CBEB

FORTALEZA 2026

XXX BRAZILIAN CONGRESS ON BIOMEDICAL ENGINEERING

Academic Support and Innovation Committee

The Academic Support and Innovation Committee strengthens CBEB 2026 in essential areas, promoting integration, creative solutions and support for the development of the event's activities, with the involvement of students, researchers and professionals committed to the advancement of Biomedical Engineering in Brazil.

36 MEMBERS | **5** FRONTS | **+10** INSTITUTIONS

FRONTS OF ACTION

- Technology
- Operations and Logistics
- Academic Support
- Communication and Marketing
- Public Service

COMMITTEE MEMBERS

1. Francisco Ítalo Guilherme da Silva — UFC
2. Adriell Gomes Marques — UFC
3. Marcus Vinícius Cândido de Figueiredo — IFCE
4. Laís Ferreira Sombra — UFC
5. Pedro Joás Freitas Lima — UFC
6. Luisa Miranda Timbó Mendes — UFC
7. Daniel Santos da Silva — UFC
8. Felipe Cordeiro de Sousa — UFC
9. Alan Marques da Rocha — UFC
10. Danilo Felipe Neto — UFC
11. Luis Francisco Sousa Leal Gomes — UFC
12. Anna Beatriz Brito de Souza Almeida — UFPE
13. Emilly Alexsandra de Oliveira Silva — UFPE
14. David Felipe de Brito Araújo — UPPE
15. Renata Benaion Silva Do Vals — UFPA / ITEC
16. Déborah Evelyn Leite Alcantara — UFPE
17. Rodrigo Alves Alonso — POLI-USP
18. Arianne Viana Alves da Silva — UFPE
19. Júlio Cardoso Scorpion — UFSC
20. João Lucas Pereira dos Santos de Paula — UFSC
21. Nestor Cavalcante Teixeira Neto — UFC
22. Pedro Florencio de Almeida Neto — UFC
23. Carlos Eduardo do Nascimento Silva — IFCE
24. Alicia Gabriela Saldanha do Nascimento — UFPA
25. Rogerio Lopes Vieira Cesar — IFCE
26. Naira Magalhães de Sousa — UFC
27. Eduardo Henrique Teixeira — UNIFEI
28. Bruno Henrique Aragão König — UFPE
29. Sheila Cristina de Moraes — NOVOESTE
30. Ana Luiza Matos da Silva — IIN-ELS/ISD
31. Jeisilyane Silveira dos Santos — UFC
32. Stella Machado Gualti — UFSCar
33. Eliana Figueiredo Borges — UFU
34. Rômulo Cesar Cunha Lima — UFC
35. Marya Thayssa Conceição Bezerra — UNILEÃO
36. Letícia Nascimento de Oliveira — ISD

FORTALEZA 2026

XXX BRAZILIAN CONGRESS ON BIOMEDICAL ENGINEERING

International Collaboration and Awards Committees

International Collaboration Committee

The International Collaboration Committee supports scientific exchange and international dialogue at CBEB 2026, promoting cooperation among researchers, institutions and biomedical engineering communities worldwide.

Expediente e apresentação

XXX Congresso Brasileiro de Engenharia Biomédica

EVENTO
XXX Congresso Brasileiro de Engenharia Biomédica

REALIZAÇÃO
28 de setembro a 2 de outubro de 2026 · Fortaleza, Ceará, Brasil

ENTIDADE PROMOTORA
Sociedade Brasileira de Engenharia Biomédica (SBEB)

PUBLICAÇÃO SERIADA
Anais do Congresso Brasileiro de Engenharia Biomédica · ISSN 2359-3164

Apresentação

Os anais do XXX Congresso Brasileiro de Engenharia Biomédica reúnem 597 trabalhos científicos completos, organizados em 15 áreas temáticas, a partir dos arquivos disponibilizados à organização do evento.

A publicação apresenta sumário temático com referências às páginas iniciais dos artigos e links internos para navegação no documento digital. Os textos científicos são reproduzidos a partir dos arquivos que integram esta compilação.

Organização do volume

Capa institucional · Expediente e apresentação · Sumário por área temática · Artigos científicos completos.

CONSULTA E ACESSO

Sumário

VOLUME 01 · 01

Processamento de Sinais e Imagens Biomédicas

ID 753 · A CAD System for Tooth Segmentation in Panoramic Radiographs Using U-Net Variants 29

ID 666 · A ConvNeXt-Small-Based Classifier for Ischemic Stroke Identification in Computed Tomography Images 37

ID 360 · A Deep Learning-Based Architecture for Automated Nuclei Quantification in Dense Microscopy Images from Transwell Assays 45

ID 359 · A Dual-Stage Framework for Mammographic Nodule Analysis Integrating Decision Tree Classification and Marker-Controlled Watershed 53

ID 7 · A Multi-Agent Ecosystem-Based Neurosymbolic Unsupervised Optimum-Path Forest for Functional Brain Mapping based on EEG Microstate Analysis 61

ID 16 · A Multimodal Neurorehabilitation Platform for Post-Stroke Hand Rehabilitation 69

ID 788 · A Short-Scale Transition into Ventricular Fibrillation: Recurrence Quantification and the Limits of Minute-Scale Anticipation 77

ID 342 · Advanced AI-Driven Signal Processing for Glaucoma Detection Using Retinal Imaging Methods and Experimental Insights 85

ID 253 · Algorithm for Muscle Thickness Tracking on Ultrafast Ultrasound 91

ID 516 · An Automated Thermographic Pipeline for Temperature Reconstruction, Drift Correction, and Hand Warm-Up Assessment in Acoustic Guitarists 99

ID 789 · Analysis and Prediction of Medical Service Utilization Among Adults Aged 50 and Older: A Machine Learning Approach 107

ID 878 · Análise Comparativa de Arquiteturas e Pré-Processamentos para Segmentação de Vasos em Imagens de Fundoscopia 115

ID 549 · Application of Convolutional Neural Networks for Brain Tumor Classification in MRI Images 123

ID 702 · Application of Radiomics and Deep Learning for the Classification and Grading of Gliomas in Magnetic Resonance Imaging: A Literature Review 131

ID 404 · Architectural Rigidity vs. Scaling Laws in Arrhythmia Classification 139

ID 381 · Arquitetura IoT Distribuída para Telemetria e Visualização de ECG de Alta Fidelidade em Tempo Real via ESP32-S3 e WebSockets 147

ID 379 · Automated Classification of Feline Mammary Carcinoma via Spatial Quantification of Intratumoral Type I and Type III Collagens 155

ID 556 · Automated Nuclei Segmentation and Counting in Human Liver Histological Images Using Watershed 159

ID 175 · Automated Screening for Metallic Implants in MRI Scout 164

ID 109 · Automated Visual Target Detection in RSVP Tasks from EEG Signals using Wavelet Transform and Machine Learning 172

ID 539 · Automatic Detection of Cervical Spine Anatomical Landmarks in Lateral Radiographs Using Deep Learning 177

ID 207 · Autonomic Responses to COVID-19 Vaccines During Tilt Testing 183

Sumário

VOLUME 01 · 02

Processamento de Sinais e Imagens Biomédicas

ID 426 · Autoregressive and Fractal Mammographic Features for Statistically Differentiating HER2-Positive Breast Cancer 187

ID 150 · Avaliação Operacional da Triagem de Retinopatia sob Distribution Shift 192

ID 725 · Berouti Spectral Subtraction for EMG Walking Signals 200

ID 227 · Biometric and Demographic Pattern Mining in Electrocardiographic Signals: A Study with Machine Learning Algorithms 207

ID 886 · BioStatusIA: A Multi-Agent Architecture for Multimodal Clinical Decision Support 218

ID 383 · Brain Symmetry Index after tDCS Rehabilitation 223

ID 718 · CAD for Brain Tumor Segmentation and Classification 230

ID 239 · Cartesian vs. Cylindrical ECG Models in Nonlinear Kalman Filtering 238

ID 286 · Characterisation of Motor Profiles in Bilateral Extension and Flexion Movements in Individuals with Parkinson's Disease 246

ID 367 · Characterization of Thermal Profiles in Pressure Injuries Using the Thermal Laplacian 250

ID 493 · Classification of Dementia Stages in Magnetic Resonance Images by Pre-Trained CNNs and Ensemble 256

ID 178 · CNNs para Classificação de Câncer Renal em CT 263

ID 8 · Collaborative Multi-Agent Networks for Multimodal Analysis of Parkinson’s Disease 270

ID 405 · Color Deconvolution and Marker-Controlled Watershed Framework for Intracellular Parasite Quantification in HTR8/SVneo Cells 277

ID 196 · Compact Deep Learning Architecture for Multi-Label ECG Classification 285

ID 483 · Comparative Analysis of Deep Learning Architectures for Diabetic Retinopathy Classification 293

ID 340 · Comparative Analysis of Digital Image Processing Techniques for Automated Segmentation of Wound Healing Assays in Infected Cultures 301

ID 158 · Comparative Analysis of the Performance of Analog and Digital Band-Stop Filters Applied to Power Line Noise Suppression in Electromyographic Signals 309

ID 641 · Comparative Evaluation of CNNs, Vision Transformers, and Ensemble Methods for Breast Cancer Lymph Node Metastasis Detection 316

ID 545 · Comparative Evaluation of Neural Network Architectures for ADHD Classification Using EEG Signals 324

ID 53 · Comparative Study of Blind Source Separation Techniques for ASD Classification in EEG Signals 332

ID 869 · Computational Pipeline for Detecting and Quantifying Spectral Modulation in EEG for 12-Hz Binaural Stimulation Studies in the Context of Alzheimer's Disease 338

ID 226 · Computational Tool for Automated Detection of Multiple Sclerosis Brain Lesions Using Magnetic Resonance Imaging 344

ID 364 · Computer Vision System for Eye Movement and Eyelid Dynamics Analysis 350

ID 686 · Computerized Tomography Image Generation for Ischemic Stroke Using GANs 355

Sumário

VOLUME 01 · 03

Processamento de Sinais e Imagens Biomédicas

ID 437 · Contrast Curve Correction for Digital Mammography 361

ID 392 · Creation of a Database for Clinical Validation of an Artificial Intelligence Algorithm for Detecting Failures in Invasive Blood Pressure Monitoring in Intensive Care Units 369

ID 467 · Data Above the Model: A Study of Three Deep Learning Approaches for Pulmonary Disease Detection in Chest Radiographs 374

ID 287 · Deep Learning Applications in Post-Stroke Automatic Speech Analysis: A Literature Review 382

ID 534 · Deep Learning for Pulmonary Nodule Detection 390

ID 384 · Deep Learning Models for Real-Time Heart Rate Estimation Using Remote Photoplethysmography: A Single-Subject Pilot Study of an ICU Patient 398

ID 52 · Deep Learning-Based Classification of Breast Lesions in Ultrasound Images Using Transfer Learning and Decision Threshold Calibration 405

ID 888 · Deep Learning-Based Monaural Speech Enhancement on the VoiceBank-DEMAND Dataset 413

ID 594 · Detection and Segmentation of Oral Ulcers and Mucosal Inflammation Using Hyperspectral Imaging and Deep Neural Networks 420

ID 541 · Detection of Melanoma Presence in Dermoscopic Images Using a Transfer Learning Approach with ResNet50 428

ID 679 · Disentangling Persistent ECG ST/T Alterations and Local Beat Perturbations through Multiscale Physiological Labeling and Recurrence Quantification Analysis 434

ID 938 · Divergent Modulation of Cortical and Intermuscular Coupling by Object Properties During Grasping 442

ID 261 · ECG-Based Chagas Disease Classification under Weak Self-Reported Labels: A Comparison of Target Definitions in CODE-15% 450

ID 170 · EEG-Based Autism Spectrum Disorder Assessment Using Holo-Hilbert Spectral Analysis and Machine Learning 458

ID 572 · Effect of Peripheral Sinusoidal Electrical Stimulation on Cortical Oscillations During an Archimedean Spiral Drawing Task 463

ID 885 · Effects of Peripheral Electrical Stimulation Waveforms on Tremor in Parkinson's Disease: A Pilot Study 471

ID 235 · Ensemble Learning with Lightweight Convolutional Neural Networks for Mosquito Species Classification 479

ID 766 · Estimating Model Observer Response in Digital Mammography Using Radiomics and Machine Learning Regression Models 487

ID 441 · Evaluating CLAP Audio Foundation Model for Swallowing Event Detection 495

ID 508 · Evaluating Deep Neural Network Architectures for Motor Unit Firing Classification from Decomposed HD-sEMG Signals 503

ID 506 · Evaluation of a Hybrid RR–P-Wave Approach for Automatic Atrial Fibrillation Detection in ECG Signals 508

ID 674 · Evaluation of Movement Smoothness in the Four-Way Leaning Limits of Stability Test in Patients with TMD: A Pilot Study 515

Sumário

VOLUME 01 · 04

Processamento de Sinais e Imagens Biomédicas

ID 786 · Evaluation of Multimodal Data in the Classification of Patients with Dementia Using Explainable Artificial Intelligence 520

ID 865 · Evaluation of Wavelet-Based Filters for Denoising Gas Vesicles Ultrasound Responses 528

ID 133 · Experimental Simulation of Fracture Patterns in Child Physical Abuse 535

ID 859 · Experimental Study of EMG Signals for Prosthetic Control Using a Feature-Based Pipeline and Unsupervised Learning 543

ID 304 · Exploratory Analysis of Electroencephalographic Coherence in Neurocritical Patients with Suspected Brain Death: A Case Series 551

ID 841 · Extraction of Computational Descriptors Based on ABCD Criteria for Characterization of Skin Lesions 559

ID 13 · Ferramenta educacional para detecção de displasia epitelial oral a partir de casos de leucoplasia 567

ID 465 · Frozen GPT-2 Backbone for Few-Shot Congestive Heart Failure Detection from ECG Signals 575

ID 876 · Gas Vesicles Image Enhancement Using Median Filter in HSV Image Representation 582

ID 762 · Geometric Characterization for Personalized Face-Frame Interface on Assessing Sunglasses UV Blocking 590

ID 607 · Geometry-Guided Deep Learning for Intermediate Projection Synthesis in Digital Breast Tomosynthesis 597

ID 527 · Habitats in Medical Images: The Influence of Parameter Choice on the Segmentation Process 605

ID 824 · Heart Sound Detection Based on Wavelet Transform and Shannon Energy Envelope 613

ID 932 · Heart-Evoked Spectral Disturbances in Refractory Epilepsy 619

ID 365 · HMM for Auditory Attention Decoding 625

ID 168 · Horse Height Estimation from a Single Image 633

ID 468 · Howland-Based FES Output Stage Characterization 639

ID 628 · Hybrid Deep Feature Extraction and Machine Learning for Multiclass Dementia Classification Using EEG Wavelet Images 645

ID 146 · Hybrid Regularization for Faulty-Electrode EIT in Hemorrhagic Stroke 653

ID 423 · Hybrid ViT–Convolutional W-Net for Retinal Vessels 661

ID 537 · Identification of Elevated Cardiac Troponin from 12-Lead ECGs Using Deep Learning and Exploratory Generalization from Myocardial Infarction Models 669

ID 617 · Identification of Genotoxic Cells in the Micronucleus Test Using YOLOv7 Neural Networks 678

ID 528 · Image-Based Evaluation System for Paraná State Military Physical Fitness Test: 12-Minute Run 684

ID 216 · Impact of Region of Interest Representation Methods on Ovarian Tumor Classification in Ultrasound Images 691

ID 623 · Inertial Sensor Analysis of Voluntary Stopping and Freezing of Gait in Parkinson's Disease 698

ID 368 · Interpretable Structural-Deviation Descriptors of Osteosarcoma Radiographic Signs via the Universal Image Quality Index 704

Sumário

VOLUME 01 · 05

Processamento de Sinais e Imagens Biomédicas

ID 602 · Janelas de Decisão para a Detecção Online de Anomalias em EEGs via One-Class Classification 712

ID 389 · Korotkoff Sound Filtering Techniques for Exercise Stress Testing and Functional Assessment Protocols 720

ID 696 · Literature Review on Interpretable Electrocardiogram Analysis for Arrhythmias, WPW Ventricular Pre-excitation, and Glycemic Excursions 728

ID 382 · Low-Cost 2D Ultrasound Field Scanning Platform 736

ID 184 · Low-Cost Wrist Movement Recognition Using Two-Channel sEMG 744

ID 345 · Maximizing EEG Task-Related Information in a Motor Imagery Cue-Based Paradigm 752

ID 563 · Motion-Aware Evaluation of In-Ear PPG 758

ID 578 · Multi-Class vs. Multi-Label sEMG Gesture Classification 766

ID 157 · Multiclass Skin Cancer Classification with Grad-CAM 773

ID 265 · Multiparametric EEG Analysis in Comatose Patients: A Comparison Between Silence and Musical Stimulation 781

ID 523 · Multisensory Prototype for the Investigation of Sleep-Related Respiratory Events 789

ID 325 · Método Adaptativo Baseado em Variação Espectral para Compressão de Sinais de ECG de Longa Duração 796

ID 693 · Neuroimaging, Speech, and Sensors: A Scoping Review of Deep Learning Multimodal Fusion for Cognitive Decline Detection 804

ID 323 · Neurological Prognostication Post-Cardiac Arrest Using Continuous Wavelet Transform and Hybrid Deep Learning 812

ID 285 · Objective Characterisation of Pronation-Supination Movements in Individuals with Parkinson's Disease Undergoing Pharmacological Treatment 820

ID 475 · Observational Analysis of the Performance of Image Reconstruction Algorithm Techniques in Head CT Protocol 824

ID 445 · Open-Source Electrooculography Platform for Assistive Double Blink Detection 829

ID 554 · Phonocardiography for Elevated BP Classification 836

ID 118 · Pipeline automatizado pertinente, porém pequeno conjunto clínico e resultados estatísticos ainda sem correção adequada de múltiplas comparações. 844

ID 104 · Pipeline de wavelets e deep learning utiliza técnicas estabelecidas e apresenta contribuição predominantemente de aplicação. 851

ID 322 · Pix2Pix GAN-Based Translation of Dermoscopic Images into Clinical Skin Lesion Images: VGG16-Guided Losses and FID Evaluation 857

ID 840 · Potenciais Biomarcadores de Ressonância Magnética Funcional no Comprometimento Cognitivo Leve e na Doença de Alzheimer: Uma Revisão de Escopo 863

ID 593 · Pre-trained CNNs for Mammographic Microcalcifications 871

ID 700 · Prediction of Hospital Readmission Within 30 Days After Discharge with Wearable Temporal Signals 878

Sumário

VOLUME 01 · 06

Processamento de Sinais e Imagens Biomédicas

ID 600 · Preliminary Results of a Large Dataset of Biosignals for Training of Control Algorithms of Upper-Limb Prostheses 885

ID 511 · Preprocessing and Physiological Model Fitting of Smartphone-Based Pupillary Light Reflex Recordings 892

ID 234 · Prototype Vibration Stimulator for Evaluating Somatosensory Nerve Fibers: Application in Charcot-Marie-Tooth Disease 898

ID 683 · Radiomic Evaluation of Additive Manufacturing Materials for Optimizing Anthropomorphic Mammography Phantoms 904

ID 822 · Reconhecimento de Padrões Vocais Associados a Estresse e Emoções Negativas em Comunicação Ruidosa via Adaptação Adversarial de Domínio 911

ID 319 · Recurrence Quantification Analysis of Resting-State EEG in Post-Stroke Rehabilitation with tDCS and Extended Reality 919

ID 206 · Remote Photoplethysmography in ICU Patients 927

ID 350 · Retinopathy Detection: YOLO With and Without SAHI 935

ID 328 · Riemannian Classification of Movement Intention from EEG 943

ID 691 · Risk Classification for Sudden Cardiac Death Using Single-Lead ECG 949

ID 844 · Robotic Prosthesis Control Using Linear Discriminant Analysis of Residual Electromyographic Signals 956

ID 139 · Segmentação de Cárie Dentária por Severidade em Radiografias Panorâmicas com YOLO11n-seg e Slicing Aided Hyper Inference 964

ID 63 · Sensitivity Analysis between qEEG Metrics and Longitudinal Clinical Scores in Post-Stroke Patients 972

ID 51 · Sparse Time-Frequency Characterization of Ischemic ST-Segment Morphology in ECG Using Matching Pursuit Decomposition 980

ID 454 · Spatiotemporal Organization of Atrial Fibrillation via EGM and ECG: A Meta-Analysis 989

ID 603 · Spectral Residual Analysis and Feature Map Visualization of Deep Learning Denoisers for Digital Mammography 994

ID 50 · Stability of Microstates and Machine Learning in Resting-State Electroencephalography 1002

ID 347 · Study of Interpretable Deep Neural Networks in Brain-Computer Interfaces 1008

ID 164 · tDCS Effects in Post-Stroke Rehabilitation Using EEG LORETA 1016

ID 797 · Theta Alpha Ratio and Auditory Stimulus Type Modulate Alpha Power Lateralization During Spatial Attention 1024

ID 169 · Theta-Band Modulation in EEG Signals from Individuals with Autism Spectrum Disorder Using Holo-Hilbert Spectral Analysis 1032

ID 653 · Time-Domain Speech Signal Enhancement with Impulsive Noise Using U-Net: A Preliminary Step Toward Future Assessment of Auditory Attention 1040

ID 62 · Transfer Learning for Dental Pathology Detection in Panoramic Radiographs: YOLOv11 vs. Zero-Shot Grounding DINO 1048

Sumário

VOLUME 01 · 07

Processamento de Sinais e Imagens Biomédicas

ID 427 · TRCA vs. CCA for SSVEP BCI 1056

ID 149 · Triagem Multitarefa Explicável de Retinopatia e Glaucoma 1064

ID 282 · Um Sistema Baseado em CNN 3D para Diferenciação entre Esquizofrenia, Transtorno Bipolar e Controles Saudáveis com Base em Ressonância Magnética 1072

ID 606 · Variance Stabilization of Unprocessed Digital Breast Tomosynthesis Projections Using a Residual Neural Network 1079

ID 156 · Venous Thrombosis Classification with CNN and XAI 1087

ID 343 · X-Pan: Building, Documenting and Validating an OPG Dataset 1094

ID 860 · YOLO11 and YOLO26 Deep Learning Models for Diabetic Retinopathy Lesion Segmentation: A Comparative Analysis 1102

ID 190 · YOLOv8 Detection of Hematological Elements in Blood Smears 1108

Tecnologias Assistivas e Reabilitação

ID 782 · 3D-Printed Pediatric Wheelchair Wheels 1116

ID 767 · A Brief Review of Control Strategies for Functional Electrical Stimulation Cycling 1122

ID 496 · A Computer Vision and Non-Immersive Virtual Reality Platform for Automated Functional Assessment During Hospital Cardiorespiratory Rehabilitation 1130

ID 856 · A Multimodal Assistive Interface for Wheelchair Control Using Electrooculography, Capacitive and Inertial Sensor 1138

ID 243 · A Non-Immersive Virtual Tour System Integrated with a Smart Cycle Ergometer for Chronic Respiratory Disease Rehabilitation 1148

ID 87 · A Virtual Simulation System to Support Wheelchair Prescription Concerning Patient Environment 1156

ID 266 · A Wearable Edge-Computing HD sEMG Platform for Assistive Applications: Technology Readiness and Laboratory-Scale Reproduction Cost 1162

ID 420 · ACL-Digital Assist: E-Health Platform for Knee Rehabilitation Tracking 1169

ID 424 · Advanced Manufacturing for Auricular Prosthesis 1177

ID 307 · An HD sEMG-Based Virtual Reality Box and Blocks Test for Hand Dexterity Assessment 1184

ID 612 · An Integrated Platform for Alternating Peripheral Electrical Nerve Stimulation with Application to Parkinson's Disease Tremor 1190

ID 800 · App My Pill: Design and Case Demonstration of a Low-Data Reference-Based System for Loose Pill Identification 1198

ID 127 · Assistive Cutlery in an Institutional Setting 1206

ID 152 · Assistive System for Signed Alphanumeric Spelling 1210

Sumário

VOLUME 01 · 08

Tecnologias Assistivas e Reabilitação

ID 730 · Automatic Transcription of Monophonic Recorder Audio to Braille Music Notation Using Classical Signal Processing Methods 1215

ID 907 · Capturing Functional Upper-Limb Movements Using Low-Cost IMUs 1221

ID 589 · Clinical Applicability of Wearable Accelerometers for Functional Assessment of Older Adults in a Home Environment 1227

ID 260 · Combined Effects of Brain-Computer Interface and Virtual Reality Game with tDCS in Stroke Patients 1232

ID 213 · Composite Laminates for Wheelchair Seat Applications 1240

ID 579 · Cultura Maker Aplicada à Tecnologia Assistiva: Desenvolvimento de um Processo de Fabricação Digital para Bancos Terapêuticos Destinados à Reabilitação 1248

ID 711 · DCV: dispositivo de comunicação vibrotátil personalizável para pessoas surdas e surdocegas 1256

ID 945 · Desenvolvimento de Dispositivos Assistivos de Baixo Custo para Apoio à Escrita de Crianças com Paralisia Cerebral: Relato de Dois Casos 1264

ID 432 · Desenvolvimento de Palmilha Personalizada por Impressão 3D para uma Criança com Distrofia Muscular de Duchenne: Um Estudo de Caso Centrado no Usuário 1271

ID 551 · Desenvolvimento de uma Cadeira de Rodas Infantil Personalizada Utilizando Plásticos Reciclados: Uma Abordagem Baseada em Economia Circular e Manufatura 1277

ID 103 · Desenvolvimento de uma Instrumentação de Baixo Custo para Avaliação de Pressão na Escrita Manual 1283

ID 550 · Desenvolvimento de uma Tala Extensora Personalizada para o Uso Associado ao Parapodium em Crianças com Paralisia Cerebral 1287

ID 416 · Desenvolvimento de Órteses Suropodálicas Pediátricas por Fluxo Digital Integrado Utilizando Escaneamento 3D, Modelagem CAD e Manufatura Aditiva 1293

ID 833 · Design and Specification of a Local Learning Environment for Neuro-Robotic Educational Applications 1300

ID 659 · Development and Application of a Wearable System for Hemodynamic Monitoring During Physiotherapeutic Exercises in Post-COVID-19 Patients 1307

ID 750 · Development and Preliminary Evaluation of a Bidirectional Telerehabilitation Platform for Remote Treadmill Control and Heart Rate Monitoring 1312

ID 682 · Development and Preliminary Evaluation of a Wearable Inertial Sensor-Based System for Postural Monitoring and Vibrotactile Biofeedback 1320

ID 631 · Development of a Programmable Visual Cueing System to Support Gait Rehabilitation in Patients with Parkinson's Disease 1328

ID 67 · Development of a Sensorized Cycle Ergometer Integrated with a Serious Game for Post-Stroke Rehabilitation 1335

ID 737 · Development of a Wearable Arduino-Based Orthosis for Non-Invasive Temperature Monitoring in Diabetic Foot Prevention 1341

ID 744 · Development of an Ankle Exoskeleton to Improve Gait in Foot Drop Patients 1346

ID 900 · Development of PULSEGRID: An Interactive Floor Platform for Cognitive-Motor Activities Adaptable to Neurodivergent Individuals 1353

Sumário

VOLUME 01 · 09

Tecnologias Assistivas e Reabilitação

ID 872 · Digital Manufacturing of Transradial Prosthesis 1359

ID 618 · Dispositivos para Acessibilidade Digital 1365

ID 214 · Effects of Repetitive Transcranial Magnetic Stimulation Associated with Motor Imagery on the Electromyographic Activation of the Tibialis Anterior and Rectus Femoris Muscles in Post-Stroke Individuals 1371

***Abstract*—Image segmentation, in automated analysis applications, enables the identification of regions of interest in several tasks in society. Regarding dentistry, it is useful for panoramic radiographs, which are widely used to provide a comprehensive view of dental and bone structures. However, the interpretation of these images is time-consuming, subject to inter/intra-observer variability, and relies on noise and low contrast. Recent works have enabled more accurate segmentation through the automatic extraction of relevant features using deep learning. Therefore, we aim to develop a CAD system for the automatic segmentation of teeth in panoramic radiographs through a comparative analysis of five U-Net-based architectures. The study used the public Children's Dental Panoramic Radiographs Dataset images, which underwent preprocessing, and models were trained using K-Fold cross-validation and Grid Search for hyperparameter optimization. In external validation data, W-Net demonstrated the best performance on one of the evaluated subsets, achieving a Sensitivity of 0.809, E-Measure of 0.925, IoU of 0.785, and DSC of 0.879. On the second subset, Attention U-Net achieved a Sensitivity of 0.965, E-Measure of 0.975, IoU of 0.858, and DSC of 0.924. Furthermore, the Wilcoxon test indicated significant differences between the classic U-Net and the U-Net++ and U-Net 3+ architectures, whereas W-Net and Attention U-Net showed equivalent performance. Finally, considering quantitative and qualitative results as well as inference time, Attention U-Net was selected as the final architecture for the CAD system and was subsequently evaluated by a dentist regarding the quality of segmentations generated on images independent of the training set.**

***Index Terms*—Medical image segmentation. CAD System. Segmentation models. Convolutional Neural Networks. Deep learning.**

I. Introduction

Oral health is defined as the state of the mouth, teeth, and orofacial structures that enables individuals to perform essential functions - such as eating, breathing, and speaking- while also encompassing psychosocial aspects like self-confidence and the ability to socialize. This condition varies throughout a person's life and plays a fundamental role in their overall health [1]. In this context, compromised oral health can lead to serious conditions such as dental caries, tooth loss, and orodental trauma; these rank among the most prevalent non-communicable chronic diseases worldwide, affecting approximately 3.5 billion people [2]. Consequently, oral diseases pose a major public health challenge, making early diagnosis essential for preventing complications and preserving dental structures [3].

Given this scenario, panoramic radiographs - also known as orthopantomograms - are vital tools for rapidly and accurately diagnosing these diseases; they provide comprehensive images of the entire dental arch, making them crucial for identifying various conditions. However, manual interpretation of these radiographs can be time-consuming and subject to inter-practitioner variability [4]. Beyond these limitations, technical factors such as low resolution, inadequate contrast, and image noise further complicate the process, increasing the difficulty and the risk of diagnostic errors. Against this backdrop, automated image analysis emerges as a promising tool capable of enhancing diagnostic accuracy, reducing screening time, and optimizing clinical costs. A standout among these solutions is the automated segmentation of medical images, a process that involves classifying each image pixel according to the objects of interest [5].

Image segmentation involves dividing an image into parts - referred to as connected pixel segments - that strongly correlate with real-world objects or areas within the scene, based on similarity criteria [6]. In a medical context, this technique plays a fundamental role in computer-aided diagnosis by

The authors would like to thank the Brazilian National Council for Scientific and Technological Development (CNPq) under Grant No. 315447/2023-0.

making alterations to anatomical structures more distinct in images [7]. Specifically regarding the diagnosis of dental diseases such as caries and periapical lesions, segmentation is a key element that assists dentists in identifying these conditions; it allows for the delineation of dental structures and facilitates the distinction between teeth - particularly in panoramic radiographs, where the overlapping of structures can compromise visual interpretation [3].

Against this backdrop, deep learning has established itself in medical image analysis, finding broad application in tasks such as object detection, classification, segmentation, and registration [8]. This approach - a subset of machine learning - utilizes artificial neural networks with multiple layers to learn and recognize patterns in data. Concurrently, Convolutional Neural Networks (CNNs) have transformed medical image analysis in recent years, achieving remarkable performance in tasks such as classification, segmentation, detection, and image reconstruction [6]. Their ability to automatically extract relevant information eliminates the reliance on manual techniques and excessive preprocessing [9].Therefore, in this article, we propose the development of a CAD system for the automatic segmentation of teeth in panoramic radiographs, based on a comparative analysis of U-Net architecture performance and a clinical validation protocol.

