automate data cleaning and standardization. Unlike approaches that require extensive prompts and multiple interactions, CleanAgent aims for an experience where the user specifies their requirements only once. While it addresses preprocessing tasks similar to those of data analysis, its scope is limited and does not support explainability or extensive discussions about the data.

Overall, our paper applies LLMs to enable exploratory analysis of DataFrames through natural language. While Data Formulator focuses on creating visualizations and CleanAgent on standardizing columns, we propose an approach that combines descriptive and interpretative analysis, using natural language responses from the LLM with statistical analyses and visualizations generated to the DataFrame and user questions. Unlike DataChat, which is integrated with knowledge graphs, our objective is to provide an exploratory analysis experience that enables users to extract insights from a dataset in an interactive, transparent, and natural manner. Our paper also presents a study on the application of three tools in open health datasets, contributing to evaluate the potential contributions of these tools in supporting exploratory data science.

III. DFChat

DFChat is an open-source tool[2] developed to enable EDA by natural language, combining LLM and RAG with complementary rule-based techniques. In this process, the user has to select an LLM from Groq[3] or use the default (`meta-llama/llama-4-maverick-17b-128e-instruct`). The objective of DFChat is to provide a conversational method to ask questions about a Pandas DataFrame and receive answers without requiring explicit programming. Figure 1 shows the execution pipeline.

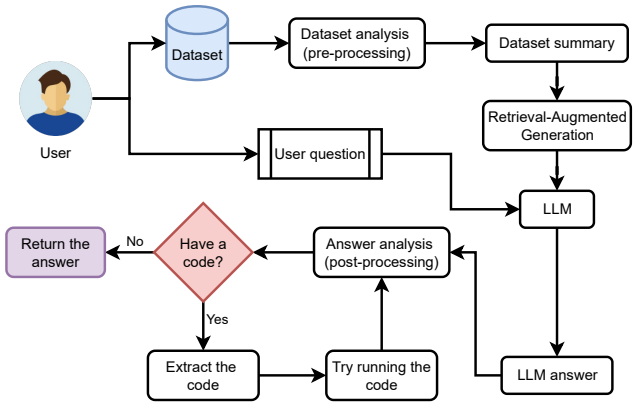

Fig. 1: DFChat execution pipeline

Upon receiving the dataset and the question, the system extracts the columns and their respective data types, which will be used to enrich the LLM context. The RAG mechanism is then activated to structure this knowledge in an interpretable textual format, allowing the model to understand the question more accurately. Based on the LLM response, a post-processing step evaluates whether there is code in the generated text, automatically extracting and executing it. This architecture makes DFChat robust to specific questions, ensuring greater accuracy in the responses generated.

A. Retrieval-Augmented Generation

RAG refers to a strategy that enriches the response generation process of language models by incorporating relevant external information before producing the final output. Rather

[2]https://github.com/fernandozagatti/DFChat/
[3]https://groq.com/

than depending exclusively on internal model parameters, this technique introduces a retrieval stage that collects contextual data from a task-specific knowledge base [12], [13]. In the context of DFChat, RAG is used to structure a textual summary of the dataset that contains relevant information for analysis, including column names, data types, basic statistics, and, when applicable, sample values. This summary is provided as an additional context to the RAG before the user's question.

In addition to enhancing the understanding of the model, the use of RAG also helps reduce incorrect responses, as the model relies on concrete data provided by the user. For example, the LLM will be aware of the columns of the dataset and will perform analyses only on those specific columns. Another significant benefit is modularity: RAG functions as a bridge between data and LLM, enabling DFChat to accurately interpret questions and provide responses without requiring model fine-tuning.

B. Execution and post-processing

Once the LLM generates the response, DFChat proceeds to a controlled execution stage. The LLM returns a response that may include plain natural language text, explanatory reasoning, and/or code intended to be executed over the provided dataset. Before any further action is taken, the system performs a post-processing step to clean the response. Specifically, if the model included internal reasoning (denoted by `<think>...</think>` tags), these tags are removed. Next, the system enters a control loop to determine whether executable code is present. If no code is found in the response, the textual output is returned directly to the user. In the case the response contains one or more code blocks (typically formatted in markdown-style backticks, identified by the markers illustrated in Figure 2), the system attempts to extract the code and execute it.

````
The shape of the dataset is (10, 8), which means it contains 10 rows
(observations) and 8 columns (variables).

To confirm this, we can use the `.shape` attribute of the DataFrame:

```python
import pandas as pd

# Display the shape of the DataFrame
display(df.shape)
```
````

Fig. 2: Code block example

The code is executed in a controlled environment with output redirection and exception handling. If the execution is successful, the results (e.g., printed output, tables, or visualizations) are captured and presented to the user; but if the code fails to execute – for instance, due to syntax errors, undefined variables, or logic faults – the system informs the user that an error occurred during execution. The exact error message is also returned to aid in understanding the failure, as shown in the error output example in Figure 3.

The loop continues until all the codes present in the response have been extracted and executed. This approach ensures that

````
```python
# Summary statistics for numerical columns
display('Summary statistics for numerical columns:')
display(df[['Unnamed:0']].describe())
```
'Summary statistics for numerical columns:'
I tried to run the code, but got the following error:
"None of [Index(['Unnamed:0'], dtype='object')] are in the [columns]"
````

Fig. 3: DFChat error example

the DFChat can handle both purely interpretative responses and those that require active computation. DFChat is integrated directly into the Python code, as shown in Figure 4, where the user imports the dataset and asks questions directly to DFChat.

```python
import pandas as pd
from dfchat import DFChat

df = pd.read_csv('Stress.csv')
chat_llm = DFChat(df)
response = chat_llm.chat("What are the main
characteristics of the dataset?")
```

Fig. 4: DFChat usage example

IV. Evaluation Process

This section investigates whether DFChat provides more accurate, complete, and interpretable responses when performing EDA tasks on real-world open health datasets. To this end, we define an evaluation pipeline that allows us to compare the outputs of different tools when faced with identical analytical questions, measured by human judges. Data Formulator, DFChat, and PandasAI were evaluated using LLaMA 4, applied to five different prompts for each of the five datasets used in the study, resulting in 15 responses per dataset, totaling 75 distinct responses. Then, each response was evaluated by three judges, based on four specific criteria, resulting in a total of 900 distinct scores.

A. Evaluation pipeline

The proposed pipeline involves multiple stages: selecting diverse healthcare datasets, defining benchmark prompts (standardized questions that reflect common EDA tasks), and implementing an evaluation protocol conducted by human experts to assess the quality of each output.

*1) **Datasets and tools**:* To evaluate the effectiveness of DFChat, we conducted a case study using five publicly available healthcare datasets obtained from the Kaggle platform (Human Stress Prediction, Fetal Health Classification, Diabetes Health Indicators Dataset, Lung Cancer Dataset and Suicide and Depression Detection)[4]. We selected the datasets with the intention of covering a range of formats and levels of complexity, including both purely tabular data and data that contain textual information. This diversity enables a more comprehensive evaluation when handling various types of data

[4]https://github.com/fernandozagatti/DFChat/blob/master/Datasets/Datasets.md

through natural language queries. Table I summarizes their characteristics.

TABLE I: Dataset characteristics

Dataset	Instances	Columns	Has text?	Class
1	2838	7	Yes	2
2	2126	22	No	3
3	253680	22	No	3
4	3000	16	No	2
5	232074	3	Yes	2

Thus, we compared DFChat performance with two tools that also use LLMs to assist in data analysis tasks: **Data Formulator** and **PandasAI**. Table II shows the key features of each tool.

TABLE II: Feature comparison between tools

Feature	DFChat	Data Formulator	PandasAI
Natural language interaction	✓	✓	✓
Textual response generation	✓	✓	✓
Graph generation	✓	✓	✓
Code generation	✓	✓*	✗
Internal process visualization	✗	✓	✗
Graphical interface	✗	✓	✗
Jupyter Notebook integration	✓	✗	✓
Dynamic LLM selection	✓	✓	✓

* Only generates SQL code.

Data Formulator is a tool for the automated creation of visualizations from data, enabling users to describe their desired visual intent in natural language. Utilizing a concept-binding architecture, the system translates user intent into data transformations and interpretable graphical components. However, its main objective is to help users express *what* they want to visualize, rather than supporting *why* the data behaves in a certain way. As a result, its analytical capabilities are limited if the inputs provided are open-ended questions and do not identify the columns that should be used.

PandasAI is an open-source library designed to extend the capabilities of the Pandas library with natural language support, using LLMs as a backend. Similar to DFChat, it allows users to ask questions about DataFrames directly in text, and the system interprets these queries by generating and executing Python code.

Since all tools allow you to choose the LLMs that will be used internally, we performed the tests using the same LLM (`meta-llama/llama-4-maverick-17b-128e-instruct`) to ensure a fair comparison.

*2) **Prompts**:* To benchmark the performance of the tools, five standardized prompts were defined that cover different levels of analytical complexity. The prompts were selected to represent everyday tasks in an EDA workflow, from simple to complete analysis of the dataset [14], [15]. This approach enables us to assess the ability of the tools to accurately interpret the intent of the user, provide correct information, and, when applicable, generate visualizations or code. The five prompts used are:

- **"What are the main characteristics of the dataset?"** - Evaluates the ability to identify general information such as the number of columns, data types, number of instances, presence of categorical and numerical variables, among other basic descriptive properties.
- **"Are there any missing values? If so, in which columns and how many?"** - Detect missing values in the dataset, identify the affected columns, and quantify the null values, whether in absolute numbers or percentages.
- **"Can you identify any outliers in the data?"** - Tests statistical methods when dealing with outliers and whether the results presented are consistent.
- **"Generate relevant visualizations that help me understand the distribution of the data"** - Evaluates the generation of useful graphs, such as histograms or boxplots, to help understand the distribution of variables.
- **"Make a complete EDA of my dataset"** - Evaluates the ability to perform a complete exploratory analysis, covering from descriptive statistics to generating visualizations, in a structured and interpretable way.

*3) **Evaluation criteria**:* We conducted a human evaluation involving three data scientists, all of whom are experts with at least six years of experience in artificial intelligence, holding a PhD in Computer Science, Statistics, and Data Science. Each judge was tasked with evaluating the responses provided by the three tools. We opt for an expert-based assessment, as specialists are better equipped to judge the responses, considering that the answers are complex and may have ambiguities. Other methods (e.g., controlled experiments, surveys) are more suitable for later stages of system evaluation. The evaluation was performed independently and anonymously. Judges rated each answer on a Likert scale [16] (from 1 = strongly disagree to 5 = strongly agree) on the following four criteria:

- **Relatedness - "Is the response related to the prompt?":** This criterion evaluates whether the generated content is related to the question.
- **Error-free - "How error-free is the response?":** Raters judged whether the answer exhibited any clear factual, logical, or programming mistakes.
- **Clarity - "Is the response clear and easy to understand?":** This criterion measures the clarity of the response, taking into account structure and overall readability.
- **Coverage - "Does the response show reasoning and cover important aspects of the prompt?":** This criterion evaluates whether the answer provides a thoughtful explanation and addresses the core elements demanded by the prompt.

Each judge assigned a score for each of the criteria in every question, allowing for an aggregated analysis of quality and consistency across tools and criteria. This evaluation design enabled us to compare the general performance of the tools and to identify specific strengths and weaknesses in how each tool interprets and responds to user prompts.

As evaluations are ordinal values (the numbers represent a position in a sequence), the data do not conform to a normal distribution. In this context, we employed two types

of analysis: **correlation metrics** to evaluate the degree of association between pairs of judges (whether they tend to rank items in the same direction, regardless of exact values), and **agreement metrics** to assess the extent to which judges assign the same (or nearby) scores to the same items; this distinction is essential because high correlation does not necessarily imply high agreement [17], [18]. Table III presents the metrics and their suggested interpretations.

B. Correlation metrics

We adopt two non-parametric rank-based coefficients: **Kendall's rank correlation coefficient** (Kendall's τ) and **Spearman's Rank-Order Correlation Coefficient** (Spearman's ρ). Kendall's τ is used to measure the ordinal association between two variables. The τ evaluates the correspondence between the rankings of two sets, specifically the strength and direction of their monotonic association [21], [22].

Like Kendall's τ, Spearman's ρ is used to assess the strength and direction of the monotonic association between two variables [23]; Spearman's ρ method is proper when the data are not normally or contain outliers [22].

C. Agreement metrics

In this study, we use **Kendall's coefficient of concordance** (Kendall's W) and the **Intraclass Correlation Coefficient** (ICC) to measure inter-rater agreement. Kendall's W is a non-parametric statistical measure used to quantify the degree of agreement among multiple raters who rank or score a common set of items. This metric is suitable for ordinal data, and for situations where the goal is to assess the overall consistency of evaluations among three or more judges [24] – Kendall's W takes into account the sum of the ranks assigned to each item and calculates the variation among these totals; the smaller the variation, the greater the agreement among the raters.

ICC is a statistical metric used to quantify consistency or reliability among raters who assign scores to the same set of items. This measure evaluates the proportion of the total variance that can be attributed to actual differences between the items, as opposed to variance arising from subjectivity or inconsistency among the annotators. The ICC is used to assess the agreement among judges, taking into account the variation in the scores assigned by them. We adopt the $ICC(3, k)$, since the judges are fixed – not represent a random sample from the population of possible raters – and the final measure corresponds to the average of the scores by each judge to the same item [25].

V. Results and analysis

The results show that different prompts led to varied performance across the tools, highlighting their strengths and limitations in addressing specific EDA tasks. Both Data Formulator and PandasAI often require multiple code executions to produce results that could be adequately evaluated. In contrast, this issue was significantly reduced with DFChat. Therefore, each tool was executed iteratively until a valid response was obtained, with a maximum of 10 attempts. If all executions resulted in errors, the process was terminated, and the last answer was recorded.

The use of up to ten execution attempts was adopted to account for the stochastic nature of LLM-based systems and the possibility of transient execution failures, such as generation errors, API failures, or unsuccessful code execution. A trial was considered valid when the tool completed the requested task and returned an interpretable response that could be submitted to the evaluation process, regardless of whether the response was ultimately correct. We set the ten-attempt limit as a fixed upper bound to prevent indefinite retries while providing enough opportunities to distinguish occasional failures from systematic execution problems.