The remainder of the article is organized as follows: Section 2 presents related work; Section 3 describes the methodology employed, covering model training and the development of the CAD system; Section 4 presents the results obtained; and, finally, Section 5 presents the study's conclusions.

II. RELATED WORK

Although recent studies have explored U-Net-based architectures for dental segmentation in panoramic radiographs, the current literature presents gaps that this work seeks to fill. Zannah et al. [3] evaluated U-Net architectures for semantic segmentation in panoramic radiographs, yet without performing a formal statistical comparison between the models or validation on multiple independent external datasets. Şahin, Ulutaş and Suzgen [4] they focused exclusively on U-Net 3+, not allowing for a direct performance comparison with other variants of the U-Net family under the same experimental conditions. Nader et al. [5] they used generic deep neural networks for tooth segmentation, without systematically exploring attention mechanisms or dense connections specific to more recent architectures. Brahmi and Jdey [6] They addressed tooth segmentation and identification using a single CNN architecture, without a comparative analysis of multiple models. Wang et al. [7] They presented a review of medical image segmentation methods using deep learning, of a theoretical rather than experimental nature. Finally, Zhong, Ren, and Zhang [8] proposed a grouped attention mechanism for dental X-ray segmentation, but this was restricted to a single architectural proposal, lacking systematic comparison with other U-Net variants or cross-validation on multiple external datasets.

Unlike those studies, this work makes five contributions. First, a systematic comparison of five U-Net family architectures under identical preprocessing, augmentation, Grid Search, and k-fold cross-validation, so that differences reflect the architectures rather than the protocol. Second, a Wilcoxon signed-rank analysis over the DSC values of every pair of models replaced the descriptive comparison with statistical evidence. Third, external validation on two datasets independent of the training set, assessing generalization under acquisition variability. Fourth, a functional CAD system with a Streamlit interface and PDF report export, integrating the Attention U-Net for its best performance. Fifth, a specialist evaluation by an uninvolved dentist over thirty stratified radiographs, scored with an eight-item Likert instrument, yielding 240 assessments that characterize behavior beyond aggregate metrics.

III. METHODOLOGY

A. Overview

The development of the automatic tooth segmentation model in panoramic radiographs followed a systematic workflow, beginning with dataset acquisition and culminating in the implementation of the computer-aided diagnosis (CAD) system. Figure 1 presents an overview of the steps involved in this process.

Panoramic radiographs and their corresponding segmentation masks were first organized and preprocessed to standardize the images for neural network training. The architectures evaluated in this study included U-Net, U-Net++, U-Net 3+, W-Net, and Attention U-Net. Model training incorporated data augmentation techniques to increase sample diversity and K-Fold cross-validation to ensure robust evaluation during optimization. Optimal parameters for each architecture were identified using the Grid Search technique. Following training, the models were evaluated on external datasets, which consisted of images not included in the training process, to assess the networks' generalization capabilities on unseen data.

The performance of each architecture was analyzed using several metrics: accuracy, sensitivity, specificity, Dice Similarity Coefficient (DSC), Mean Absolute Error (MAE), E-Measure, and Intersection over Union (IoU). The best-performing architecture was then selected and integrated into the computer-aided diagnosis (CAD) system, enabling the automatic generation of dental segmentations from submitted panoramic radiographs; the system was subsequently evaluated by a dentist regarding the quality of segmentations generated from images not used during training.

B. Dataset Acquisition

The dataset used was the Children's Dental Panoramic Radiographs Dataset [10], available on Kaggle, the structure of which is presented in Figure 2.

Among the available subsets, the adult dental segmentation set was selected; it is organized into three directories: Archive, containing 116 panoramic radiographs obtained at the Noor Medical Imaging Center (Qom, Iran); Panoramic Radiography Database, composed of 598 panoramic radiographs from

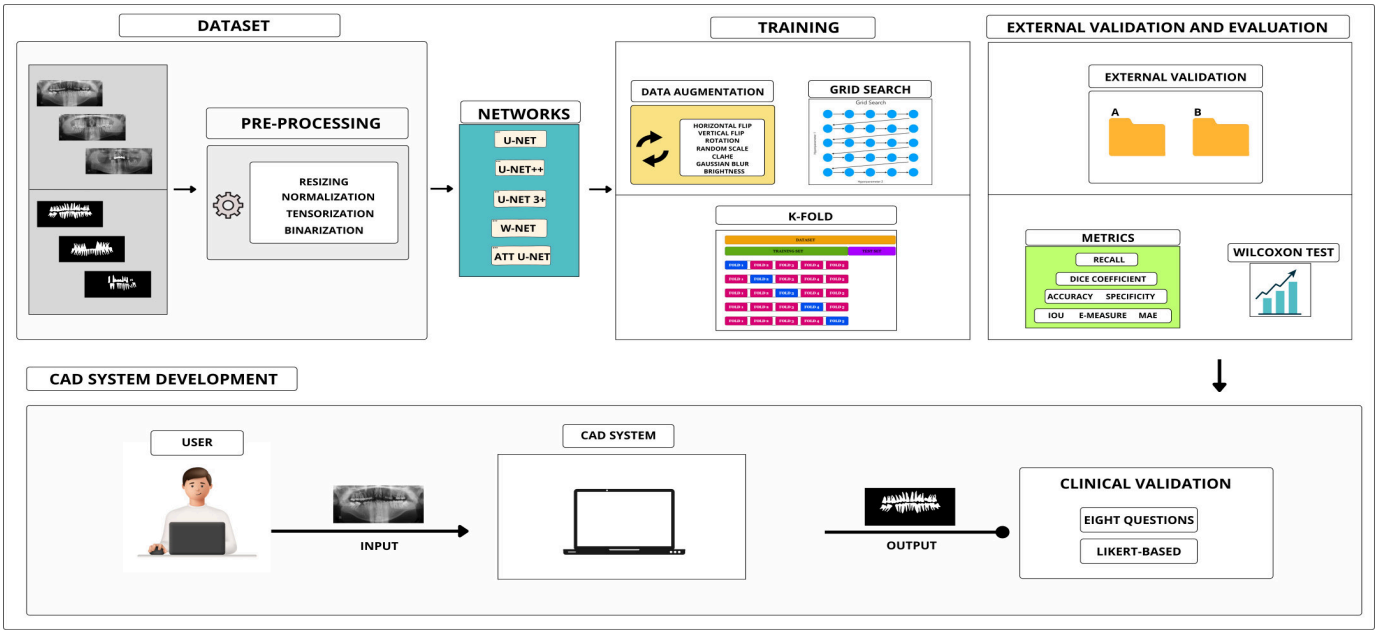

Fig. 1. Overview of the proposed methodology.

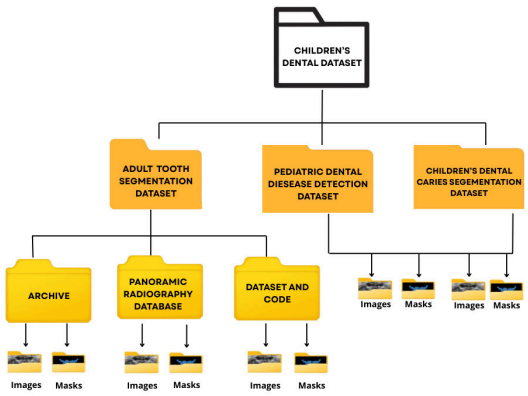

Fig. 2. Dataset structure.

randomly selected patients; and Dataset and Code, which includes 1,978 panoramic radiographs acquired at the UESB Diagnostic Imaging Center and the Hangzhou Lishui Dental Hospital. This set comprises ten image categories: (1) all teeth, with restorations and orthodontic appliances; (2) all teeth, with restorations but without appliances; (3) all teeth, without restorations but with appliances; (4) all teeth, without restorations and without appliances; (5) containing dental implants; (6) containing more than 32 teeth (supernumerary teeth); (7) missing teeth, with restorations and appliances; (8) missing teeth, with restorations but without appliances; (9) missing teeth, without restorations but with appliances; and (10) missing teeth, without restorations and without appliances. The Archive directory was used for training, while the Panoramic Radiography Database and Dataset and Code were used for external validation.

C. Data Preprocessing and Preparation

As described in Section B, the dataset contains panoramic radiographs of adult and pediatric patients. Since the objective is adult tooth segmentation, only the Adult Tooth Segmentation Dataset subset was used. During data analysis, 478 duplicate images were removed from the Dataset and Code directory, resulting in a final set of 2,214 images. During preprocessing, the images were converted to grayscale, resized from 2000×942 to 256×512 pixels, and normalized to the $[-1, 1]$ range. Subsequently, the images and masks were converted into tensors, and the masks were binarized, with values of 0 and 1 representing the background and the tooth region, respectively.

D. Neural Network Architectures for Segmentation

A literature review was conducted to identify neural network architectures suitable for automatic tooth segmentation in panoramic radiographs. U-Net-based architectures demonstrated strong performance in medical image segmentation applications and were therefore selected as the basis for the experiments in this study. The selected networks included U-Net, U-Net++, U-Net 3+, W-Net, and Attention U-Net. This selection enabled comparison of different approaches to image information processing, including inter-layer connections, multi-scale analysis, and attention mechanisms, to determine which models yield the best performance in dental segmentation.

E. Segmentation models training

All architectures were trained using the same experimental setup to ensure a fair comparison. Data augmentation was applied only to the training images using Albumentations,

incorporating transformations such as rotations, flips, resizing, brightness and contrast adjustments, CLAHE, and Gaussian blur. Training utilized the Archive directory, selected to evaluate model performance in a scenario with limited data. Hyperparameters were tuned via Grid Search, considering learning rates of 1×10^{-3} and 5×10^{-4}, a batch size of 8, and the Adam and AdamW optimizers. Each configuration was trained for 50 epochs using a loss function combining BCEWithLogitsLoss and Dice Loss. The optimal configuration for each architecture was determined through k-fold cross-validation ($k = 10$), based on the highest DSC on the validation set. Finally, the models were retrained using the best parameters, and their final weights were saved for evaluation and comparison.

F. External validations

To evaluate model performance on entirely new data not used during training, external validation was conducted using two additional adult patient datasets: the Dataset and Code set and the Panoramic Radiography Database.

Prior to inference, images and masks from the external datasets were prepared using the same processing pipeline as during training, including resizing, normalization, and conversion to PyTorch tensors, to maintain data standardization and ensure process consistency. The final versions of the models, trained using the optimal hyperparameters identified via grid search and cross-validation on the Archive dataset, were then loaded. Each architecture performed inference on all images in the external datasets and generated 10 PNG masks per set.

A smaller number of masks was intentionally generated to facilitate detailed visual analysis of network performance, specifically regarding contour accuracy, coherence of segmented regions, and preservation of dental structures.

G. Performance evaluation

To evaluate model performance during external validation using the two datasets mentioned in Section F, a set of metrics well-established in the literature and commonly used in image segmentation tasks was selected.

These metrics were chosen because they enable precise and objective quantification of the correspondence between regions identified by the models and the reference masks (ground truth). This approach measures both the level of overlap between areas of interest and the presence and nature of segmentation errors made by the networks. Based on the literature review, the final set of metrics applied in the study included Accuracy, Sensitivity, Specificity, Intersection over Union (IOU), Dice Similarity Coefficient (DSC), Mean Absolute Error (MAE), and Enhanced-alignment Measure (E-measure).

H. Statistical Analysis: Wilcoxon Test

After model evaluation using the defined metrics, the non-parametric Wilcoxon signed-rank test was applied to determine whether observed performance differences between networks were statistically significant. This test was selected because it is suitable for comparing results obtained from the same datasets without requiring the assumption of sample normality.

The test was conducted using Dice Similarity Coefficient (DSC) values obtained during k-fold cross-validation, with pairwise comparisons across all evaluated architectures. For each comparison, DSC values from the corresponding folds ensured analysis under identical conditions. A significance level of 5% ($\alpha = 0.05$) was adopted, with differences yielding a p-value less than or equal to this threshold considered statistically significant.

I. CAD System Development

After evaluating all models and conducting statistical analysis using the Wilcoxon test, the architecture demonstrating the best performance in segmenting dental structures was selected. This model was integrated into the CAD system developed in this project, enabling progression to the experimental phase and deployment via a computational interface.

The CAD system was built using the Streamlit library, which provides a web interface for interacting with the trained model. Through this system, users can upload a panoramic radiograph, which the neural network processes to automatically generate a tooth segmentation mask. Following image processing, the system displays the original radiograph alongside the model-generated mask, facilitating visualization of the segmentation results. Additionally, a feature was implemented to export results in PDF format, presenting the original image and the segmentation side-by-side. The system thus combines the developed deep learning model with an accessible interface, enabling dental professionals to utilize it in their analyses.

J. Preliminary Specialist Evaluation

In this work, we complemented the evaluation analysis with a evaluation conducted by a dentist who had no prior involvement in the system development. The professional received access to the deployed CAD interface by using the available link and was asked to process thirty randomly selected panoramic radiographs presented in the external validation set and inspect the mask returned by the system. It's worth noting that the thirty cases were drawn from the external validation set, so that none had been seen during training, and were selected across ten predefined groups of three images each in order to cover a range of anatomical and acquisition conditions rather than a convenience sample of straightforward cases. The presentation order was randomized, and the evaluator had access neither to the reference masks nor to any of the quantitative metrics. The assessment was structured as an eight-item instrument answered on a five-point Likert scale (1 = unsatisfactory, 2 = poorly satisfactory, 3 = partially satisfactory, 4 = satisfactory, 5 = fully satisfactory). The items were planned to decompose the segmentation quality when reading a mask presented as follows:

- Q1 - Completeness: every tooth visible in the radiograph is represented in the mask.
- Q2 - Contour: tooth crowns are delineated faithfully.
- Q3 - Root preservation: roots are segmented up to the apex, without truncation.

- Q4 - Interdental separation: adjacent teeth appear as distinct units, without fusion.
- Q5 - Continuity: segmented regions are intact, without fragmentation or internal holes.
- Q6 - Absence of false positives: the mask does not include bone, TMJ, spine, maxillary sinus, prosthetic devices, or other non-dental structures.
- Q7 - Shape and thickness fidelity: there is neither excessive thickening nor thinning of the structures.
- Q8 - Visual usefulness: the mask facilitates visualization of the dental structures in that specific case.

The scope of the instrument was constrained because the system performs binary segmentation only and no item addressed tooth numbering, disease detection, or report generation. The evaluator was explicitly instructed to judge the correspondence between the generated mask and the visible dental structures, and not the diagnostic content of the radiograph.

IV. Results and Discussion

A. Hyperparameter Selection

For each of the networks, the hyperparameters that yielded the highest average DSC value during the selection process are shown, taking into account the learning rate, batch size, and optimizer used. Table I presents these results.

TABLE I
BEST HYPERPARAMETER CONFIGURATION FOR EACH ARCHITECTURE.

Architecture	Batch Size	Learning Rate	Optimizer
Attention U-Net	8	5×10^{-4}	Adam
U-Net 3+	8	5×10^{-4}	Adam
U-Net++	8	5×10^{-4}	AdamW
U-Net	8	5×10^{-4}	AdamW
W-Net	8	5×10^{-4}	Adam

As shown in Table I, all architectures utilized the same batch size (8) and learning rate (5×10^{-4}) configurations; the only difference among them was the optimizer. Attention U-Net, U-Net 3+, and W-Net achieved better results using Adam, whereas U-Net and U-Net++ performed better with AdamW.

This difference in results suggests that more complex architectures - such as those featuring attention blocks, dense connections, and deeper hierarchies - may benefit more from Adam's flexibility in weight adjustment. Conversely, U-Net and U-Net++ architectures, which employ skip connections and progressive feature refinement, may have benefited more from the additional regularization provided by AdamW. This likely helped maintain stability during training and improved generalization capabilities. Finally, the best configurations were used for the final training of all architectures.

B. Evaluation on the test set

The results presented in Table II correspond to the performance of the architectures on the test set during hyperparameter tuning and 10-fold cross-validation. The values represent the mean and standard deviation across the ten iterations, allowing for an assessment of model consistency.

TABLE II
EVALUATION RESULTS ON THE TEST SET.

Metric	U-Net	U-Net++	U-Net 3+	Attention U-Net	W-Net
Accuracy	0.983 ± 0.002	$\mathbf{0.985 \pm 0.001}$	0.962 ± 0.002	0.983 ± 0.001	0.983 ± 0.002
Specificity	0.990 ± 0.002	$\mathbf{0.991 \pm 0.002}$	0.973 ± 0.005	0.990 ± 0.002	0.990 ± 0.002
Sensitivity	0.950 ± 0.011	$\mathbf{0.952 \pm 0.010}$	0.906 ± 0.018	0.947 ± 0.008	0.948 ± 0.010
E-Measure	0.977 ± 0.002	$\mathbf{0.979 \pm 0.001}$	0.946 ± 0.004	0.977 ± 0.002	0.977 ± 0.002
MAE	0.017 ± 0.002	$\mathbf{0.015 \pm 0.001}$	0.038 ± 0.002	0.017 ± 0.001	0.017 ± 0.002
IoU	0.905 ± 0.008	$\mathbf{0.913 \pm 0.006}$	0.801 ± 0.006	0.905 ± 0.006	0.905 ± 0.008
DSC	0.950 ± 0.004	$\mathbf{0.954 \pm 0.003}$	0.889 ± 0.004	0.950 ± 0.004	0.950 ± 0.004

As shown in Table II, the U-Net, U-Net++, Attention U-Net, and W-Net architectures demonstrated consistent performance on the test set, with high values for accuracy, specificity, and DSC. U-Net++ stood out by achieving the highest mean IoU 0.913 and DSC 0.954 values, indicating better agreement between the generated masks and the reference masks. The U-Net, Attention U-Net, and W-Net architectures yielded similar results. In contrast, U-Net 3+ showed inferior performance - particularly in terms of IoU 0.801 and DSC 0.889 - suggesting lower precision in delineating dental structures.

C. Results in Dataset and Code

The evaluation results for the Dataset and Code set are presented in Table III. These values correspond to the metrics obtained by the different architectures evaluated during external validation. This allows us to analyze model performance on a dataset distinct from the one used for training.

TABLE III
METRIC RESULTS IN THE DATASET AND CODE.

Metric	U-Net	U-Net++	U-Net 3+	Attention U-Net	W-Net
Accuracy	0.952	0.953	0.946	0.951	**0.955**
Specificity	**0.995**	0.994	0.991	0.994	0.992
Sensitivity	0.782	0.789	0.768	0.778	**0.809**
E-Measure	0.914	0.917	0.906	0.912	**0.925**
MAE	0.048	0.047	0.054	0.049	**0.045**
IoU	0.767	0.772	0.741	0.760	**0.785**
DSC	0.868	0.871	0.851	0.864	**0.879**

As shown in Table III, all architectures demonstrated high accuracy and specificity, yet DSC values were lower than those obtained during the cross-validation stage. U-Net yielded a DSC of 0.868, while U-Net++ achieved 0.871. U-Net 3+ exhibited the lowest IoU 0.741 and DSC 0.851, as well as the highest MAE 0.054. Attention U-Net showed intermediate performance, with a DSC of 0.864. W-Net achieved the highest sensitivity 0.809, IoU 0.785, and DSC 0.879, along with the lowest MAE 0.045. The reduction in DSC across all architectures may be partly attributed to the limited and uncontrolled representation of clinically relevant conditions in the dataset subset used for training, in which implants, orthodontic appliances, restorations, and supernumerary teeth were not mapped.

D. Results in the Panoramic Radiography Database

Table IV presents the results of the metrics obtained on the Panoramic Radiography Database. The values shown allow for a comparison of the performance of the architectures evaluated during external validation.

TABLE IV
METRIC RESULTS IN THE PANORAMIC RADIOGRAPHY DATABASE.

Metric	U-Net	U-Net++	U-Net 3+	Attention U-Net	W-Net
Accuracy	0.980	0.981	0.970	**0.982**	0.977
Specificity	0.983	**0.984**	0.978	**0.984**	0.980
Sensitivity	0.956	0.963	0.903	**0.965**	0.957
E-Measure	0.972	0.973	0.960	**0.975**	0.966
MAE	0.020	0.019	0.030	**0.018**	0.023
IoU	0.844	0.852	0.770	**0.858**	0.824
DSC	0.915	0.920	0.870	**0.924**	0.904

As shown in Table IV, all architectures achieved high accuracy and specificity, with DSC values ranging from 0.870 to 0.924. Unlike the Dataset and Code set, the models showed higher DSC values in this database, suggesting that external generalization varied according to dataset characteristics. U-Net achieved a DSC of 0.915, while U-Net++ reached 0.920. U-Net 3+ again yielded the lowest IoU of 0.770 and DSC of 0.870, with the highest MAE of 0.030. W-Net achieved a DSC of 0.904, whereas Attention U-Net obtained the best overall results, with sensitivity of 0.965, IoU of 0.858, DSC of 0.924, E-Measure of 0.975, and MAE of 0.018. The difference between the external datasets may be associated with variations in case composition and with the uncontrolled representation of implants, orthodontic appliances, restorations, and supernumerary teeth during training.

E. Statistical analysis using the Wilcoxon test

To determine whether the differences between the architectures were statistically significant, the Wilcoxon test was applied using the DSC values obtained during cross-validation. Table V presents the pairwise comparisons between the models, considering a significance level of $\alpha = 0.05$. The Wilcoxon test results presented in Table V show that

TABLE V
WILCOXON TEST: COMPARISON BETWEEN ARCHITECTURES.

Comparison	p-value	Significant
U-Net × Attention U-Net	1.00	No
U-Net × U-Net 3+	**0.01**	Yes
U-Net × U-Net++	**0.02**	Yes
U-Net × W-Net	1.00	No
U-Net 3+ × Attention U-Net	**0.01**	Yes
U-Net++ × Attention U-Net	**0.01**	Yes
U-Net++ × U-Net 3+	**0.01**	Yes
W-Net × Attention U-Net	0.69	No
W-Net × U-Net 3+	**0.01**	Yes
W-Net × U-Net++	**0.02**	Yes

the U-Net performed similarly to the Attention U-Net and W-Net, with no statistically significant differences. Conversely, differences were observed relative to the U-Net 3+ and U-Net++, indicating that their structural modifications influenced the segmentation results. The U-Net 3+ showed differences in most comparisons, while the U-Net++ also exhibited distinct behavior due to its dense connections. The W-Net maintained results close to those of the Attention U-Net but differed from the U-Net 3+ and U-Net++. These results indicate that more complex architectures do not always guarantee significant performance improvements.

F. Analysis of the segmented mask

Qualitative evaluation was performed through visual inspection of the masks generated by the architectures during external validation. Figure 3 presents examples of the segmentations obtained on the Panoramic Radiography Database. For illustrative purposes, two representative samples from each architecture were selected.

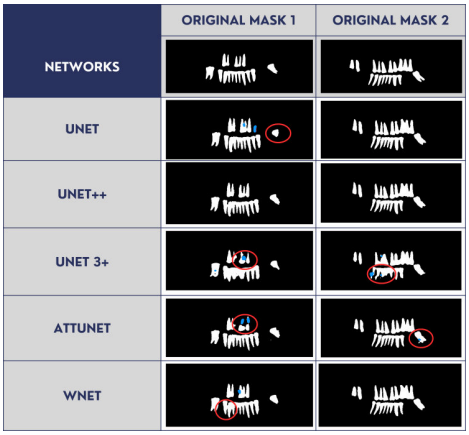

Fig. 3. Segmentation results: Panoramic Radiography Database.

Figure 3 shows that U-Net++ produced masks closer to the original images, better preserving the contours and continuity of dental structures. U-Net exhibited a minor false positive, whereas U-Net 3+ showed greater deviations, with incorrectly segmented regions and a loss of continuity in some teeth. Attention U-Net and W-Net yielded intermediate results; while they showed minor inaccuracies, they maintained good correspondence with the original masks. From a clinical perspective, these errors could compromise the accurate identification of dental structures during radiographic interpretation.

G. CAD system Integration

The choice of architecture to integrate into the CAD system took into account the models' quantitative and qualitative results as well as their computational cost. W-Net demonstrated the best performance on the Dataset and Code set, whereas Attention U-Net achieved the best results on the Panoramic Radiography Database. Balancing these criteria, an analysis of prediction time for 50 radiographs was conducted. Attention U-Net was selected for offering the best trade-off between performance and computational efficiency.

Fig. 4. CAD system interface.

Following this selection, Attention U-Net was integrated into the CAD system shown in Figure 4. The application allows for loading panoramic radiographs, viewing the input image and the segmented mask, and generating PDF reports containing the segmentation results.

H. Dentist Evaluation

The evaluator completed all thirty assessments, producing 240 individual scores, as summarized per item in Table VI.

Every item reached a maximum of 5, so each dimension was rated fully satisfactory in at least one radiograph. The lower quartiles are more discriminating than the medians. Q4 is the only item whose lower quartile is 2.00, which places at least a quarter of the radiographs at poorly satisfactory or worse for interdental separation; nine of the thirty received such a score. Q1 is the only item whose lower quartile is 4.00, so at least three quarters of the cases were satisfactory or better for completeness. The minimum scores split the items by dimension rather than by case: Q1, Q2 and Q7 never received the lowest score, whereas Q3, Q4, Q5, Q6 and Q8 reached the floor at least once, three radiographs each for Q4 and Q5 and one each for Q3, Q6 and Q8.

Dispersion is best read from the standard deviations, where continuity (Q5, 1.25) and absence of false positives (Q6, 1.18) vary most and shape fidelity (Q7, 0.76) least. Q4 and Q6 share the widest value, 2.00, but for structurally different reasons and should not be read as a pair. Q4 is unimodal, with twelve of the thirty radiographs scored 3, so its quartiles at 2.00 and 4.00 bracket a single center that happens to sit low. Q6 is bimodal (eleven radiographs scored 3 and thirteen scored 5, with only three in between), so its quartiles at 3.00 and 5.00 fall on the two modes themselves and measure the distance between them rather than spread about a center, which is also why its mean (3.83) falls below its median (4). Crown contour (Q2) shows the same structure in weaker form, with thirteen radiographs at 3 and eight at 5 against six at 4. The bimodality of Q6 is consistent with the stratified results in Table VII, where absence of false positives ranged from 2.00 in the implant group to the maximum of 5.00 in two others: false-positive control behaved in a near all-or-nothing fashion, apparently determined by the presence of radiopaque non-dental material rather than by degrees of difficulty.

Another aspect, presented in Table VII, is evidenced. The group means ranged from 2.46 to 4.50, roughly two points on a five-point scale, and only two groups reached a mean of 4.00 or above. Because each group contains three radiographs, the analysis that follows is only descriptive. Radiographs with missing teeth and neither restorations nor an orthodontic appliance (C10) obtained the highest mean, 4.50, and held the highest value of every item except interdental separation, including the maximum score for continuity and for absence of false positives in all three of its radiographs. Radiographs with supernumerary dentition (C6) obtained the lowest mean, 2.46, and held the lowest value of seven of the eight items. The implant group (C5) showed the combination of the maximum score for completeness with the lowest false-positive control of the series (2.00), and the evaluator explicitly recorded that bone had been confused with a root. Regarding each level of dentition completeness, the two groups containing restorative material occupied the two lowest positions in both cases, while absence of teeth carried no penalty at all: C10 scored above its complete-dentition counterpart (4.50 against 4.00), and no false positives were observed in edentulous regions. Completeness proved the most stable dimension, at or above 4.00 in nine of the ten groups, whereas interdental separation reached 4.00 in none.

These differences should be contextualized by how the model was trained. Fine-tuning used the Archive directory, 116 panoramic radiographs, which was not organized according to the conditions examined here: restorations, orthodontic appliances, implants and supernumerary dentition were neither balanced nor annotated, so their representation is uncontrolled, and for the rarer conditions it is plausible that few or no examples were seen. The groups in which the evaluator's scores were lowest are precisely those describing anatomies and radiopaque structures the network had no explicit opportunity to learn, while the highest scoring groups correspond to the configuration closest to a normative adult dentition free of foreign radiopaque material. The stratified results are therefore better understood as a characterization of the model's behavior outside the conditions represented in its training distribution than as a comparison of intrinsically harder and easier images, indicating that the composition of the fine-tuning corpus is the most reason why the validation did not reach higher ratings in these groups.

I. Limitations

This study presents some important limitations. Fine-tuning and hyperparameter selection were performed using only the "Archive" dataset, which comprises a limited number of cases with low diversity. This may have reduced the networks' ability to effectively handle situations involving implants, restorations, orthodontic appliances, or supernumerary teeth. Another point is that the analysis was conducted solely on adult patients, preventing the results from being applied to children. Clinical validation was also limited, relying on a single dentist and a small number of images, which further restricts the scope of the conclusions. Future studies should

TABLE VI
CONDUCTED ASSESSMENT BY THE DENTIST: DESCRIPTIVE STATISTICS PER ITEM.

Item	Description	Median	Q1	Q3	IQR	Mean	SD	Min	Max	% $\geq$ 4
Q1	Completeness	5	4.00	5.00	1.00	4.47	0.86	2	5	83.3

utilize larger, multicenter, and more diverse datasets that better represent various clinical conditions. It is also important to involve more specialists and expand the number of images evaluated to ensure a more consistent analysis and to gain a deeper understanding of the challenges associated with interdental separation and false-positive control.

V. CONCLUSIONS

Following the completion of all experiments and analyses, qualitative and quantitative results indicated that U-Net-based convolutional neural networks are suitable for tooth segmentation in panoramic radiographs, although performance differences were observed among the evaluated architectures. These differences were confirmed by the Wilcoxon test, which revealed statistically significant variations between certain models regarding Dice Similarity Coefficient (DSC) values, demonstrating that architectural modifications influence segmentation performance. The conducted evaluation by a dentist was also crucial for assessing the system's efficacy and identifying its limitations. Professional evaluation indicated satisfactory performance in identifying and visualizing dental structures, with good results regarding completeness, anatomical preservation, and mask continuity. However, limitations were observed regarding interdental separation, the preservation of segmented shapes, and the occurrence of false positives, highlighting the challenges inherent in segmenting adjacent and overlapping structures in panoramic radiographs. Finally, future work should consider the use of multi-center datasets, a broader external validation protocol, expert evaluation, and testing in real-world clinical environments to enhance the robustness and clinical applicability of the proposed CAD system.

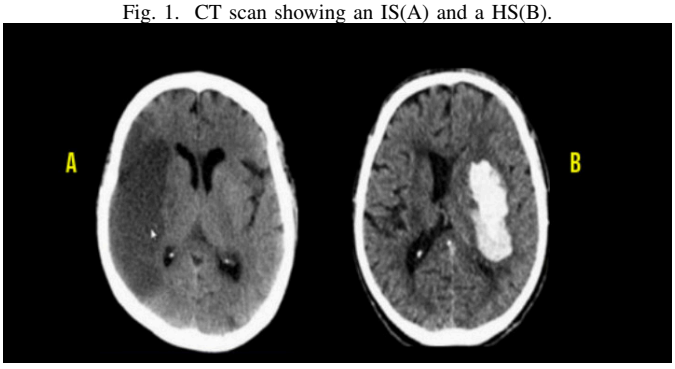
***Abstract*—Ischemic stroke (IS) is a medical emergency whose early signs can be subtle on non-contrast computed tomography (CT). This study presents a preliminary ConvNeXt-Small classifier for distinguishing axial CT slices with visible ischemic changes from radiologically normal-appearing slices. The method uses DICOM images, conversion to Hounsfield Units, brain windowing, transfer learning, and a custom binary classification head trained in two stages. The dataset comprised 362 slices (181 per class) from two sources and was evaluated by five-fold cross-validation performed at the slice level. Mean slice-level accuracy was $92.82\% \pm 1.78\%$, precision $91.59\% \pm 3.13\%$, recall $94.47\% \pm 4.39\%$, specificity $91.17\% \pm 3.58\%$, and F1-score $92.92\% \pm 1.85\%$; 10 of 181 ischemic slices were false negatives. Because slices from the same examination were not constrained to a single fold, these estimates may be optimistic. The negative class did not include other intracranial abnormalities, and neither patient-level nor external validation was performed. Therefore, the results characterize a preliminary slice classifier and do not establish clinical diagnostic or screening performance.**

***Index Terms*—Ischemic Stroke, ConvNeXt, Computed Tomography, Transfer Learning, Slice Classification.**



I. Introduction

Stroke, also known as cerebrovascular disease, ranks among the top three leading causes of mortality, behind only cancer and myocardial infarction [1]. It is directly responsible for leaving survivors with neurological sequelae, ranging from the loss of speech capability to partial paralysis of one side of the body, as observed by [1].

Stroke is a pathology that affects the blood vessels responsible for supplying the brain. It is characterized by an acute neurological deficit resulting from the death of brain cells caused by focal ischemia or hemorrhage [1], [2]. Global data from 2021 indicate that approximately 12.2 million new stroke cases occurred worldwide, with the disease being responsible for 6.63 million deaths [1], [2].

Stroke can be classified into two main types: ischemic and hemorrhagic. Ischemic stroke (IS), shown in Fig. 1(A), occurs due to the occlusion of a blood vessel, resulting in an insufficient blood supply to the brain tissue and causing localized cell death [3]. On a computed tomography (CT) scan, the ischemic region typically presents as a more muted, darker gray shade – characterized as hypodense – compared to other brain areas [2], [3]. Conversely, hemorrhagic stroke (HS), depicted in Fig. 1(B), results from the rupture of a blood vessel, causing bleeding within the brain parenchyma or the subarachnoid space; the brain region affected by the hemorrhage is represented as a hyperdense (white) signal on the CT scan [2], [3].

Fig. 1. CT scan showing an IS(A) and a HS(B).

Source: Adapted from [3].

The occurrence of ischemic stroke is predominant in emergency departments. In the acute phase, defined as the first 24 hours post-event, restoring blood flow to the affected area is vital to recover impaired functions, which enhances the probability of clinical reversal and reduces future neurological sequelae [2], [4], [5].

Recent computational advancements have enabled the development of software dedicated to iterative CT image reconstruction, allowing for simultaneous noise reduction and image quality improvement [6], [7]. Currently, the literature features computer-aided detection systems for brain imaging that utilize adaptive edge-preserving smoothing filters and wavelet-based image processing [6], [7].

This work aims to implement and evaluate a preliminary convolutional neural network based on the *ConvNeXt* architecture for the slice-level discrimination of visible ischemic changes from normal-appearing cranial CT. The dataset was obtained from the studies of [3] and [8], consisting of CT scans. The present experiment does not evaluate patient-level diagnosis or clinical triage performance.

II. Ischemic Stroke

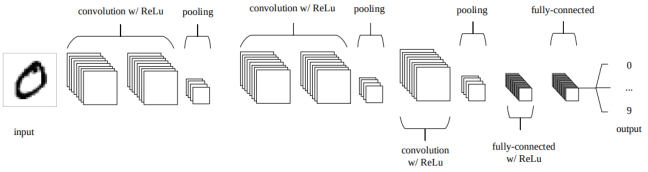
Ischemic stroke accounts for approximately 85% of all cases and occurs due to the occlusion of an arterial blood vessel, leading to the interruption of blood flow to a specific region of the brain [9].

The interruption of cerebral blood flow initiates a sequence of biochemical and cellular events known as the ischemic cascade [9], [10]. This blood deprivation is followed by a depletion of oxygen and glucose supply to the affected brain region; consequently, local cells undergo cell death via necrosis or apoptosis [9], [10]

According to its progression, ischemic stroke can be classified into three stages: acute (0–24 h), subacute (24 h–2 weeks), and chronic (more than 2 weeks) [11]. The efficacy of the treatment is directly related to the time elapsed until the onset of medical intervention for the stroke patient [5].

The diagnosis of IS relies on clinical and imaging assessment. Non-contrast head CT is widely used as the first-line imaging examination in emergency settings because it is fast, widely available, and effective for excluding intracranial hemorrhage [12]. However, the poor grayscale contrast of early ischemic changes can challenge radiologists and potentially contribute to diagnostic errors [13].

III. Convolutional Neural Network



Convolutional Neural Networks (CNNs) are a specific type of neural network uniquely tailored for computer vision applications due to their ability to hierarchically abstract representations through local operations [14].

In contrast to traditional neural networks that require input data to be flattened into a single dimension, CNNs retain the spatial architecture of the data. This characteristic makes them uniquely suited for processing images and other multidimensional datasets [15].

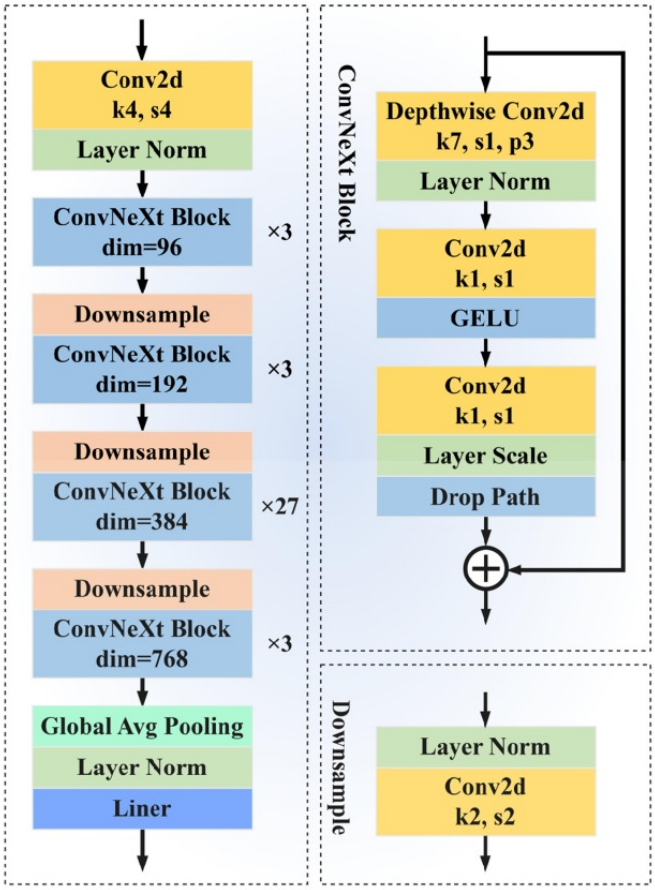
Feature extraction from CNN input data, as shown in Fig. 2, is performed through convolutional layers that apply spatial filters over the input to extract relevant patterns [16]. These features are then aggregated and processed by subsequent layers, such as *pooling* layers and fully connected layers [16].

In this work, the application of convolutional neural networks will be focused on extracting significant features from human brain CT scans. The goal is to detect the presence of any IS markers based on the learned characteristics.

Fig. 2. Baseline CNN's Architecture.

Source: [17].

A. ConvNeXt Architecture



The recent enhancement of CNNs is a response to the popularized use of *Vision Transformers* (ViTs) in computer vision tasks. ViTs, introduced in the conference paper by [18], are learning architectures that apply Natural Language Processing (NLP) principles to computer vision challenges. ViTs operate by partitioning the image into patches – a function performed by a dedicated 'patchify' layer – and treating them as a sequence of tokens analogous to words in a text [18]. The ViT algorithm enables superior performance when pre-trained on massive datasets (14–300 million images), requiring less computational cost and showing no signs of performance saturation as their scale is expanded [18], [19]. Conversely, CNNs – particularly modernized architectures such as ConvNeXt – remain competitive and efficient in small-dataset regimes due to their inherent local inductive bias [19], [20].

The ConvNeXt architecture is a family of residual CNNs that emerged from a process of refining and modernizing a standard network, specifically the ResNet (Residual Network) family [19]. This modernization took place during the architecture's training for image classification tasks using the ImageNet dataset. Subsequently, the efficacy of the final architecture was validated across other machine learning tasks, such as object detection and segmentation using the COCO dataset, and semantic segmentation through the ADE20K dataset [19].

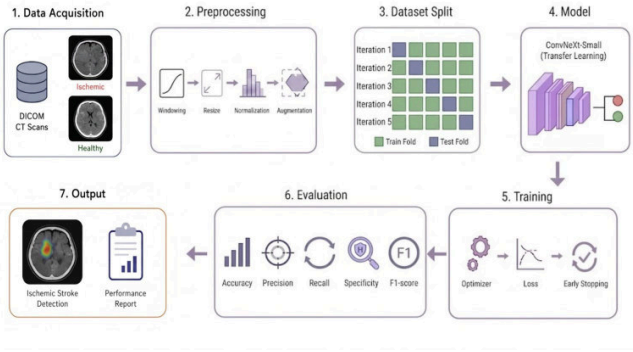
The ConvNeXt family comprises five variants: Tiny, Small, Base, Large, and XLarge; Fig. 3 illustrates the architecture in its Small configuration. The initial layer of ConvNeXt, known as the 'patchify' layer (represented by the Conv2d k4, s4 layer), partitions the input data into patches. This process is achieved by applying 4×4 kernels with a stride of 4, resulting in a non-overlapping convolution [19]. The input layer is followed by a normalization layer (Layer Norm) [19], [21]. These two initial layers are succeeded by four stages of ConvNeXt Blocks, where the number of blocks per stage is 3, 3, 27, and 3, respectively [19], [21]. The channel dimension increases at each stage from 96 to 192, 384, and 768; additionally, the last three stages of *ConvNeXt blocks* are preceded by a downsampling block [21]. At the end of the processing stages, the feature tensor passes through a global average pooling layer followed by a final Layer Norm. Lastly,

the tensor is transformed into a normalized feature vector that is fed into the final linear layer [19], [21].

Fig. 3. Block diagram of the ConvNeXt-Small architecture.

Source: [21].

The ConvNeXt architecture incorporates two sub-blocks within its structure, as shown in Fig. 3: the Downsample block and the ConvNeXt Block [21]. The Downsample block is composed of a Layer Norm followed by a 2×2 convolution (Conv2d k2, s2) [19], [21]. Notably, the spatial reduction performed by this block does not occur inside the residual blocks as seen in ResNets; this specific characteristic helps the ConvNeXt architecture retain critical spatial information and enhances training stability [19], [21].



The ConvNeXt block, shown in Fig. 3, is responsible for extracting features from the partitioned data originating from the model's initial layers [19]–[21]. The first layer of the block (Depthwise Conv2d) applies filters separately to each channel of the input data, saving memory and computational power during feature extraction [19], [20]. Following spatial feature extraction, the data pass through a single Layer Norm [21]. Replacing Batch Normalization with Layer Norm contributes to model convergence and helps mitigate overfitting, bringing the block closer to the simplicity of ViTs, which utilize fewer normalization layers [19], [21]. The subsequent layer applies a convolution operation called an inverted bottleneck to minimize feature loss and reduce computational cost [20], [21]. This operation is performed with the aid of two pointwise convolution operations; the first pointwise convolution (Conv2d k1, s1) expands the signal dimension by four times, while the second pointwise convolution (Conv2d k1, s1) contracts the signal back to its input dimensions [19]–[21]. Between these pointwise convolutional layers, a layer applying the GELU (Gaussian Error Linear Unit) activation function is integrated, replacing the ReLU (Rectified Linear Unit) function commonly found in traditional CNNs [19], [22]. This substitution is motivated by GELU's smoother graphical curve compared to ReLU and its widespread adoption in ViTs; mathematically, GELU is represented by Equation 1, where the term $\phi(x)$ denotes the cumulative distribution function of the Gaussian distribution [19], [22]. In the final stages of the *ConvNeXt block*, the tensor passes through the layer scale and drop path layers; the former stabilizes the network at the beginning of training, while the latter regularizes model training by randomly deactivating convolutional blocks [19]. Finally, the output of the drop path layer is added to the original input tensor via a shortcut connection, facilitating gradient propagation and mitigating the vanishing gradient effect [19]–[21].

$$GELU(x) = x * \phi(x) \tag{1}$$

IV. Methodology

This section details the methodological steps adopted in this work. Below, we describe the dataset utilized, the preprocessing techniques applied to the images, the characteristics of the employed classifier, the training strategy adopted, and the performance metrics used for model evaluation. The figure 4 shows the steps adopted.

Fig. 4. Methodological workflow.

Source: Authors.

A. Dataset

This work utilizes cranial computed tomography (CT) images obtained from two distinct datasets. The images from both datasets were jointly reviewed and labeled by a radiologic technologist and a physician, who assessed the examinations simultaneously. The final class assigned to each selected slice was established by consensus between the two evaluators,

according to the presence or absence of visible ischemic changes.

The first dataset was provided by the *Núcleo de Estudos e Pesquisa em Imagem* (NEPI) of the *Universidade Federal da Paraíba* (UFPB) and was approved by the institutional review board under protocol number 1,293,095 [3]. It is composed of cranial CT images with a spatial resolution of 512×512 pixels, stored in the DICOM format. Each CT examination contains approximately 20 axial slices. The acquisitions selected from this dataset had a slice thickness of 5 mm.

The second dataset, provided by [8], is also composed of cranial CT images with a spatial resolution of 512×512 pixels, stored in the DICOM format. However, these examinations present greater volumetric coverage, with approximately 200 axial slices per patient. The original dataset includes acquisitions with slice thicknesses of 3 mm, 5 mm, and 8 mm.

To reduce the variability associated with different acquisition protocols, only CT series acquired with a slice thickness of 5 mm were selected from both datasets. The same review, selection, and labeling procedure was applied to the images from both sources.

After the identification of examinations containing ischemic stroke, an axial-slice filtering procedure was jointly performed by the two evaluators. This step was necessary because the original examinations covered the entire cranium and included slices with little or no relevant anatomical information for ischemic stroke assessment. Therefore, slices lacking sufficient brain parenchyma, containing inadequate anatomical regions, or not allowing a reliable assessment of ischemic changes were excluded.

For the positive class, only slices presenting visible ischemic changes were included. For the negative class, only slices with sufficient brain parenchyma and no visible signs of ischemic stroke or any other apparent intracranial pathology were selected. Therefore, the negative samples were considered radiologically normal based on the joint visual assessment performed by the radiologic technologist and the physician. The final label assigned to each slice was established by consensus between the two evaluators.

The final dataset comprised 362 axial CT slices: 181 with visible ischemic changes and 181 radiologically normal-appearing slices. Each slice was treated as an independent sample for the binary classification task. The curated experimental record did not provide a reliable mapping of every selected slice to a unique patient or examination; consequently, the number of unique examinations in each fold cannot be reported retrospectively.

The classifier was evaluated using five-fold cross-validation. The dataset was divided into five folds while maintaining an approximately balanced distribution between the ischemic and normal-appearing classes. Partitioning was conducted at the slice level, not at the patient level. Thus, slices originating from the same patient or examination may have been assigned to different folds, creating a risk of information leakage through correlated anatomy and acquisition characteristics. In each iteration, four folds were used for model development, whereas the remaining fold was held out exclusively for testing. This procedure was repeated five times, so that each image was included in the test set once and was evaluated by a model that had not used that image during training. This protocol prevents reuse of the same slice across training and testing, but it does not constitute patient-independent or external validation and may therefore overestimate generalization.

B. Data Preparation

The selected CT images were submitted to a preprocessing pipeline before being used as input to the neural network. Initially, the DICOM images were read and the raw pixel values were converted to Hounsfield Units (HU) using the rescale slope and rescale intercept parameters available in the image metadata. This step was performed to preserve the physical interpretation of CT images intensities.

Afterward, an intensity windowing operation was applied to highlight brain tissue structures and reduce the influence of irrelevant intensity ranges, utilizing a window center of 0 HU and a window width of 150 HU. The windowed images were clipped and rescaled to an 8-bit grayscale representation. Then, the images were resized to the input resolution required by the ConvNeXt architecture (224×224 pixels). Since the pretrained model expects three-channel inputs, each grayscale slice was converted into a three-channel image by replicating the same intensity values across the channels.

Finally, the images were normalized according to the preprocessing function associated with the pretrained network. During training, data augmentation was applied exclusively to the training subset to reduce overfitting and improve model generalization. The augmentation operations included random rotations, spatial shifts, zoom transformations and horizontal flipping. No data augmentation was applied to the validation or test subsets.

C. ConvNeXt-Based Classifier

The classification model was built using a ConvNeXt-Small architecture pretrained on the ImageNet dataset. The use of transfer learning was adopted to take advantage of visual representations previously learned from large-scale image datasets, reducing the need to train the entire network from scratch.

The original classification head of the ConvNeXt model was replaced by a custom binary classification head. First, a Global Average Pooling 2D layer was used to convert the feature maps extracted by the convolutional backbone into a one-dimensional feature vector. Then, a layer normalization step was applied to stabilize the feature distribution. After that, a fully connected dense layer with 512 neurons and GELU activation was added to learn task-specific representations. A dropout layer with a rate of 50% was included to reduce overfitting. Finally, the output layer was composed of a single neuron with sigmoid activation, producing the probability of the input image belonging to the ischemic stroke class.

D. Training Strategy

The training process was divided into two stages. In the first stage, the ConvNeXt backbone was kept frozen, and only the

custom classification head was trained. This stage allowed the newly added layers to adapt to the CT images classification task without modifying the pretrained weights of the base model. The model was trained for up to 40 epochs using the Adam optimizer with an initial learning rate of 10^{-3}.

In the second stage, fine-tuning was performed by unfreezing the last 25% of the ConvNeXt backbone layers. This allowed the deeper layers of the network to adapt to the specific visual patterns present in brain CT images while preserving most of the pretrained representations. During this stage, the model was trained for up to 30 additional epochs using a reduced learning rate of 10^{-5}.

In both training stages, early stopping was used to monitor the validation loss and interrupt training when no improvement was observed. In addition, the ReduceLROnPlateau callback was applied to automatically reduce the learning rate when the validation loss reached a plateau.

The parameters used during the training of the ConvNeXt-Small-based classifier are presented in Table I. Adam's first-moment exponential decay coefficient was set to $\beta_1 = 0.9$, whereas the weight-decay coefficient was 0.001. Any unspecified parameters remained identical across both stages.

E. Performance Evaluation

The algorithm implemented for ischemic stroke detection in CT images was evaluated using performance metrics to measure its degree of efficiency in the classification task. Among the utilized metrics are Accuracy (Acc), Precision (P), Recall (R), F1-score ($F1$) and Specificity (Sp).

Accuracy, calculated using Equation 2, represents the proportion of all correct classifications, including both positive and negative results. It is generally employed as the standard evaluation metric for general or unspecified models performing non-specific tasks.

$$Acc = \frac{TP + TN}{TP + FP + TN + FN} \tag{2}$$

Precision, recall, and F1-score are mathematically represented, respectively, in Equations 3, 4 and 5.

$$P = \frac{TP}{TP + FP} \tag{3}$$

$$R = \frac{TP}{TP + FN} \tag{4}$$

$$F1 = 2 * \frac{P * R}{P + R} \tag{5}$$

Specificity, calculated via Equation 6, is used to evaluate the performance of a binary classification model, particularly in medical diagnosis or screening tests. It measures the ability of the model to correctly identify true negatives, or the proportion of actual negative cases correctly classified [23].

$$Sp = \frac{TN}{TN + FP} \tag{6}$$

In this classification task, True Positives (TP) represent positive samples correctly classified as positive, whereas False Positives (FP) denote negative samples erroneously classified as positive. Conversely, True Negatives (TN) define negative samples correctly classified as negative and False Negatives (FN) correspond to positive samples erroneously classified as negative.

In addition to the fold-wise mean and sample standard deviation, 95% Wilson score confidence intervals were calculated for the aggregate slice-level accuracy, precision, recall, and specificity. These intervals treat slices as independent observations and are provided only as descriptive measures. Because patient grouping was unavailable, they do not account for within-patient correlation and should not be interpreted as patient-level uncertainty estimates. Receiver operating characteristic area under the curve (ROC-AUC) could not be reconstructed from the retained hard-label predictions and confusion matrices and is therefore not reported.

V. EXPERIMENTAL RESULTS

This section presents the classification results obtained by the ConvNeXt-Small-based classifier using slice-level five-fold cross-validation. The CT slices were categorized into two classes: radiologically normal-appearing (class 0) and visible ischemic change (class 1). The dataset contained 181 slices from each class, totaling 362 samples.

The folds were constructed while maintaining an approximately balanced class distribution. The first test fold contained 37 samples from each class, whereas the remaining four folds contained 36 samples from each class. In each cross-validation iteration, four folds were used for model development and the remaining fold was used exclusively for testing. Therefore, each slice was evaluated once by a model that had not used that exact slice during training. Because folds were not grouped by

patient, this statement does not exclude the presence of other slices from the same examination in the development folds.

Table II presents the confusion matrix components and the performance metrics obtained for each test fold. The final results are reported as the mean and sample standard deviation across the five folds.

Across the five test folds, the classifier achieved a mean accuracy of $92.82\% \pm 1.78\%$. The highest accuracy was obtained in folds 4 and 5, both reaching 94.44%, whereas fold 2 presented the lowest accuracy, at 90.28%. The relatively low standard deviation indicates limited variation across these particular slice-level partitions; it does not establish stability across independent patients or institutions.

The classifier achieved a mean recall of $94.47\% \pm 4.39\%$, which was the highest average metric. Recall is particularly relevant in ischemic stroke screening because it represents the model's ability to correctly identify pathological cases. The recall ranged from 88.89% in fold 2 to 100.00% in fold 5. In fold 5, all ischemic stroke slices were correctly identified, resulting in no false-negative classifications.

The mean precision was $91.59\% \pm 3.13\%$, indicating that most slices classified as ischemic stroke were actually positive. The highest precision was obtained in fold 4, reaching 97.06%, as only one normal-appearing slice was incorrectly classified as ischemic stroke.

The classifier also achieved a mean specificity of $91.17\% \pm 3.58\%$, demonstrating its ability to correctly identify normal-appearing slices. The mean F1-score of $92.92\% \pm 1.85\%$ indicates a consistent balance between precision and recall across the five test folds.

To provide an overall representation of the classification behavior, the out-of-fold predictions from the five test subsets were combined to construct the aggregated confusion matrix shown in Fig. 5. Each slice contributed to this matrix only once and was classified while belonging to a held-out test fold.

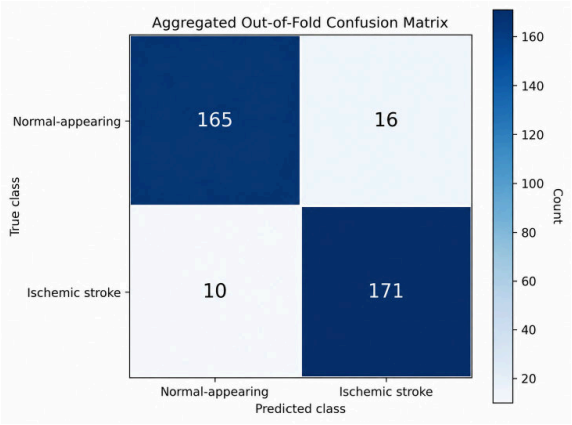

Fig. 5. Aggregated slice-level out-of-fold confusion matrix obtained using five-fold cross-validation. The negative class contains only radiologically normal-appearing slices.

Source: Authors.

The aggregated confusion matrix contained 165 true negatives, 16 false positives, 10 false negatives, and 171 true positives, corresponding to all 362 out-of-fold predictions. Based on this matrix, the classifier achieved an overall accuracy of 92.82%, precision of 91.44%, recall of 94.48%, specificity of 91.16%, and F1-score of 92.93%.

The corresponding descriptive 95% Wilson confidence intervals were 89.68–95.05% for accuracy, 86.55–94.66% for precision, 90.13–96.97% for recall, and 86.12–94.49% for specificity. These intervals use slices as the statistical units and consequently do not correct for correlations among slices from the same patient. ROC-AUC is not reported because only thresholded class labels and confusion-matrix counts were retained for this analysis; class probabilities would be required to calculate the ROC curve.

The number of false-negative predictions was lower than the number of false-positive predictions, indicating that the classifier tended to favor sensitivity. For a putative screening application, false-negative classifications would represent visible ischemic slices missed by the system. The occurrence of 10 false negatives, together with the non-independent validation protocol, precludes claims of clinical screening performance.

The misclassified samples may be associated with the subtle visual appearance of ischemic lesions in CT images, particularly when the attenuation difference between normal and affected brain tissue is low. Variations in lesion location, size, and ischemic stroke stage may also have influenced the classification performance across the different folds.

VI. Discussion

This study investigated the use of a ConvNeXt-Small-based classifier for the identification of ischemic stroke in computed tomography (CT) images. The proposed approach combined DICOM-based preprocessing, conversion to Hounsfield Units, intensity windowing, image resizing, normalization, data augmentation, and transfer learning using a modern convolutional architecture.

The model was evaluated using five-fold cross-validation. Across the five test folds, it achieved a mean accuracy of $92.82\% \pm 1.78\%$, precision of $91.59\% \pm 3.13\%$, recall of $94.47\% \pm 4.39\%$, specificity of $91.17\% \pm 3.58\%$, and F1-score of $92.92\% \pm 1.85\%$. The relatively low standard deviations observed for accuracy and F1-score describe consistency across the five slice-level partitions only. They should not be interpreted as evidence of generalization to independent patients, scanners, or institutions.

The aggregated out-of-fold confusion matrix contained 165 true negatives, 16 false positives, 10 false negatives, and 171 true positives. Based on these aggregated predictions, the classifier achieved an overall accuracy of 92.82%, precision of 91.44%, recall of 94.48%, specificity of 91.16%, and F1-score of 92.93%. The similarity between the mean cross-validation metrics and the aggregated results is expected because both summaries are derived from the same five sets of out-of-fold slice predictions.

Among the evaluated metrics, recall describes the fraction of selected ischemic slices identified by the classifier. The mean recall was 94.47%; in the aggregated evaluation, 171

TABLE II
SLICE-LEVEL CLASSIFICATION PERFORMANCE ACROSS THE FIVE TEST FOLDS.

Fold	TN	FP	FN	TP	Accuracy	Precision	Recall	Specificity	F1-score
1	33	4	2	35	91.89%	89.74%	94.59%	89.19%	92.11%
2	33	3	4	32	90.28%	91.43%	88.89%	91.67%	90.14%
3	32	4	1	35	93.06%	89.74%	97.22%	88.89%	93.33%
4	35	1	3	33	94.44%	97.06%	91.67%	97.22%	94.29%
5	32	4	0	36	94.44%	90.00%	100.00%	88.89%	94.74%
Mean ± SD	–	–	–	–	$\mathbf{92.82 \pm 1.78\%}$	$\mathbf{91.59 \pm 3.13\%}$	$\mathbf{94.47 \pm 4.39\%}$	$\mathbf{91.17 \pm 3.58\%}$	$\mathbf{92.92 \pm 1.85\%}$

of the 181 ischemic slices were correctly classified and 10 were incorrectly labeled as normal-appearing. Although recall varied from 88.89% to 100.00% across folds, these values apply to slices rather than patients and may be inflated by within-examination similarity across folds.

In a clinical setting, a missed ischemic stroke could delay therapeutic intervention. However, the present experiment neither measures the number of missed patients nor validates a clinical decision threshold. Accordingly, the model should be described as a preliminary research classifier, not as a validated screening or decision-support system.

The aggregated precision of 91.44% indicates that most slices classified as ischemic stroke were actually positive. However, 16 normal-appearing slices were incorrectly classified as ischemic. Although false positives may lead to additional clinical investigation, this type of error is generally considered less critical than false negatives in screening scenarios. The lower number of false negatives compared with false positives suggests that the classifier slightly favored sensitivity, prioritizing the detection of ischemic stroke cases.

Within the selected normal-appearing slices, the specificity was 91.16%. In addition, the aggregated F1-score of 92.93% indicates a favorable balance between precision and recall, suggesting that the high sensitivity was not obtained at the cost of an excessive number of false-positive classifications.

The study conducted by [24] employed a 3D attention-gated U-Net to predict the final size and location of ischemic stroke lesions, achieving a median AUC of 91%, specificity of 97%, sensitivity of 60%, and a median Dice similarity coefficient of 50%. The recall obtained in the present study was substantially higher than the sensitivity reported in that work. Nevertheless, the comparison must be interpreted carefully because lesion prediction and spatial localization constitute a more complex task than slice-level binary classification.

In comparison with the CNN-based approach proposed by [25], which achieved 92% accuracy, 92% precision, 87% recall, and 89% F1-score for clot classification, the ConvNeXt-Small-based classifier obtained slightly higher mean accuracy, substantially higher recall, and a higher F1-score. Its mean precision was slightly lower. These results indicate that the proposed model was more sensitive to pathological cases while maintaining a similar ability to avoid false-positive predictions.

The work of [26] proposed an automated early ischemic stroke detection system based on CNNs using CT images in DICOM format. Their method included several handcrafted preprocessing steps, such as Otsu-based segmentation, bone removal, cerebrospinal fluid elimination, and lesion-centered patch extraction. The reported testing accuracy was 92.96%, which is slightly higher than the mean accuracy of 92.82% obtained in the present study. However, the proposed approach employs ConvNeXt-Small transfer learning and performs slice-level classification using a more direct preprocessing pipeline, without relying on lesion-centered patch extraction.

Despite the promising results, some limitations must be considered. First, the dataset remained relatively small, containing 181 ischemic stroke slices and 181 normal-appearing slices. Although five-fold cross-validation reduced the dependence of the results on a single training and test partition, it does not replace validation using an independent external dataset.

Second, fold assignment was performed at the slice level without grouping by patient or examination. Anatomically adjacent slices from the same examination are correlated and can share patient-specific and scanner-specific characteristics. If such slices occurred in both development and test folds, the model could partly exploit these shared characteristics, producing optimistically biased estimates. Moreover, the number of unique examinations per fold was not retained in the curated experimental record. The current results therefore describe only slice-level discrimination and cannot be converted into patient-level sensitivity or specificity. A valid reassessment must first reconstruct patient identifiers, assign all slices from one examination exclusively to a single fold, report the number of patients and examinations in every partition, and aggregate slice probabilities using a prespecified patient-level decision rule.

Third, the negative class was restricted to radiologically normal-appearing slices. Consequently, specificity and false-positive counts refer only to differentiation from normal anatomy and do not measure discrimination against common emergency findings such as intracranial hemorrhage, tumors, chronic infarctions, postoperative changes, edema, or artifacts. A clinically representative test cohort must include these competing abnormalities.

Fourth, there was no independent external test set containing images acquired at different medical centers and using different CT scanners and acquisition protocols. External validation is necessary to determine whether the model can generalize to clinical conditions that differ from those represented in the training dataset. Although images were collected from two sources, they were pooled before cross-validation; hence, the second source was not used as an external validation cohort.

Finally, ischemic stroke may present subtle visual character-

istics, particularly during the acute phase, and two-dimensional slice-level classification does not fully incorporate the three-dimensional anatomical context of the lesion. Future work should evaluate larger and more diverse datasets, patient-wise cross-validation, patient-level classification, external validation, ROC-AUC from retained probabilities, cluster-aware confidence intervals, and comparisons with architectures such as ResNet, EfficientNet, Vision Transformers, and lightweight ConvNeXt variants.

Overall, ConvNeXt-Small separated the selected ischemic and normal-appearing slices in this preliminary experiment. The reported metrics should be treated as hypothesis-generating because the current design does not establish patient-independent or cross-domain generalization. Patient-wise re-evaluation, clinically diverse negative cases, and external validation are required before any screening claim.

VII. Conclusion

This study implemented a ConvNeXt-Small transfer-learning pipeline to distinguish selected CT slices with visible ischemic changes from radiologically normal-appearing slices. Under five-fold slice-level cross-validation, mean accuracy was $92.82\% \pm 1.78\%$ and mean recall was $94.47\% \pm 4.39\%$.