A. Correlation between judges

The degree of correlation among the three judges was measured using Kendall's τ and Spearman's ρ. These metrics were applied to evaluate the strength and direction of the scores assigned by each pair of human judges across the four criteria defined in Section IV-A3. Figures 5a and 5b present the results, along with their respective 95% confidence intervals (CI95%) – The CI95% indicates how reliable the estimated value is.

Based on the presented figures, a moderate to good correlation can be observed between the judge pairs. The **"Clarity"** criteria showed the highest levels of agreement between Judge 1 and Judge 3 across both metrics, indicating consistency in the evaluation of this characteristic; in contrast, the **"Coverage"** criteria revealed lower agreement between Judge 2 and Judge 3, suggesting subjectivity or divergence in the interpretation.

B. Agreement between judges

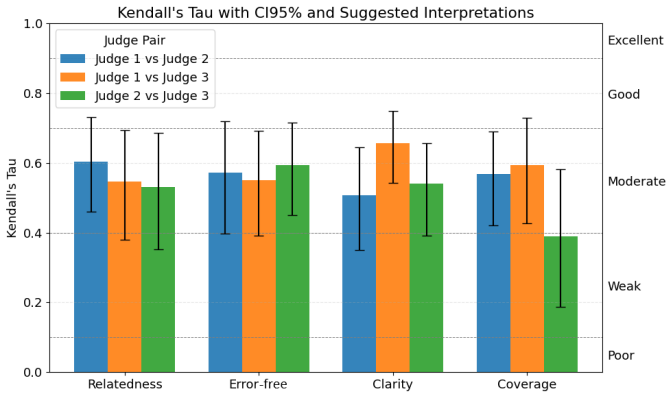
Subsequently, the degree of agreement among the three judges was measured using Kendall's W. This metric was employed to assess the consistency across all human evaluations. Table IV presents the values obtained for each of the evaluated criteria, along with their respective CI95%.

The Kendall's W results indicate an overall level of agreement classified as good among the judges across all criteria. In this way, **"Clarity"** achieved the highest coefficient (W = 0.790), reflecting the greatest consistency in the evaluations. **"Coverage"** showed the lowest value (W = 0.698), although still within the range considered as good agreement. These findings reinforce the overall reliability of the evaluations and corroborate the results of the first two metrics presented in Section V-A. Finally, the degree of agreement among the judges was calculated using $ICC(3, k)$, as shown in Table V, which presents the ICC values and the CI95% obtained.

The $ICC(3, k)$ results showed a good to excellent level of agreement between the judges, with the CI95% ranging from moderate to excellent, indicating that the adopted criteria were interpreted relatively uniformly. However, some variations between judgments were still observed. The **"Error-free"** achieved the highest ICC (0.859), suggesting that the judges

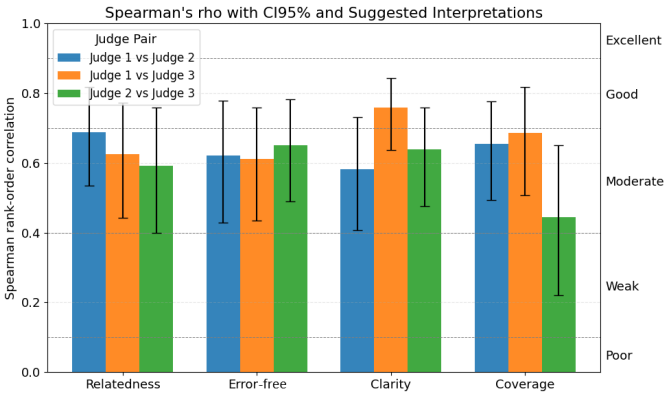
TABLE III: Three suggested interpretations found in the literature

Corr. Range (±)	Interpretation
0.00 - 0.09	Poor
0.10 - 0.39	Weak
0.40 - 0.69	Moderate
0.70 - 0.89	Good
0.90 - 1.00	Excellent



(a) Correlation coefficients [19]

W Range (±)	Interpretation
0.00 - 0.19	Poor
0.10 - 0.39	Weak
0.40 - 0.59	Moderate
0.60 - 0.79	Good
0.80 - 1.00	Excellent



(b) Kendall's W [20]

ICC Range (±)	Interpretation
0.00 - 0.39	Poor
0.40 - 0.54	Weak
0.55 - 0.69	Moderate
0.70 - 0.84	Good
0.85 - 1.00	Excellent

(c) Intraclass correlation [19]

(a) Kendall's τ values with CI95%

(b) Spearman's ρ with CI95%

TABLE IV: Kendall's W Results

Criteria	Kendall's W	CI95% (Range)	Interpretation
Relatedness	0.723	[0.65-0.83]	Good
Error-free	0.748	[0.63-0.83]	Good
Clarity	0.790	[0.67-0.82]	Good
Coverage	0.698	[0.62-0.81]	Good

TABLE V: ICC Results

Criteria	ICC3k	CI95% (Range)	Interpretation
Relatedness	0.813	[0.73-0.88]	Good
Error-free	0.859	[0.79-0.91]	Excellent
Clarity	0.834	[0.76-0.89]	Good
Coverage	0.787	[0.69-0.86]	Good

were able to identify errors with greater objectivity. This behavior is also evident in Kendall's τ and Spearman's ρ, where the correlations of the responses appear more stable than in the other criteria evaluated. The **"Coverage"** criteria showed the lowest agreement (0.787), reflecting the subjectivity involved in this type of judgment.

C. Analysis of the results

Since the judges achieved a high degree of agreement and considering the various aspects evaluated in the experiment conducted, it was decided to present the results as aggregated averages in Table VI rather than listing the raw results individually. In total, 3 tools were evaluated (Data Formulator, DFChat, and PandasAI), all using the same language model (LLaMA 4), applied to 5 different prompts for each of the 5 datasets used in the study – this resulted in 15 responses per dataset, totaling 75 distinct responses. Each of these responses was then evaluated by 3 annotators, based on 4 specific criteria, resulting in a total of 900 distinct scores. Given the large volume of data, presenting the average values allows for the identification of general performance patterns without overwhelming the reader with excessively granular data[5].

Across all prompts, DFChat outperformed the other tools, providing more relevant responses, with greater clarity and coverage, as well as a lower error rate (all LLMs answers are available in Github[6]). The only exception was observed in the fifth prompt, **"Make a complete EDA of my dataset"**, where PandasAI showed a slightly higher average error score (4.2) compared to DFChat (4.1); nonetheless, DFChat showed superior performance in the other three criteria. Figure 6 provides a representation of these results.

Data Formulator, although it also allows interaction with data through natural language, has a distinct focus: it operates by generating SQL queries and presenting a single chart, which limits the analysis. DFChat, even when errors occurred, it often provided the corresponding code and explained their causes. Finally, PandasAI yielded intermediate results: with a similar goal to DFChat, it was capable of generating charts and performing analyses, but with lower transparency and a higher occurrence of failures.

For the fundamental task of identifying missing values, using the Prompt 2 – **"Are there any missing values? If so, in which columns and how many?"** –, DFChat confirmed the integrity of all datasets by reporting zero missing values across every column. When using Prompt 3 – "**Can you identify any outliers in the data?**" –, DFChat utilized the Interquartile

[5]The raw results remain available for detailed analysis on Github.

	DFChat	**4.5 ± 0.3**	4.1 ± 0.1	**4.2 ± 0.2**	**4.5 ± 0.3**
	PandasAI	3.9 ± 0.5	**4.2 ± 0.9**	2.9 ± 0.7	3.1 ± 0.6

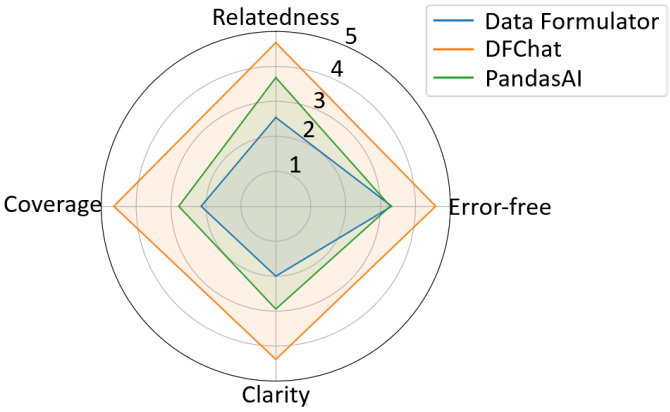

Fig. 6: Radar chart of the general mean scores

Range (IQR) method to identify and quantify anomalous observations in numerical features. Data Formulator often fails or merely suggests visualizing outliers without providing numerical counts. PandasAI gives counts in some cases, but does not do so with the same depth and interpretability as DFChat, typically presenting the graph or outlier count without explaining how it arrived at those results.

DFChat also provided visualizations and relationship mapping to characterize data distributions. Analysis of the "**Suicide and Depression**" dataset revealed a balanced class distribution, with 116037 instances classified as "**suicide**" and an equal number of instances as "**non-suicide**". The "**Human Stress**" dataset identified that the "**ptsd**" (584 entries), "**relationships**" (552 entries), and "**anxiety**" (503 entries) are the most frequent subreddits contributing data. And the "**Fetal Health Classification**" dataset displayed a class imbalance, with 1655 cases classified as "**1.0**" (Normal), 295 as "**2.0**" (Suspect), and 176 as "**3.0**" (Pathological). Data Formulator and PandasAI deliver less detailed results and exhibit a higher frequency of errors when more complex analyses are requested.

VI. Limitations

Although DFChat reduced the number of execution failures compared to competitors, it remains susceptible to occasional misinterpretations and errors, particularly when handling text-based information. The human-based evaluation also introduces a degree of subjectivity, as the evaluation criteria depend on the interpretation of individual judges. Furthermore, as the generated responses are based on a predefined LLM model, the quality of the responses will depend on the size and data used to train this model – therefore, further experiments with additional models are required to investigate the robustness of the observed results.

In parallel, the use of externally hosted LLM APIs also introduces a reproducibility limitation. Model availability, API versions, inference parameters, rate limits, service configurations, and model updates may affect the generated responses over time. Consequently, reproducing the exact experimental results may not always be possible even when using the same prompts and datasets.

Finally, the evaluation was conducted using only five healthcare datasets, which may limit the generalization of the findings to other domains. Although they cover different dataset sizes, numbers of variables, data types, and levels of complexity, this selection represents only a limited subset of the characteristics found in healthcare and biomedical data. Consequently, selection bias may affect the observed results, limiting their generalization to other healthcare datasets and to datasets from domains with different statistical, structural, or semantic properties.

VII. Conclusions and Future Work

This study evaluated DFChat, an interactive and open-source tool for conducting EDA through natural language interaction. By integrating RAG with rule-based execution control, DFChat consistently demonstrated the ability to interpret user questions, generate meaningful visualizations, and deliver accurate insights. Compared to existing tools like Data Formulator and PandasAI, DFChat presented more complete

answers, greater clarity, and lower error rates across all evaluated criteria.

The human evaluation process reinforced the reliability of DFChat. The agreement among judges, measured by Kendall's τ, Spearman's ρ, Kendall's W, and $ICC(3,k)$, reflected moderate to good alignment between the annotators, indicating that the evaluation criteria were well-defined and consistently interpreted. These findings support the conclusion that DFChat provides coherent responses to EDA tasks applied to open healthcare datasets.

For future work, we propose three main directions. First, we aim to evaluate multiple LLMs (both large and lightweight) to assess trade-offs between performance, speed, and resource consumption. This will enable us to determine whether all tools maintain the same quality across different models, or whether there is any gain depending on the LLM used. Second, test the usability of DFChat with non-specialists, such as healthcare professionals, policy analysts, and domain experts without programming experience. Third, integrate DFChat with web-based interfaces to simplify its use; by embedding the tool into intuitive dashboards or interactive platforms (e.g., Streamlit), users will be able to perform data exploration and ask natural language questions without writing code. This direction aims to democratize access to data analysis capabilities, promoting broader adoption in multidisciplinary contexts where data-driven decisions are essential but technical expertise is limited.

Ethics Statement

This work uses publicly available datasets obtained from the Kaggle platform and does not involve direct interaction with human participants.

Disclosure of Generative AI Usage

No generative AI system was used to generate experimental results, fabricate data, or perform the scientific evaluation presented in this work. During the preparation of this manuscript, generative AI tools were used exclusively to assist with language refinement, grammar correction, and text clarity improvement.

Abstract— **Infrared thermography is a non-invasive imaging technique increasingly used in the assessment of orofacial functional conditions. However, technical factors, such as acquisition distance, can influence the reliability of measurements. This study evaluates whether human manual analysis and artificial intelligence (AI) computational analysis recognize the same variation in orofacial thermal patterns when the acquisition distance changes from 50 cm to 100 cm across four bilateral regions of interest (ROIs): right and left temporomandibular joints (TMJ) and right and left temporal muscles. Twelve asymptomatic volunteers were assessed via infrared thermography (FLIR E40). Human statistical analysis detected a systematic absolute temperature reduction at 100 cm in 45 of 48 ROI-volunteer pairs (93.75%), with mean reductions ranging from 0.38 °C to 0.75 °C ($p < 0.001$). Support Vector Machine (SVM) and K-Nearest Neighbors (KNN) classifiers discriminated acquisition distances with point accuracies of 95.83% and 87.50%, respectively. This investigation constitutes a metrological and computational evaluation rather than a clinical diagnostic study. The findings demonstrate that acquisition distance is a relevant source of technical bias that alters absolute temperature values by a magnitude capable of masking or mimicking physiological asymmetries. Consequently, relational or spatial thermal biomarkers are structurally more robust than isolated absolute measurements. Results remain preliminary (n = 12) and restricted to healthy individuals.**

Keywords— Infrared thermography, Temporomandibular joint, Machine learning, Orofacial analysis, Thermal asymmetry

I. INTRODUCTION

Infrared thermography (IRT) is an imaging technique for orofacial assessment, as it allows mapping of skin surface temperature, reflecting underlying physiological processes such as blood flow and metabolic activity. Previous studies have demonstrated that IRT is sensitive to vascular and inflammatory changes associated with TMD, supporting its use as a complementary diagnostic tool [1], [2]. Haddad et al. demonstrated that thermography can detect subtle thermal asymmetries in the orofacial region, while Dibai-Filho et al. reinforced the association between thermal asymmetry and musculoskeletal dysfunction.