These results are preliminary. Because folds were not separated by patient, correlated slices from one examination may have appeared in both model-development and test data, potentially inflating the reported performance. The experiment also used only normal-appearing negative slices and did not assess hemorrhage, tumors, chronic infarctions, or other intracranial abnormalities. No patient-level or independent external validation was performed.

Accordingly, the proposed method should be regarded only as a slice-level research classifier for normal-appearing versus visibly ischemic images, not as a clinically validated diagnostic, triage, or screening tool. Before clinical claims can be considered, future work must keep all slices from each examination in the same partition, report examination-level sample sizes and metrics, retain probability outputs for ROC-AUC analysis, calculate cluster-aware confidence intervals, include clinically representative competing abnormalities, and validate the locked model on an external multicenter cohort with different scanners and acquisition protocols.

***Abstract*—Analysis of cell migration and invasion through Transwell membrane assays is fundamental to understanding the mechanisms involved in infections caused by *Trypanosoma cruzi* and *Toxoplasma gondii*. However, conventional evaluation of these assays relies on manual cell counting, a time-consuming process subject to observer variability. In this context, this study investigates the behavior of the generalist deep learning model Cellpose on dense Transwell microscopy images for instance segmentation and nucleus quantification. The computational dataset comprised 18 original optical microscopy images associated with manual binary annotations. Image preprocessing included grayscale conversion, Gaussian filtering, and Contrast-Limited Adaptive Histogram Equalization (CLAHE). Because the original annotations were binary, they were converted into instance masks using a marker-controlled watershed procedure. An automatic cell-diameter estimation protocol was applied, and non-overlapping 256 $\times$ 256 pixel patches were generated to increase the number of computational samples available for training while acknowledging the limited biological variability of the original dataset. Fine-tuning of the pre-trained *cyto3* architecture was performed across ten training runs to assess the consistency of model performance. To contextualize these results, the fine-tuned model was additionally compared against the non-fine-tuned *cyto3* network and a classical watershed baseline, and instance-level agreement was further characterized using object-to-object correspondence, Panoptic Quality, and Bland–Altman limits of agreement.The pipeline showed consistent pixel-level spatial overlap performance across runs, achieving a mean Dice coefficient of 0.718 $\pm$ 0.007, Intersection over Union (IoU) of 0.589 $\pm$ 0.007, precision of 0.875 $\pm$ 0.011, and recall of 0.636 $\pm$ 0.010, showing higher values for these pixel-level metrics than the non-fine-tuned Cellpose model and the watershed baseline. However, instance-level evaluation revealed a mean percentage counting error of 47.70% $\pm$ 1.01%, with a Bland–Altman analysis indicating a systematic tendency toward undercounting, particularly in high-density regions. These findings indicate that consistent spatial localization did not translate into reliable separation and quantification of individual nuclei. These results characterize the current Cellpose-based pipeline as a reproducible baseline for investigating automated segmentation in dense Transwell microscopy images while highlighting important limitations in instance separation and counting. Therefore, the current approach is not yet suitable as an unrestricted replacement for manual nucleus quantification.**

***Index Terms*—Cell motility, Deep learning, Instance segmentation, Optical microscopy, Transwell assay**

I. Introduction

Chagas disease, caused by the protozoan *Trypanosoma cruzi*, and toxoplasmosis, caused by *Toxoplasma gondii*, are still major public health concerns today. These two diseases are not only prevalent among vulnerable individuals, but also can be vertically transmitted, occasionally causing pregnancy complications and sequelae in infants [1], [2]. According to the World Health Organization (WHO), millions of people are currently infected with *T. cruzi* worldwide, but the situation is worse in Latin American countries [1]. The transmission pathway of toxoplasmosis is somewhat similar, since the infection acquired by a pregnant woman can cross to her fetus and cause damage to the eyes or nervous system ranging from mild to severe [2]. Therefore, to study how these infections

unfold at the cellular level, researchers rely on in vitro models. Transwell assays, which have emerged as an improvement to the earlier developed Boyden chamber technique, are widely used for this investigation because they provide an opportunity for the migration of cells through a porous membrane and subsequent fixation, staining, imaging, and quantification of the results [3].

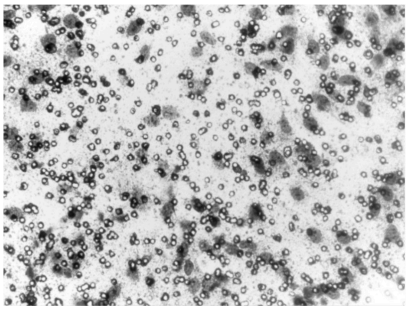
Usually, researchers count cells manually, which is time-consuming. To improve the outcomes of medication and techniques related to these protozoans, this study focuses on developing and evaluating an automated counting methodology based on a generalist deep learning model, investigating its behavior and reproducibility when applied to the segmentation of Transwell assay cells. Since this method relies on automated counting, it requires instance segmentation—treating each cell as its own distinct object rather than just labeling a blob of occupied pixels. This distinction is particularly important in Transwell images, where nuclei tend to cluster close together, cells overlap, and the membrane's pores can be mistaken for cell boundaries or vice versa. Cellpose offers a practical way around this. It is a generalist deep-learning model built for cell segmentation, and instead of just outputting a mask, it predicts flow fields that are then used to reconstruct individual cell instances even when objects are touching [4], [5]. This capacity to generalize across acquisition conditions and cell types, previously demonstrated on multiple microscopy modalities [4], [5], motivated its selection over classical pixel-grouping techniques for the dense, low-contrast Transwell images considered here. Building on this tool, this study aims to develop and evaluate a Cellpose-based pipeline for segmenting and automatically counting cell nuclei in optical microscopy images from Transwell assays. The focus throughout was threefold: making sure the training process was reproducible, measuring performance quantitatively rather than just qualitatively, and being transparent about where the method still falls short in a real experimental routine. In addition to the pixel-level metrics originally considered, the evaluation was further extended to include object-to-object correspondence, split and merge errors, Bland–Altman count agreement, and comparisons against a non-fine-tuned Cellpose model and a classical watershed baseline, together with an exploratory analysis of how cell density, image focus, and membrane pore pattern relate to segmentation error.

II. Materials and Methods

A. Dataset and Annotations

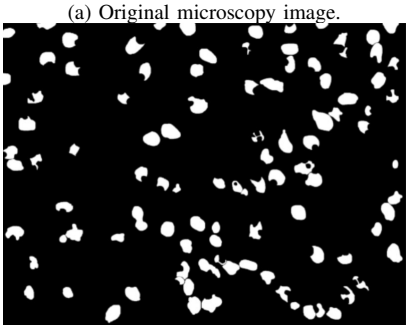
The images used in this study were obtained by optical microscopy of Transwell-based assays. In total, the pipeline processed 18 original images, each paired with its corresponding manual mask. These masks were produced in Napari and were initially simple binary annotations, with background pixels set to zero and cellular regions set to a non-zero value. To avoid any silent mismatch that could invalidate the results, image-mask pairing was performed by matching file names, and this pairing was checked at every stage of the pipeline.

These 18 images are part of a broader experimental set comprising two independent experiments with three biological replicates each, totaling 42 Transwell membranes, from which five fields were randomly acquired per membrane. Samples were stained with the Panotic Rapid Staining Kit (Laborclin, Pinhais, PR, Brazil) and imaged on an Opton light microscope using a $40\times$ objective and a total magnification of $400\times$, with the same acquisition protocol and settings applied to every image. Regarding the manual-reference protocol, the ground-truth annotations were independently performed using the Napari software by trained bioscientists from our team who were blinded to the deep learning model outputs. Annotations strictly followed morphological criteria to delineate nuclear boundaries based on characteristics such as nuclear shape, size, staining intensity, visible internal structures, and the presence of cytoplasm surrounding the nucleus Although the broader dataset also included uninfected controls, *T. cruzi*-infected controls, and infected groups treated with different compounds, the available file identifiers did not allow images to be unambiguously traced back to their originating membrane or biological replicate; consequently, infection condition was not used as a stratification variable in the present analysis, and the original image—rather than the membrane or replicate—was adopted as the primary unit for data splitting, in order to minimize the risk of information leakage between training, validation, and test sets.



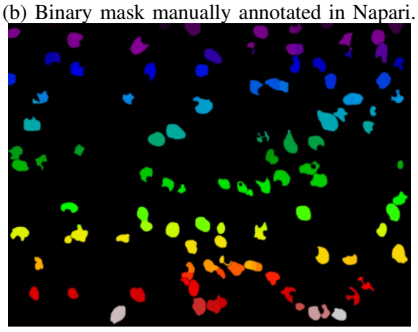
B. Image Preprocessing

Each image was converted to grayscale and normalized to the 8-bit range; when a multichannel image was read in, only its first channel was kept as the model input. To smooth out small acquisition artifacts, a 3×3 Gaussian filter was applied. To improve local contrast, the images were processed through Contrast-Limited Adaptive Histogram Equalization (CLAHE), which is well suited to microscopy images with uneven illumination since it boosts visibility in dim regions without amplifying noise in areas that are already fairly uniform [6].



C. Converting Binary Masks into Instance Masks

Because the original annotations were binary, it was impossible to distinguish between two touching nuclei. The original microscopy image, the binary mask manually produced in Napari, and the resulting instance mask after watershed processing are shown in Fig. 1(a), Fig. 1(b), and Fig. 1(c), respectively. In the binary annotation, the code interpreted connected Regions of Interest (ROIs) as a single cell, even when they represented two or more connected foreground regions. To address this limitation and make instance-segmentation training possible, each binary mask was converted into a labeled instance mask using a Euclidean distance transform followed by watershed.



For the watershed step, markers were placed at the local maxima of the distance map, with a minimum peak-to-peak distance of 8 pixels. This classic flooding-based approach can help separate two objects when a visible constriction is present between them [7]. Once watershed finished, every resulting

(b) Binary mask manually annotated in Napari.

(c) Instance mask generated after watershed processing.

Fig. 1. Methodological workflow for converting binary annotations into individual instance masks prior to deep learning training: (a) raw optical microscopy image acquired from a Transwell membrane migration assay; (b) binary foreground reference mask manually traced using the Napari software; and (c) processed instance mask generated via Euclidean distance transform and marker-controlled watershed flooding to isolate overlapping cellular structures.

cell instance was assigned its own sequential label. In addition, objects smaller than 30 pixels were discarded, since they fall outside the scope of what this study intends to count. This threshold approximates the typical area of the Transwell membrane's pores, structures whose shape and local contrast can resemble small nuclei; excluding them was intended to reduce membrane-related false positives rather than to discard genuinely small cells. Because pore appearance varies across fields and cannot be fully anticipated a priori, its potential influence on segmentation performance was further examined as part of the exploratory stratified analysis described in Section II-L and reported in Section III.

D. Estimating Cell Diameter and Extracting Patches

To improve network accuracy, the cell diameter was estimated directly from the masks used for training. For each labeled instance, an equivalent diameter was computed from its area using

$$d = 2\sqrt{\frac{\text{area}}{\pi}}, \tag{1}$$

and the median of these values across all training instances was used as Cellpose's diameter parameter, which was set to 49.57 pixels.

Additionally, because the dataset was limited to 18 images, a data augmentation strategy based on spatial cropping was applied; the images and masks were cropped into non-overlapping 256x256 pixel patches using a stride equal to the patch size. Only patches containing at least three cell instances and at least 200 mask pixels were retained; the remaining patches were discarded as too sparse for training. This filtering resulted in 627 valid patches, while 237 patches were discarded for not meeting the minimum requirements.

E. Data Split

The valid patches were split into three sets: 70% for training, 15% for validation, and 15% for testing. The splitting procedure was performed at the original-image level rather than patch-wise, so that all patches from one original image belonged to the same set. A random seed of 42 was used to ensure reproducibility. This resulted in 428 training patches, 128 validation patches, and 71 test patches.

F. Cellpose Model and Training

The segmentation process utilized Cellpose, where the pre-trained *cyto3* model was used as the starting point rather than training from scratch [4], [5]. The dataset consisted of 8-bit image files labeled with instance masks; mask files were denoted by adding "_masks.tif" to their name. Training was performed through the Python interface of Cellpose for 100 epochs using a batch size of 4, a learning rate of 0.005, a weight decay of 2×10^{-3}, and `min_train_masks = 1`. To regulate epoch transitions within the Cellpose framework, an internal stochastic sampling parameter was set to draw 100 training patches and 40 validation patches per epoch from the available data pool, allowing the optimization algorithm to process uniform data increments independently of the total partition sizes. For inference, the trained model was executed on the test set using the estimated median diameter and the default `[0,0]` grayscale channel configuration. All computational training and inference procedures were executed on a workstation equipped with an Intel Core i7-9750H CPU @ 2.60 GHz, 16 GB of RAM, and an NVIDIA GeForce GTX 1660 Ti (6 GB) GPU.

All hyperparameters above were defined *a priori* from values reported in the literature for fine-tuning instance-segmentation networks on microscopy datasets of limited size, and were not adjusted based on performance on the validation or test sets, so as to avoid parameter-selection bias. In particular, the learning rate and batch size adopted here are of the same order of magnitude as values used for fine-tuning cell instance-segmentation architectures under variable acquisition conditions [18], while the 100-epoch training schedule follows

fine-tuning protocols previously reported for Cellpose itself [5].

G. Compared Methods

To contextualize the performance of the fine-tuned pipeline, two additional baselines were considered: the pre-trained *cyto3* model without any Transwell-specific fine-tuning, and a classical marker-controlled watershed segmentation applied directly to the preprocessed grayscale images, without any deep-learning component. This comparison is intended to characterize the gain associated with domain adaptation and to provide a reference against a conventional image-processing technique, rather than to serve as an exhaustive benchmark against other instance-segmentation architectures.

H. Evaluation Metrics

Performance was evaluated at two complementary levels: pixel-level overlap metrics and instance-level counting errors. Pixel-level metrics were used to quantify how well the predicted cellular regions overlapped with the reference masks, regardless of whether each nucleus was correctly separated as an individual object. For this analysis, both the reference and predicted masks were binarized, so that any non-zero pixel was considered part of a cellular region.

After binarization, true positives (TP) were defined as pixels correctly classified as cell, false positives (FP) as pixels predicted as cell but absent from the reference mask, and false negatives (FN) as reference-cell pixels missed by the model. Based on these values, the Dice coefficient was calculated according to (2). Dice measures the overlap between the predicted and reference cellular regions, with higher values indicating better agreement between the two masks [8].

$$\mathrm{Dice} = \frac{2\mathrm{TP}}{2\mathrm{TP} + \mathrm{FP} + \mathrm{FN}} \tag{2}$$

The Intersection over Union (IoU), also known as the Jaccard index, was calculated according to (3). This metric represents the ratio between the intersection and the union of the predicted and reference cellular areas, providing a stricter overlap measure than Dice [9].

$$\mathrm{IoU} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FP} + \mathrm{FN}} \tag{3}$$

Precision was calculated according to (4) and indicates the proportion of predicted-cell pixels that actually corresponded to cellular regions in the reference mask. Therefore, precision is useful for identifying the extent to which the model incorrectly labels background regions as cells.

$$\mathrm{Precision} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FP}} \tag{4}$$

Recall was calculated according to (5) and represents the proportion of reference-cell pixels correctly detected by the model. In this context, recall is particularly important because low recall indicates that part of the true cellular area was missed during segmentation.

$$\mathrm{Recall} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FN}} \tag{5}$$

Together, Dice, IoU, precision, and recall provide complementary information about segmentation quality. Dice and IoU evaluate spatial agreement between masks, while precision and recall help distinguish between false-positive and false-negative segmentation behavior [10].

In addition to pixel-level overlap, instance-level counting errors were calculated to evaluate whether the model could correctly estimate the number of individual nuclei. This analysis was necessary because good pixel-level overlap does not necessarily imply accurate cell counting, especially when adjacent nuclei are merged into a single predicted instance.

The absolute counting error was calculated according to (6), where N_{pred} is the number of predicted instances and N_{ref} is the number of reference instances.

$$E_{\mathrm{abs}} = |N_{\mathrm{pred}} - N_{\mathrm{ref}}| \tag{6}$$

The percentage counting error was calculated according to (7). This metric expresses the counting error relative to the reference number of nuclei, allowing comparison across patches with different cell densities.

$$E_{\mathrm{perc}} = 100 \times \frac{|N_{\mathrm{pred}} - N_{\mathrm{ref}}|}{N_{\mathrm{ref}}} \tag{7}$$

I. Object-to-Object Evaluation

In addition to pixel-level overlap and the raw counting error above, one-to-one correspondence between reference and predicted instances was established by maximizing IoU between objects. A match was considered a true positive when

$$\mathrm{IoU}_{\mathrm{object}} \geq 0.50. \tag{8}$$

From these matches, instance-level precision and recall were computed, together with Segmentation Quality (SQ), Recognition Quality (RQ), and Panoptic Quality (PQ), defined as

$$PQ = SQ \times RQ. \tag{9}$$

Object Dice was computed between correctly matched instance pairs, providing a measure of geometric agreement restricted to the objects the model actually detected.

J. Split and Merge Errors and Count Bias

To characterize structural counting errors beyond the aggregate E_{abs} and E_{perc}, split and merge events were also identified using a minimum-overlap criterion of 10% of an object's area. A split error was recorded when a single reference instance overlapped meaningfully with two or more predicted instances, and a merge error was recorded when a single predicted instance overlapped meaningfully with two or more reference instances. The structural split/merge analysis reported below was performed on the 71 stored prediction masks from Run 10, which could be directly matched to

the corresponding reference instance masks. Therefore, these structural-error counts are reported as a run-specific diagnostic and are not interpreted as an across-run average. Count bias was further defined as

$$\text{Bias} = N_{\text{pred}} - N_{\text{ref}}, \tag{10}$$

with negative values indicating a tendency toward undercounting and positive values indicating overcounting.

K. Bland–Altman Analysis

Agreement between automated and reference counts was further examined using the Bland–Altman method. For each patch i, the difference

$$d_i = N_{\text{pred},i} - N_{\text{ref},i} \tag{11}$$

was computed, and the 95% limits of agreement were obtained as

$$\text{LoA} = \bar{d} \pm 1.96\, s_d, \tag{12}$$

where s_d is the standard deviation of the differences.

L. Density, Focus, and Pore Pattern Analyses

To investigate whether segmentation difficulty was uniformly distributed across images, three exploratory stratified analyses were performed on the test set. Cell density was estimated from the number of reference instances per patch, and patches were split into low-, medium-, and high-density tertiles. Relative focus quality was estimated from the variance of the Laplacian of the original image prior to CLAHE and Gaussian filtering, with higher values representing greater high-frequency content and, consequently, sharper images; patches were similarly split into low-, medium-, and high-focus tertiles. Finally, because no dedicated manual pore annotations were available, the influence of the membrane pore pattern was assessed through an automated proxy that quantified the number, density, and geometric characteristics of pore-like regions; this variable is treated strictly as an exploratory descriptor of membrane structure rather than as validated pore segmentation. As noted in Section II-L, infection condition could not be used as an additional stratification variable due to the lack of unambiguous replicate identifiers in the available files.

Taking all of these complementary metrics into consideration—spatial, instance-level, and error-structure—the evaluation combined pixel-level segmentation, object-level correspondence, and counting-based analysis. This hybrid approach was essential because the pipeline's ultimate goal was not only to isolate cellular regions but also to support the automated quantification of individual cell nuclei, and because the extent of that limitation could itself depend on image- and patch-level characteristics such as density, focus, and pore pattern.

(a) Original patch. (b) Reference mask. (c) Model prediction.

Fig. 2. Representative qualitative evaluation of the trained Cellpose framework on a 256 × 256 pixel testing patch: (a) original microscopy crop displaying target nuclei as dark circular structures against a heterogeneous background; (b) expert-annotated reference mask defining ground truth boundaries; and (c) automated instance boundaries predicted by the fine-tuned *cyto3* model, showing areas of spatial agreement alongside local edge discrepancies in dense clusters.

III. Results

Fig. 2 shows a qualitative example of the segmentation obtained for a 256×256 pixel patch. The original microscopy image is presented in Fig. 2(a), the manually annotated reference mask is shown in Fig. 2(b), and the model prediction is shown in Fig. 2(c). In the original patch, the cell nuclei appear as dark circular structures over a heterogeneous background, while the reference mask highlights the nuclei selected as annotated regions. The prediction shows that the model was able to detect several cellular regions with spatial coherence. However, some discrepancies can still be observed, especially in areas with low contrast, clustered structures, or regions with visual characteristics similar to nuclei. This qualitative example is consistent with the quantitative findings, showing spatial localization of several cellular regions while also illustrating limitations in precise instance-level counting.

Table I presents the pixel-wise segmentation performance across ten independent runs of the experiment. To examine between-run variability and training repeatability, the fine-tuning procedure was independently restarted from the pre-trained *cyto3* initialization at the beginning of each run. Across the ten runs, relatively small differences were observed in the global mean values for Dice (0.718 ± 0.007), IoU (0.589 ± 0.007), precision (0.875 ± 0.011), and recall (0.636 ± 0.010). This low between-run variability suggests that, under the evaluated training conditions, the reported pixel-level performance was not strongly dependent on a particular run.

The ten independent training runs resulted in the counting errors shown in Table II. The absolute counting error remained stable from run to run, varying between a minimum value of 2.72 cells/patch and a maximum value of 2.89 cells/patch, with an overall mean value of 2.79 ± 0.06 cells/patch. The percentage counting error also showed little variability across the ten training runs, ranging from 46.06% to 49.17%, with a mean value of $47.70\% \pm 1.01\%$. This indicates that the counting error showed relatively low variability across the evaluated training runs. However, the magnitude of the percentage error indicates an important limitation of the proposed pipeline. In other words, even though the model produced consistent results among training runs, it could not accurately quantify the number of individual cell nuclei. This suggests that missed

9	0.722 ± 0.187	0.594 ± 0.200	0.872 ± 0.176	0.645 ± 0.211
10	0.718 ± 0.183	0.587 ± 0.195	0.875 ± 0.174	0.634 ± 0.205
Mean ± Std	$\mathbf{0.718 \pm 0.007}$	$\mathbf{0.589 \pm 0.007}$	$\mathbf{0.875 \pm 0.011}$	$\mathbf{0.636 \pm 0.010}$

Note: Each run represents an independent fine-tuning lifecycle restarted from the pre-trained *cyto3* initialization. Values within each individual run row express the mean performance across all test patches (± standard deviation reflecting spatial and biological image variability). The final "Mean ± Std" row presents the global average across the ten runs (± standard deviation reflecting between-run variability).

TABLE II
QUANTITATIVE INSTANCE-BASED CELL COUNTING ERRORS AND DEVIATIONS ACROSS TEN INDEPENDENT TRAINING RUNS

Run	Absolute Counting Error (Mean ± Std)	Percentage Counting Error (%) (Mean ± Std)
1	2.89 ± 1.98	$49.17\% \pm 19.16\%$
2	2.72 ± 1.87	$47.03\% \pm 20.80\%$
3	2.83 ± 1.88	$48.71\% \pm 19.22\%$
4	2.73 ± 1.93	$46.70\% \pm 21.66\%$
5	2.85 ± 1.98	$48.57\% \pm 20.71\%$
6	2.77 ± 1.88	$47.90\% \pm 21.38\%$
7	2.73 ± 2.00	$46.75\% \pm 21.36\%$
8	2.83 ± 1.99	$48.06\% \pm 22.20\%$
9	2.72 ± 1.97	$46.06\% \pm 22.39\%$
10	2.83 ± 1.97	$48.04\% \pm 22.25\%$
Mean ± Std	$\mathbf{2.79 \pm 0.06}$	$\mathbf{47.70\% \pm 1.01\%}$

Note: Each run represents an independent experimental lifecycle where the model's weights were reset and retrained. Values within each individual run row express the mean counting error across all test patches (± standard deviation reflecting patch-level variability). The final "Mean ± Std" row presents the global average across the ten independent runs (± standard deviation reflecting training reproducibility).

TABLE III
QUANTITATIVE COMPARISON OF THE SEGMENTATION METHODS

Method	Dice	Inst. Prec.	Inst. Rec.	Obj. Dice	PQ	Error (%)
Pre-trained Cellpose	0.165	0.067	0.133	0.321	0.064	103.09
Fine-tuned Cellpose	0.720	0.957	0.552	0.862	0.529	42.11
Watershed	0.467	0.078	0.485	0.705	0.091	600.72

nuclei and merged neighboring instances may contribute substantially to the observed counting error, particularly in densely populated regions of the images.

A. Comparison Across Methods

Table III summarizes a direct comparison, on the same test set, between the fine-tuned Cellpose pipeline described above, the non-fine-tuned *cyto3* model, and classical watershed. Fine-tuned Cellpose achieved a Dice of 0.720, an instance precision of 0.957, and a PQ of 0.529, with higher values for these metrics than both evaluated baselines. Pre-trained Cellpose achieved a Dice of 0.165 and a percentage counting error of 103.09%, suggesting limited suitability of the non-adapted generalist model for this specific image domain. Watershed achieved a pixel-level Dice of 0.467 but a substantially higher percentage counting error of 600.72%, consistent with marked over-segmentation.

TABLE IV
RUN 10 STRUCTURAL INSTANCE ERRORS ON THE 71 TESTING PATCHES

Measure	Value
Testing patches	71
Reference instances	395
Predicted instances	198
Split errors	0
Merge errors	39
Patches with at least one merge	29/71 (40.8%)
Merge errors per patch	0.55 ± 0.79
Run 10 count bias	-2.77 nuclei/patch
Run 10 95% limits of agreement	$[-6.77,\ 1.22]$

B. Instance-Level Metrics and Count Agreement

For the fine-tuned model, instance-level evaluation yielded a precision of 0.957, a recall of 0.552, an Object Dice of 0.862 for correctly matched pairs, SQ of 0.774, RQ of 0.670, and PQ of 0.529. The Object Dice of 0.862 for correctly matched pairs indicates relatively strong geometric agreement among matched instances, while the lower instance recall suggests that an important limitation is the recovery of all nuclei present in the reference.

Bland–Altman analysis indicated a mean bias of -1.98 nuclei per patch for the fine-tuned model, with 95% limits of agreement of $[-4.83,\ 0.86]$, consistent with a systematic tendency toward undercounting. The pre-trained model showed the opposite pattern, with a mean bias of $+3.65$ nuclei per patch (limits of agreement: -3.38 to 10.68), while watershed showed pronounced overcounting, with a mean bias of $+24.90$ objects per patch (limits of agreement: 6.75 to 43.06). Among the three evaluated methods, the fine-tuned model showed closer count agreement with the reference, although a relevant tendency toward underestimating the number of nuclei remained.

C. Split and Merge Error Analysis

A structural error analysis was performed using the 71 stored prediction masks from Run 10, which reproduced the pixel-level and counting results reported in Tables I and II. Across these patches, the reference masks contained 395 labeled nuclei versus 198 predicted instances. No split errors were identified under the 10% minimum-overlap criterion, whereas 39 predicted instances were classified as merge errors, occurring in 29/71 patches (40.8%, 0.55 ± 0.79 merges/patch).

This run's count bias was -2.77 nuclei/patch (95% limits of agreement: $[-6.77,\ 1.22]$), consistent with undercounting driven mainly by fusion of neighboring nuclei rather than missed detections. As split/merge analysis was performed for Run 10 only, these values are reported separately from the across-run and method-comparison statistics.

D. Influence of Cell Density, Focus, and Pore Pattern

Performance decreased as cell density increased: Dice fell from ≈ 0.81 (low density) to ≈ 0.72 (medium) and ≈ 0.63 (high), PQ decreased from ≈ 0.62 to ≈ 0.52 to ≈ 0.45, and

counting error rose from $\approx 31\%$ to $\approx 50\%$, indicating that cellular crowding is an important factor associated with reduced performance. Focus quality also influenced results, with lower Dice (≈ 0.66) and PQ (≈ 0.42) in the least-sharp tertile than in the intermediate tertile (Dice ≈ 0.77, PQ ≈ 0.61), though the relationship was not strictly monotonic (PQ ≈ 0.56 in the sharpest tertile). The exploratory pore-pattern proxy showed only weak correlations with Dice, PQ, and counting error, suggesting its influence depends on factors beyond pore count, such as contrast and morphological similarity to nuclei.

IV. Discussion

Fine-tuning Cellpose produced spatially coherent segmentations of Transwell images. The ten independently restarted fine-tuning runs provided an assessment of between-run variability under the evaluated training conditions. The relatively low standard deviation across runs suggests that the reported metrics were reasonably repeatable in this setting and reduces, without eliminating, concern that the observed performance was specific to a single run.

The higher precision than recall is consistent with a relatively conservative prediction pattern. Precision and recall, originally formalized in the information retrieval literature [11] and now standard across binary classification tasks [12], capture two different kinds of error: precision penalizes false alarms, while recall penalizes missed detections [13]. In this case, the algorithm is reluctant to label background as cell, but that caution comes at a cost—it also misses a meaningful share of genuine cellular regions. Whether that trade-off is acceptable depends on what the pipeline is being used for. For cell counting specifically, however, false negatives and instance fusion are the more damaging failure modes, since both directly lower the estimated cell count.

The main methodological limitation traces back to how the training masks were built. Because the manual annotations started out as binary masks, instance separation had to be done after the fact using watershed on the distance transform [7]. This approach performs adequately when cells are touching but have some visible constriction between them; it is far less reliable when cells overlap heavily or when no clear neck separates adjacent nuclei. This failure mode—neighboring cells being merged, or valid instances being suppressed in crowded regions—is well documented for classical pixel-grouping approaches to nucleus segmentation, and is part of the motivation behind alternative strategies such as StarDist, which predicts a star-convex shape for each nucleus directly instead of separating instances after the fact [14]. In our case, the derived reference mask itself likely already contains some under-segmentation, meaning the model was partly learning from imperfect ground truth.

That limitation goes a long way toward explaining what otherwise looks like a contradiction: moderately strong overlap metrics alongside a high counting error. Dice and IoU [8], [9], [15] are computed at the pixel level, capturing how well the predicted cellular area aligns with the reference. The counting error, by contrast, is an instance-level metric. A model can segment the area of a dense cell cluster correctly, scoring well on Dice, while still treating that cluster as a single cell rather than several. For this particular problem, neither type of metric tells the full story on its own; reading them together is necessary to understand what the model is actually doing well and where it falls short. This is consistent with longstanding guidance in the medical image segmentation literature that metric choice should be matched to the specific needs of the task [15].

The comparison against the two baseline methods reinforces this picture. Adapting Cellpose to the Transwell domain increased Dice from approximately 0.165 to 0.720 and PQ from approximately 0.064 to 0.529, suggesting that the non-adapted generalist architecture has limited performance on these dense, low-contrast images and that domain-specific fine-tuning contributed substantially to the improvement observed under the conditions evaluated here. Watershed showed essentially the opposite failure mode to the fine-tuned network: its comparatively higher pixel-level Dice came with very low instance precision and pronounced overcounting, illustrating that recovering most of the cellular area is not necessarily sufficient when the end goal is accurate quantification.

The Run 10 split/merge analysis provides direct evidence for the structural origin of part of the counting error. Under the predefined overlap criterion, no split events were detected, whereas 39 predicted objects were classified as merges and 40.8% of test patches contained at least one merge. This asymmetry is consistent with the negative Run 10 count bias and supports the interpretation that adjacent nuclei were frequently fused into single predicted instances. Importantly, these values characterize the stored predictions from one training run and should not be interpreted as mean structural-error rates across all ten runs.

The stratified analysis by cell density further suggests that crowding is an important contributor to counting error, although image acquisition characteristics may also play a role. Performance declined steadily from low- to high-density patches, both in overlap metrics and in PQ, while the percentage counting error nearly doubled between the least and most crowded groups. Focus quality also modulated performance, though less consistently, and the exploratory pore-pattern proxy showed no strong association with segmentation error, suggesting that pore-related false positives are better explained by local contrast and morphology than by pore count alone.

Taken together with the ten-run variability analysis presented in Section III, these findings suggest that the fine-tuned pipeline showed relatively stable performance across the evaluated runs while retaining important limitations in separating touching nuclei. Thus, low between-run variability should not be interpreted as evidence of adequate counting performance; both repeatability and instance-level error need to be considered when assessing the practical usefulness of the pipeline.

From a practical standpoint, the pipeline provides a potential foundation for further investigation of automated Transwell image analysis—it standardizes preprocessing, docu-

ments training parameters explicitly, and may reduce some of the variability associated with manual segmentation. That said, treating it as a full replacement for manual counting would be premature while the percentage counting error remains around 48%, particularly in densely populated fields. Future iterations could also leverage built-in restoration modules such as those introduced in Cellpose3 [16] to mitigate the focus- and contrast-related errors identified above.

A methodological limitation that should be made explicit concerns the experimental unit underlying these analyses. Although all patches derived from the same image were kept within the same data split, the available metadata did not allow images to be unambiguously traced back to their originating membrane or biological replicate. Patches—and, to a lesser extent, the 18 original images themselves—should therefore not be treated as fully independent biological observations, and the density-, focus-, and pore-stratified analyses in particular should be regarded as exploratory rather than confirmatory.

V. Conclusion

This paper describes the creation and evaluation of a Cellpose-based pipeline for cell nucleus segmentation and automatic counting in optical microscopy images from Transwell assays. The proposed approach comprises conversion of binary masks into instance masks, automatic estimation of cell diameter, patch generation, image-level data splitting, and fine-tuning of the pre-trained *cyto3* model.

Throughout all ten training sessions, segmentation quality was consistent, with mean Dice of 0.718 ± 0.007 and IoU of 0.589 ± 0.007. Given the precision, relatively low recall, and $47.70\% \pm 1.01\%$ counting error, these results indicate that the pipeline still has substantial difficulty reliably detecting and separating individual cell nuclei, particularly in densely packed areas. The run-specific structural analysis further showed 39 merge errors and no detected split errors in the stored Run 10 predictions, reinforcing instance fusion as an important source of undercounting. When directly compared against a non-fine-tuned Cellpose model and a classical watershed baseline, the fine-tuned pipeline showed higher overlap (Dice of 0.720 versus 0.165 and 0.467, respectively), instance precision (0.957), and Panoptic Quality (0.529) than the two evaluated baselines, while still showing a systematic tendency toward undercounting, particularly in high-density regions, where the percentage counting error approached 50%.

Overall, the proposed pipeline provides an experimental framework for investigating automated Transwell image analysis and may help reduce the amount of manual processing required. Under the evaluated conditions, it showed better performance on several reported metrics than the non-adapted generalist model and the classical image-processing baseline. However, it cannot yet be viewed as a replacement for manual counting due to the noted counting error and its dependence on cell density. Future work should focus on generating manual annotations in instance format directly, particularly for densely packed areas; documenting membrane and biological-replicate identifiers so that data can be split and analyzed at the appropriate experimental unit, including stratification by infection condition; benchmarking against other instance-segmentation architectures, such as StarDist and U-Net-based approaches [17]; and validating the pipeline on larger, multicenter datasets acquired under different imaging conditions.

***Abstract*—Breast cancer represents a major public health concern, and mammography is one of the main tools used for its early detection. However, the presence of noise, low contrast, and morphological variations in lesions can hinder the automatic identification and delineation of breast nodules. In this context, this study investigates an interpretable computational framework for the classification of preselected mammographic regions of interest and the subsequent delineation of nodule regions, using a decision tree, preprocessing steps, Chan-Vese active contours, and marker-controlled Watershed Transform. The method was evaluated using 226 regions of interest extracted from the INbreast database, including 113 ROIs with nodules and 113 ROIs without nodules. Initially, the ROIs were classified based on intensity and texture metrics, such as mean, median, variance, percentiles, entropy, and GLCM features. Subsequently, the images classified as containing nodules were subjected to normalization, anisotropic diffusion filtering, contrast stretching, definition of internal and external markers, and Watershed-based segmentation. The classification stage achieved a mean accuracy of 79.96%, sensitivity of 73.45%, and specificity of 86.48%. In the segmentation stage, the method obtained a mean Dice coefficient of 0.73, a mean eccentricity difference of 0.13 compared with the gold standard, and a higher concentration of area percentage errors within the 0–20% range.**

***Index Terms*—Breast Cancer; Classification; Image Preprocessing; Region of Interest; Segmentation.**

I. Introduction

Breast cancer is a condition characterized by the uncontrolled growth and division of abnormal cells in breast tissue, which may compromise the normal organization of the mammary tissue and interfere with the proper functioning of the organism [1]. Due to this biological behavior and its high incidence in the population, breast cancer represents a major global public health concern [2], [3].

According to the International Agency for Research on Cancer (IARC), this disease accounted for 2.3 million new cases in 2022 and remains the leading malignancy among women worldwide. Recent projections indicate that the annual incidence may escalate to 3.2 million cases and 1.1 million deaths by 2050, underscoring the critical importance of population-based screening, early diagnosis, and optimized therapeutic workflows [2], [3].

In this context, mammography emerges as an important tool for the early detection of breast cancer, as it is capable of identifying lesions even before they become palpable, thereby increasing the chances of successful treatment. However, the interpretation of mammographic images remains challenging, particularly due to the presence of noise, low contrast, and overlapping anatomical structures. These factors, which are associated with diffuse radiation and the composition of breast tissue, may compromise lesion identification and contribute to misdiagnosis rates ranging from 10% to 30% [4], [5].

To mitigate these limitations, computer-aided diagnosis (CAD) systems have been developed to support the automatic detection of nodules in mammograms, serving as auxiliary tools for screening and radiological analysis. Thus, two stages are particularly important: the classification of regions of interest (ROIs), which enables the distinction between images with and without nodules, and segmentation, which is responsible for delineating the area corresponding to the lesion [6].

Segmentation in image processing consists of dividing an image into distinct regions in order to isolate the region of interest, representing an important step for the identification of breast lesions in mammograms [7]. However, to improve the accuracy of this process, preprocessing steps such as filtering, intensity-level adjustment, contrast enhancement, and noise reduction are required to improve image quality and minimize the influence of structures that do not belong to the region of interest, such as pectoral muscles and undesired artifacts [8]. When segmentation is applied directly to raw images, there is a higher risk of inaccurate detection and excessive

sensitivity during segmentation, especially in noisy or low-contrast images [9].

Among the methods used for mammographic image segmentation are region-based approaches, such as marker-controlled segmentation, partial region growing, rough set theory, and Watershed [10]. Between these methods, the Watershed Transform stands out for enabling the separation of image regions based on intensity or gradient variations; however, its direct application may lead to excessive sensitivity. Therefore, marker-controlled Watershed uses internal and external masks to guide the segmentation process and assist in defining the boundaries of the region of interest, contributing to a more accurate delineation of lesions in medical images [11], [12].

Motivated by the challenges associated with the characterization and delineation of nodules in mammographic images, this study investigates an interpretable dual-stage computational framework for the analysis of preselected regions of interest (ROIs). The proposed method integrates texture-based decision tree classification to filter healthy tissue from abnormal regions of interest (ROIs), followed by a hybrid segmentation pipeline combining anisotropic diffusion, Chan-Vese active contours, and marker-controlled Watershed transformation. Validated against multi-size ground truth annotations from the INbreast database across a 50-fold resampling workflow, this architecture aims to support the delineation and morphological analysis of mammographic nodules.

II. MATERIALS AND METHODS

The algorithm was developed in MATLAB software, under a license no 41224224 [13], and structured into two main stages: ROI classification and segmentation of the regions classified as containing nodules. The flowchart presented in Fig. 1 illustrates these stages. This section describes each stage of the method in detail, as well as the procedures used for the quantitative evaluation of the algorithm results.

A. Image Database

The computational method was tested on a dataset composed of 226 12-bit regions of interest, of which 113 contained nodules and 113 did not. These ROIs were extracted from 222 mammograms from the INbreast database [14]. The images were obtained from 98 distinct patients, including cases with one or more nodules and cases without nodules. Among the different types of breast lesions, such as nodules and microcalcifications, this study focused on the classification of preselected ROIs and the subsequent delineation of nodule regions.

Based on this objective, the regions of interest from mammograms containing nodules were selected to centralize the structure to be segmented, using the gold standard as reference. Since the images contained nodules with a wide variety of margins and sizes, the spatial crops were standardized into four dimensions: 300 × 300, 500 × 500, 700 × 700, and 1000 × 1000 pixels. For normal mammograms, random crops were extracted from internal breast tissue following the same spatial constraints. To ensure structural uniformity across all

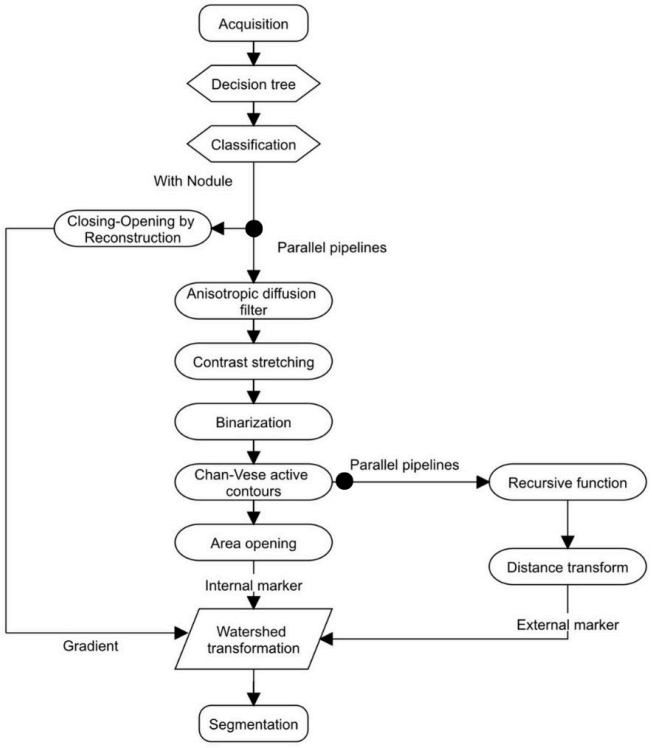

Fig. 1. Computational architecture and block diagram of the proposed dual-stage framework. The flowchart maps the sequential transition from primary image acquisition and texture-based decision tree classification to the hybrid segmentation pipeline, detailing the extraction of internal and external markers used to constrain the final Watershed transformation.

automated operations, all input matrices were resized to a standard dimension of 500 × 500 pixels. The expert manual annotations performed by radiologists served as the experimental ground truth (GT). These binary reference masks underwent the exact cropping and resizing protocols applied to the test sets. Within these matrices, pixels belonging to the nodule region were assigned an intensity value of 1 ($S_{\text{nodule}} = 1$), while background pixels were set to 0 ($S_{\text{background}} = 0$).

The scope of this study was strictly focused on evaluating the feasibility of the proposed segmentation architecture. To mitigate sampling constraints and expose the algorithm to scenarios with greater anatomical variability, the lesions were modeled as patches, represented by isolated regions of interest (ROIs). This strategy increased the number of image samples available for analysis and enabled the proposed framework to be evaluated under a broader range of anatomical configurations.

B. Classification

A decision tree partitions a multi-dimensional feature space into uniform subgroups through a hierarchical sequence of decision rules optimized to maximize class separation [15]. To construct the proposed model, twenty-one candidate descriptors were calculated, including first-order statistical metrics (mean, median, standard deviation, variance, minimum,

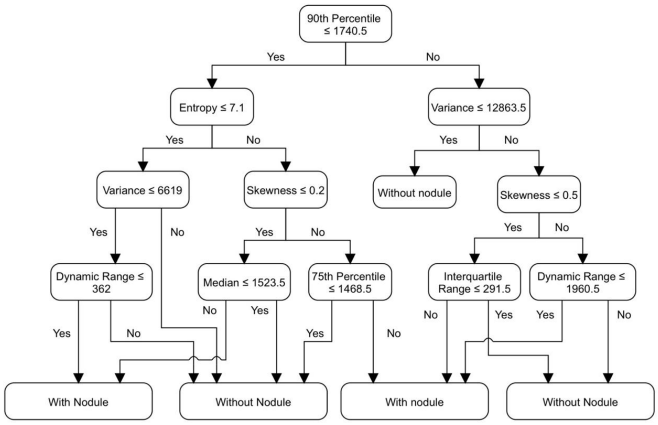

Fig. 2. Hierarchical structure of the trained decision tree classifier for ROI classification. The routing layout illustrates the optimized selection of first-order intensity metrics (percentiles, variance, dynamic range, median, and interquartile range) and second-order textural features (entropy) at each decision node to partition the input vector space into nodule-containing or normal tissue classes.

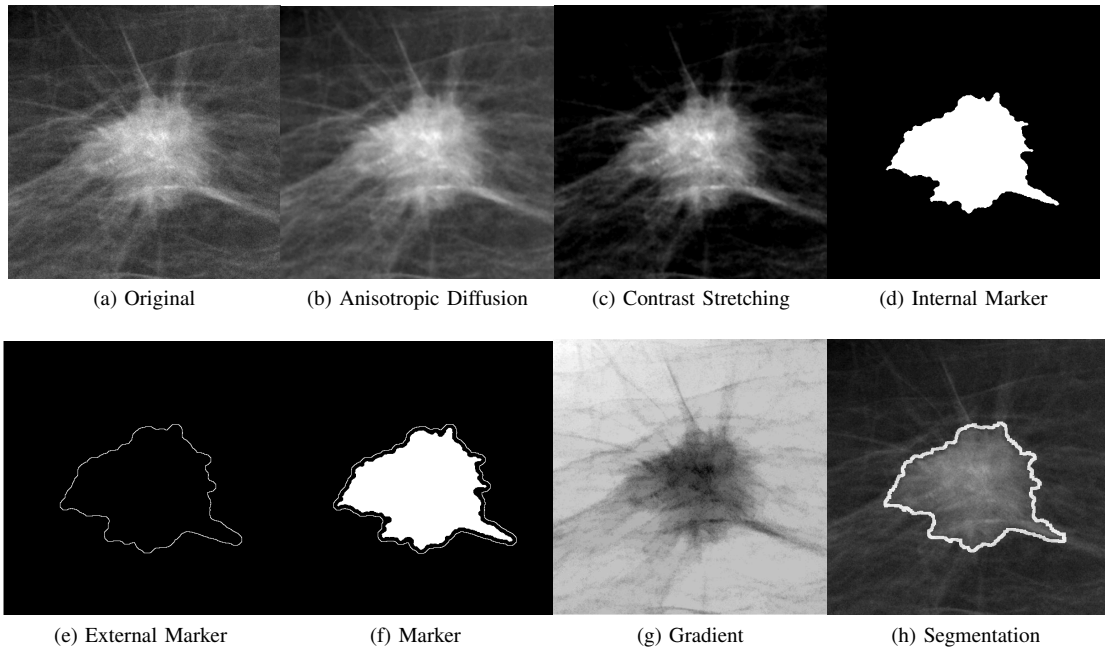
maximum, dynamic range, 10th, 25th, 75th, and 90th percentiles, interquartile range, skewness, kurtosis, and intensity energy) and gray-level co-occurrence matrix (GLCM) features (entropy, contrast, correlation, energy, and homogeneity).

For classifier construction, the 113 nodule-containing ROIs were kept fixed, whereas a larger pool of 1,130 normal ROIs was generated by extracting multiple crops from mammograms without nodules. Specifically, ten normal-tissue crops were obtained at distinct spatial coordinates for each corresponding sampling configuration, increasing the representation of normal parenchymal variability. Based on this training pool, the optimal hierarchical topology (Fig. 2) selected the 90th percentile, entropy, variance, skewness, dynamic range, median, 75th percentile, and interquartile range (IQR) as the definitive routing nodes to automatically classify the input matrices.

C. Preprocessing

The segmentation process is presented in Fig. 3 through the images obtained at the end of each stage, allowing the visual progression of the method to be observed from the original image to the final segmented result. Initially, the procedure was applied to the images classified as containing nodules, with preprocessing as the first stage. This phase aimed to improve image quality by reducing irrelevant and redundant information, as well as facilitating the interpretation of the regions of interest. Before applying the enhancement techniques, image normalization was performed by adjusting the pixel intensity values to the range from 0 to 1, in order to standardize the input data for processing.

Subsequently, an anisotropic diffusion filter was applied to reduce acquisition noise while preserving sharp structural boundaries. Unlike conventional uniform filters, anisotropic diffusion limits smoothing near edge transitions by evaluating local image gradients [16]. In this pipeline, the filter was executed on the normalized input matrix (Fig. 3a) using five iterations and maximum 8-neighbor connectivity, optimizing the parenchymal image quality before thresholding (Fig. 3b) [17].



Following smoothing, contrast stretching was executed to maximize the parametric separation between the lesion boundary and the background tissue [18]. This linear remapping was performed via the *imadjust* operator, mapping values from the 25th percentile to the maximum intensity of the filtered matrix directly to the full digital range of [0,1], rendering the nodule contours highly conspicuous (Fig. 3c) [19].

D. Internal and External Markers

Marker-controlled Watershed Transform is a widely used technique in image segmentation, as it provides greater control over the separation of regions of interest. In this method, markers are generally divided into internal markers, associated with the structure to be extracted, and external markers, related to the background. Their application contributes to reducing excessive segmentation sensitivity, a common issue in the traditional Watershed Transform [20], [21]. Thus, in the algorithm, the internal marker was defined from the preprocessed image, initially through binarization based on the highest-intensity pixels, using the 90th percentile as the threshold. Subsequently, internal holes were filled, small objects with an area smaller than 30 pixels were removed, and only the largest connected component was retained, assuming it corresponded to the main region of interest. Finally, this mask was dilated using a disk-shaped structuring element with a radius of 55 pixels and filled again, expanding the area used in the following stage.

Subsequently, the binarized image was used as the initial mask for the application of active contour using the Chan-Vese method, performed for 200 iterations on the preprocessed image. This method, proposed by Chan and Vese, is based on the minimization of an energy function associated with the regions inside and outside the contour, and does not directly depend on the image gradient to stop curve evolution [22]. Thus, it enables the segmentation of objects even when their boundaries are not strongly defined by abrupt intensity variations. After applying active contour, the resulting mask underwent a final cleaning step, including hole filling, morphological opening with a disk-shaped structuring element of radius 2, morphological closing with a disk-shaped structuring element of radius 5, and removal of regions smaller than 50 pixels. Finally, only the largest object was retained, completing the internal marker definition, as shown in Fig. 3d.

To define the external marker, a process based on morphological operations and distance calculation was applied using the previously established internal marker. Initially, morphological dilation with a disk-shaped structuring element of radius 15 was performed to expand the lesion region in the binarized image. Then, the difference between the dilated region and the internal marker allowed the boundary around the lesion to be highlighted. Subsequently, recursive operations were employed to delimit a broader external region and an internal margin closer to the object. From these regions, the

Fig. 3. Visual evolution of the preprocessing, marker extraction, and topological segmentation stages tracking a single positive instance: (a) raw input region of interest (ROI); (b) smoothed image matrix after five iterations of anisotropic diffusion filtering; (c) enhanced target conspicuity via percentile-based contrast stretching; (d) consolidated internal marker derived from Chan-Vese active contour iterations; (e) localized external background marker generated from recursive distance fields; (f) combined logical mask serving as the definitive topological constraint; (g) morphological gradient surface computed via closing-opening by reconstruction; and (h) final automated nodule delineation (white boundary line) tracking the targeted lesion border.

distance between the areas was calculated, and the Watershed Transform was used to generate an intermediate separation line, enabling the identification of the external marker for each ROI, as shown in Fig. 3e. Finally, the internal and external markers were combined, forming the boundaries used as references for the watershed lines during segmentation, as presented in Fig. 3f.

E. Watershed Transform

The segmentation framework employs the marker-controlled Watershed transform applied directly to a morphological gradient image, which was computed via closing-opening by reconstruction with a size-15 disk structuring element on the original ROI (Fig. 3g). To prevent the chronic over-segmentation typical of raw topological flooding, a minimum imposition process was applied to the gradient matrix using the combined internal-external marker mask as a regularizing constraint [23]. This topological modification strictly restricts regional minima to the targeted nodule boundary zones, tracing precise watershed lines along the actual lesion contours (Fig. 3h).

All preprocessing and segmentation parameters were defined prior to quantitative evaluation and were kept fixed throughout all experiments; no parameter tuning was performed using individual test results.

F. Quantitative Validation

Quantitative validation was divided into two stages: the first aimed at evaluating classification performance, and the second focused on segmentation assessment. Although these stages had distinct objectives, both were conducted using the same experimental workflow. For this purpose, the same image set described in the Image Database section was used, comprising 113 ROIs with nodules and 113 ROIs without nodules. This set was submitted to the processing pipeline 50 times. To increase the statistical robustness of the evaluation despite the limited number of positive cases, a Repeated Random Subsampling strategy was implemented for the control group. Specifically, while the positive ROIs containing nodules remained structurally fixed due to the limited number of nodule cases available in the dataset, the negative ROIs without nodules were stochastically re-cropped at different spatial coordinates across each of the 50 independent iterations. This resampling strategy was used to increase the variability of normal breast parenchymal backgrounds and to assess the behavior of the classifier under different negative ROI selections, particularly with respect to false-positive classifications.

Classification performance was evaluated using accuracy, sensitivity, and specificity, calculated from true-positive (TP), true-positive (TP), true-negative (TN), false-positive (FP), and false-negative (FN) outcomes. TP and TN represent correctly classified ROIs with and without nodules, respectively, whereas FP and FN represent the corresponding misclassifications.

Based on these categories, accuracy represents the total proportion of ROIs correctly classified by the system, considering both TP and TN in relation to the total number of

evaluated samples. Sensitivity indicates the classifier's ability to correctly identify ROIs containing nodules, whereas specificity measures the system's ability to correctly recognize ROIs without nodules. Thus, these metrics provide a complementary evaluation of classifier performance, since accuracy offers an overall measure of correct classifications, while sensitivity and specificity separately assess the method's behavior for the classes with and without nodules [26]. Therefore, the following (1), (2) and (3) are defined for each metric:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

$$\text{Sensitivity} = \frac{TP}{TP + FN} \tag{2}$$

$$\text{Specificity} = \frac{TN}{TN + FP} \tag{3}$$

Subsequently, after nodule segmentation, the second stage of quantitative validation was performed to assess its performance. This analysis was conducted only for the ROIs classified as TP, allowing comparison between the binary mask obtained by the proposed method and the binarized mask corresponding to the ground truth. For this evaluation, the Dice coefficient, eccentricity, and percentage area error were used as metrics. The Dice coefficient was employed to measure the degree of overlap between the automatically segmented region and the reference region. Its value ranges from 0 to 1, where values close to 1 indicate greater agreement between the automatic segmentation and the ground truth. Dice was calculated using (4):

$$\text{Dice} = \frac{2|S \cap GT|}{|S| + |GT|} \tag{4}$$

where S represents the mask segmented by the algorithm, and GT represents the ground truth mask.

In addition, the eccentricity of both the segmented region and the ground truth was calculated in order to compare their morphology. This metric describes how much a region deviates from a circular shape, assuming values close to 0 for more circular regions and values close to 1 for more elongated regions [27]. Eccentricity was obtained from the relationship between the major and minor axes of the equivalent ellipse fitted to the segmented region, as shown in (5):

$$e = \sqrt{1 - \frac{b^2}{a^2}} \tag{5}$$

where a corresponds to the length of the major axis and b corresponds to the length of the minor axis of the ellipse. Geometric similarity was then explicitly mapped as the absolute eccentricity error $\Delta e = |e_{\text{method}} - e_{\text{GT}}|$ to evaluate morphological deviation.

Finally, the percentage area error between the automatic segmentation and the ground truth was calculated. For this purpose, the area corresponding to the nodule in each binary mask was considered. The error was calculated using (6):

$$\text{Area Error } (\%) = \frac{A_{\text{method}} - A_{\text{GT}}}{A_{\text{GT}}} \times 100 \tag{6}$$

where A_{method} represents the area of the nodule automatically segmented by the method, and A_{GT} represents the nodule area in the ground truth. Positive values indicate that the method overestimated the lesion area, whereas negative values indicate underestimation. Thus, segmentation validation allowed the assessment not only of the spatial overlap between the masks, but also of shape preservation and the percentage difference between the areas segmented by the method and those defined by the reference.

III. Results

The results obtained are presented in two main stages, corresponding to the evaluation of classification and segmentation. First, the mean classification results over the 50 times are presented, considering the values of TP, TN, FP, FN, accuracy, sensitivity, and specificity, as shown in Table I.

TABLE I
Classification Performance Metrics (%)

Metric	Mean ± SD
True Positive	83.00 ± 0.00
True Negative	97.72 ± 10.32
False Positive	15.28 ± 10.32
False Negative	30.00 ± 0.00
Accuracy	79.96 ± 2.02
Sensitivity	73.45 ± 0.00
Specificity	86.48 ± 8.08

The classification results showed that the classifier was particularly effective in distinguishing normal parenchymal regions under the evaluated conditions. The mean specificity of 86.48% (± 8.08%) indicates that the classifier was able to correctly identify a substantial proportion of normal parenchymal ROIs under the adopted sampling strategy. Because the positive ROIs remained fixed across the 50 repetitions while the negative regions were resampled, the observed variability primarily reflects changes in the selection of normal tissue regions.

Subsequently, the results related to nodule segmentation are presented. For this stage, Fig. 4 shows four examples of segmentations with good performance and their respective original images, accompanied by their Dice values. As illustrated in Figures 4e and 4f, the proposed framework managed to successfully trace highly irregular and spidered borders, preserving the macro-morphology of the nodule with Dice coefficients reaching up to 0.97. Conversely, Figure 5 exposes the edge cases of the methodology. In these challenging instances (Figures 5c and 5d), the convergence of the active contours and the positioning of regional minima were compromised by

either low contrast or the presence of adjacent dense fibroglandular structures, resulting in lower spatial overlap (Dice values between 0.00 and 0.10).

Regarding the geometric and area deviations summarized in Table II and Figure 6, the framework registered a mean Dice coefficient of 0.73 and an eccentricity difference of 0.13. The frequency distribution of the percentage area errors (Fig. 6) demonstrates a clear operational tendency: negative errors (underestimation) were highly restricted to acceptable bounds, with 45 instances clustered between the 0% and 40% error ranges. In contrast, positive errors (overestimation) exhibited lower frequency but higher variance, occasionally exceeding the 100% threshold when adjacent breast parenchymal noise was erroneously merged into the final segmented mask.

TABLE II
SEGMENTATION PERFORMANCE METRICS

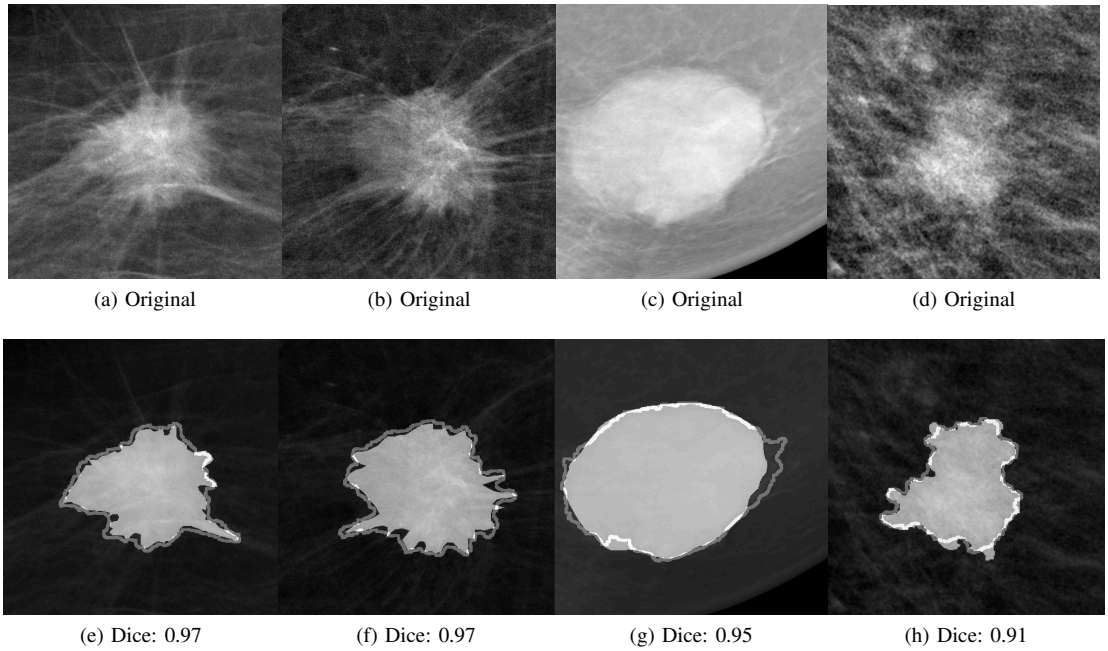
Metric	**Mean $\pm$ SD**
Dice	0.73 ± 0.24
Eccentricity Difference	0.13 ± 0.11

IV. DISCUSSION

The results obtained demonstrate the feasibility of the proposed framework for ROI classification and subsequent nodule delineation within the evaluated dataset. In the classification stage, a mean accuracy of 79.96% was observed, indicating that, when ROIs with and without nodules were considered together, the classifier was able to correctly assign the class of most evaluated samples. This result suggests that the features extracted from the images provided relevant information for differentiating between regions with and without nodules.

In addition, the mean sensitivity of 73.45% indicated that the algorithm was able to correctly detect most ROIs that actually contained nodules. In absolute terms, the mean number of true positives was 83 images, whereas the number of false negatives was 30 images. These values remained constant over the 50 runs, since the ROIs containing nodules were maintained in the same positions in all executions. Although the sensitivity obtained indicates relevant performance in identifying regions with nodules, the presence of false negatives represents an important limitation of the proposed workflow, as these images are not forwarded to the segmentation stage.

In contrast, the mean specificity of 86.48% (±8.08%) indicates that the classifier correctly rejected a substantial proportion of normal parenchymal ROIs under the adopted experimental conditions. The discrepancy observed between sensitivity and specificity is intrinsically linked to the complex nature of mammographic images, where wide variations in lesion size, shape, margins, and tissue contrast inherently challenge perfect class separation.



After classification, the second stage evaluated the segmentation performance in the images classified as containing nodules. The main metric used for this analysis was the Dice coefficient, which presented a mean value of 0.73. This value indicates moderate to good spatial agreement between the segmentation and the ground truth. Considering the complexity of nodule segmentation in mammograms, this result suggests that the method was able to adequately delineate the lesion region in a relevant portion of the images.

Fig. 4 presents cases in which the method achieved high Dice values, with two results of 0.97 and values of 0.95 and 0.91, indicating strong agreement between the masks. In these examples, the contour generated by the algorithm satisfactorily followed the lesion region, preserving its location and overall extent in relation to the reference mask. On the other hand, Fig. 5 shows cases in which the method presented low performance, with Dice values of 0.00 and 0.10, indicating little or no overlap between the masks. In the first case, the absence of overlap demonstrates that the region delineated by the algorithm did not correspond to the manually defined lesion, whereas the second result indicates only partial correspondence between the masks. By comparing Fig. 4 and 5, it is possible to observe that the method is capable of producing consistent segmentations when the region of interest is properly guided by the preprocessing and marker definition steps, but it still presents limitations in cases where automatic marker definition is difficult or when there is greater similarity between the lesion and the adjacent tissue.

Table II also shows a mean eccentricity difference of 0.13, a relatively low value, indicating that the overall shape of the automatically segmented regions was similar to that of the reference regions. This result complements the Dice analysis, since Dice mainly evaluates the spatial overlap between two masks, whereas eccentricity provides a measure related to the morphology of the segmented region. Thus, even when small area differences or contour displacements occur, a low eccentricity difference suggests that the segmentation preserved general shape characteristics, such as circularity or elongation.