The clinical applicability of IRT remains dependent on methodological standardization. Factors such as environmental conditions, emissivity settings, and acquisition parameters can significantly influence temperature measurements. Acquisition distance represents a critical variable that directly affects the amount of infrared radiation captured by the camera sensor. Variations in distance can lead to systematic changes in measured temperature values, potentially compromising data comparability [3], [4],[5].

Thermal asymmetry has been recognized as an important parameter in thermographic analysis. Recent studies suggest that spatial thermal patterns can provide more robust information than isolated temperature values, particularly when analyzed using advanced computational approaches [6].

In this context, machine learning techniques have gained attention for their ability to identify complex patterns in biomedical data. Algorithms such as Support Vector Machines (SVM) and K-Nearest Neighbors (KNN) have been successfully applied to thermographic datasets, enabling automated classification and enhanced pattern recognition [7],[10]. These approaches complement traditional statistical methods, allowing the assessment of data structure and separability.

Among technical sources of variability, target-to-camera acquisition distance represents a critical parameter that directly affects atmospheric attenuation, optical field of view, and effective spatial resolution per unit area. Despite standard consensus guidelines strongly capture distance control, practical clinical research often exhibits minor variations in patient positioning. The degree to which such distance shifts distort extracted thermal biomarkers has not been fully elucidated in orofacial applications, where anatomical structures are small and thermal variations of 0.3 °C to 0.5 °C are frequently interpreted as clinically significant.

The primary objective of this study is to perform a comparative metrological and computational evaluation between human quantitative analysis and supervised machine-learning algorithms in detecting thermal pattern alterations induced by varying capture distance (50 cm versus 100 cm) across four bilateral orofacial regions. It is explicitly highlighted that this work does not propose a diagnostic tool for temporomandibular disorders (TMD), nor does it evaluate pathological classification. Instead, its core contribution lies in quantifying the technical bias generated by acquisition distance and demonstrating that relational or spatial thermal features provide superior stability compared to raw absolute surface temperatures.

CNPq, CAPES, and FAPERJ for financial support

The presence or absence of temporomandibular disorders was not an inclusion criterion and was not evaluated in this study; the investigation is restricted to the metrological effect of acquisition distance on orofacial thermal patterns.

II. MATERIALS AND METHODS

A cross-sectional observational metrological study was conducted involving 12 asymptomatic adult volunteers (both sexes, aged between 20 and 40 years). The study protocol was approved by the Research Ethics Committee of the Clementino Fraga Filho University Hospital and the Faculty of Medicine (HUCFF) of the Federal University of Rio de Janeiro (UFRJ), under number CAAE: 78605524.3.00005257 and ReBEC number: RBR-10367s7j. A physiotherapist was responsible for capturing, processing, and analyzing the infrared images. All participants signed an informed consent form. Inclusion criteria imply healthy individuals presenting complete natural dentition, absence of facial pain, and absence of temporomandibular signs or symptoms verified through anamnesis. Exclusion criteria encompassed history of facial trauma or surgery, orthodontic treatment within the preceding 12 months, systemic metabolic or rheumatic diseases, use of analgesics, anti-inflammatory drugs, or vasoactive substances in the 72 hours prior to examination, and presence of beard or makeup in the evaluated areas. Image acquisitions occurred in an acclimatized room maintained between 21 °C and 23 °C, with relative humidity at approximately 50%, following a 10-minute stabilization period per subject.

A. Image Acquisition and Human Analysis Protocol

Thermographic images were acquired using an uncooled focal plane array infrared camera (FLIR E40, FLIR Systems Inc., Wilsonville, OR, USA) featuring a native thermal resolution of 160 × 120 pixels, thermal sensitivity (NETD) < 0.07 °C at 30 °C, measurement range of −20 to 650 °C, and measurement accuracy of ± 2 °C or ± 2% of overall reading. Surface emissivity was set at 0.98. For each participant, images were captured perpendicular to the cutaneous surface at two standardized distances: 50 cm and 100 cm, previously marked on the floor. Five consecutive thermograms were captured per region and per distance, generating 20 thermographic images per participant at each distance. Human quantitative evaluation was performed by a specialized physiotherapist with extensive experience in infrared image interpretation using dedicated radiometric software (FLIR Tools). Four anatomical regions of interest (ROIs) were manually delimited bilaterally: Right TMJ, Left TMJ, Right Temporal Muscle, and Left Temporal Muscle. Mean surface temperature (°C), standard deviation, and coefficient of variation (CV) were extracted for each ROI across the five sequential frames per subject and distance.

B. Artificial Intelligence Framework and Tool Differentiation

To ensure methodological clarity and reproducibility, artificial intelligence tools were implemented under two strictly distinct operational modalities. Generative Artificial Intelligence (ChatGPT, OpenAI) was used as a computational assistance tool to implement and execute the conventional machine-learning classifiers (SVM and KNN), generating and running the classification code under the supervision of the authors, and as an auxiliary tool for descriptive summarization, structured textual organization, and comparative interpretation, including the comparison between the computational results and the independent statistical analysis performed by the authors. The generative model was not used for statistical inference: all statistical analyzes (normality assessment, paired comparisons, effect sizes, and confidence intervals) were performed independently by the authors. The conventional machine-learning classifiers (Support Vector Machine and K-Nearest Neighbors) are standard supervised models implemented through reproducible Python scripts (Python 3.9, scikit-learn 1.0). The specifications are:

- Algorithms: SVM (RBF kernel) and KNN (k=5, Euclidean)
- Features: 4 average temperatures per ROI, label: distance (50 vs. 100 cm)
- Split: StratifiedGroupKFold, 5 folds, by participant
- Validation: bootstrap (10,000 iterations), 95% CI
- SVM outperformed KNN (95.83% vs. 87.50% accuracy).

C. Statistical Analysis

Data distribution normality was evaluated using the Shapiro-Wilk test. Continuous variables with Gaussian distribution were analyzed using the paired Student's t-test (Left TMJ and Left Temporal Muscle), while variables exhibiting non-normal distribution were evaluated using the Wilcoxon signed-rank test (Right TMJ and Right Temporal Muscle). Variance homogeneity across distances was verified via Levene's test. Effect sizes for paired samples were quantified using Cohen's d alongside their respective 95% confidence intervals (95% CI). Statistical power was computed post-hoc considering sample size (n = 12), observed effect sizes, and two-tailed alpha of 0.05. Binary directional agreement between human detection and actual physical distance shift was assessed as the proportion of ROI-volunteer pairs in which the temperature decreased at 100 cm relative to 50 cm (reported in Table III). A significance level of $p < 0.05$ was adopted for all analyses.

D. Machine Learning Classification Pipeline

Machine learning techniques were applied to investigate the influence of acquisition distance on thermal patterns. The initial objective was to determine whether temperature patterns in the temporomandibular joint and temporal muscle exhibited thermal variations in thermograms captured at distances of 50 cm and 100 cm. Following the presentation of the image acquisition methodology, Support Vector Machine (SVM) and K-Nearest Neighbors (KNN) classification algorithms were selected and employed to classify the thermographic data based on the two acquisition distances. Model performance was interpreted as an indicator of thermal patterns across the conditions. In the second stage of the neural network analysis, a table containing independently

CNPq, CAPES, and FAPERJ for financial support.

obtained statistical values was included, and the network was tasked with statistically analyzing and comparing these values.

The computational classification task was designed to determine whether statistical thermal representations could discriminate between capture distances (0 = 50 cm; 1 = 100 cm). The feature vector comprised the four mean ROI temperatures [right ATM, left ATM, right temporal muscle, left temporal muscle] for each participant. So rigorouslyavoid data leakage and performance estimate inflation resulting from repeated captures (pseudoreplication), a participant-level cross-validation strategy was employed. Performance was evaluated using Classification Accuracy, Sensitivity (True Positive Rate for 100 cm), Specificity (True Negative Rate for 50 cm), Positive Predictive Value (PPV), Negative Predictive Value (NPV).

III. RESULTS

Thermographic analysis of the 12 volunteers revealed temperature patterns consistent with the normal physiology of the orofacial region. Table I presents the mean temperatures and standard deviation (SD) for each region of interest (ROI) at both distances, obtained through independent (human) analysis.

In Table I, the average temperatures showed statistically significant reductions in all areas evaluated at a distance of 100 cm, except for the left temporal region. The right temporal region (ATM D) showed a decrease from 34.80 ± 0.65 °C to 34.04 ± 0.64 °C, representing a thermal differential of -0.76 °C. A similar pattern was observed in the left temporal region (ATM E), with a drop from 34.83 ± 0.49 °C to 34.15 ± 0.48 °C.= -0.68°C.ΔT

TABLE I. HUMAN STATISTICAL ANALYSIS BY ROI AT 50 AND 100 CENTIMETERS.

Region of Interest (ROI)	Distance	Mean (°C)	SD (°C)	CV (%)	Median (°C)	Statistical Test	p-value
Left TMJ	50 cm	34.83	0.412	1.18	35.00	Paired t-test	< 0.001
Left TMJ	100 cm	34.17	0.345	1.01	34.20	Paired t-test	< 0.001
Right TMJ	50 cm	34.80	0.751	2.16	35.10	Wilcoxon	< 0.001
Right TMJ	100 cm	34.05	0.582	1.71	34.15	Wilcoxon	< 0.001
Left Temporal Muscle	50 cm	34.83	0.314	0.90	34.90	Paired t-test	< 0.001
Left Temporal Muscle	100 cm	34.45	0.355	1.03	34.60	Paired t-test	< 0.001
Right Temporal Muscle	50 cm	34.73	0.479	1.38	34.90	Wilcoxon	< 0.001
Right Temporal Muscle	100 cm	34.19	0.592	1.73	34.40	Wilcoxon	< 0.001

Source: Author

The effect size (Cohen's d) for the temporomandibular joints ranged from 1.74 to 2.30, indicating a fairly significant effect size. The statistical power of 1.00 for these measures suggests that the observed differences are significant and do not result from random variation.

The 95% confidence intervals (95% CI) for the thermal variation (ΔT) between acquisition distances of 50 cm and 100 cm demonstrate high metrological consistency. The fact that neither interval crosses the zero threshold confirms the statistical significance ($p<0.001$) of the distance-induced thermal displacement.

Regarding the comparative recognition of the distance effect, human evaluation correctly identified a downward thermal shift at 100 cm in 45 out of 48 individual ROI-volunteer pairs, yielding a directional detection accuracy of 93.75%. The only three discordant pairs where temperature increased at 100 cm were Participant #1 (Left Temporal Muscle: 34.60 °C vs 34.62 °C), Participant #5 (Right TMJ: 33.46 °C vs 33.76 °C), and Participant #10 (Left Temporal Muscle: 34.20 °C vs 34.30 °C). Supervised machine-learning models operating on the 4-dimensional ROI thermal vectors demonstrated strong discriminative capacity between capture distances, as shown in Table II.

TABLE II. COMPARATIVE PERFORMANCE METRICS: HUMAN ANALYSIS VS MACHINE LEARNING

Method	Accuracy (%)	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)
Human Analysis (Decision Rule)	93.75	93.75	93.75	93.75	93.75
Support Vector Machine (SVM)	95.80	92.30	100.00	100.00	91.70
K-Nearest Neighbors (KNN)	87.50	91.70	83.30	84.60	90.90

Source: Author

A. Calculation of the Mean Percentage Error

Based on the average value of -0.7 °C at the average reference temperature (34.6 °C) at 50 cm, the average percentage error caused by the increase in distance is:

$$\text{Erro } \% = \left(\frac{0.7}{34.6}\right) \cdot 100 \approx \mathbf{2.02}\%$$

Although it may seem small in percentage terms, in terms of thermal physiology, a variation can mask or simulate a pathological thermal asymmetry, validating justifying the use of a fixed distance of 50 cm.

According to Table II, the automated model achieved superior levels of accuracy, sensitivity, and specificity. The integration of Support Vector Machine (SVM) algorithms allowed for a more precise identification of thermal asymmetries, minimizing interobserver variability.

B. Confusion Matrix in the SVM and KNN models

The confusion matrix shown in Figure 1 was used to analyze the performance of the SVM (Support Vector Machine) and KNN (K-Nearest Neighbors) machine learning models in classifying thermographic images obtained from different capture distances (50 cm and 100 cm).

The aim of the analysis was to determine whether the algorithms could detect thermal variations related only to the distance from which the thermographic image was captured, and not to physiological changes in the volunteers. The images analyzed were of the same individuals but were captured at two different distances from the thermographic camera.

It was noted that the images obtained at 50 cm showed apparently higher temperatures compared to the images captured at 100 cm, a result that had also been identified previously through human analysis [11].

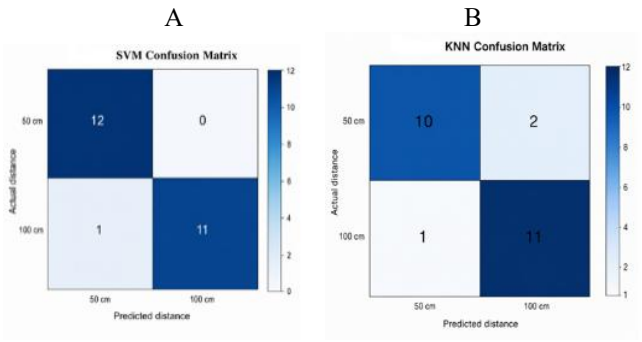

Fig. 1. SVM (A) and KNN (B) Confusion Matrix (Accuracy 95.8%)
Source: Author

In the confusion matrix of the SVM model (Fig. 1 A), the results demonstrated:

- 12 correct classifications for images obtained up to 50 cm;
- 11 correct classifications for images obtained at 100 cm;
- only 1 classification error;
- Absence of false positives for the 100 cm class.

The overall accuracy of the model was approximately:

The accuracy of 95.8% indicates the discriminatorycapacityof the SVM model in recognizing thermal differences resulting from variations in acquisition distance.

C. Positive Predictive Value (PPV)

Positive Predictive Value (PPV) This indicates a 100% probability that images classified as 100 cm (positive class) belong to the 100 cm class.

VPP = 100%

D. Negative Predictive Value (NPV)

Negative Predictive Value (NPV) This indicates a 91.7% probability that images classified as 50 cm (negative class) actually belong to the 50 cm class.

VPN = 91.7%

In Table III, the sensitivity of 92.3% demonstrates efficiency in identifying images acquired at 100 cm (positive class), whereas the specificity of 100% indicates that all images acquired at 50 cm were correctly recognized by the model (negative class). These results indicate that the machine learning algorithm is able to discriminate the two acquisition distances based on the variation of mean absolute temperature, confirming the human analysis reported previously. Thus, the observed thermal variations can be attributed to a technical effect of image acquisition, rather than to physiological alterations in the volunteers

TABLE III. DIAGNOSTIC PERFORMANCE METRICS OF THE SVM AND KNN CLASSIFIERS

Diagnostic Performance Metrics: SVM vs. KNN			
Model	**Sensibility (%)**	**Specificity (%)**	**Acurácia (%)**
SVM (Support Vector Machine)	92,30%	100,00%	95,80%
KNN (K-Nearst Neighbors)	91,70%	83,33%	87,50%

Source: Author

The objective of the KNN analysis was to verify if the model would be able to recognize thermal patterns related to the distance from the thermal imaging camera, distinguishing images acquired at 50 cm from those obtained at 100 cm. The results were also compared to human analysis, which identified apparently higher temperatures in images captured at shorter distances. The confusion matrix of the KNN model (Fig. 1B) showed:

- 11 true positives;
- 10 true negatives;
- 2 false positives;
- 1 false negative.

The overall accuracy of the model was calculated by:

Accuracy = 87.5%

The results indicate that the KNN model correctly classified 87.5% of the evaluated thermographic images but performed worse than the SVM due to a greater number of incorrect classifications. The positive predictive value (PPV = 84.6%) indicates the probability that images classified as 100 cm (positive class) indeed belong to the 100 cm class. The negative predictive value (NPV = 90.9%) indicates the probability that images classified as 50 cm (negative class) indeed belong to the 50 cm class.

The detection of the offset by both SVM and KNN models indicated that the algorithms were able to identify this abrupt temperature variation and classify whether the image was captured at a short or long distance (50 or 100 cm). This confirms that the thermal alteration is a reproducible technical artifact, rather than a physiological alteration in the volunteer, as also evidenced by the human analysis.

Although the KNN presented sensitivity (91.67%), its specificity was 83.33%, the lowest among the tested models, as shown in Table III. This difference indicates that KNN, by relying on neighborhood similarity, is more sensitive to biological variations between individuals. In cases where the volunteer's basal temperature is naturally low, images acquired at 50 cm may "converge" to the 100 cm class of another individual, leading to an increase in the occurrence of False Positives.

IV. DISCUSSION

The results of this research provide information on the technical reliability of infrared thermography (IRT) for orofacial clinical assessment. A key observation is that absolute temperature readings are significantly sensitive to

acquisition distance, as demonstrated by the thermal reduction observed at 100 compared to 50 centimeters.

The findings of this investigation provide evidence that acquisition distance introduces a systematic metrological bias in orofacial infrared thermography. Increasing capture distance from 50 cm to 100 cm resulted in an average absolute temperature reduction of 0.38 °C to 0.75 °C across all four evaluated ROIs. This attenuation is close to the principles outlined in ASTM E2582-17 guidelines standards and fundamental radiation transfer equations, wherein atmospheric absorption, radiation dispersion, and decreased pixel coverage per unit anatomical area degrade thermal readings at extended distances [3] [4].

The implementation of the automated machine learning pipeline resulted in advancements in both diagnostic operational precision and efficiency. SVM showed the highest discriminative performance between the two acquisition distances among the tested models. However, this result reflects a metrological discrimination task and does not support any claim of diagnostic automation or clinical diagnostic robustness. As suggested by Lahiri et al. (2022) [5], machine learning excels at identifying the subtle, non-linear relationships that often remain undetected during manual analysis.

The stability observed consistently with the facial symmetry mapping proposed by Santos et al. (2024) [12], supports the use of relational biomarkers as diagnostic indicators that are more robust than isolated temperature readings. From a physiological perspective, the anterior temporalis muscle and the TMJ regions remain critical to the functioning of the masticatory system, validating the methodology of using bilateral reference points to mitigate environmental or technical noise [4], [7].

The identification of a systematic error of approximately 2.02% (≈0.7 °C) when moving the camera 100 cm away has implications for the validity of thermal asymmetry analysis. In the specialized literature, thermal asymmetry thresholds considered pathological for orofacial structures are frequently set at 0.3°C.

Importantly, the observed thermal discrepancy of up to 0.75 °C at the TMJs is of the same order of magnitude as thermal asymmetry thresholds (frequently defined between 0.3 °C and 0.8 °C) used in clinical literature to suggest unilateral pathology, joint effusion, or localized muscular inflammation. Therefore, unstandardized capture distances in clinical practice or research protocols may either generate false-positive asymmetries if distance varies across bilateral captures or mask true underlying pathological asymmetries if captures are improperly scaled.

The high classification performance achieved by the SVM (95.83%) and KNN (87.50%) algorithms must be interpreted with strict technical caution. These models were trained to perform a metrological discrimination task (distinguishing between 50 cm and 100 cm setups) based on a 4-dimensional vector of mean surface temperatures. The high discriminatory accuracy indicates that the thermal shift is uniform and substantial enough across the face for computational algorithms to readily partition the feature space. However, this does not represent diagnostic accuracy for clinical dysfunction. The algorithms are primarily detecting the gross shift in mean absolute temperature rather than subtle spatial pattern reconfigurations. The classification task distinguishes acquisition distances and does not diagnose temporomandibular disorders; Accordingly, expressions such as diagnostic accuracy, clinical automation, or diagnostic robustness are not supported by the present evidence and were deliberately avoided.

Several methodological limitations must be addressed. First, the sample size was restricted to 12 asymptomatic healthy volunteers, limiting the generalizability of statistical distributions; the presence or absence of temporomandibular disorders was not evaluated in this study. Second, the spatial resolution of the FLIR E40 camera (160 × 120 pixels) results in fewer measurement pixels covering small anatomical targets like the TMJ at 100 cm, increasing susceptibility to partial volume effects and background radiative contamination. Third, inter-individual baseline thermal variability and physiological fluctuations can influence absolute cutoffs, as reflected in the wide 95% confidence intervals for Cohen's d. Fourth, because the features were the mean temperatures per ROI, the present analysis does not provide a voxel-level evaluation of spatial patterns; the stability of the relative thermal organization was inferred from the consistency of the bilateral thermal distribution across distances. Future investigations should incorporate larger cohorts, include patients with clinically confirmed temporomandibular disorders, evaluate spatial texture and gradient features, and implement multi-centric validation.

V. CONCLUSION

The acquisition distance (50 cm versus 100 cm) significantly alters the absolute surface temperature values in orofacial infrared thermography, producing a systematic thermal reduction of 0.38 °C to 0.75 °C in healthy individuals. The magnitude of this technical artifact is sufficient to compromise clinical interpretations by masking or mimicking physiological asymmetries. Both human analysis and machine learning classifiers recognized this distance-dependent variation with high agreement.

Metrological standardization of the patient-to-camera distance is essential to ensure reproducibility in quantitative thermographic protocols. Relational and asymmetry biomarkers demonstrated higher stability than isolated absolute temperatures. Further validation in symptomatic clinical populations and larger cohorts is required.

ACKOWLEDGMENT

We thank CNPq, CAPES, and FAPERJ for financial support.

Análise Comparativa de Doses e Parâmetros de Aquisição para Diferentes Tecnologias de Mamografia Digital

Alexsandra Pavani Xavier e Homero Schiabel
Depto. de Engenharia Elétrica e de Computação
Escola de Engenharia de São Carlos (EESC/USP)
São Carlos, Brasil

***Resumo*—Este trabalho apresenta uma análise da Dose de Entrada na Pele (DEP) e Dose Glandular Média (DGM) em oito sistemas de mamografia digital utilizando um simulador estruturado desenvolvido em pesquisa prévia pelo grupo e extração automatizada de metadados DICOM. O objetivo foi avaliar e comparar os parâmetros dosimétricos e de aquisição entre os diferentes sistemas de mamografia digital. Os resultados mostraram que o equipamento 4A apresentou os maiores valores médios de DEP, comportamento mantido nas exposições com espessura de 48 mm. Essa tendência pode estar relacionada à estratégia automática de exposição, à combinação alvo/filtro e aos parâmetros de aquisição selecionados pelo sistema. O maior nível de dose não foi acompanhado por maior contraste RMS. Apesar disso, os valores de DGM permaneceram abaixo dos níveis de tolerância adotados como referência da ANVISA . Conclui-se que a extração automatizada de metadados DICOM, associada ao uso de simuladores estruturados, é uma ferramenta útil para o rastreamento e a otimização dosimétrica em mamografia digital.**

***Index Terms*—Mamografia Digital, Dose Glandular Média, Metadados DICOM, Simulador de Mama, Garantia de Qualidade.**

I. Introdução

O câncer de mama é a neoplasia de maior incidência mundial e a principal causa de mortalidade por câncer na população feminina no Brasil [1]. A detecção precoce da doença permanece como o pilar fundamental para a obtenção de prognósticos favoráveis e tratamentos terapêuticos menos invasivos, sendo a mamografia consolidada como método padrão-ouro de rastreamento populacional [1].

Com a evolução tecnológica, os sistemas tradicionais ecrã-filme foram amplamente substituídos pela mamografia digital, subdividida em radiografia computadorizada (CR) e digital direta (DR). Essa transição proporcionou ampla faixa dinâmica de exposição e recursos avançados de pós-processamento, otimizando a detecção de estruturas milimétricas, como as microcalcificações. No entanto, a flexibilidade inerente aos sistemas digitais introduz o risco de sobre-exposição da paciente sem que ocorra uma degradação visível da qualidade da imagem, tornando o monitoramento das doses radiológicas um aspecto crítico da garantia de qualidade [2].

Neste contexto, a avaliação dosimétrica deste estudo fundamenta-se em duas grandezas principais extraídas dos metadados das imagens: a Dose de Entrada na Pele (DEP) e a Dose Glandular Média (DGM). Ambas as grandezas são relevantes para a radioproteção da paciente. A otimização desses níveis de radiação depende do equilíbrio entre os parâmetros técnicos de aquisição, como a tensão do tubo (kVp), a carga (mAs), a combinação alvo/filtro e a lógica do controle automático de exposição implementada por cada fabricante.

Para a avaliação de sistemas mamográficos em ambiente clínico, simuladores mamográficos (*phantoms*) podem ser utilizados para reproduzir características de atenuação do tecido mamário [3]. Somado a isso, os metadados presentes nos cabeçalhos DICOM fornecem parâmetros técnicos e dosimétricos relevantes para o rastreamento dosimétrico dos sistemas mamográficos.

A partir dessa fundamentação, o presente trabalho tem como objetivo avaliar e comparar os parâmetros dosimétricos e de aquisição registrados em oito sistemas de mamografia digital em rotina clínica, a partir dos metadados DICOM, utilizando um *phantom* desenvolvido pelo grupo [4], [5]. Foram analisados os valores de DEP e DGM, os parâmetros técnicos selecionados pelos sistemas automáticos e, de forma complementar, o contraste RMS local e global de imagens obtidas nos equipamentos [6].

Buscou-se, assim, identificar diferenças no comportamento dos sistemas e possíveis associações entre os parâmetros de aquisição e os níveis de dose observados. Além disso, os valores de DGM foram comparados aos níveis de referência estabelecidos pela normativa nacional da Agência Nacional de Vigilância Sanitária (ANVISA) [7].

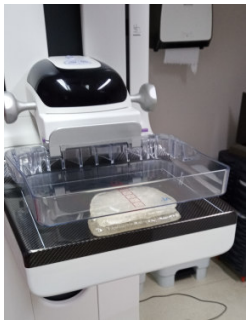
II. Metodologia

Foram avaliados, de forma individualizada, oito sistemas de mamografia digital direta em rotina clínica, abrangendo a tecnologia Digital de Campo Total (Digital Radiography - DR). A amostragem foi estruturada de modo a analisar o comportamento de cada equipamento, sendo composta por dispositivos de quatro fabricantes distintos: três unidades de um mesmo modelo do Fabricante I, operando respectivamente na Clínica I (equipamento 1A), na Clínica II (equipamento 1B) e na Clínica III (equipamento 1C); uma unidade do Fabricante II na Clínica IV (equipamento 2); uma unidade do Fabricante III no Hospital I (equipamento 3); e três modelos com tecnologias distintas do Fabricante IV, distribuídos entre

o Hospital II (equipamento 4A), a Clínica V (equipamento 4B) e a Clínica VI (equipamento 4C).

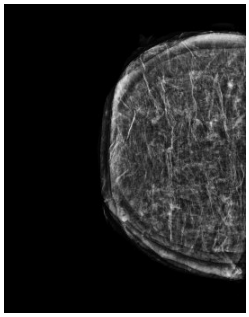
Cada um dos oito sistemas possui características próprias, operando com combinações específicas de alvo/filtro e lógicas de controle automático de exposição, incluindo os modos convencional (*Automatic Exposure Control* - AEC), dinâmico de contraste (CNT) e otimização automatizada de parâmetros (AOP).

O número de exposições consideradas variou entre os equipamentos, com amostras de $n = 1$ a $n = 8$. Nos equipamentos 1A, 1B, 1C, 3 e 4B, as aquisições foram realizadas em modo AEC. No equipamento 2, foram consideradas duas aquisições, correspondentes aos modos OPDOSE e AEC. Para o equipamento 4A, foram consideradas as exposições em modo CNT, enquanto no equipamento 4C a aquisição foi realizada em modo AOP.



As especificações detalhadas de cada sistema estão apresentadas na Tabela I.

TABELA I
CARACTERÍSTICAS TÉCNICAS E PARÂMETROS DOS SISTEMAS DE MAMOGRAFIA AVALIADOS



Equipamento	Fabricante	Tecnologia do detector	Ânodo/filtro	Exposições (n)
1A	Fabricante I	a-Se	W/Rh	3
1B	Fabricante I	a-Se	W/Rh	4
1C	Fabricante I	a-Se	W/Rh	4
2	Fabricante II	a-Si+CsI	W/Rh	2
3	Fabricante III	a-Se	W/Rh	1
4A	Fabricante IV	a-Si+CsI	Rh/Rh	8
4B	Fabricante IV	a-Si+CsI	Mo/Mo	1
4C	Fabricante IV	a-Si+CsI	W/Rh	1

Utilizaram-se para a avaliação os dados de testes da exposição de um *phantom* desenvolvido em pesquisa anterior pelo nosso grupo [4], [5]. O *phantom* é composto por camadas de filme de cloreto de polivinila (PVC) submersas em parafina gel, simulando tecidos adiposo e glandular humanos. Um aspecto característico de sua aplicação é que ele é composto por diferentes densidades mamárias que podem ser sobrepostas durante cada exposição, incluída a possibilidade de inserir simuladores de estruturas de interesse clínico, como nódulos e microcalcificações [4], [5].