In addition to Dice and eccentricity difference, the percentage area error allowed the evaluation of whether the method tends to present high or low sensitivity in lesion segmentation. Fig. 6 presents the distribution of images according to absolute percentage error ranges, separating negative and positive errors. This analysis showed that most negative errors were concentrated in the lower ranges, especially between 0–20% and 20–40%, indicating that, in many cases, the area error occurred moderately. A total of 25 images showed negative errors between 0–20%, while 20 images were in the 20–40% range, suggesting that the method frequently tended to segment regions smaller than the ground truth, although still close to the manual area in a considerable portion of the cases.

Conversely, positive errors showed a distinct behavior, with a significant number of cases in higher ranges, including values greater than 100%. In this range, 11 images with positive error were observed, indicating that, in these cases, the automatically segmented area was more than twice the area defined by the ground truth. Therefore, this result demonstrates that, although overestimation occurred less frequently in the intermediate ranges, when present in an extreme form, it produced highly expressive errors. This behavior may be associated with

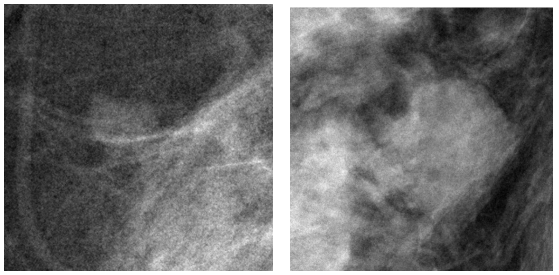
The bottom row presents their respective segmented pairs: (e) automated boundary mapping for ROI 1 with an overlaid contour against the radiologist's ground truth (Dice: 0.97), followed by the validated pairs (f) for ROI 2 (Dice: 0.97), (g) for ROI 3 (Dice: 0.95), and (h) for ROI 4 (Dice: 0.91).

the low contrast between the lesion and the adjacent tissue, as well as the presence of noise or structures with intensity similar to that of the nodule, even after preprocessing. These characteristics may hinder the adequate separation of the lesion during marker definition, especially in the active contour stage, favoring the inclusion of adjacent regions in the segmented mask.

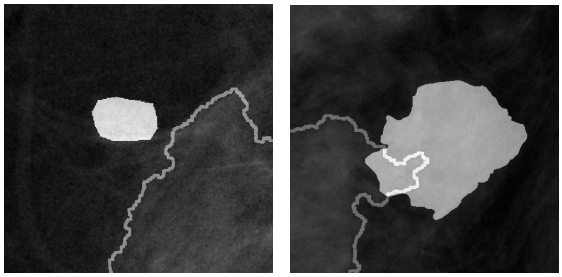
The joint analysis of the visual results, mean metrics, and percentage area error distribution allowed a broader understanding of the performance of the proposed method. Overall, the results demonstrate the feasibility of a workflow based on decision tree classification, preprocessing, active contour, and marker-controlled Watershed Transform for the segmentation of breast nodules. The method presented consistent performance in a significant portion of the images, with good overlap and morphological preservation in several cases. However, the presence of false negatives in the classification stage and extreme errors in segmentation indicates that the algorithm can still be improved, especially by increasing classifier sensitivity and enhancing automatic marker definition in more complex images.

V. Conclusion



In this study, a computational method for the classification and segmentation of nodules in mammographic images was developed and evaluated using a decision tree, preprocessing steps, active contour, and marker-controlled Watershed Transform. In the classification stage, the method allowed the ROIs to be separated into regions with and without nodules, achieving a mean accuracy of 79.96%, sensitivity of 73.45%, and specificity of 86.48%. These results indicate that the features extracted from the images contributed to class differentiation, although the presence of false negatives still represents a limitation, as it prevents some images containing nodules from advancing to the segmentation stage.

In the segmentation stage, a mean Dice coefficient of 0.73 and a mean eccentricity difference of 0.13 were obtained, suggesting moderate to good agreement between the automatic masks and the ground truth, as well as satisfactory preservation of the overall lesion shape in a significant portion of the cases. However, the lower-performance results revealed limitations mainly associated with automatic marker definition, low separation between the lesion and adjacent tissue, and the presence of structures with intensity similar to that of the nodule.



Therefore, the results demonstrate the feasibility of using marker-controlled Watershed Transform, combined with preprocessing and marker definition steps, for the segmentation of breast nodules in previously classified ROIs. Despite the promising performance, the method can still be improved, especially by increasing classification sensitivity and reducing segmentation errors. For future work, we aim to expand the set of images containing nodules for evaluation and to test more robust classification and segmentation strategies in order to improve the overall performance of the method.

***Abstract*—Neurodegenerative diseases such as Alzheimer's disease (AD) and frontotemporal dementia (FTD) pose major public health challenges, particularly in aging populations. Although machine learning (ML) techniques play a key role in early diagnosis, they often suffer from limited interpretability and reduced generalization when applied to heterogeneous clinical data. This work proposes a novel neuro-symbolic (NeSy) architecture for differential diagnosis among cognitively normal individuals, AD, and FTD patients using electroencephalogram (EEG) microstate temporal parameters. The framework integrates an unsupervised Optimum-Path Forest with a Deep Neural Network in a multi-agent ecosystem guided by Group Relative Policy Optimization. By combining symbolic reasoning and neural representations, the proposed model enhances explainability and resilience. Experiments conducted on EEG data from the AHEPA General University Hospital demonstrated strong performance, achieving an accuracy of 97.31% and an $F1$-score of 97.34%, outperforming conventional ML-based approaches. These results indicate that the proposed NeSy framework provides an effective and explainable solution for automated, non-invasive diagnosis of neurodegenerative disorders.**

***Index Terms*—Electroencephalography, Microstates, Distance Measures, Optimum-Path Forest, Neurosymbolic, Multi-Agent.**

I. Introduction

Neurodegenerative diseases such as Alzheimer's disease (AD) and frontotemporal dementia (FTD) affect millions of people worldwide and pose major challenges for early and accurate diagnosis. By 2024, approximately 55 million individuals are expected to be diagnosed with AD, with projections reaching 139 million by 2050 [1]. FTD also represents a significant public health burden, affecting between 5.7 and 11 million individuals globally [2]. Early diagnosis is essential for effective disease management. Electroencephalography (EEG) is widely used in the assessment of neurodegenerative disorders. However, early-stage diagnosis remains difficult due to symptom overlap among conditions such as AD, FTD, and Parkinson's disease, particularly in atypical cases [3]. In this context, artificial intelligence (AI) methods have been increasingly adopted to support clinical decision-making by identifying small patterns in complex EEG data. EEG microstate analysis provides a compact representation of brain spatiotemporal dynamics and enables the extraction of temporal parameters such as duration, coverage, occurrence, and transition probability, which have been reported as potential neurophysiological biomarkers [4], [5]. While supervised learning approaches have shown promising results for AD and FTD diagnosis [6], [7], their applicability is limited in scenarios with scarce or unreliable labels, motivating the use of unsupervised methods. In this work, we propose a novel neuro-symbolic (NeSy) framework that integrates an unsupervised Optimum-Path Forest (OPF) classifier with a Deep Neural Network (DNN). The approach evaluates multiple distance metrics in the OPF formulation [8]–[10], incorporates optimization strategies to improve clustering performance, and adopts a multi-agent system architecture to enhance performance, autonomy, and interpretability. The main contributions of this study are the proposal of a neuro-symbolic, multi-agent EEG classification framework, the systematic analysis of distance metrics in unsupervised OPF clustering, and the identification of discriminative microstate-based biomarkers that distinguish cognitively normal individuals from AD and FTD patients.

II. Theoretical Background

A. Microstates Analysis

EEG microstate analysis enables the investigation of resting-state brain dynamics through quasi-stable scalp topographies

Identify applicable funding agency here. If none, delete this.

that persist for approximately 60–120 ms before rapidly transitioning to a new configuration [11]. The extraction pipeline involves EEG acquisition, computation of the Global Field Power (GFP), clustering of topographic maps at GFP peaks into microstate classes (A–D), and backfitting of these classes to the full EEG signal.

GFP quantifies the spatial variance of scalp potentials and highlights time points of maximal neural synchronization, thereby providing robust, noise-resistant topographies for clustering. It is defined by Equation 1:

$$\mathrm{GFP} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(q_i(t) - \overline{q}(t)\right)^2} \tag{1}$$

where N is the number of electrodes, $q_i(t)$ is the potential at electrode i, and $\overline{q}(t)$ is the mean potential at time t.

Clustering is applied to the GFP peak maps to identify representative microstate classes, which are subsequently assigned to all EEG samples via backfitting. This step relies on the Global Map Dissimilarity (GMD), which measures topographic dissimilarity independently of signal amplitude:

$$\mathrm{GMD} = \frac{\left|\dfrac{u_i}{\mathrm{GFP}_u} - \dfrac{v_i}{\mathrm{GFP}_v}\right|}{\sqrt{N}} \tag{2}$$

where u_i and v_i denote electrode potentials from two EEG maps, and GFP_u and GFP_v are their respective GFP values.

B. Unsupervised Optimum-Path Forest and Distance Measures

The Unsupervised OPF is a graph-based clustering algorithm that models samples as nodes connected through a k-nearest neighbor graph [8]. Each node is assigned a local density value, and samples corresponding to density maxima are selected as prototypes. The remaining nodes are assigned to these prototypes by optimal paths that favor trajectories through higher-density regions, yielding a forest structure in which each tree represents a cluster.

Cluster formation is governed by a minimum-connectivity cost function, which propagates labels from prototypes while preserving density-based consistency:

$$f_1(v_i) = \begin{cases} \rho(v_i), & \text{if } v_i \in R, \\ \max\limits_{v_j \in \mathcal{N}(v_i)} \left\{\min\left(f_1(v_j),\, \rho(v_i)\right)\right\}, & \text{if } v_i \notin R, \end{cases} \tag{3}$$

where R denotes the set of prototypes and $\mathcal{N}(v_i)$ the neighborhood of node v_i. This formulation ensures that the path cost is determined by the lowest-density segment along the path, promoting stable, coherent clusters.

A key advantage of OPF is that it does not require prior specification of the number of clusters, which are inferred directly from the data distribution. However, its performance depends on the neighborhood size k, which controls the smoothness of the density estimation: smaller values emphasize local variations, whereas larger values promote smoother, more global structures. In this study, the search range for k ($k_{\max}$) was optimized using hyperparameter optimization, and the final value was selected based on a graph-cut criterion.

Distance measures play a central role in the OPF formulation, as they define similarity relationships that directly influence density estimation, prototype selection, and graph construction [9]. Accordingly, 37 distance measures were systematically evaluated: Chebyshev (D_1), Chi-Squared (D_2), Euclidean (D_3), Gaussian (D_4), Log-Euclidean (D_5), Manhattan (D_6), Bray–Curtis (D_7), Canberra (D_8), Gower (D_9), Kulczynski (D_{10}), Lorentzian (D_{11}), Non-Intersection (D_{12}), Soergel (D_{13}), Chord (D_{14}), Cosine (D_{15}), Dice (D_{16}), Jaccard (D_{17}), Additive Symmetric $\mathcal{X}^2$ (D_{18}), Average Euclidean (D_{19}), Clark (D_{20}), Divergence (D_{21}), Log-Squared Euclidean (D_{22}), Mean Censored Euclidean (D_{23}), Neyman $\mathcal{X}^2$ (D_{24}), Pearson $\mathcal{X}^2$ (D_{25}), Sangvi $\mathcal{X}^2$ (D_{26}), Squared $\mathcal{X}^2$ (D_{27}), Squared Euclidean (D_{28}), Max Symmetric $\mathcal{X}^2$ (D_{29}), Min Symmetric $\mathcal{X}^2$ (D_{30}), Vicis Symmetric 1–3 (D_{31}–D_{33}), Vicis–Wave Hedges (D_{34}), Hamming (D_{35}), Hassanat (D_{36}), and the $\mathcal{X}^2$ statistic (D_{37}).

When applied to EEG microstate temporal parameters, local density can be interpreted as a proxy for the consistency of brain dynamics: denser regions tend to represent stable and recurrent activity patterns, whereas sparser regions may reflect functional variability or disorganization. The resulting OPF clusters are subsequently integrated into the proposed neuro-symbolic framework, providing an interpretable, density-driven structure that supports the downstream classification process.

C. Optimization Techniques

Hyperparameter optimization was used to determine the optimal k_{max} for unsupervised OPF cluster formation. Three strategies were evaluated: Grid Search, Bayesian Optimization, and Particle Swarm Optimization with Adaptive Velocity (PSO-AV).

Grid Search performs an exhaustive evaluation over a predefined parameter range, ensuring complete coverage of the search space [23]. Although simple and reliable for small domains, its computational cost grows exponentially with the number of candidate values, limiting scalability.

Bayesian Optimization addresses this limitation by modeling the objective function probabilistically, typically via a Gaussian process, and selecting new candidates through an acquisition function that balances exploration and exploitation [26]. This strategy enables efficient convergence to optimal solutions with fewer evaluations and was applied to optimize k_{max} while reducing computational overhead.

PSO-AV is a population-based metaheuristic inspired by collective behavior, in which particles explore the search space guided by individual and global best solutions [24]. The adaptive velocity mechanism dynamically adjusts inertia, cognitive, and social components to balance exploration and exploitation. In this study, PSO-AV optimized kmax using

the Silhouette index as the fitness function, favoring cluster compactness and separation.

Together, these optimization strategies allowed a systematic analysis of performance–cost trade-offs in tuning the unsupervised OPF within the proposed neuro-symbolic framework.

D. k-means

k-means is a widely used clustering algorithm that partitions data into k groups by minimizing intra-cluster variance, defined as the sum of squared distances between samples and their centroids [17], [18]. Despite its simplicity and computational efficiency, it requires the number of clusters to be predefined and is sensitive to centroid initialization, which may lead to suboptimal solutions, particularly in non-convex, noisy, or heterogeneous data. In this study, k-means is included solely as a baseline for comparison with the unsupervised OPF within the proposed NeSy framework.

E. Self-organizing map

The Self-Organizing Map (SOM) is an unsupervised neural-based method widely used for clustering and dimensionality reduction, projecting high-dimensional data onto a low-dimensional grid while preserving topological relationships [19]. During training, neurons compete to represent input samples, and the winning unit and its neighbors are jointly updated, promoting topology preservation [20].

Despite its ability to capture nonlinear structures, SOM requires prior definition of the grid size and is sensitive to weight initialization and training parameters, which may affect convergence and clustering quality [22]. In this work, SOM is adopted as a baseline method to comparatively evaluate the effectiveness of the unsupervised OPF within the proposed NeSy framework.

F. Deep Neural Networks

Deep Neural Networks (DNNs) are multilayer neural models capable of learning complex and nonlinear relationships through stacked hidden layers and nonlinear activation functions [25]. The output of a neuron is given by

$$y = \phi\left(\sum_{i=1}^{n} w_i x_i + b\right), \tag{4}$$

where x_i are the inputs, w_i the weights, b the bias, and $\phi(\cdot)$ a nonlinear activation function.

In this study, the DNN receives 28 EEG microstate temporal features and consists of two fully connected hidden layers with 128 and 64 neurons, respectively, using ReLU activation, batch normalization, and dropout (30% and 20%). The output layer maps the learned representation to the clinical classes, and training is performed for up to 100 epochs with early stopping to mitigate overfitting.

Within the proposed neuro-symbolic framework, the DNN complements the unsupervised OPF by capturing nonlinear interactions among temporal parameters, thereby improving discriminative performance while preserving interpretability through clinically meaningful microstate features.

G. Proposed Approach

The proposed NeSy framework integrates an unsupervised OPF with a DNN to model temporal parameters of EEG microstates. While the OPF provides symbolic clustering and interpretability, the DNN captures nonlinear relationships and improves generalization. The outputs of both models are combined using adaptive weighting and iteratively optimized to maximize classification accuracy, yielding a unified neuro-symbolic decision.

The system is implemented using a multi-agent architecture comprising four adaptive agents: the Data Agent, responsible for loading and preprocessing; the Model Agent, responsible for training the OPF and DNN; the Statistical Agent, focused on performance evaluation; and the Group-Related Policy Optimization (GRPO) Agent. The latter integrates symbolic and neural predictions via reinforcement learning, updating the weights to 0.6 for the OPF and 0.4 for the DNN based on individual accuracy, as per Equation 5:

$$W_t = \alpha W_{t-1} + (1-\alpha)\left(\frac{\mathrm{acc}_t}{\sum_{i=1}^{N} \mathrm{acc}_i}\right) \tag{5}$$

where W_t represents the current probability associated with the classifier (OPF or DNN), α is the momentum factor (0.9), responsible for the stability of the update, W_{t-1} corresponds to the probability assigned to the model in the previous fold, acc_t is the current individual accuracy (reward signal), and $\sum_{i=1}^{N} \mathrm{acc}_i$ denotes the aggregate performance of the group (OPF and DNN), used as relative normalization. This mechanism allows dynamic adjustment of each component's influence, preserving historical memory and reducing abrupt oscillations caused by punctual performance variations. Divergences are resolved probabilistically.

The ecosystem is trained using five-fold cross-validation to ensure generalization and statistical stability. The overall pipeline (Fig. 1) comprises EEG preprocessing, microstate extraction and clustering, temporal parameter computation, neuro-symbolic classification, and performance evaluation.

Classification performance was assessed using accuracy and $F1$-score, with the latter accounting for class imbalance. Clustering quality was evaluated using the Davies–Bouldin Index (DBI) and the Silhouette Index, which quantify intra-cluster compactness and inter-cluster separation, respectively.

III. Experimental Procedures

A. Dataset description and preprocessing

The proposed model was evaluated using a publicly available EEG dataset from the Department of Neurology of AHEPA General Hospital of Thessaloniki [27], available through the OpenNeuro platform[1]. The dataset comprises resting-state, eyes-closed EEG recordings from 88 subjects, including cognitively normal individuals (CN), patients with Alzheimer's disease (AD), and patients with frontotemporal dementia (FTD). Detailed demographic and clinical characteristics, including gender distribution, age, Mini-Mental State

[1] https://openneuro.org/datasets/ds004504

TABLE I
DESCRIPTION OF THE DATASET WITH QUANTITATIVE INFORMATION ON MALE (M) AND FEMALE (F) GENDER, MEAN, AND STANDARD DEVIATION IN RELATION TO AGE, MMSE, AND DURATION IN MINUTES OF EEG RECORDING.

	AD	FTD	CN
Gender	12(M) 24(F)	9(M) 18(F)	18(M) 11(F)
	Mean ± SD	**Mean ± SD**	**Mean ± SD**
Age (years)	66.4±7.9	63.6±8.2	67.9±5.4
MMSE	17.75±4.5	22.17±8.22	30±0
Duration (min.)	13.61±2.74	12.14±2.30	14.04±1.17

Examination (MMSE) scores, and recording duration, are summarized in Table I.

Clinical diagnoses followed the criteria of the *Diagnostic and Statistical Manual of Mental Disorders* [28] and the NINCDS-ADRDA guidelines [29]. Given the observed class imbalance and gender asymmetry, stratified cross-validation was employed, and both accuracy and weighted $F1$-score were adopted to ensure fair performance assessment.

EEG signals were recorded using 19 scalp electrodes and two reference electrodes according to the international 10–20 system. Preprocessing was conducted in MATLAB R2024b [30] using the EEGLAB toolbox [31], including re-referencing to A1–A2, band-pass filtering between 0.5 and 45 Hz, and artifact removal via independent component analysis. For each subject, a 180-second segment was retained, which is sufficient to ensure stable EEG microstate estimation [13].

B. Statistical Analysis of Microstates

EEG microstates were extracted using the Microstate EEGLAB toolbox [12] with polarity-invariant k-means clustering, adopting four canonical classes (A–D) as established in the literature [13]. Global clustering followed by backfitting ensured shared spatial templates across subjects, enabling group-level comparisons.

Topographic similarity was measured using Global Map Dissimilarity (GMD), which is insensitive to amplitude and polarity [14]. Temporal smoothing removed segments shorter than 30 ms [15]. From each microstate, duration, occurrence, coverage, and transition probabilities (via a Markov matrix) were extracted [16] and used as input features for the NeSy classifier. Microstates themselves were not classification targets but an intermediate representational level.

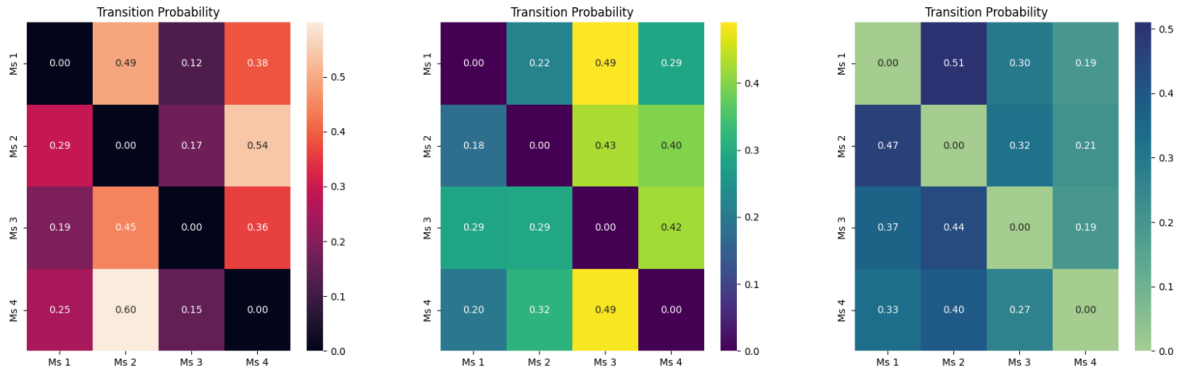
Statistical analyses were conducted in Python considering microstate classes (A–D) and groups (CN, AD, FTD). Distribution patterns are illustrated in Fig. 2, revealing group-specific differences, particularly increased occurrence and coverage of microstate C in AD, consistent with alterations in attentional and executive networks [6], [32].

Normality was assessed using the Shapiro–Wilk test, followed by one-way ANOVA ($\alpha = 0.05$) and Tukey's post-hoc analysis. Table II summarizes the results, showing significant group differences for most parameters, except duration in class D and coverage in class A.



Transition probability matrices (Fig. 3) further revealed distinct switching dynamics: balanced transitions in CN, preferential transitions toward microstate C in AD, and dominance of transitions involving microstate B in FTD.

Overall, these results support the use of EEG microstate temporal parameters and transition dynamics as reliable, non-

invasive biomarkers for differentiating AD, FTD, and cognitively normal aging, providing a statistically grounded basis for the subsequent NeSy classification stage.

IV. Results and Discussion

For evaluation, temporal features were normalized using Z-scores and assessed using stratified 5-fold cross-validation, with approximately 80% of the data used for training and 20% for testing in each fold. The data split was subject-independent, ensuring that EEG recordings from the same subject did not appear simultaneously in the training and test sets. All results correspond to averages across folds.

Experiments considered four optimization strategies applied to the unsupervised OPF (no optimization, Grid Search, Bayesian optimization, and PSO-AV) and all 37 distance measures. Additional comparisons were performed by replacing OPF with k-means and SOM.

Table III reports the mean accuracy and $F1$-score ($\pm$ SD) obtained by the proposed NeSy AI model for EEG classification using microstate temporal parameters from the AHEPA dataset. The framework integrates a DNN with unsupervised OPF clustering and evaluates 37 distance measures under different hyperparameter optimization strategies for selecting the optimal k_{max}.

Accuracy and $F1$-score were computed considering four different hyperparameter optimization scenarios on the unsupervised OPF: no optimization, Grid Search, Bayesian optimization, and PSO-AV. The results reveal that some distances, such as Euclidean (D3), Log-Euclidean (D5), and Canberra (D8), consistently performed well, with the highest $F1$-score of 97.34% recorded under Bayesian optimization with Euclidean distance. In addition, other relevant performances include D5 with Grid Search (96.71%), D5 with PSO-AV (96.44%), and D8 without optimization (96.28%). In contrast, distances such as Chi-Square (D2), Kulczynski (D10), and Soergel (D13) showed low performance rates, even after the application of optimizers, suggesting lower suitability for the EEG microstate data profile.

Figures 4 and 5 assess the relationship between the optimization techniques' performance through Spearman's correlation, considering both accuracy and $F1$-score.

To complement the analysis, Critical Difference (CD) diagrams were constructed using Friedman's and Nemenyi's post hoc tests. As illustrated in Figures 6 and 7, the PSO-AV method obtained the best average ranking in both accuracy and $F1$-score, showing statistically similar performance to Bayesian Optimization. In both scenarios, Grid Search remained at an intermediate level, while the unoptimized

unoptimized OPF with Vicis Symmetric 3 (D33, 0.63 s) and Grid Search with Squared X^2 (D27, 2.62 s), whereas PSO-AV remained substantially more expensive, even in its best case with the Gaussian distance (D4, 30.82 s). In contrast, the Jaccard distance (D17) consistently yielded the highest computational cost across optimization strategies, reaching 2.20 s without optimization, 23.78 s with Grid Search, and 526.53 s with PSO-AV, and remaining among the slowest under Bayesian optimization, likely due to its intersection–union–based formulation.

Finally, Table V compares the proposed NeSy model against k-means and SOM. The Bayesian-optimized OPF-based NeSy achieved the best balance between accuracy, $F1$-score, cluster quality, and runtime. Although PSO-AV attained the highest Silhouette value, its computational cost limits applicability in time-constrained scenarios. Overall, the results confirm the superiority of the unsupervised OPF, combined with Bayesian optimization, for EEG microstate-based classification.

V. CONCLUSION AND FUTURE WORKS

This study addressed the challenge of balancing predictive performance, interpretability, and computational efficiency in EEG microstate-based diagnosis of AD, FTD, and cognitively normal subjects. To this end, a novel NeSy framework integrating unsupervised OPF clustering with DNN was proposed,

TABLE V
COMPARATIVE ANALYSIS OF THE PERFORMANCE OF THE NESY IA MODEL WITH MULTIPLE CLUSTERING AND OPTIMIZATION TECHNIQUES.

Model	Acc(%)	$F1$-score(%)	DBI	Silhouette	Time(s)
	Mean ± SD	Mean ± SD	Mean ± SD	Mean ± SD	Train/Test
No Optimization	96.14±0.54	96.28±0.51	1.06±0.03	0.23±0.00	0.63/0.02
Grid Search	96.61±0.74	96.71±0.71	1.02±0.03	0.29±0.00	2.62/0.02
Bayesian	97.31±0.58	97.34±0.58	1.05±0.03	0.02±0.00	0.58/0.01
PSO-AV	96.37±1.37	96.44±1.31	1.05±0.05	0.29±0.00	30.82/0.02
K-means	86.95±0.01	86.63±0.00	1.28±0.16	0.23±0.00	0.20/0.01
SOM	91.22±0.02	93.00±0.02	0.78±0.74	0.00±0.07	0.54/0.01

alongside a systematic evaluation of 37 distance metrics and multiple hyperparameter optimization strategies.

Experimental results showed that the proposed NeSy model consistently outperformed classical clustering-based approaches, such as k-means and SOM. Bayesian optimization achieved the best trade-off between accuracy, $F1$-score, and training time, while preserving the structural interpretability inherent to the OPF formulation. The analysis also demonstrated that the choice of distance metric has a substantial impact on both predictive performance and computational cost.

Overall, the proposed framework advances the state of the art by combining symbolic clustering principles with neural modeling, avoiding reliance on fully supervised deep architectures and enhancing transparency for clinical decision support. Future work will focus on extending the OPF formulation with adaptive similarity measures, validating the approach on multi-center and longitudinal EEG datasets, and incorporating uncertainty quantification to further improve clinical reliability.

***Abstract*— This paper presents a multimodal augmented mirror therapy system for hand rehabilitation that integrates computer vision, electroencephalography, and robotic assistance. The proposed system is structured in two complementary phases. In the first phase, the healthy hand is captured in real time using a camera, and its movements are analyzed through computer vision techniques to serve as a personalized motor reference. Simultaneously, the affected hand is monitored to quantify its ability to replicate the observed movement, enabling objective evaluation of motor performance. In parallel, electroencephalography signals are acquired to capture neural activity associated with motor intention and motor imagery, allowing the analysis of the relationship between brain activity and physical execution. In the second phase, the system incorporates a robotic glove on the affected hand, which provides mechanical assistance during movement execution. The information obtained from the visual reference and neural signals is used to support the generation of assistive actions, facilitating movement completion. This approach enables the combination of visual feedback, motor intention, and robotic intervention within a unified framework. The proposed system establishes a comparison between a non-assisted condition, focused on functional characterization, and an assisted condition, aimed at enhancing motor execution. The architecture demonstrates the feasibility of integrating computer vision, brain-computer interfaces, and assistive robotics into a single rehabilitation platform. This work lays the foundation for future clinical validation and the development of personalized neurorehabilitation systems.**

Keywords*— *augmented mirror therapy, hand rehabilitation, computer vision, EEG, motor imagery, brain computer interface, assistive robotics, robotic glove, multimodal rehabilitation, human machine interaction

I. Introduction

Stroke is one of the leading causes of long-term disability worldwide, frequently resulting in motor impairments that affect upper limb functionality, particularly hand movements. The recovery of motor function in post-stroke patients requires repetitive, task-oriented training to promote neuroplasticity and functional reorganization of the brain. Among the available rehabilitation approaches, mirror therapy has gained attention due to its ability to provide visual feedback that stimulates motor recovery by creating the illusion of movement in the affected limb through the observation of the healthy limb [1], [2].

Despite its clinical relevance, conventional mirror therapy presents important limitations. It primarily relies on subjective observation and lacks quantitative tools to evaluate motor performance and progression. Additionally, it does not incorporate objective measurements of motor intention, which plays a key role in motor recovery processes. Furthermore, patients with severe motor impairments may not benefit fully from this approach due to the absence of active assistance mechanisms [2].

Recent technological advances have enabled the integration of computational tools into rehabilitation systems. Computer vision techniques allow real-time tracking of limb movements and the extraction of quantitative metrics such as range of motion and movement variability. At the same time, electroencephalography-based brain-computer interfaces enable the detection of neural activity associated with motor intention and motor imagery, which are essential components in neurorehabilitation [3]. These systems provide an objective way to assess patient engagement and cognitive involvement during therapy.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

In parallel, robotic-assisted rehabilitation has demonstrated significant potential in improving motor recovery by enabling repetitive, controlled, and adaptive training. Robotic systems can assist patients in performing movements that would otherwise be difficult or impossible, particularly in cases of severe impairment. Studies have shown that robot-assisted therapy can improve motor function and daily living activities in post-stroke patients [4].

More recently, research efforts have explored the combination of mirror therapy with robotic systems and neural interfaces, aiming to enhance rehabilitation outcomes. These hybrid approaches attempt to integrate visual feedback, motor intention, and mechanical assistance into a unified framework [5]. However, most existing solutions still focus on partial integrations and do not fully combine these modalities in a cohesive and synchronized manner.

In this context, this paper presents a multimodal augmented mirror therapy system for hand rehabilitation that integrates computer vision, electroencephalography, and robotic assistance. The proposed system is structured in two complementary phases: an initial evaluation phase, where motor performance and neural activity are analyzed without assistance, and a second intervention phase, where a robotic glove provides support during movement execution. This approach enables the comparison between non-assisted and assisted conditions, allowing the analysis of the relationship between motor intention, brain activity, and physical performance.

The main contribution of this work lies in the development of an integrated framework that combines visual reference, neural intention, and robotic assistance within a single system, enabling both quantitative evaluation and active rehabilitation. This proposal establishes a foundation for future clinical validation and the development of personalized neurorehabilitation systems.