Para a análise, as exposições foram realizadas utilizado o Molde 9A, cuja configuração específica simula uma mama predominantemente adiposa, para o qual a exposição aos raios X resulta em imagens como a ilustrada na Figura 1(a). Durante os ensaios, o *phantom* foi centralizado e fixado nos mamógrafos de forma padronizada, conforme ilustrado na Figura 1(b), com o objetivo de reduzir variações relacionadas ao posicionamento entre as aquisições.

(a) *Phantom* Molde 9A utilizado para os ensaios experimentais posicionado em um mamógrafo digital.

(b) Imagem mamográfica do *Phantom* Molde 9A obtida após a exposição.

Figura 1: *Phantom* Molde 9A utilizado nos ensaios experimentais.

A coleta de dados baseou-se na extração automatizada de parâmetros técnicos e dosimétricos diretamente dos metadados presentes nos cabeçalhos das imagens no padrão DICOM, utilizando o software Readicom [8]. Os valores de DEP foram obtidos a partir do parâmetro DICOM *Entrance Dose in mGy*, enquanto os valores analisados como DGM foram associados ao parâmetro *Organ Dose*. Além desses parâmetros dosimétricos, foram compiladas as seguintes variáveis:

- Tensão do tubo (kVp);
- Carga do tubo / Exposição (mAs);
- Espessura do objeto comprimido (mm);
- Material do ânodo (alvo) e do filtro;
- Modo de operação do controle de exposição;

A utilização dos metadados DICOM para o rastreamento de doses foi previamente avaliada pelo grupo. Nessas avaliações, os parâmetros dosimétricos registrados nos arquivos foram comparados com medições independentes realizadas com dosímetro calibrado, sendo observada boa concordância entre os resultados [8], [9].

Nessas avaliações dosimétricas prévias, a determinação da Dose Glandular Média foi baseada no formalismo recomendado para mamografia [10], expresso por

$$DGM = K_i \cdot g \cdot c \cdot s, \tag{1}$$

em que K_i representa o kerma no ar incidente e os fatores g, c e s consideram, respectivamente, a conversão para dose

glandular, a composição da mama e a qualidade espectral associada à combinação alvo/filtro.

Os dados foram organizados e processados em cinco frentes distintas de análise:

1) Comparação global de doses: avaliação comparativa das médias de DEP e DGM entre todos os fabricantes utilizando o Molde 9A;
2) Engenharia de aquisição: análise das interações entre os parâmetros de controle (relação kVp vs. mAs) para identificar padrões de compensação e tendências à sobre-exposição;
3) Análise por espessura: análise do subconjunto de exposições com espessura registrada de aproximadamente 48 mm, com o objetivo de reduzir a influência da espessura na comparação entre os sistemas;
4) Influência das inserções simuladas: análise das variações dos parâmetros de exposição associadas às diferentes configurações internas disponíveis do molde, incluindo nódulos redondos, espiculados e microcalcificações;
5) Análise de contraste RMS: avaliação quantitativa complementar das imagens por meio do contraste RMS (*Root Mean Square*) local e global [6].

Os resultados foram analisados de forma descritiva, considerando os valores individuais e, quando aplicável, a média, o desvio-padrão e o coeficiente de variação.

O contraste RMS global foi calculado a partir da razão entre o desvio-padrão e a média das intensidades dos pixels da região correspondente ao *phantom*. Para a análise local, o mesmo cálculo foi realizado em janelas de 64×64 pixels, sendo o resultado final obtido pela média dos valores calculados.

Como as imagens selecionadas apresentavam diferentes inserções, o contraste RMS foi utilizado como uma medida quantitativa complementar de contraste, sem representar isoladamente a qualidade diagnóstica dos sistemas.

Por fim, os valores de DGM foram comparados aos níveis de referência estabelecidos pela Instrução Normativa n° 92/2021 da Agência Nacional de Vigilância Sanitária (ANVISA).

III. Resultados e Discussões

A análise dos dados extraídos de forma automatizada, por meio dos metadados DICOM, permitiu organizar a avaliação dos oito mamógrafos nas cinco frentes metodológicas consideradas. Assim, foram correlacionadas as grandezas dosimétricas com o processo de aquisição de cada sistema e, ainda, com uma análise quantitativa de contraste das imagens.

A. Comparação Global de Doses

Os resultados iniciais analisaram o comportamento dos sistemas diante da atenuação do Molde 9A do *phantom*.

As Figuras 2 e 3 apresentam, respectivamente, os valores de DEP e DGM obtidos nas exposições para cada equipamento, juntamente com as respectivas médias.

Os equipamentos 1A, 1B e 1C apresentaram valores médios de DEP de $1,857 \pm 0,074$ mGy, $2,300 \pm 0,089$ mGy e $2,545 \pm 0,091$ mGy, respectivamente, com coeficientes de variação inferiores a 4%. Os respectivos valores médios de DGM foram $0,570 \pm 0,010$ mGy, $0,665 \pm 0,017$ mGy e $0,718 \pm 0,013$ mGy, também com baixa dispersão relativa.

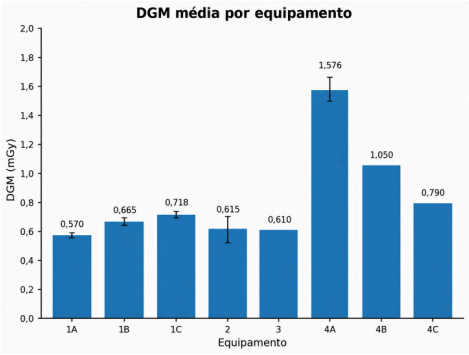


Figura 2: DEP média dos equipamentos analisados.

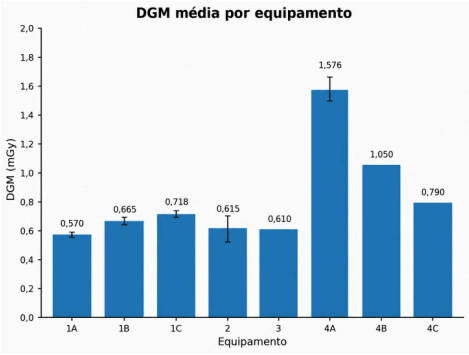

Figura 3: DGM média dos equipamentos analisados.

O equipamento 2 apresentou DEP média de $1,859 \pm 0,309$ mGy e DGM média de $0,615 \pm 0,120$ mGy, correspondendo a coeficientes de variação de 16,62% e 19,55%, respectivamente. Essa maior dispersão pode ser interpretada considerando que estavam disponíveis apenas duas exposições, realizadas em modos automáticos distintos.

O equipamento 4A apresentou os maiores valores médios do conjunto avaliado, com DEP de $5,246 \pm 0,472$ mGy e DGM de $1,576 \pm 0,073$ mGy. Os coeficientes de variação foram de 8,99% para DEP e 4,66% para DGM.

Os equipamentos 3, 4B e 4C foram representados por uma única exposição automática e, portanto, não foram calculadas medidas de dispersão para esses sistemas. Seus valores de DEP foram, respectivamente, 1,950 mGy, 3,760 mGy e 1,721 mGy, enquanto os valores de DGM foram 0,610 mGy, 1,050 mGy e 0,790 mGy.

Como o número de exposições variou entre os equipamentos, a comparação entre os sistemas foi interpretada principalmente com base nos valores observados e nas medidas de dispersão disponíveis.

B. Aquisição e Interação de Parâmetros Técnicos

As diferenças observadas nas doses foram analisadas em conjunto com os parâmetros radiográficos selecionados automaticamente pelos equipamentos.

A Figura 4 apresenta a relação entre a espessura do *phantom*, a tensão do tubo (kVp) e a carga de exposição (mAs) de cada mamógrafo.

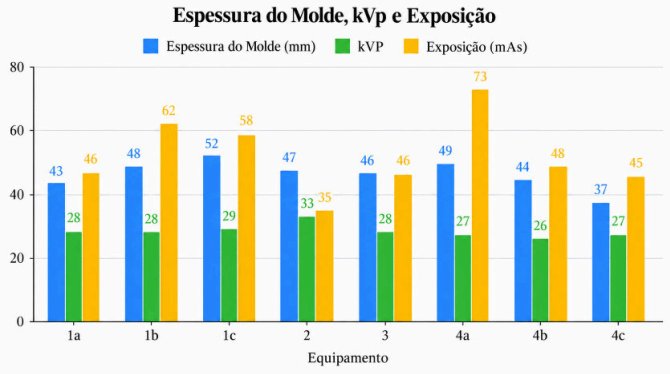

Figura 4: Espessura, kVp e exposição dos *phantoms* molde 9A por equipamento.

O sistema 2 operou com tensão de 33 kVp e carga média de aproximadamente 35 mAs nas exposições. O aumento da tensão do tubo tende a elevar a energia média do espectro de raios X e sua capacidade de penetração, podendo permitir redução da carga necessária para a formação da imagem em determinadas condições de aquisição [11], [12].

Ao contrário desse comportamento, o equipamento 4A operou com uma tensão menor, de 27 kVp, e uma carga de exposição média de aproximadamente 73 mAs, superior à empregada pelo equipamento 2. Essa configuração corresponde ao modo de exposição CNT, associado à combinação alvo/filtro Rh/Rh.

As diferenças observadas também podem estar relacionadas às características espectrais das combinações alvo/filtro utilizadas. Na configuração Rh/Rh, empregada pelo equipamento 4A, o alvo de Ródio ($Z = 45$) produz radiação característica com energias K_α e K_β em aproximadamente 20,2 keV e 22,7 keV, respectivamente, sendo o espectro posteriormente modulado pela filtração de Ródio. Nos sistemas W/Rh, por outro lado, o alvo de Tungstênio ($Z = 74$) produz predominantemente radiação de frenagem (*bremsstrahlung*) nas tensões, formando um espectro contínuo que também é modulado pelo filtro de Ródio [11], [12].

Nas condições avaliadas, essa diferença espectral, associada à maior tensão utilizada pelos sistemas W/Rh, pode ter contribuído para a maior penetração do feixe e para os menores valores de carga do tubo observados nesses equipamentos. Apesar disso, as diferenças de dose não podem ser atribuídas exclusivamente à combinação alvo/filtro, pois também podem estar relacionadas às características próprias de funcionamento e às condições operacionais de cada equipamento.

C. Análise por Espessura Fixa

Com o objetivo de reduzir a influência da espessura sobre a comparação dosimétrica, foi analisado separadamente o subconjunto de exposições com espessura registrada de 48 mm, conforme apresentado na Figura 5.

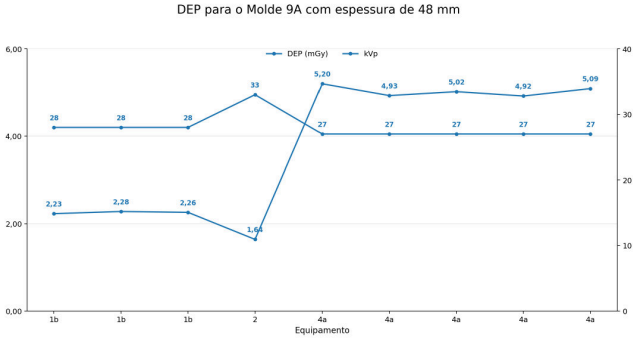

Figura 5: DEP para o *phantom* molde 9A com espessura de 48 mm.

Sob essa condição, o equipamento 1B apresentou três exposições realizadas a 28 kVp e entre 60 e 62 mAs, com valores de DEP entre 2,23 e 2,28 mGy. A DEP média foi de $2,257 \pm 0,025$ mGy, com CV de 1,12%. A DGM média foi de $0,657 \pm 0,006$ mGy, com CV de 0,88%.

O equipamento 2 apresentou uma exposição nessa espessura, realizada a 33 kVp e 31 mAs, com DEP de 1,641 mGy e DGM de 0,530 mGy.

No equipamento 4A, cinco exposições apresentaram espessura registrada de 48 mm, todas realizadas a 27 kVp e com carga entre 68 e 73 mAs. Os valores de DEP variaram de 4,921 a 5,196 mGy, com média de $5,031 \pm 0,116$ mGy, CV de 2,31%. A DGM média foi de $1,538 \pm 0,033$ mGy, com CV de 2,14%.

Mesmo considerando a mesma espessura registrada e o posicionamento padronizado do *phantom*, o equipamento 4A manteve valores de DEP superiores aos observados nos equipamentos 1B e 2 no subconjunto analisado.

D. Resposta do Controle Automático às Inserções de Lesões

O comportamento do controle automático de exposição foi avaliado a partir da inserção de diferentes estruturas internas simuladas no Molde 9A.

Para o equipamento 4A, considerando as exposições com espessura registrada de 48 mm, a DEP foi de 5,196 mGy para a configuração contendo nódulo espiculado e de 4,927 mGy para a configuração contendo nódulo redondo pequeno.

Como observado no conjunto de exposições realizadas nessa espessura, a dispersão dos valores de DEP foi baixa, com CV de 2,31%. As diferentes configurações internas do *phantom* estiveram, portanto, associadas a variações relativamente pequenas da DEP nas condições avaliadas. Esse comportamento é compatível com uma maior influência das características globais de atenuação do objeto, como espessura e composição, sobre a resposta do controle automático de exposição [11], [13].