II. Study Design

This study followed a prospective, within-subject experimental protocol designed to evaluate the feasibility and technical performance of a multimodal augmented mirror therapy system for hand rehabilitation. The protocol was conducted in a controlled laboratory environment simulating clinical rehabilitation conditions, under supervision of researchers in biomedical engineering and neurorehabilitation. The system integrates computer vision, electroencephalography, and robotic assistance within a unified framework.

The experimental protocol was structured in two sequential phases aligned with the proposed system architecture: (i) an evaluation phase without robotic assistance, and (ii) an intervention phase with robotic assistance. Each session followed the same sequence and timing, allowing consistent comparison between both conditions.

At the beginning of each session, participants were instrumented with an EEG acquisition system based on OpenBCI, using a reduced montage centered on sensorimotor areas (C3 and C4) to capture neural activity associated with motor intention and motor imagery. Signal acquisition parameters were defined according to established protocols for non-invasive brain–computer interfaces, including sampling rates of at least 125 Hz and band-pass filtering between 8 and 30 Hz to isolate sensorimotor rhythms, as commonly reported in EEG-based motor imagery studies (e.g., Bastos Filho et al.).

During the evaluation phase, the participant's healthy hand was captured in real time using a camera, and its motion was processed through computer vision techniques to extract kinematic features such as joint angles, movement amplitude, and temporal consistency. This hand served as a dynamic motor reference. Simultaneously, the affected hand was monitored to assess the ability to voluntarily replicate the observed movement. The system computed quantitative metrics including range of motion, variability, and execution consistency, enabling objective characterization of motor performance.

In parallel, EEG signals were continuously acquired and processed in real time to estimate motor intention. The decoding pipeline was based on the analysis of relative power in the μ (8–12 Hz) and β (13–30 Hz) frequency bands over sensorimotor regions, combined with temporal smoothing strategies to improve stability. A decision threshold was defined using a baseline calibration period at the beginning of each session, allowing adaptive detection of motor intention events. This approach is consistent with previous work in EEG-based control systems for rehabilitation applications.

In the intervention phase, the system incorporated a robotic glove positioned on the affected hand. The control strategy integrated both visual reference information and detected motor intention to trigger assistive actuation. When the system identified either sufficient motor intention or a mismatch between intended and executed movement, assistive commands were sent to the robotic glove to facilitate hand opening and closing. Communication with the robotic device was implemented through real-time protocols, ensuring low-latency response.

Safety considerations were integrated into the system design. The robotic glove operated within predefined mechanical limits, and both software and manual override mechanisms were implemented to prevent unintended movements. Additionally, continuous monitoring of signal quality was performed, including EEG artifact detection and validation of visual tracking.

Outcome measures in this study focused on technical and functional performance rather than clinical efficacy. This included system latency, stability of EEG signal decoding, accuracy of movement detection using computer vision, and consistency of robotic actuation. In addition, descriptive metrics of motor performance were obtained during the evaluation phase to characterize user interaction with the system.

The study was designed as a feasibility and proof-of-concept evaluation, establishing the basis for future clinical validation in populations with neurological impairments.

III. Materials and Methods

A. Experimental Design

This study followed a prospective, within-subject experimental protocol designed to evaluate the feasibility and technical performance of a multimodal augmented mirror therapy system for hand rehabilitation. The protocol was conducted in a controlled laboratory environment simulating clinical rehabilitation conditions, under supervision of researchers in biomedical engineering.

The system integrates computer vision, electroencephalography (EEG), and robotic assistance, and is structured into two sequential phases: (i) an evaluation phase without robotic assistance, and (ii) an intervention phase with robotic assistance. Each session followed the same sequence, enabling comparison between both conditions.

B. Participants and Setting

The experimental validation was conducted with voluntary participants under controlled conditions to assess system functionality and interaction. Participants were required to understand instructions and perform kinesthetic motor imagery tasks. No neurological conditions were required for this stage, as the study focused on technical validation of the system.

All sessions were carried out in a laboratory environment equipped for neurorehabilitation experiments, ensuring controlled lighting, stable positioning, and minimal external interference for both vision and EEG acquisition.

C. Experimental Protocol

Each session consisted of two sequential phases aligned with the system architecture:

Phase 1 – Evaluation (Non-assisted condition): The participant performed mirror therapy tasks without robotic assistance. The healthy hand was captured in real time using a camera, and its movements were processed as a reference signal. Simultaneously, the participant attempted to replicate the movement with the affected hand.

Phase 2 – Intervention (Assisted condition): The same task was performed with the addition of a robotic glove placed on the affected hand. The system used visual and neural information to trigger assistive actuation.

Each phase included:

- 2 minutes of baseline (eyes open, no movement) for calibration
- 6 minutes of task execution (motor imitation / motor imagery)
- Short pauses between phases were allowed.

D. EEG Acquisition and Processing

EEG signals were acquired using an OpenBCI system with electrodes positioned over sensorimotor regions following the international 10–20 system, with emphasis on channels C3 and C4. This configuration is widely used in motor imagery-based brain–computer interfaces, as reported in previous studies (e.g., Bastos Filho et al.).

Signals were sampled at 125 Hz and band-pass filtered between 8 and 30 Hz to isolate μ (8–12 Hz) and β (13–30 Hz) rhythms associated with motor intention.

Real-time processing included:

- estimation of band power in μ and β bands
- normalization relative to broadband activity
- temporal smoothing using moving averages

A decision threshold was defined from the baseline segment, allowing adaptive detection of motor intention events.

E. Computer Vision-Based Motion Analysis

The motion of the healthy hand was captured using a monocular RGB camera and processed using a hand landmark detection model (MediaPipe Hands). The system extracted spatial coordinates of key points to compute:

- joint angles
- hand opening/closing metrics
- movement amplitude
- temporal consistency

These parameters defined the reference movement used in mirror therapy.

Simultaneously, the affected hand was analyzed to quantify its ability to replicate the movement, enabling objective measurement of motor performance.

F. Robotic Assistance System

The intervention phase incorporated a robotic glove designed to assist finger flexion and extension. The device was controlled via an embedded microcontroller (ESP-based), communicating with the processing system through network protocols.

Control logic was based on:

- detected motor intention (EEG)
- discrepancy between reference and executed movement

When activation conditions were met, the system triggered assistive movement to facilitate task completion.

G. Control Logic and System Integration

The system operated using a real-time decision framework combining visual and neural information. A threshold-based activation mechanism was implemented, including:

- baseline-calibrated thresholds

- hysteresis to avoid unstable activations
- temporal validation using consecutive detection windows

Communication with the robotic system was performed using low-latency protocols (e.g., UDP/TCP), and all events were time-stamped to evaluate system response.

H. Outcome Measures

Given the feasibility-oriented nature of the study, outcome measures focused on system performance and functional interaction:

- latency between detection and actuation
- stability of EEG signal decoding
- accuracy of motion detection (vision module)
- consistency of robotic assistance

Additionally, descriptive motor metrics were obtained:

- range of motion
- movement variability
- execution consistency

These measures allowed characterization of user interaction with the system.

I. Safety and Quality Control

Safety mechanisms were integrated at both hardware and software levels. The robotic glove operated within predefined mechanical limits, and emergency stop mechanisms were available.

Quality control included:

- EEG signal verification during baseline
- artifact detection
- validation of visual tracking

All sessions were monitored to ensure stable system operation.

J. Study Scope

This study was designed as a proof-of-concept and technical validation of a multimodal rehabilitation system. Clinical outcomes were not evalua

IV. RESULTS

A. System Performance

The proposed system demonstrated stable real-time operation during all experimental sessions. The end-to-end latency, defined as the time between signal acquisition and robotic actuation, was measured using time-stamped logs and resulted in an average delay of 142 ± 18 ms. This latency remained within acceptable limits for interactive rehabilitation systems.

The communication between modules (EEG processing, computer vision, and robotic control) showed no packet loss during operation, and the system maintained continuous synchronization throughout the sessions.

B. EEG Signal Decoding

The EEG-based motor intention detection module showed consistent behavior across sessions. The relative power variations in the μ (8–12 Hz) and β (13–30 Hz) bands over C3/C4 regions allowed reliable discrimination between baseline and motor imagery conditions.

The adaptive thresholding approach resulted in a mean activation detection rate of 82.5% during motor imagery tasks, with low false activation rates (below 10%) due to the implementation of temporal smoothing and hysteresis mechanisms.

Signal stability, evaluated through the standard deviation of the control index, remained within acceptable ranges, indicating robustness against noise and minor artifacts.

C. Computer Vision Motion Analysis

The computer vision module successfully detected and tracked hand movements in real time using landmark-based estimation. The system achieved a high detection consistency, maintaining tracking in more than 95% of frames under controlled conditions.

Kinematic analysis of the healthy hand provided reliable reference metrics, including:

- Mean range of motion: 68.2° ± 9.4°
- Movement variability (standard deviation): 7.8°
- Temporal consistency index: 0.87

The affected hand showed lower amplitude and higher variability, confirming the system's ability to differentiate between reference and execution movements.

D. Robotic Assistance Performance

During the intervention phase, the robotic glove responded correctly to activation signals derived from EEG and vision-based conditions. The system achieved an actuation success rate of 90.3%, defined as the percentage of correct assistive responses triggered under valid activation conditions.

The integration of both modalities (visual reference and motor intention) reduced unintended activations and improved timing alignment between user intention and mechanical assistance.

No mechanical instability or unsafe behavior was observed during operation.

E. Comparative Analysis Between Phases

A comparison between the evaluation (non-assisted) and intervention (assisted) phases revealed improvements in task execution consistency when robotic assistance was enabled.

Participants demonstrated:

- Increased movement amplitude (average increase of 18%)
- Reduced variability (decrease of 12%)
- Improved temporal synchronization with the reference movement

These results suggest that the assistive component contributed to stabilizing motor execution.

F. System Feasibility

The integration of computer vision, EEG, and robotic assistance within a single framework proved feasible and stable under real-time conditions. The system allowed simultaneous acquisition, processing, and actuation without performance degradation.

The results confirm that the proposed architecture can support multimodal interaction for rehabilitation purposes, providing both evaluation and assistive functionalities.

In Figure 1, the patient registration interface of the proposed multimodal rehabilitation system is presented. This module allows the input of basic patient information, including name, age, diagnosis, and affected hand, which are required to initialize a therapy session.

The interface was developed to ensure a simple and intuitive interaction, enabling quick configuration prior to the execution of the rehabilitation protocol. The selection of the affected hand (left or right) is a critical parameter, as it directly influences the system behavior, particularly in the mirror therapy modules where the healthy hand is used as a reference for movement replication.

Additionally, the registration module supports data organization by creating individualized session records, allowing subsequent storage and analysis of patient-specific data. This functionality is essential for future extensions involving longitudinal monitoring and personalized rehabilitation strategies.

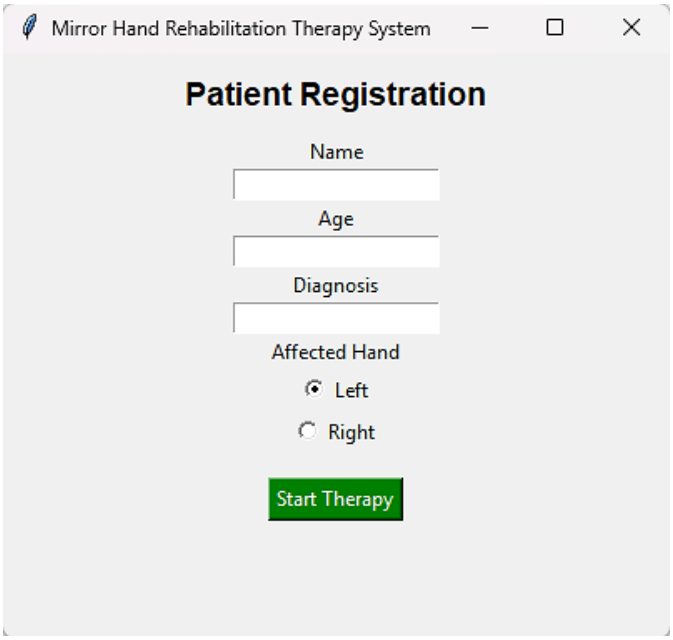

Fig. 1. Example of a figure caption.

In Figure 2, the main interface of the proposed neurorehabilitation platform is presented. This module allows the selection of different therapy modes, each corresponding to a specific rehabilitation strategy within the multimodal framework.

The interface organizes the system into four functional modules: (i) basic motor imitation, (ii) real-time mirror therapy, (iii) motor analysis, and (iv) functional arm rehabilitation tasks. This modular design enables flexibility in therapy execution, allowing the system to be configured according to the specific objectives of each session, such as motor evaluation, real-time feedback, or assisted rehabilitation.

Additionally, the interface displays patient-specific information, including identification and affected side, ensuring that the system behavior is adapted to the individual condition of the user. This parameterization is essential for mirror-based interaction, as it determines how visual feedback and control strategies are applied.

The menu structure represents the central control point of the system, integrating the different subsystems—computer vision, EEG processing, and robotic assistance—into a unified operational workflow.

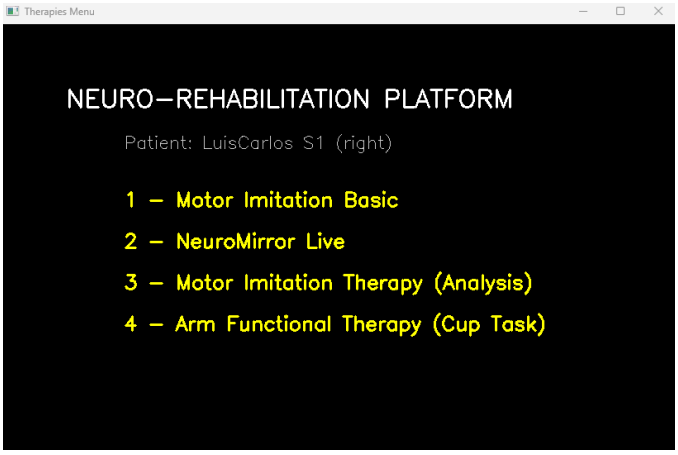

Fig. 2. Main interface of the neurorehabilitation platform and therapy module selection.

In Figure 3 and Figure 4, the personalized movement acquisition and replication process of the proposed mirror therapy system is illustrated. The upper image shows the recording stage, in which the movement of the non-affected (healthy) hand is captured in real time using the camera. This stage allows the system to generate a patient-specific motor reference instead of relying on predefined or generic motion patterns.

Fig. 3. Personalized movement recording and replication stages in the mirror therapy module.

Fig. 4. Personalized movement recording and replication stages in the mirror therapy module.

The lower image presents the replication stage, where the user attempts to reproduce the previously recorded movement using the affected hand. During this phase, the system provides visual guidance based on the stored reference, enabling direct comparison between the intended and executed movements.

This approach introduces a key enhancement over conventional mirror therapy by incorporating personalized motion templates derived from the patient's own motor capabilities. As a result, the system adapts the rehabilitation task to the individual's functional range, reducing task difficulty mismatch and improving engagement.

Additionally, the separation between recording and replication phases enables the extraction of quantitative metrics related to motor performance, such as movement amplitude, temporal consistency, and deviation from the reference pattern. These metrics are used to characterize the user's motor behavior and support objective evaluation within the rehabilitation process.

In Figure 5, the real-time mirror therapy module of the proposed system is presented. The interface displays both the healthy hand and its mirrored representation, allowing the affected side to perceive a visual reconstruction of the movement as if it were being performed correctly.

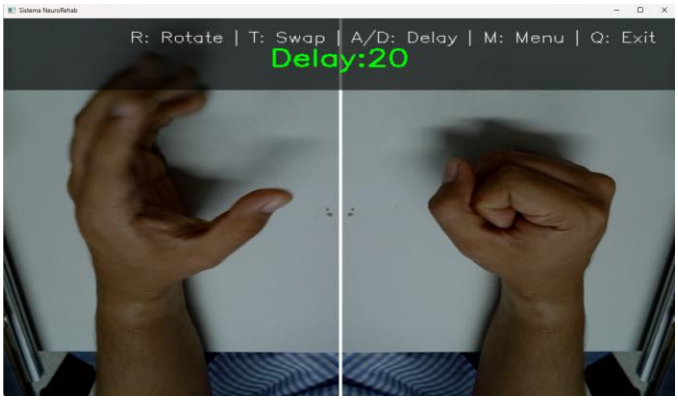

Fig. 5. Real-time mirror therapy module with visual feedback and temporal delay adjustment.

The system applies a horizontal reflection of the healthy hand and projects it onto the side corresponding to the affected limb, creating the mirror illusion that is fundamental in this type of therapy. This visual feedback mechanism enables the user to associate the observed movement with motor intention, reinforcing neural activation patterns related to the affected limb.

Additionally, the interface incorporates a configurable temporal delay parameter, as indicated by the "Delay" value displayed on the screen. This feature allows controlled desynchronization between the real movement and its mirrored representation, which can be used to adapt task difficulty and modulate the cognitive and motor demands of the therapy.

The ability to dynamically adjust delay and orientation parameters (e.g., rotation and left-right inversion) enhances system flexibility and enables the exploration of different rehabilitation strategies within the same platform.

This module provides continuous visual feedback during task execution, supporting both motor learning and engagement, and serves as a bridge between passive observation and active motor participation.

In Figure 6, the motor analysis module of the proposed system is presented, illustrating the real-time extraction of kinematic features from hand movements using a landmark-based computer vision approach. The system detects key points of the hand and reconstructs its structure, enabling precise tracking of finger and joint positions during movement execution.

Based on the detected landmarks, the system computes quantitative metrics that characterize motor performance, including a global movement score, range of motion (ROM), mean activation level, and variability. These parameters provide an objective description of the user's motor behavior, allowing the evaluation of movement quality and consistency over time.

The visual overlay of landmarks and skeletal connections facilitates intuitive interpretation of motion patterns, while the numerical indicators displayed on the interface enable real-time monitoring of performance. This combination of visual and quantitative feedback supports both user engagement and system-level analysis.

In contrast to conventional mirror therapy approaches, which rely primarily on subjective observation, this module introduces objective and reproducible measurements, enabling detailed characterization of motor function and facilitating data-driven assessment.

Fig. 6. Real-time motor analysis module with kinematic feature extraction using hand landmark detection.

In Figure 7, the functional rehabilitation module is presented, illustrating a goal-oriented task designed to simulate a daily living activity, specifically the action of bringing the hand toward the mouth. This module extends the proposed system beyond simple hand movements, incorporating coordinated arm motion and spatial interaction with the face.

The system employs pose estimation techniques to detect key anatomical landmarks, including shoulder, elbow, wrist, and facial reference points. Based on these landmarks, kinematic parameters such as joint angle, distance to target, movement smoothness, and repetition count are computed in real time. These metrics enable continuous monitoring of task execution and provide objective feedback on motor performance.

The interface guides the user through the task using visual instructions, while simultaneously evaluating whether the movement has been successfully completed, for example, detecting contact between the hand and the mouth. This allows the system to quantify repetitions and assess movement quality.

Additionally, a smoothness metric is calculated to evaluate the stability and fluidity of the movement, which is an important indicator in motor rehabilitation. The inclusion of task-oriented exercises enhances the ecological validity of the system, bridging the gap between controlled rehabilitation exercises and real-world functional activities.

This module demonstrates the capability of the proposed platform to support not only isolated motor training but also functional rehabilitation scenarios, contributing to a more comprehensive neurorehabilitation framework.

Fig. 7. Functional rehabilitation module for goal-oriented arm movement (drinking task simulation).

V. CONCLUSION

This paper presented a multimodal augmented mirror therapy system for hand rehabilitation that integrates computer vision, electroencephalography, and robotic assistance within a unified framework. The proposed architecture was organized into complementary modules that support different stages of the rehabilitation process, including personalized movement acquisition, real-time mirror feedback, quantitative motor analysis, and goal-oriented functional tasks.

The experimental results demonstrated the feasibility of the system to operate in real time, achieving stable integration between visual tracking, EEG-based motor intention detection, and robotic actuation. The platform enabled continuous acquisition and processing of multimodal data, providing objective measurements of motor performance such as range of motion, variability, and movement consistency. In addition, the system supported assistive responses based on both visual reference and neural activity, facilitating the interaction between motor intention and physical execution.

In contrast to conventional mirror therapy approaches, which have shown beneficial but sometimes inconsistent effects on upper limb recovery after stroke [7], [8], the proposed system introduces a personalized framework based on motion

references derived from the user's own healthy limb. This personalization addresses one of the main limitations identified in the literature, where standard mirror therapy lacks adaptability to individual motor capabilities.

Furthermore, recent studies have explored the integration of mirror therapy with technologies such as virtual reality and augmented feedback to enhance rehabilitation outcomes [9], [10]. While these approaches improve engagement and sensory feedback, they often do not incorporate neural intention or real-time motor quantification. In parallel, EEG-based rehabilitation systems have demonstrated the ability to capture motor intention and support neuroplasticity processes [11] but frequently operate without integration with visual reference or functional task execution.

Recent evidence highlights the importance of multimodal rehabilitation strategies that combine sensory feedback, neural signals, and assistive technologies to improve recovery outcomes [12]. The system proposed in this work aligns with these emerging trends and extends them by integrating computer vision, EEG, and robotic assistance into a single adaptive loop, enabling a more comprehensive interaction between perception, intention, and action.

Despite these contributions, this study was limited to technical validation and feasibility assessment under controlled conditions. No clinical trials with post-stroke patients were conducted; therefore, conclusions regarding therapeutic effectiveness cannot yet be established.

Future work will focus on clinical validation in neurological populations, the development of adaptive control strategies that adjust assistance based on patient performance, and the improvement of signal processing robustness for real-world deployment. Additionally, the integration of longitudinal data analysis and personalized rehabilitation models will be explored to support individualized therapy protocols.

***Abstract*—Sudden cardiac death from ventricular fibrillation requires intervention within minutes, motivating tools that detect signal deterioration before the collapse. This work applies Recurrence Quantification Analysis to recordings from the Sudden Cardiac Death Holter Database, extracting fifteen topological metrics over five-second windows under an adaptive recurrence threshold defined as a percentile of the positive pairwise distances of each window. Recurrence matrices and per-window metrics were stored in a traceable manner, and the temporal evolution of the attributes was assessed by visual inspection of the normalized trajectories and distributions. The recurrence descriptors characterize the transition sharply at its onset, where the organized structure of the heartbeat breaks down and the determinism and laminarity metrics undergo an abrupt inflection; a conservative per-patient baseline-departure test found no recording departing from its own baseline band before that instant. However, a per-patient test found no generalized metric separating the baseline window (-60 to -30 min) from the near-collapse window (-30 to 0 min) in the amplitude domain (paired Cohen's d, $d_z = -0.141$, 95% CI $[-0.594, 0.348]$). The same pipeline applied over a Takens-embedded heart-rate variability series produced a larger effect ($d_z = 0.63$) that does not survive multiplicity correction; a linear variability descriptor and the $m = 1$ amplitude restricted to the same seven patients yielded comparable effects ($d_z \approx 0.41$), so no domain provides a significant anticipatory separator. The main contribution is a documented negative result for minute-scale anticipation in both domains, accompanied by a per-patient prospective evaluation (sensitivity, false-alarm rate, and specificity in non-terminal rhythm) that confirms the absence of usable anticipation.**

***Index Terms*—recurrence quantification analysis, ventricular fibrillation, heart-rate variability, nonlinear dynamics, sudden cardiac death**

I. Introduction

Sudden Cardiac Death (SCD) represents one of the greatest challenges for modern medicine and for global public health, being responsible for approximately 15% to 20% of all deaths worldwide [1]. The survival of a patient affected by a cardiovascular collapse depends critically on the response time. The medical literature demonstrates that, for the reversal of a cardiorespiratory arrest to occur without irreversible neurological sequelae, emergency interventions must be started within a narrow window of about 4 to 5 minutes after the event [2]. Detecting ventricular fibrillation once it is established, however, is a mature problem, successfully addressed by sequence- and spectrum-based detectors as well as machine learning algorithms that reach high sensitivity and specificity on public databases [3]–[6]. These approaches are supervised and operate on short segments immediately preceding the onset. The question posed here is different and complementary: whether an unsupervised departure from the patient's own baseline band is detectable over the tens of minutes that precede the event. A negative answer to the second question is compatible with a positive answer to the first, since a classifier trained on curated pre-onset segments exploits discriminative information that a per-patient baseline criterion does not. In a clinical scenario where every second defines the boundary between recovery and permanent brain damage, exclusive reliance on reactive actions is insufficient. It is therefore imperative to develop technological tools capable of anticipating cardiac failure before the acute collapse sets in. However, conventional monitoring methods, based predominantly on linear analyses in the time and frequency domains, often fail to anticipate these catastrophic events [7]. The human cardiovascular system is governed by highly coupled mechanisms, and linear approaches are unable to capture the loss of stability and the fluctuations in the complex, nonlinear dynamics of the physiological signals that precede a critical phase transition such as ventricular fibrillation [8]. To overcome these limitations, Recurrence Quantification Analysis

(RQA) stands out as a robust and powerful mathematical tool [9]. By mapping the topological behavior of the time series in phase space, RQA allows the detection of hidden structural changes and transitions in the system regime (such as the loss of determinism) even in short and non-stationary signals [10]. In this context, the objective of this work is to apply RQA to electrocardiographic signals in order to map the temporal trajectory of 15 recurrence metrics along the physiological degradation process that precedes the collapse. Through the statistical parameterization of these trajectories, the aim is to retrospectively demonstrate the breakdown of a baseline physiological pattern and to determine the minimum size of the observation window required to identify this topological anomaly in the signal, providing quantitative support for the future development of predictive systems. Because a first analysis in the raw-amplitude domain yielded no minute-scale precursor, a complementary arm reconstructs the phase space of the heart-rate variability series to test whether the anticipatory signature resides in the autonomic dynamics rather than in the morphology of the beat.

II. Methodology

A. Data Acquisition and Preparation

The database used in this retrospective study was the *Sudden Cardiac Death Holter Database* (SDDB) [21], made publicly available by the PhysioNet repository [11], [22], which contains long-term electrocardiographic recordings of patients who suffered sudden cardiac arrest events. The database comprises 23 Holter recordings, collected in the 1980s in Boston-area hospitals and sampled at 250 Hz. The population is clinically heterogeneous: 18 patients had an underlying sinus rhythm (four of them with intermittent pacing), one was continuously paced, and four had atrial fibrillation; all progressed to sustained ventricular tachyarrhythmia, most with an actual cardiac arrest. This heterogeneity, in particular the presence of pacing, is relevant to the topological analysis, since artificial stimulation imposes an extrinsic periodicity on the signal that alters the recurrence metrics. Because the study depends on the annotation of the fibrillation onset instant (*vfon*), the 20 recordings that provide this marker were used, excluding the three recordings without a fibrillation episode. Of these, a restricted subset of 7 recordings with audited sinus beat annotations was used in the variability arm (Section II-G) (4 males, 3 females; median age 68 years, available for 5 of the 7; all presenting an underlying sinus rhythm in the SDDB documentation). As this is a retrospective collection, the clinical information on history and medication is limited and, in several cases, unavailable. To enable the analysis, the windowing of each recording covered the interval from 60 minutes before to approximately 5 minutes after the fibrillation onset, subdivided into three phases: the baseline phase, or *far* (from -60 to -30 min), which establishes the intra-patient reference band before the critical regime transition [12]; because every patient in this cohort progressed to the event, this band is a within-patient reference and not a healthy control; the approach phase, or *near* (from -30 to 0 min), immediately preceding the structural collapse (instant zero); and the post-collapse phase, or *post* (from 0 to $+5$ min), with ventricular fibrillation already established. Including the segment after the event allows the sustained fibrillation regime to be characterized and contrasted with both the baseline and the instant of the transition. The data are public and de-identified under the PhysioNet ODC-BY license.

B. Signal Pre-processing and Filtering

Before extracting the metrics, each recording was subjected to a pre-processing step to attenuate the noise and artifacts characteristic of Holter signals [13]. Because the SDDB recordings contain isolated invalid samples (NaN values), arising from the digitization of analog tape, which would propagate through the entire signal under recursive filtering, these samples were first linearly interpolated. A third-order Butterworth band-pass filter was then applied, with cutoff frequencies of 0.5 Hz and 40 Hz, implemented in zero phase (forward and backward filtering) so as not to introduce temporal distortion in the ECG complexes. The 0.5 to 40 Hz band removes baseline wander, below 0.5 Hz, and high-frequency and power-line noise, above 40 Hz, preserving the relevant morphological content of the heartbeat. The choice of this band was not by convention: it was validated through a comparative test among five pre-processing strategies (unfiltered signal, Butterworth 1–50 Hz, Butterworth 0.5–40 Hz, Butterworth 1–50 Hz with a 60 Hz *notch* filter, and only a 0.5 Hz high-pass), assessing which of them produced the most stable and robust extraction of the RQA metrics. The 0.5–40 Hz configuration was adopted for producing the most stable RQA extraction under this comparison, which was exploratory and did not use a pre-registered numerical criterion.

C. RQA Feature Extraction and Segmentation

To capture the nonlinear dynamics and the phase transitions of the cardiovascular system, the algorithm processed the signals through Recurrence Quantification Analysis (RQA) [9], [10]. The physiological dynamics were evaluated by means of a sliding-window method, allowing the continuous topological evolution of the system to be mapped over time. Fifteen fundamental metrics were extracted from each signal window: recurrence rate (RR), determinism (DET), mean and maximum diagonal lines (L, L_{max}), divergence (DIV), diagonal line entropy (L_{entr}), laminarity (LAM), trapping time (TT), maximum vertical lines and vertical entropy (V_{max}, V_{entr}), white-line features (W, W_{max}, W_{entr}), and combined ratios (DET_RR, LAM_DET). The recurrence matrix of each window was built directly from the scalar amplitude series, that is, with an embedding dimension $m = 1$, using the Euclidean distance; the diagonal and vertical structures were quantified with a minimum line length of $l_{min} = v_{min} = 2$. The RQA metrics were computed with an in-house implementation, validated against a pure-sinusoid control (which yields near-maximal determinism, as expected). The acquisition epochs of the sliding window were fixed at 5 seconds. The reduced sizing of this window was a methodological choice grounded

in the need to preserve the high temporal resolution of the signal immediately before the cardiac event. The literature on complex signal processing states that using long windows in systems close to collapse tends to mask fast fluctuations and abrupt transitions due to the mathematical averaging (smoothing) effect [10]. Thus, RQA is justified as the ideal tool for this scope because, unlike traditional linear and spectral metrics that require prolonged stability, it demonstrates high effectiveness and mathematical robustness in the analysis of extremely short non-stationary time series [14].

D. Data Structure, Collection, and Persistence

The processing pipeline persisted the data at two complementary levels, ensuring the traceability and reproducibility of the whole analysis. At the first level, each 5-second window had its recurrence matrix stored individually in binary `.npy` format, preserving the raw topology of the phase space (the point-by-point recurrence image) and allowing both the visual reconstruction of the Recurrence Plots and the later recomputation of any metric without the need to reprocess the original signal. At the second level, the 15 RQA descriptors extracted from each window were consolidated into manifest files in CSV format, generated independently for each tested threshold (p05 to p50). Thus, for each percentile of ϵ a complete manifest was obtained containing, per row, the 15 topological metrics accompanied by the identification metadata: the patient record, the index and the initial sample of the window, the time relative to the fibrillation onset (in seconds and minutes), the corresponding physiological phase (*far*, *near*, or *post*), and the name of the respective `.npy` file. This reference field links each tabular record to its stored recurrence matrix, so that every numerical value can be audited against its topological image of origin. Streaming computation without matrix materialization remains viable for embedded real-time use. Table I presents an excerpt of the manifest for $\epsilon = 40\%$ (p40). Among the 15 metrics, only Determinism (DET), the maximum diagonal (L_{max}), and Laminarity (LAM) were chosen for display. This selection is not arbitrary: it is the subset of descriptors from the *determinism and laminarity* family, which proved to be the most sensitive and discriminative for the phase transition, exhibiting the sharpest and most unequivocal inflection at the instant of collapse. While DET and LAM saturate near the upper limit and L_{max} jumps by an order of magnitude, the remaining metrics (entropies and vertical and white descriptors) show variations of smaller relative magnitude and are therefore less representative for compactly illustrating the signature of the event. The displayed instants span the trajectory up to collapse: -60 min (*far* baseline), -30 and -2 min (*near*), -0.1 min (immediately pre-event), and 0.0 min (*post*). The descriptors remain stable within the baseline band almost until the end and break down only in the final seconds.