E. Análise do Contraste RMS

Como complemento à avaliação dosimétrica, foram analisados os valores de contraste RMS local e global obtidos

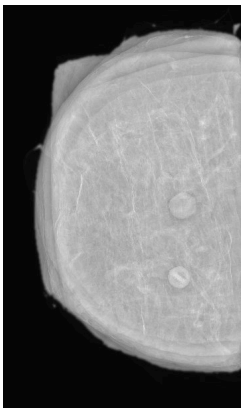

TABELA II
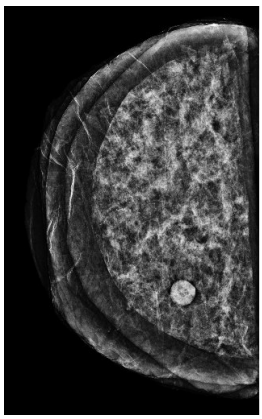
VALORES DE CONTRASTE RMS LOCAL E GLOBAL DAS IMAGENS SELECIONADAS

Equipamento	$\mathbf{C}_{\mathrm{RMS,local}}$	$\mathbf{C}_{\mathrm{RMS,global}}$
1A	0,3932	0,5399
1B	0,4192	0,5353
1C	0,4062	0,5087
2	0,3382	0,4197
3	0,2513	0,3402
4A	0,0516	0,0950
4B	0,0505	0,0791
4C	0,0189	0,0792



para uma imagem representativa de cada equipamento. Os resultados são apresentados na Tabela II.

Os equipamentos 1A, 1B e 1C apresentaram os maiores valores de contraste RMS global, entre 0,5087 e 0,5399. Os equipamentos 2 e 3 apresentaram valores intermediários, de 0,4197 e 0,3402, respectivamente, enquanto os equipamentos 4A, 4B e 4C apresentaram valores entre 0,0791 e 0,0950. Esse comportamento foi semelhante para o contraste RMS local.

A análise conjunta dos parâmetros dosimétricos e dos valores de contraste mostrou que maiores níveis de dose não estiveram associados a maiores valores de contraste RMS no conjunto avaliado. O equipamento 4A, por exemplo, apresentou a maior DEP média, $5,246 \pm 0,472$ mGy, enquanto os valores de contraste RMS local e global da imagem selecionada foram 0,0516 e 0,0950, respectivamente. Em contrapartida, os equipamentos 1A, 1B e 1C apresentaram menores valores médios de DEP e os maiores valores de contraste RMS entre as imagens analisadas. A Figura 6 apresenta as imagens mamográficas representativas obtidas nos equipamentos 1B e 4A.

(a) Imagem mamográfica do *phantom* molde 9A com nódulos e microcalcificaçõesdo equipamento 4A.

(b) Imagem mamográfica do *phantom* molde 9A com nódulos e microcalcificações do equipamento 1B.

Figura 6: Imagens mamográficas dos equipamentos avaliados utilizadas na comparação quantitativa de contraste.

Esse padrão pode estar relacionado à influência conjunta da tecnologia do detector, do processamento da imagem e dos parâmetros de aquisição. Como as imagens selecionadas não apresentavam exatamente as mesmas inserções, os valores de contraste RMS não devem ser interpretados isoladamente como uma classificação da qualidade diagnóstica dos equipamentos.

F. Comparação Normativa e Diretrizes de Otimização

Diante das diferenças observadas entre os equipamentos mamográficos, os valores de DGM foram situados em relação aos valores de referência estabelecidos pela Instrução Normativa n° 92/2021 da ANVISA [7], apresentados na Tabela III

TABELA III
VALORES DE REFERÊNCIA E TOLERÂNCIA PARA DGM EM MAMOGRAFIA SEGUNDO A IN N° 92/2021 DA ANVISA

PMMA (cm)	**Mama eq. (cm)**	**Referência (mGy)**	**Tolerância (mGy)**
2,0	2,1	0,6	$< 1,0$
3,0	3,2	1,0	$< 1,5$
4,0	4,5	1,6	$< 2,0$
4,5	5,3	2,0	$< 2,5$
5,0	6,0	2,4	$< 3,0$
6,0	7,5	3,6	$< 4,5$

Para as exposições em que a espessura não correspondia exatamente aos valores apresentados na normativa, foi adotada como referência a espessura normativa mais próxima. Considerando esse critério, todos os valores de DGM analisados permaneceram abaixo dos respectivos níveis de tolerância.

Apesar de permanecer abaixo dos níveis de tolerância, o equipamento 4A apresentou valores de dose superiores aos demais sistemas e, como apresentado na análise das imagens, esse aumento não foi acompanhado por maiores valores de contraste RMS. Sendo assim, os resultados indicam que o atendimento aos valores de referência dosimétrica não exclui a possibilidade de otimização dos parâmetros de aquisição, buscando a redução da dose sem comprometer as características da imagem, que são necessárias para o diagnóstico [10], [11], [13].

IV. CONCLUSÃO

Este estudo reforça a eficácia do uso de simuladores estruturados, como o desenvolvido pelo grupo, associado à extração automatizada de metadados DICOM como uma metodologia objetiva para a avaliação e o rastreamento dosimétrico em mamografia digital. A abordagem permitiu realizar análises em ambiente clínico sem a necessidade de exposição de pacientes à radiação, utilizando um simulador com características físicas e anatômicas compatíveis com exames mamográficos.

Os resultados mostraram diferenças entre os sistemas avaliados. O equipamento 4A (Fabricante IV - Hospital II) apresentou os maiores valores de DEP, comportamento que se manteve na análise das exposições com espessura registrada de 48 mm. Nessa condição, os valores de DEP permaneceram superiores aos observados nos equipamentos 1B e 2.

As diferenças observadas podem estar associadas à interação entre o modo de exposição, a combinação alvo/filtro, os parâmetros selecionados automaticamente e as características próprias de funcionamento de cada sistema. Embora a maior dose observada no equipamento 4A possa estar relacionada à combinação Rh/Rh e à estratégia automática de exposição, esse comportamento não pode ser atribuído exclusivamente a esses fatores.

Apesar dos maiores níveis de dose apresentados pelo equipamento 4A, os valores de DGM permaneceram abaixo dos níveis de tolerância adotados como referência pela normativa da ANVISA. A análise complementar das imagens mostrou ainda que o maior nível de dose desse equipamento não foi acompanhado por maiores valores de contraste RMS. Esses resultados indicam que o atendimento aos valores de referência dosimétrica não exclui a possibilidade de otimização dos parâmetros de aquisição, buscando a redução da dose sem comprometer as características da imagem necessárias ao diagnóstico.

Dessa forma, a extração automatizada de metadados DICOM mostrou-se útil como ferramenta de rastreamento e triagem dosimétrica, permitindo identificar equipamentos ou condições de aquisição com comportamento distinto e direcionar avaliações específicas de controle de qualidade, quando necessário.

AGRADECIMENTOS

Os autores agradecem à FAPESP o apoio financeiro e também à Gerência de Ensino e Pesquisa do Hospital Universitário da Universidade Federal de São Carlos (SP, Brasil) - Empresa Brasileira de Serviços Hospitalares (EBSERH), bem como a Oswaldo Jorge Neto e à Dra. Luciana B. Verçosa pelo suporte técnico.

***Resumo*—O Diabetes Mellitus é uma doença crônica de alta prevalência mundial, associada a diversas complicações de saúde e cuja identificação precoce pode contribuir para o acompanhamento adequado dos indivíduos em risco. Este trabalho apresenta o desenvolvimento de um aplicativo móvel, denominado *Análise de Risco de Diabetes*, que integra técnicas de aprendizado de máquina para atuar como ferramenta de triagem do risco de diabetes, associada a funcionalidades voltadas à educação em saúde. A aplicação foi desenvolvida com uma arquitetura cliente-servidor, utilizando Flutter no desenvolvimento móvel e Python com FastAPI na construção da API REST responsável pelo processamento das predições. Foram avaliados cinco algoritmos de classificação, sendo o modelo Multilayer Perceptron (MLP) selecionado para compor a aplicação por apresentar o melhor desempenho geral, alcançando acurácia de 97,08%, precisão de 99,00% e F1-Score de 81,00% para a classe diabética. O modelo foi treinado utilizando seis parâmetros: Índice de Massa Corporal, Hemoglobina Glicada, idade, glicose sanguínea, hipertensão e doença cardíaca. A técnica *Local Interpretable Model-agnostic Explanations* (LIME) foi empregada para analisar localmente as predições do modelo, permitindo identificar os atributos que mais contribuíram para a classificação de instâncias individuais. Os resultados demonstram a possibilidade de integrar aprendizado de máquina e mecanismos de explicabilidade a uma aplicação móvel voltada à triagem e à educação em saúde, ressaltando que as estimativas produzidas possuem caráter complementar e não substituem a avaliação de profissionais de saúde.**

I. Introdução

O Diabetes Mellitus (DM) representa um importante problema de saúde pública, e um dos principais desafios para os sistemas de saúde em todo o mundo, apresentando crescimento contínuo no número de casos [1]. A doença está associada ao desenvolvimento de complicações cardiovasculares, renais, neurológicas e visuais, comprometendo significativamente a qualidade de vida dos pacientes [2].

Apesar dos avanços nas estratégias de diagnóstico e monitoramento do diabetes, ainda existe um conhecimento limitado por parte da população em relação aos principais fatores de risco associados à doença. Essa lacuna de informação contribui para a identificação tardia de indivíduos em risco e, consequentemente, para a progressão silenciosa da condição ao longo do tempo [3].

Nesse contexto, fatores metabólicos como obesidade, níveis elevados de hemoglobina glicada (HbA1c) e alterações na glicemia de jejum continuam sendo amplamente reconhecidos como indicadores importantes de risco. No entanto, a ausência de valores críticos nesses marcadores não exclui a possibilidade de desenvolvimento futuro da doença, especialmente quando associados a outros determinantes clínicos e comportamentais [4].

Entre os marcadores clínicos amplamente utilizados na triagem e no rastreamento do diabetes mellitus, destacam-se o Índice de Massa Corporal (IMC), associado à obesidade como um dos principais fatores de risco; a Hemoglobina Glicada (HbA1c), que reflete a média dos níveis glicêmicos dos últimos meses; a idade, uma vez que o risco aumenta progressivamente ao longo da vida; e a glicose sanguínea. Adicionalmente, comorbidades como hipertensão e doenças cardíacas são determinantes agravantes frequentemente associados ao diabetes. Esses seis parâmetros compõem um referencial primário na avaliação de risco da doença [2]. Adicionalmente, o desbalanceamento entre classes positivas e negativas é um desafio recorrente em bases de dados clínicas, sendo a técnica SMOTE (*Synthetic Minority Over-sampling Technique*) amplamente empregada para mitigar esse efeito [5]. Por fim, no que diz respeito à explicabilidade dos modelos, a técnica *Local Interpretable Model-agnostic Explanations* (LIME) [6] tem sido adotada para tornar as predições de modelos complexos mais transparentes, aspecto especialmente relevante em aplicações voltadas à saúde.

Paralelamente, a Inteligência Artificial (IA), especialmente por meio de técnicas de Aprendizado de Máquina (ML), tem demonstrado resultados promissores na área da saúde, possibilitando a identificação de padrões clínicos e o apoio à tomada de decisão [7]. Diversos estudos têm empregado algoritmos capazes de estimar o risco de diabetes com elevada

precisão. [13]

Entretanto, a maioria dessas pesquisas permanece restrita ao ambiente acadêmico e não disponibiliza ferramentas acessíveis diretamente à população. Nesse sentido, torna-se relevante integrar modelos de ML em aplicações que podem contribuir para aproximar essas tecnologias da população e ampliar o acesso a informações relacionadas à prevenção e aos fatores associados ao diabetes. [13]

Diante desse cenário, este trabalho apresenta o desenvolvimento de um aplicativo que integra técnicas de ML para atuar como uma ferramenta de triagem do risco de diabetes, aliada a funcionalidades voltadas à educação em saúde. A aplicação utiliza dados clínicos e características individuais (IMC, HbA1c, glicose, idade, presença de hipertensão e de doenças cardíacas) fornecidas pelo usuário para realizar uma estimativa de risco baseada no modelo treinado. Vale salientar que a saída do aplicativo atua estritamente como uma triagem computacional, não constituindo um diagnóstico médico formal, mas sim um indicativo para auxiliar na identificação de indivíduos que necessitem buscar avaliação profissional. Além da funcionalidade preditiva, o aplicativo disponibiliza informações sobre sintomas, fatores de risco, prevenção e orientações básicas, buscando ampliar o acesso ao conhecimento e incentivar a procura por atendimento qualificado.

II. Trabalhos Relacionados

A aplicação de técnicas de ML para a predição do Diabetes Mellitus tem crescido significativamente nos últimos anos, impulsionada pela disponibilidade de grandes bases de dados clínicos e pela necessidade de desenvolver ferramentas capazes de auxiliar na identificação precoce da doença. Além da busca por modelos cada vez mais precisos, pesquisas recentes também têm enfatizado a importância da Inteligência Artificial Explicável (Explainable Artificial Intelligence - XAI), permitindo compreender os fatores que influenciam as decisões dos algoritmos e aumentando a confiança em sua utilização na área da saúde.

Costa *et al.* [10] desenvolveram e avaliaram modelos de aprendizado de máquina para a predição de diabetes, utilizando cinco algoritmos de classificação: Random Forest, Regressão Logística, KNN, SVC e MLP. O estudo também empregou técnicas de explicabilidade para analisar a influência das variáveis nas predições, destacando a relevância dos níveis de glicose sanguínea e hemoglobina glicada. Os resultados demonstraram o potencial de modelos de aprendizado de máquina aliados a mecanismos de explicabilidade para apoiar sistemas de predição de diabetes. Embora o estudo tenha se concentrado na avaliação dos modelos e na análise de suas predições, o presente trabalho amplia essa abordagem ao integrar o modelo preditivo e o mecanismo de explicabilidade a uma aplicação móvel voltada à triagem e à educação em saúde.

[7] realizaram uma revisão sobre aplicações de IA na área da saúde, destacando o potencial dos algoritmos de ML no auxílio ao diagnóstico e à predição de doenças crônicas, incluindo o Diabetes Mellitus. Os autores discutem o emprego de modelos como Redes Neurais Artificiais, *Random Forest* e Máquinas de Vetores de Suporte, ressaltando que essas técnicas apresentam elevado potencial para apoiar a tomada de decisão clínica. Entretanto, também apontam desafios relacionados à explicabilidade dos modelos e à sua adoção em ambientes clínicos reais.

Em [8] desenvolveram modelos de ML para predição de diabetes utilizando dados do Behavioral Risk Factor Surveillance System (BRFSS). O estudo comparou diferentes algoritmos de classificação e empregou técnicas de XAI para analisar a influência das variáveis utilizadas pelo modelo. Os resultados evidenciaram que fatores como idade, índice de massa corporal e indicadores metabólicos estão entre as características mais relevantes para a classificação dos pacientes, demonstrando que a utilização de métodos explicáveis contribui para aumentar a transparência das predições.

No estudo de [9] foi investigado o uso de modelos explicáveis para avaliação do risco de diabetes, enfatizando que técnicas como LIME e SHAP possibilitam compreender quais atributos mais influenciam as decisões dos algoritmos de ML. Segundo os autores, a explicabilidade representa um requisito essencial para aplicações médicas, pois permite que profissionais da saúde compreendam as justificativas das predições e utilizem essas informações como apoio ao processo de decisão clínica.

Foi proposto por [11] uma abordagem que combina a técnica SMOTE para balanceamento das classes com o método SHAP para explicação das predições realizadas pelos modelos. Os autores compararam diferentes algoritmos de classificação, analisando o impacto do balanceamento de dados sobre as métricas de desempenho. Os resultados indicaram melhora na capacidade de identificação da classe minoritária, além de fornecer explicações detalhadas sobre a contribuição de cada variável para as predições realizadas.

Observa-se que os estudos encontrados na literatura concentram seus esforços principalmente na comparação entre algoritmos de ML e na avaliação de técnicas de XAI, demonstrando elevados índices de desempenho na predição do Diabetes Mellitus. Entretanto, a maioria dessas pesquisas permanece restrita ao ambiente acadêmico, disponibilizando apenas modelos experimentais ou protótipos voltados para pesquisadores e profissionais da área. Poucos trabalhos apresentam aplicações móveis destinadas ao público geral que integrem, em uma única solução, um modelo preditivo, mecanismos de explicabilidade e recursos voltados à educação em saúde.

Nesse contexto, o presente trabalho diferencia-se por propor um aplicativo móvel multiplataforma que integra um modelo de ML baseado em Multilayer Perceptron (MLP) para estimativa do risco de Diabetes Mellitus, empregando a técnica LIME para explicar as predições realizadas. Além da funcionalidade preditiva, a aplicação disponibiliza conteúdo educativo sobre sintomas, fatores de risco, prevenção e controle da doença, buscando aproximar os avanços da IA do público em geral e contribuir para a conscientização e o incentivo à busca por atendimento médico quando necessário.

III. METODOLOGIA

A. Arquitetura do aplicativo

O aplicativo Análise de Risco de Diabetes foi projetado com base em uma arquitetura cliente-servidor de três camadas: (i) Camada de Apresentação, composta pela interface do aplicativo móvel com a qual o usuário interage diretamente; (ii) Camada de Negócio, responsável pelo processamento das requisições por meio de uma API REST; e (iii) Camada de Dados, onde o modelo de ML realiza as predições.

A comunicação entre o aplicativo e o servidor ocorre por meio de requisições HTTP seguras. Ao concluir o formulário de checkup, o aplicativo envia os dados do usuário ao servidor por meio de uma requisição HTTP POST. O servidor processa essas informações utilizando o modelo preditivo e retorna ao cliente o resultado da avaliação de risco (baixo, moderado ou alto), acompanhado das orientações correspondentes.

Esse fluxo reduz o processamento realizado no dispositivo móvel, permitindo que modelos de ML mais complexos sejam executados no servidor. Além disso, centraliza a atualização do modelo preditivo, facilitando sua manutenção e possibilitando sua evolução sem a necessidade de modificar a aplicação instalada no dispositivo do usuário.

B. Casos de Uso

Os casos de uso foram definidos com base nas funcionalidades centrais do aplicativo e no perfil do público-alvo: usuários do público geral, sem necessidade de conhecimento técnico prévio em saúde ou tecnologia. O único ator identificado no sistema é o *Usuário*, que representa qualquer indivíduo que acessa a aplicação. A Tabela I descreve os casos de uso identificados para o sistema.

Tabela I: Casos de Uso do Aplicativo *Análise de Risco de Diabetes*

ID	Caso de Uso	Descrição	Fluxo Principal
UC01	Acessar Aplicativo	O usuário acessa o aplicativo e visualiza a tela inicial, que apresenta informações introdutórias sobre diabetes e orientações gerais de saúde.	(1) Usuário inicia o aplicativo; (2) Sistema exibe a tela inicial; (3) Usuário visualiza as informações e as opções de navegação.
UC02	Realizar Checkup de Diabetes	O usuário realiza a avaliação de risco informando os seis parâmetros clínicos utilizados pelo modelo: IMC, HbA1c, idade, glicose sanguínea, hipertensão e doença cardíaca.	(1) Usuário acessa a opção de checkup; (2) Sistema apresenta o formulário; (3) Usuário informa os dados solicitados; (4) Usuário confirma os dados; (5) Sistema realiza a avaliação de risco.
UC03	Visualizar Resultado de Risco	O usuário visualiza o resultado da avaliação de risco após o processamento dos dados informados.	(1) Sistema processa os dados informados; (2) Sistema apresenta a classificação de risco como baixo, moderado ou alto; (3) Sistema apresenta orientações relacionadas ao resultado.
UC04	Acessar Conteúdo Educativo	O usuário acessa conteúdos informativos relacionados ao diabetes, com o objetivo de ampliar seu conhecimento sobre a doença e seus fatores de risco.	(1) Usuário acessa a seção educativa; (2) Sistema apresenta informações sobre diabetes, sintomas, fatores de risco, prevenção e controle.
UC05	Receber Orientação para Atendimento Profissional	O usuário recebe orientação para procurar atendimento de um profissional de saúde, especialmente após a visualização do resultado da avaliação de risco.	(1) Sistema apresenta orientação para busca de atendimento profissional; (2) Usuário é informado de que a avaliação realizada pelo aplicativo não substitui o diagnóstico clínico.

A Tabela I apresenta as principais interações entre o usuário e o aplicativo, contemplando desde o acesso às informações iniciais e aos conteúdos educativos até a realização da avaliação de risco e a visualização do resultado. Os casos de uso também evidenciam o caráter de triagem da aplicação, uma vez que o resultado apresentado tem como finalidade orientar o usuário quanto à necessidade de buscar avaliação de um profissional de saúde, não substituindo o diagnóstico clínico.

C. Tecnologias utilizadas

Para o desenvolvimento do aplicativo móvel, foi adotado o framework **Flutter**, mantido pelo Google, que permite a criação de aplicações multiplataforma (Android e iOS) a partir de uma única base de código escrita na linguagem Dart. Essa escolha justifica-se pela eficiência no ciclo de desenvolvimento, pelo desempenho nativo em dispositivos móveis e pela facilidade na construção de interfaces responsivas e visualmente agradáveis.

No lado do servidor, foi utilizado **Python** em conjunto com o framework **FastAPI** para a construção da API REST responsável pelo recebimento das requisições do aplicativo, processamento pelo modelo preditivo e retorno dos resultados. O FastAPI foi selecionado por sua alta performance, suporte nativo à programação assíncrona e geração automática de documentação por meio do OpenAPI/Swagger.

D. Modelo de Machine Learning

Para o treinamento e a avaliação dos modelos preditivos, utilizou-se o *Diabetes Prediction Dataset* **[12]**, uma base de dados de domínio público disponibilizada na plataforma

Kaggle. O repositório original conta com 100.000 registros e engloba diversas características demográficas e clínicas dos pacientes. Dentre os atributos disponibilizados, foram selecionados seis parâmetros para compor as variáveis de entrada dos modelos: (i) Índice de Massa Corporal (IMC), obtido a partir do peso e da altura do paciente; (ii) Hemoglobina Glicada (HbA1c); (iii) Idade; (iv) Glicose sanguínea; (v) Hipertensão, representada por um indicador binário; e (vi) Doença Cardíaca, também representada por um indicador binário.

A base apresenta assimetria na distribuição das classes, sendo constituída por aproximadamente 91,5% de instâncias de indivíduos não diabéticos e 8,5% de indivíduos diabéticos. Como etapa de pré-processamento, as variáveis contínuas foram padronizadas por meio do *StandardScaler*. Em razão do desbalanceamento observado, também foi avaliada a aplicação da técnica SMOTE (*Synthetic Minority Over-sampling Technique*). A comparação entre os cenários com e sem balanceamento indicou que, embora a aplicação do SMOTE tenha proporcionado aumento no *recall* da classe positiva, o cenário sem balanceamento apresentou melhor desempenho global, considerando principalmente a acurácia e o F1-Score. Dessa forma, optou-se pela utilização da distribuição original das classes na configuração final dos modelos empregados na aplicação.

Os dados foram divididos em 80% para treinamento e 20% para teste, sendo o conjunto de teste reservado para a avaliação dos modelos. Foram utilizados cinco algoritmos de classificação:*Random Forest*, Regressão Logística, *KNN*, *SVC* e MLP. A comparação entre os modelos considerou as métricas de acurácia, precisão, *recall* e F1-Score. Os principais parâmetros explicitamente definidos na implementação são apresentados na Tabela II.

Tabela II: Parâmetros utilizados nos modelos avaliados.

Modelo	**Parâmetros**
Random Forest	$n_estimators = 100$, $random_state = 42$
Regressão Logística	$max_iter = 1000$
KNN	$n_neighbors = 5$
SVC	$kernel =$ linear
MLP	$hidden_layer_sizes = (50, 50)$, $max_iter = 1000$, $random_state = 42$

Os parâmetros foram definidos diretamente na configuração dos modelos, sem a realização de procedimentos automatizados de otimização, como *Grid Search*. Entre os modelos avaliados, o MLP apresentou o melhor desempenho geral e foi selecionado como modelo final da aplicação. O MLP foi configurado com duas camadas ocultas, cada uma contendo 50 neurônios, totalizando uma arquitetura $(50, 50)$. O treinamento foi limitado a 1000 iterações e foi utilizado *random state*=42 para favorecer a reprodutibilidade dos resultados.

E. Explicabilidade do Modelo

Para conferir explicabilidade às predições do modelo MLP, foi aplicada a técnica LIME. O método fornece explicações locais para predições individuais por meio da aproximação do comportamento do modelo na vizinhança da instância analisada, permitindo identificar quais variáveis exerceram maior influência na classificação de cada paciente.

O LIME foi aplicado de forma *post-hoc*, ou seja, após o treinamento do modelo. A técnica analisa o comportamento do modelo treinado sem alterar seus parâmetros, os dados de entrada ou o pipeline de classificação utilizado pela API. Dessa forma, a predição de risco retornada ao aplicativo é produzida exclusivamente pelo modelo MLP, enquanto o LIME é utilizado como ferramenta de análise das decisões do modelo.

F. Classificação das Faixas de Risco

Para a apresentação do resultado da avaliação de risco no aplicativo, a probabilidade retornada pelo modelo MLP foi categorizada em três faixas: *Risco Baixo*, para probabilidades inferiores a 35%; *Risco Moderado*, para probabilidades entre 35% e 69%; e *Risco Alto*, para probabilidades iguais ou superiores a 70%.

Essa categorização foi utilizada exclusivamente para apresentação do resultado da triagem ao usuário, não correspondendo a categorias clínicas ou critérios de diagnóstico. O objetivo é facilitar a comunicação do resultado e orientar o usuário quanto à necessidade de buscar acompanhamento de um profissional de saúde.

G. Desenvolvimento da interface

A interface do aplicativo foi projetada com foco na acessibilidade e na experiência do usuário do público geral, sem presumir familiaridade prévia com aplicações de saúde. O design segue princípios de usabilidade amplamente reconhecidos, como clareza visual, *feedback* imediato e navegação intuitiva e progressiva.

A tela de início apresenta uma mensagem de conscientização sobre o diabetes, com destaque para a importância do diagnóstico precoce e um incentivo explícito à busca por atendimento médico profissional. O aplicativo deixa claro ao usuário, desde a primeira interação, que a avaliação fornecida representa uma estimativa de risco e não substitui o diagnóstico clínico.

A paleta de cores adota tons de azul e verde, associados à saúde e ao bem-estar, com alto contraste para garantir legibilidade em diferentes condições de luminosidade e acessibilidade para usuários com baixa acuidade visual. O fluxo de navegação foi estruturado de forma linear e progressiva: conscientização $\rightarrow$ checkup $\rightarrow$ resultado $\rightarrow$ conteúdo educativo, minimizando a carga cognitiva e guiando o usuário de forma clara ao longo da avaliação.

A Figura 1 apresenta a tela inicial do aplicativo, enquanto a Figura 2 apresenta a tela utilizada para a realização do checkup.

H. Funcionalidades do aplicativo

O aplicativo *Análise de Risco de Diabetes* disponibiliza as seguintes funcionalidades principais:

- Tela de Início e Conscientização: apresenta ao usuário informações gerais sobre o Diabetes Mellitus, incluindo

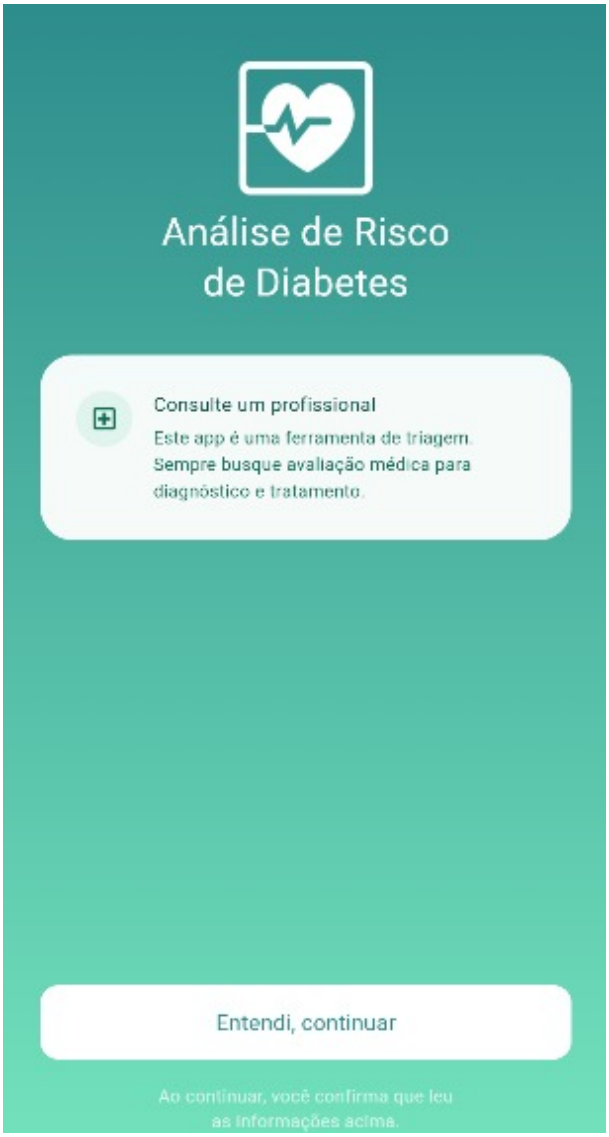

Figura 1: Tela inicial do aplicativo.

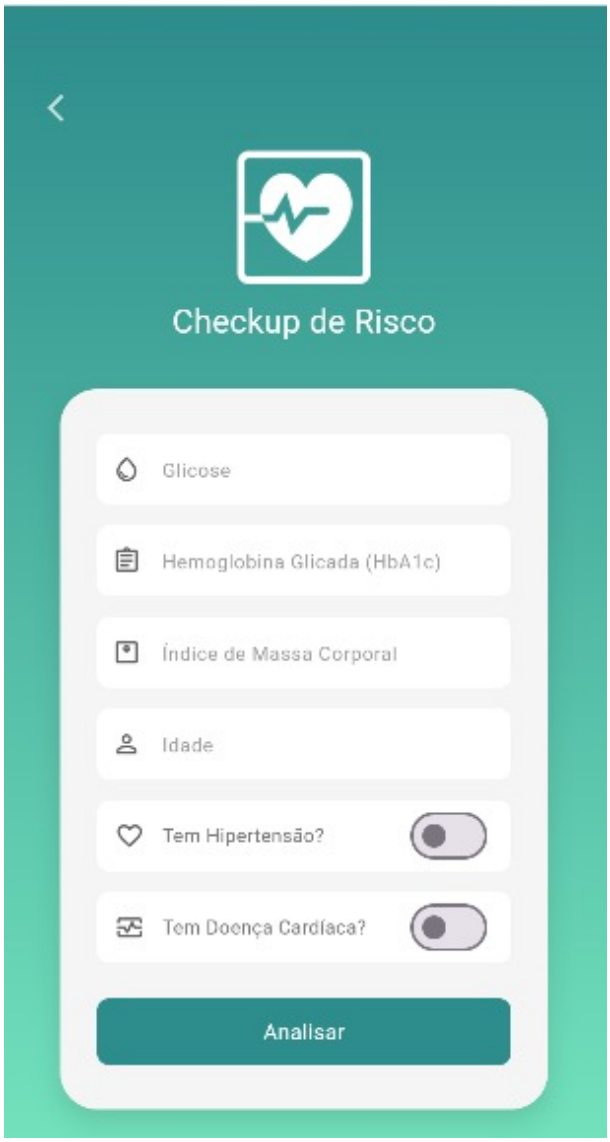

Figura 2: Tela de checkup do aplicativo.

definição, principais sintomas e fatores de risco associados. Uma mensagem de alerta destaca a importância de buscar orientação de um profissional de saúde para confirmação diagnóstica, reforçando o caráter complementar — e não substitutivo — da aplicação.

- Checkup de Diabetes: permite ao usuário preencher um formulário com seis parâmetros de saúde: Índice de Massa Corporal (IMC), nível de Hemoglobina Glicada (HbA1c), idade, nível de glicose sanguínea, e a presença prévia de hipertensão ou doenças cardíacas. O aplicativo orienta o usuário sobre o preenchimento e, ao concluir, os dados são enviados ao servidor para processamento pelo modelo preditivo.
- Resultado da Avaliação de Risco: exibe, de forma clara e acessível, o resultado do checkup, classificando o risco em três categorias: *baixo*, *moderado* ou *alto*. Cada categoria é acompanhada de orientações específicas e recomendações de acompanhamento médico.
- Conteúdo Educativo: disponibiliza informações sobre prevenção, controle e convivência com o diabetes, com linguagem acessível e adaptada ao público geral. O objetivo é promover a educação em saúde e o empoderamento do usuário para a adoção de hábitos mais saudáveis.

IV. Resultados e Discussões

Nesta seção são apresentados e discutidos os resultados obtidos durante o desenvolvimento e a avaliação do aplicativo proposto. Inicialmente, são analisados os desempenhos dos modelos de aprendizado de máquina considerados, incluindo a comparação entre as abordagens com e sem balanceamento das classes. Em seguida, são apresentados os resultados relacionados à explicabilidade das predições por meio do LIME e à integração do modelo ao aplicativo móvel.

A. Desempenho do Modelo

Os experimentos de avaliação foram realizados utilizando o *Diabetes Prediction Dataset*, composto por registros de indivíduos com características clínicas e demográficas relacionadas à ocorrência de diabetes. Os dados foram divididos em conjuntos de treinamento e teste, correspondendo a 80% e 20% dos registros, respectivamente. Os modelos foram treinados utilizando o conjunto de treinamento e, posteriormente, avaliados no conjunto de teste por meio das métricas de acurácia, precisão, revocação, F1-score. Sem a aplicação de técnicas de balanceamento das classes, os modelos apresentaram os resultados apresentados na Tabela III.

Tabela III: Comparação dos modelos de ML

Modelo	Acurácia	Precisão	Recall	F1-Score
Random Forest	96,68	91,00	**69,00**	79,00
Regressão Logística	95,69	85,00	63,00	72,00
KNN	96,32	91,00	65,00	76,00
SVC	95,78	92,00	58,00	71,00
MLP	**97,08**	**99,00**	68,00	**81,00**

A Tabela III apresenta o desempenho dos modelos de classificação avaliados no conjunto de teste. O MLP apresentou a maior acurácia, de 97,08%, além da maior precisão (99,00%) e do maior F1-Score (81,00%) para a classe diabética. O *Random Forest* apresentou desempenho próximo, com acurácia de 96,68% e F1-Score de 79,00%, enquanto KNN, Regressão Logística e SVC apresentaram F1-Scores de 76,00%, 72,00% e 71,00%, respectivamente.

Embora o MLP tenha apresentado o melhor desempenho geral entre os modelos avaliados, observa-se que o recall da classe diabética foi de 68,00%, indicando que parte dos indivíduos pertencentes à classe positiva não foi identificada pelo modelo. Esse resultado deve ser interpretado considerando o desbalanceamento da base, na qual 91,18% das amostras pertencem à classe não diabética e apenas 8,82% à classe diabética. Dessa forma, a análise das métricas específicas da classe positiva é relevante para evitar que a elevada proporção da classe majoritária produza uma percepção superestimada do desempenho do modelo.

De modo geral, os resultados evidenciam que o MLP apresentou uma combinação mais favorável entre as métricas analisadas, especialmente em relação à acurácia, precisão e F1-Score. A diferença observada em relação aos demais modelos reforça sua escolha para as etapas posteriores de análise e explicabilidade. Além disso, a avaliação conjunta das métricas permitiu considerar não apenas o desempenho global, mas também o comportamento do modelo na identificação da classe diabética.

Também foi avaliado o emprego da técnica SMOTE como estratégia de balanceamento das classes, conforme abordagens descritas na literatura [11]. A aplicação do SMOTE contribuiu para o aumento do *recall* da classe positiva, indicando maior capacidade de identificação dos indivíduos pertencentes à classe minoritária. Entretanto, essa melhoria foi acompanhada por redução da acurácia geral e da precisão da classe positiva. Diante desse comportamento, foi adotado o cenário sem balanceamento para o modelo final, por apresentar melhor desempenho global segundo as métricas consideradas.

B. Análise da matriz de confusão

A matriz de confusão do modelo MLP, apresentada na Figura 3, permite observar o desempenho do classificador em cada classe. Dos indivíduos classificados como não diabéticos, 17.503 foram corretamente identificados, enquanto 6 foram classificados incorretamente como diabéticos. Para a classe diabética, 1.166 indivíduos foram corretamente classificados, ao passo que 555 foram classificados como não diabéticos.

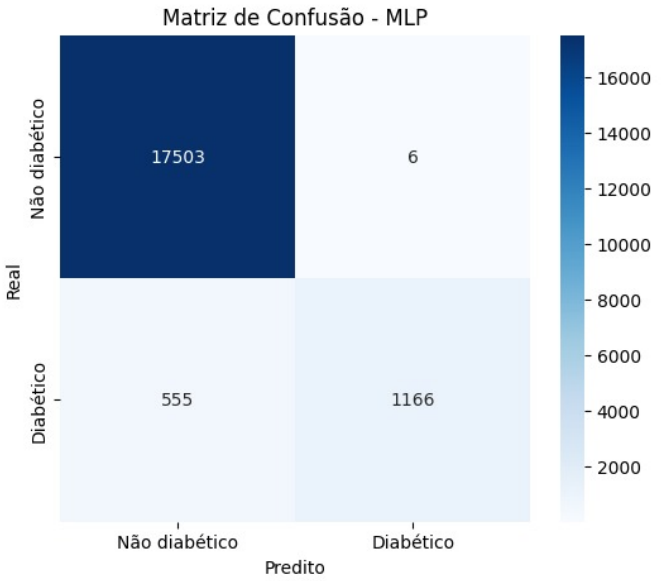

Figura 3: Matriz de confusão do modelo MLP.

Esses resultados evidenciam que, embora o modelo apresente elevada acurácia global, ainda são observados falsos negativos na identificação da classe diabética, aspecto particularmente importante em uma tarefa de avaliação de risco, uma vez que indivíduos diabéticos podem ser classificados como não diabéticos.

C. Análise de Explicabilidade via LIME

Para complementar a explicabilidade do modelo, foi empregada a técnica LIME, com o objetivo de explicar as predições realizadas pelo modelo MLP em instâncias individuais. Diferentemente de métodos de explicabilidade global, o LIME gera explicações locais, identificando quais atributos tiveram maior influência na classificação de cada amostra.

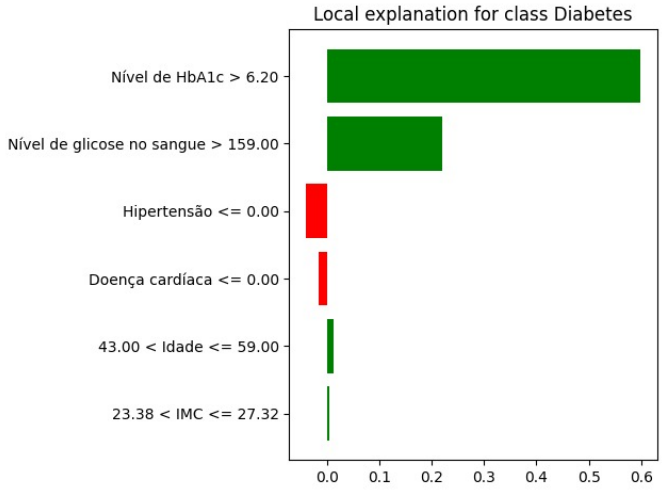

Figura 4: Explicação local da predição do modelo MLP utilizando LIME.

A Figura 4 apresenta uma explicação local para uma instância classificada como pertencente à classe diabetes. Observa-se que o *nível de HbA1c* apresentou a maior contribuição positiva para a classificação, seguido pelo *nível de glicose no sangue*. As condições apresentadas no gráfico, com valores de HbA1c superiores a 6,20 e de glicose no sangue superiores a 159,00, exerceram maior influência na decisão do modelo.

Em contrapartida, as condições de *hipertensão* e *doença cardíaca* apresentaram contribuições negativas para a classificação dessa instância, ambas associadas à ausência dessas condições. A *idade*, representada pelo intervalo entre 43 e 59 anos, e o *IMC*, situado entre 23,38 e 27,32, apresentaram contribuições positivas de menor magnitude em comparação às variáveis laboratoriais.

Esses resultados indicam que, para essa instância específica, o modelo concentrou sua decisão principalmente nos níveis de HbA1c e glicose no sangue, enquanto as demais características apresentaram influência menos expressiva. A explicação local fornecida pelo LIME permite, assim, visualizar quais atributos contribuíram para a classificação realizada pelo modelo, favorecendo maior transparência em seu processo de decisão.

V. Conclusão

Este trabalho apresentou o desenvolvimento do aplicativo *Análise de Risco de Diabetes*, uma solução móvel que integra técnicas de aprendizado de máquina para atuar como ferramenta de triagem do risco de diabetes mellitus, associada a funcionalidades de educação em saúde. A proposta integra um modelo preditivo a uma aplicação móvel, buscando aproximar recursos de aprendizado de máquina do usuário final e possibilitar sua utilização em um contexto aplicado de triagem e educação em saúde.

A arquitetura cliente-servidor adotada, combinando Flutter no cliente e Python com FastAPI no servidor, permitiu separar as responsabilidades entre a aplicação móvel e o processamento do modelo preditivo. Entre os algoritmos avaliados, o modelo MLP apresentou o melhor desempenho geral, alcançando acurácia de 97,08%, precisão de 99,00% e F1-Score de 81,00% para a classe diabética. Apesar do desempenho observado, o *recall* de 68,00% evidencia a ocorrência de falsos negativos, reforçando a necessidade de interpretar os resultados com cautela, especialmente em uma aplicação voltada à triagem de risco. Dessa forma, a saída do aplicativo deve ser compreendida como uma estimativa computacional, não substituindo a avaliação e o diagnóstico realizados por profissionais de saúde.

A aplicação da técnica LIME permitiu analisar localmente os fatores que mais contribuíram para predições individuais do modelo MLP. Na instância analisada, as variáveis *HbA1c_level* e *blood_glucose_level* apresentaram as maiores contribuições positivas para a classificação, possibilitando uma análise mais transparente da decisão do classificador. A integração desse mecanismo de explicabilidade ao processo de análise contribui para uma compreensão mais detalhada das predições realizadas pelo modelo.

Como contribuição, o trabalho apresenta uma aplicação móvel que reúne, em uma mesma solução, uma abordagem de aprendizado de máquina para estimativa de risco, um mecanismo de explicabilidade baseado em LIME e recursos de educação em saúde. Como trabalhos futuros, pretende-se: (i) realizar testes de usabilidade com usuários de diferentes perfis para avaliar a aceitação e a experiência de uso da ferramenta; (ii) investigar modelos alternativos, como XGBoost, buscando melhorar a identificação da classe minoritária e o *recall*, considerando o equilíbrio entre as diferentes métricas de desempenho; e (iii) incorporar a visualização das explicações geradas pelo LIME diretamente na interface do aplicativo, tornando os resultados das predições mais compreensíveis para o usuário final.