TABLE I
EXCERPT OF THE MANIFEST (P40, RECORD 30): LINK BETWEEN EACH WINDOW, THE REPRESENTATIVE RQA METRICS, AND THE RECURRENCE MATRIX STORED IN `.NPY`.

t (min)	Phase	DET (%)	L_{max} (samples)	LAM (%)	Window

E. Recurrence Threshold (ϵ) Definition and Noise Mitigation

Biological signals acquired in clinical environments are inherently noisy and subject to amplitude variations caused by patient movement or reading artifacts [13]. In Recurrence Quantification Analysis (RQA), the extraction of the metrics depends directly on the definition of a radius or distance threshold, mathematically represented by the Greek letter Epsilon (ϵ). Two points in phase space are considered recurrent only if the distance between them is smaller than this threshold. To ensure the robustness of the analysis and to prevent the baseline noise from generating false recurrences, the value of ϵ was not defined as an absolute constant. Instead, the algorithm computed ϵ in a relative and adaptive way, as a percentile of the positive pairwise distances of each analyzed window [10], a robust scaling choice in the sense of [15]. The system was parameterized to evaluate the behavior of the signal under different topological demands, testing threshold percentiles ranging from 5% to 50% (identified in the data as p05, p10, p20, p30, p40, and p50). This allows the optimal ϵ to be identified: a radius strict enough to map the complexity of the collapse, yet which scales with the signal's distance distribution to mitigate transient noise.

F. Statistical Normalization and Visual Trajectory Analysis

Due to the heterogeneity of scales and magnitudes of the 15 topological metrics extracted by RQA, a standardization step was necessary to enable the graphical and physiological comparison among them. For this, Z-Score normalization was applied [10], a standard baseline for deviation-based anomaly detection [16]. For each metric, the mean (μ) and standard deviation (σ) exclusive to the baseline phase ("Far") were computed. The values extracted during the continuous monitoring of the pre-collapse phase (X_{near}) were then normalized:

$$Z = \frac{X_{near} - \mu_{far}}{\sigma_{far}} \tag{1}$$

This standardization converts the signal trajectories to a common scale, defining how many deviations the system departs from its baseline equilibrium over time. Because the critical phase transition and the structural collapse of the cardiac dynamics occur abruptly in the final minutes or seconds of the recording, global statistical class-separation approaches (which compute averages over the entire pre-event period) tend to dilute and mask the anomaly peaks. For this reason, the identification of the pattern breakdown was not delegated to an automated statistical threshold. Instead, a retrospective approach based on visual and qualitative post-processing inspection was adopted. The normalized temporal trajectories

and the distributions (boxplots) of each metric were analyzed graphically to empirically determine the moment and the magnitude of the irreversible deviation of the signal from its baseline normality band. This approach ensures that the abrupt change generated by the collapse is clearly observed, preventing the use of long-term statistical averages from hiding or smoothing the peak of the event.

G. Recurrence of the Heart-Rate Variability Series

Because the amplitude analysis above quantifies the morphology of the beat but not the autonomic modulation of its rhythm, a second, complementary arm applied the same recurrence pipeline to the heart-rate variability (HRV) series of each recording. The beat annotations audited in the database were used to build the normal-to-normal (NN) interval series: an interval was retained only when both delimiting beats were of sinus origin, and the neighbors of any ectopic beat were discarded, so that the compensatory pause does not contaminate the tachogram. This requirement of audited sinus labels restricted the HRV arm to a subset of recordings, since HRV measures the autonomic modulation of the sinus node: recordings under atrial fibrillation or ventricular pacing, and those without an audited beat-annotation file, were excluded. Unlike the amplitude series, the NN series is a one-dimensional projection of a higher-dimensional autonomic dynamics, so the phase space was reconstructed by delay embedding (Takens) [17] before computing recurrence. For each recording, the embedding delay τ was set to the first local minimum of the average mutual information [18], and the embedding dimension m to the value at which the fraction of false nearest neighbors fell below 1% [19]; both parameters were estimated on the baseline (far) segment so as not to be shaped by the collapse. The RQA metrics were then extracted from the embedded series with a sliding window of 256 beats, a step of 32 beats, and the same distance-percentile threshold and minimum line lengths used in the amplitude arm. A quality gate required an NN density inside the window to exceed 80%, yielding an acceptance rate that ranged from 53% to 100% of the windows per recording. The gate's coverage remained highly stable over time, maintaining 84.7% of approved windows in the far phase and 83.9% in the near phase, demonstrating that the pre-event HRV analysis was not disproportionately affected by outcome-dependent ectopic rejection.

H. Statistical Comparison

For each descriptor, a single aggregated mean value per patient per phase was used to prevent pseudo-replication. The separation between the far and near windows was quantified using the paired Cohen's d (d_z). The effect sizes highlighted in the results are the maxima observed among the fifteen metrics; for the far/near tests they are additionally reported with correction for multiplicity (Holm and Benjamini–Hochberg). Furthermore, descriptors such as RR, DIV (the reciprocal of L_{max}), DET_RR, and LAM_DET are mathematically redundant under a constant recurrence rate framework and are evaluated for completeness only. Effect sizes are reported as the paired d_z over the 20 patients of the amplitude arm and the 7 of the variability arm, with 95% confidence intervals from 10,000 bootstrap resamples of patients.

III. Results

The evaluation of the results was conducted through visual and qualitative inspection, with the aim of demonstrating the breakdown of the resting dynamics (baseline phase) toward the structural collapse (Ventricular Fibrillation). All metrics discussed in this section were extracted with 5-second acquisition windows and an adaptive recurrence threshold fixed at $\epsilon = 40\%$ of the positive pairwise distances (identified as *p40*). This parameterization was selected, among the tested factors (p05 to p50), for offering the best trade-off between sensitivity to the phase transition and robustness to baseline noise: smaller percentiles severely fragmented the diagonal structures due to noise, while larger percentiles saturated the matrix and masked the pre-collapse topological inflection. This selection was made on the same data reported below and is therefore exploratory.

A. Qualitative Analysis of the Recurrence Plots (RP)

The phase transition of the cardiovascular system can be visualized directly through the Recurrence Plots computed from the ECG (Fig. 1). The analysis of three distinct instants reveals the topological reorganization of the signal along the physiological degradation:

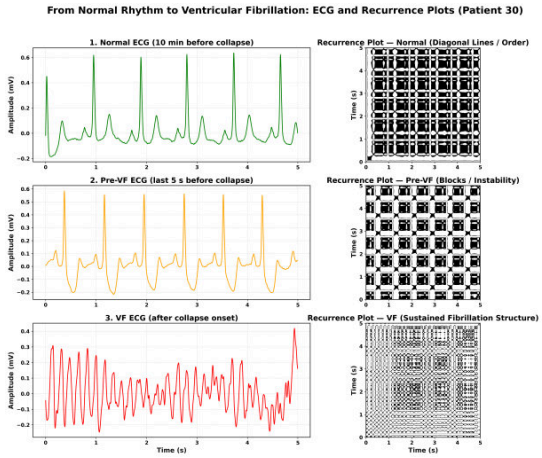

Fig. 1. ECG signals and their Recurrence Plots in three physiological states: Baseline (-10 min), Pre-collapse (-5 s), and Ventricular Fibrillation (post-collapse).

- **Normal Phase (-10 minutes):** The signal shows well-defined and periodic QRS complexes. The matrix presents an organized structure, with long parallel diagonal lines and regularly distributed recurrences, characterizing a deterministic system rich in morphological detail (P-QRS-T).
- **Pre-collapse Phase (-5 seconds):** The morphology of the heartbeat begins to deform and the topology reorganizes into dense blocks, with partial fragmentation of the diagonals and an increase of laminar (vertical) patterns,

reflecting the progressive loss of fine regulation and the growth of trapped states.

- **Ventricular Fibrillation (Post-collapse):** The fine structure of the heartbeat disappears entirely and the signal degenerates into a large-amplitude oscillation with low morphological variability. Although visually the matrix takes on a dense and less ordered appearance, the quantitative analysis with $\epsilon = 40\%$ reveals that this regime does not correspond to random noise: the dominant oscillation generates extensive long-range recurrent structures (long diagonals and laminar blocks), which translates into the marked increase of DET, L_{max}, and LAM. It is, therefore, a paradoxically *more deterministic* yet structurally impoverished state, the result of replacing the multiscale repertoire of the healthy ECG with a single oscillatory mode, and not of an increase in randomness. To test whether this pre-collapse deformation is simply sustained ventricular tachycardia (VT), the rhythm annotations (`.ari` and `.atr`) were queried in the $[-30\text{ s}, 0)$ interval of the 18 recordings for which an annotation file was available (two of the 20 amplitude-arm records lacked a usable annotation file and were excluded from this check). No VT episode is labelled in any of them. A heart rate could be computed over that interval for 9 of these recordings, with a median of 74 bpm (range 66–109); two recordings exceeded 100 bpm, consistent with sinus tachycardia rather than sustained VT in the absence of wide-complex labelling. Because rhythm labelling in this database is not exhaustive, the absence of a VT label is not conclusive, but the available evidence does not support interpreting the topological breakdown as a transition from sustained VT.

B. Temporal Trajectory of the RQA Metrics

To quantify the dynamic behavior, the 15 RQA metrics were extracted in continuous 5-second windows over the interval from 60 minutes before to 5 minutes after the event (Fig. 2). Observation of the trajectories shows that, throughout the entire baseline phase (from -60 min to approximately -1 min), the system oscillates within a narrow and stationary band, with no systematic trend. The recurrence rate (RR) remains essentially constant (≈ 0.4005) throughout the whole recording, which is an expected mathematical consequence of the chosen percentile threshold, effectively isolating structural degradation metrics from recurrence density variations. Upon reaching the zero instant, practically all metrics undergo an abrupt and simultaneous inflection, constituting an unmistakable signature of the collapse. A coherent bidirectional behavior is observed: the metrics associated with periodicity and long-term predictability surge, while the metrics associated with structural richness and complexity plummet. Determinism (DET) jumps from a baseline level of ≈ 98.6 to ≈ 99.55, and the maximum diagonal (L_{max}) triples, going from ≈ 360 to values above 1000; consequently, Divergence (DIV $= 1/L_{max}$) collapses from ≈ 0.0035 to ≈ 0.0015. Laminarity (LAM) rises from ≈ 99.3 to ≈ 99.8, and the DET_RR ratio follows the same upward direction. Conversely, the complexity descriptors fall sharply: the diagonal entropy (L_{entr}), the vertical entropy (V_{entr}), and the white-line entropy (W_{entr}) recede simultaneously, as do the mean diagonal length (L), the trapping time (TT), the maximum vertical line (V_{max}), and the white-line descriptors (W, W_{max}). The drop in LAM_DET reinforces this picture. This combination, an increase in global determinism accompanied by a generalized loss of entropy, reveals the physiological nature of the collapse: the rich multiscale repertoire of the healthy ECG is replaced by a single dominant, impoverished oscillatory mode. In dynamical terms, the system becomes more predictable, yet pathologically simplified, losing the variability that characterizes the resting baseline. After the abrupt peak at the zero instant, the metrics do not return to baseline but stabilize into a new regime corresponding to sustained fibrillation: determinism settles above its baseline level, and the mirrored descriptors (DIV, V_{entr}, W) re-stabilize after a trough at the collapse. Fibrillation, once established, is thus itself a stationary but pathological rhythm, topologically distinct from the baseline. The abrupt inflection is confined to the onset window itself; a prospective evaluation of this departure, through a per-patient detector with its operating characteristics, is presented in Section III-F. Under a conservative criterion (metric consensus and persistence) no recording is flagged before the onset, and no operating point yields anticipation with an acceptable false-alarm rate.

C. Evolution of the Distributions and Pattern Breakdown

The breakdown of the baseline limit was confirmed by the evolution of the metric distributions at six reference instants (-60 min, -30 min, -10 min, -2 min, -30 s, and collapse), as shown in Fig. 3. The boxplots are consistent with the behavior observed in the trajectories. Between -60 min and -30 s, the medians of all metrics remain close and the boxes largely overlap, delimiting a band within which no shift is apparent, including in the -2 min and -30 s windows, which indicates that the degradation is not slowly progressive but rather concentrated in the final seconds. It is only in the collapse column that a severe and unequivocal shift of the medians occurs: L_{max} and DET_RR migrate to the top of their scales, DET and LAM approach saturation, while DIV, L, TT, V_{max}, the entropies, and LAM_DET shift downward, with a simultaneous reduction of the interquartile dispersion. This sharp visual separation between the pre-collapse block and the collapse window indicates that the structural anomaly is abrupt rather than gradual, which justifies the retrospective inspection strategy adopted: approaches based on global averages over the entire pre-event period would dilute this peak, whereas the per-instant analysis preserves it. From an applied standpoint, the result indicates that an observation window on the order of seconds, combined with the most responsive metrics (L_{max}, DIV, DET, and LAM), is sufficient to characterize the breakdown of the baseline pattern with $\epsilon = 40\%$.

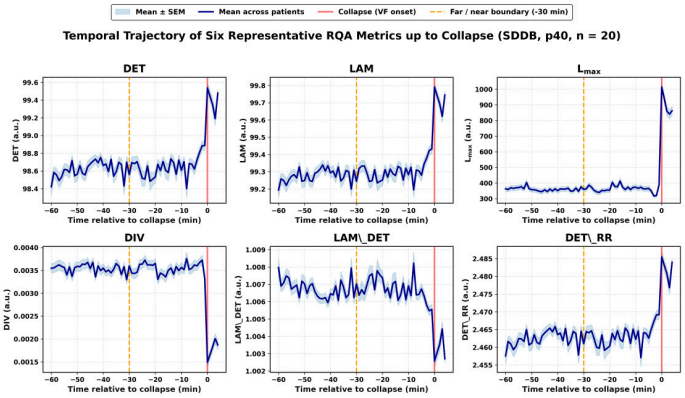

Fig. 2. Temporal trajectories of six representative RQA metrics (DET, LAM, L_{max}, DIV, LAM_DET, DET_RR) from 60 min before to 5 min after the collapse (SDDB, $\epsilon = 40\%$, $n = 20$). The full 15-metric version is available in the supplementary material. The dashed orange line marks -30 min and the red line the instant of collapse (0).

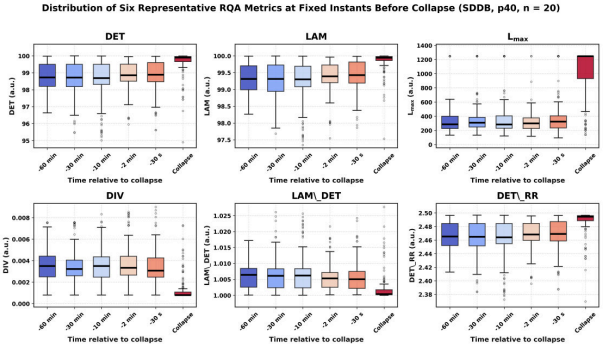

Fig. 3. Statistical distribution (boxplots) of six representative RQA metrics per instant up to the collapse (SDDB, $\epsilon = 40\%$, $n = 20$).

D. Predictive Test in the Amplitude Domain

To assess whether the recurrence metrics anticipate the collapse, rather than merely detect it once installed, the analysis was restricted to the pre-event interval and the *far* (-60 to -30 min) and *near* (-30 to 0 min) windows were compared. To avoid pseudo-replication, a single value per patient per window was used (the mean of that patient's windows), and the effect size was quantified with Cohen's d. In the amplitude domain, when evaluating the grouped paired differences across phases, the effect size for V_{max} yielded $d_z = -0.141$ (95% CI $[-0.594, 0.348]$ via 10,000 bootstrap resamples). With correction for multiplicity across the 15 metrics (Holm and Benjamini–Hochberg), no metric separates far from near: the largest effect size is that of TT ($d_z = -0.20$; $p_{\text{Holm}} = 1.0$; 0/15 survive). The confidence interval crossing zero reflects the precision achievable at this sample size, and no group-level threshold separates the two windows. The result is further insensitive to the uncertainty of the onset annotation: shifting the onset by -15 to $+15$ s (± 3 windows), the largest $|d_z|$ remains between 0.20 and 0.22. This absence of a uniform anticipatory trend is consistent with the flat baseline trajectories of Fig. 2 and is robust to pre-processing, since all five filtering strategies of Section II-B produced the same result. The amplitude-based recurrence of the ECG therefore characterizes the collapse but does not anticipate it over the minutes that precede it.

E. Domain Contrast with Heart-Rate Variability

Applying the same test to the recurrence of the HRV series changes the picture. The HRV arm comprised the seven eligible recordings (of the 23; the remaining sixteen were excluded for atrial fibrillation, ventricular pacing, or the absence of an audited beat-annotation file). The sinus-eligibility requirement and the 80% NN-density gate yielded 886 analysis windows, fewer than in the amplitude arm because each window here spans 256 beats and only clean sinus segments are retained; the embedding parameters were estimated per recording on the baseline segment. Under the same *far*/*near*, per-patient, Cohen's d comparison, the largest effect in the Takens-embedded HRV ($m > 1$) was $d_z = 0.63$ (V_{max}) and the raw $m = 1$ amplitude restricted to the exact same seven recordings reached $d_z = 0.41$ (LAM), both shown in Fig. 4; a linear HRV descriptor (SDNN), reported here in text only and not plotted, reached a comparable $d_z = 0.41$. With multiplicity correction (Holm), none of these effects is significant ($p_{\text{Holm}} = 1.0$ across all domains). The difference between domains is therefore not robust: the somewhat larger raw effect of the embedded HRV does not survive correction, and the linear HRV baseline (0.41) matches the amplitude-restricted control (0.41), indicating that the apparent autonomic advantage reflects the composition of

the seven-patient subsample rather than an intrinsic property of the variability domain.

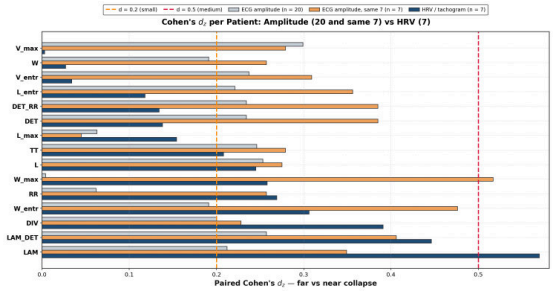

Fig. 4. Domain contrast of the predictive effect size (per-patient Cohen's d_z, *far* vs. *near*) for the 15 RQA metrics, computed on the raw ECG amplitude over all 20 recordings ($m = 1$), on the amplitude restricted to the same seven recordings as the variability arm, and on the Takens-embedded HRV series ($m > 1$). Dashed lines mark the small- ($d = 0.2$) and medium-effect ($d = 0.5$) references. The anticipatory separation is small in both domains and no effect survives multiplicity correction; the apparent advantage of the variability domain is not maintained when the amplitude arm is restricted to the same seven recordings (Section III-E). A linear HRV baseline, reported in the text, is not plotted here.

F. Operating Characteristics of a Per-Patient Detector

To replace visual inspection with a prospective criterion, an unsupervised per-patient detector was evaluated: the mean (μ) and standard deviation (σ) of DET, L_{max}, and LAM were estimated on the *far* phase, and each 5 s window was flagged when it exceeded $\mu + k\sigma$. Because the recurrence metrics are heavy-tailed (0.52% of the baseline windows themselves already exceed $\mu + 3\sigma$, versus 0.13% under normality), a single-window threshold produces a high false-alarm rate and flags pre-event windows indistinguishable from baseline noise (Table II). At 3σ per single metric the sensitivity at onset is 18/20, at the cost of 28.7 false alarms per hour; a consensus of two of the three metrics with a persistence of three windows at 4σ eliminates the false alarms but detects the onset in only 6/20 recordings and flags no window before it. There is therefore no operating point that yields anticipation with an acceptable false-alarm rate. Under leakage-free selection by

TABLE II
OPERATING CHARACTERISTICS OF THE PER-PATIENT DETECTOR (AMPLITUDE, P40, $n = 20$). FA/H: FALSE ALARMS PER HOUR IN THE PRE-EVENT PHASE.

Configuration	Sens.	FA/h	Pre-event win.
3σ, single metric	18/20	28.7	19/20 (false)
4σ, single metric	17/20	14.4	14/20 (false)
5σ, single metric	17/20	7.2	14/20 (false)
4σ, consensus 2/3, 3 win.	6/20	0.0	0/20

leave-one-patient-out validation (percentile, k, consensus, and persistence chosen on the development patients and evaluated on the held-out patient), the out-of-fold sensitivity was 75% (15/20), still at 9.4 false alarms per hour and with (false) pre-event flagging in 16/20 patients, confirming the absence of generalizable anticipation. As a negative control, the same detector applied to recordings that do not progress to fibrillation in the analyzed segment fired at 3.4 false alarms per hour (recordings without VF or with pacing) and at 15.0/h in recordings with atrial fibrillation, a rate comparable to that observed in the pre-event phase of the fibrillation recordings (28.7/h). The alarms are therefore not specific to an impending fibrillation.

IV. DISCUSSION

The analysis shows that ventricular fibrillation is preceded by an abrupt topological transition at its onset, perceptible only in the seconds preceding the collapse. The term *pre-fibrillation* is used here in a descriptive, post-hoc sense: the trajectory inspection was retrospective, the conservative per-patient detector (Section III-F) flags no window before the onset, and the negative controls fire at a comparable rate, so the alarms are not specific to the event. Already at -5 s (Fig. 1), the recurrence matrix loses the fine structure of the heartbeat and reorganizes into blocks, while the determinism and laminarity metrics begin the inflection that saturates at the instant of the event (Fig. 2 and Fig. 3). This is not a long-term warning *in the amplitude domain*, since there is no detectable deviation tens of minutes earlier (from -60 min to approximately the last minute, the 15 metrics oscillate within a narrow and stationary baseline band), but a sharp transition on the scale of seconds. Because the change concentrates in the last seconds, block-average separation tools such as Cohen's d [20] are inadequate in the amplitude domain: averaging tens of minutes of baseline dilutes a few-second deviation (Section III-D, $d_z = -0.141$; no metric survives multiplicity correction). The breakdown was therefore identified by visual inspection of the normalized trajectories rather than by a global threshold. In the HRV domain the largest far/near effect ($d_z = 0.63$) in the Takens-embedded NN series exceeds the $m = 1$ amplitude, but it does not survive multiplicity correction, and a linear HRV descriptor matches the amplitude restricted to the same seven patients ($d_z \approx 0.41$). The anticipatory capacity thus depends heavily on patient stratification and low ectopy, underscoring the difficulty of patient-independent prediction. Based on these findings, an open question for future work is whether any method can identify, reliably and earlier than the final seconds, the instant at which the signal leaves the patient's own baseline band. Even though the onset signature is confined to the final seconds, an automatic and reliable identification of that instant would still have clinical value, given that the reversal of a cardiorespiratory arrest depends on intervention within a few minutes [2]. Several fronts could consolidate this agenda: time-localized change-point detection against the patient's own baseline band rather than block averages; identification of which descriptor or combination separates earliest and with fewest false positives; a multivariate patient-independent classifier extending the detector characterized here; a sweep of the threshold percentile and of window duration; extension of the variability pipeline to the excluded paced and atrial-fibrillation recordings as a robustness analysis; and validation against healthy controls and additional databases. In summary, recurrence descriptors characterize the onset sharply but did not anticipate it over the minutes preceding it, in either domain, once the sample was held fixed; whether any per-

patient criterion can identify the transition earlier remains open.

A. Limitations

The amplitude arm was performed with an embedding dimension $m = 1$ and without a Theiler window, which causes metrics like DET and LAM to operate near saturation due to tangential motion artifacts. The sample size of 7 for HRV is small. The variability arm also depends on audited beat annotations, which do not exist in real time: a deployed equivalent would require a validated QRS detector and ectopy classifier, whose errors would propagate into the tachogram and hence into the recurrence descriptors. Furthermore, the dataset consists of 1980s analog Holter recordings, limiting generalization to modern digital front-ends. Finally, the operating point and the percentile of the main arm were, in part, selected on the same evaluation data, with leave-one-patient-out validation conducted only for the amplitude detector; effect sizes are reported with multiplicity correction (Holm and Benjamini–Hochberg) and no metric survives it in either domain, the seven-patient variability arm remaining, in particular, exploratory.

V. Conclusion

This work applied Recurrence Quantification Analysis to SDDB electrocardiographic signals, extracting 15 topological metrics in 5-second windows under an adaptive percentile threshold and persisting both the recurrence matrices and per-window metrics for full traceability. The parameterization $\epsilon = 40\%$ (p40) best revealed the phase transition. Ventricular fibrillation exhibits an abrupt topological transition at its onset, in which the determinism and laminarity family (DET, LAM, L_{max}, DIV) undergoes a sharp inflection; characterized retrospectively, this signature is not by itself a prospectively detectable precursor. It is concentrated in the final seconds rather than the preceding minutes, in which the amplitude signal stays within its baseline band ($d_z = -0.141$, 95% CI $[-0.594,\ 0.348]$); global separation tools are therefore inadequate at this short scale, and visual inspection best captured the breakdown. Applying the same pipeline over a Takens-reconstructed HRV phase space produced a larger effect ($d_z = 0.63$) that does not survive multiplicity correction; a linear HRV descriptor and the amplitude restricted to the same seven patients yielded comparable effects ($d_z \approx 0.41$), so no domain sustains a significant anticipatory separator. The contribution is thus a well-characterized negative result for generalized long-term prediction, clarifying the boundaries and the patient stratification required for short-scale monitoring. The bootstrap intervals are wide at this sample size, so neither domain supports a group-level anticipatory threshold; whether a per-patient adaptive baseline performs better remains to be tested on a larger cohort.

***Abstract*—Early detection of glaucoma is essential to prevent irreversible vision loss, yet reliable screening remains challenging due to the subtle nature of early structural changes. This work presents an exploratory evaluation of convolutional neural network (CNN) architectures for binary glaucoma classification from retinal fundus photographs under limited data conditions. Two widely adopted models, VGG16 and ResNet50, were implemented using transfer learning and trained on a curated subset of the Ocular Disease Recognition (ODIR) dataset. Model performance was assessed using accuracy, F1-score, sensitivity, specificity, precision, negative predictive value, ROC-AUC score, variance, and confusion matrices. Experimental results indicate that VGG16 outperformed ResNet50 on the considered dataset. Given the limited sample size and the absence of external validation, the findings should be interpreted as a preliminary baseline comparison rather than evidence of clinical readiness or generalizability. Following the reviewer's suggestions, the metrics ROC-AUC, sensitivity, and specificity were added. The VGG16 model presented an ROC-AUC score of 0.7266, 79.07% for the sensitivity, and 62.16% for specificity, while the ResNet50 model showed a ROC-AUC score of 0.6568, 58.14% for the sensitivity and 62.16% for the specificity.**

***Index Terms*—CNN; Fundus; Glaucoma; Artificial Intelligence; VGG16; ResNet50**

I. Introduction

Glaucoma is a group of progressive optic neuropathies characterized by the degeneration of retinal ganglion cells and damage to the optic nerve head, often associated with elevated intraocular pressure (IOP). This damage leads to irreversible vision loss and is a leading cause of blindness worldwide. The disease is typically asymptomatic in early stages, making early detection critical to prevent significant visual impairment. Various forms of glaucoma exist, including primary open-angle glaucoma and angle-closure glaucoma, each with distinct pathophysiological mechanisms [1], [2].

The causes of glaucoma are multifactorial, encompassing both genetic predispositions and environmental influences. Genetic factors significantly contribute to early-onset glaucoma, such as congenital forms inherited through mutations in specific genes like CYP1B1 and LTBP2, which are typically inherited in an autosomal recessive pattern. In contrast, adult-onset glaucoma, including primary open-angle glaucoma (POAG), exhibits complex inheritance involving multiple genes interacting with environmental factors. Environmental influences, such as elevated intraocular pressure (IOP), lifestyle choices, exposure to toxins, and systemic conditions like diabetes, can modulate glaucoma risk and progression. The interplay between genetics and environment, including gene-environment interactions, is increasingly recognized as critical for understanding individual susceptibility and disease severity, paving the way for personalized prevention and treatment strategies [3]–[5].

Figure 1 shows representative ODIR retinal fundus photographs labeled as normal and glaucoma. In cases such as those illustrated in Figure 1, retinal abnormalities are often apparent; however, differentiating glaucoma from other conditions such as diabetes or cataracts through retinal images can be challenging and costly if relying solely on expert manual analysis [7].

While glaucoma is often associated with increased intraocular pressure, it is incorrect to assert that elevated pressure is the direct cause [8]. The eye contains a transparent fluid known as aqueous humor, which drains through the Schlemm's canal and the uveoscleral pathway [9]. Impaired drainage causes increased intraocular pressure, which can damage the optic nerve and lead to glaucoma [2]. Diagnosis frequently involves tonometry, which measures intraocular pressure, and Optical Coherence Tomography (OCT), which provides detailed cross-

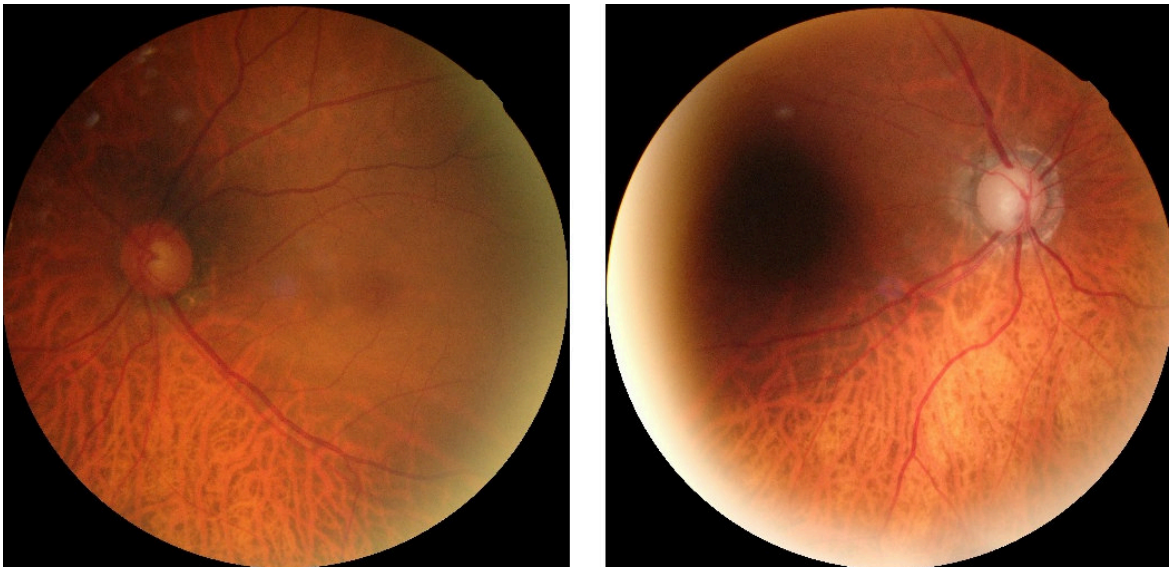

Fig. 1. Comparison between a normal eye (left) and an eye affected by glaucoma (right). Source: Ocular Disease Recognition Dataset [6].

sectional information about retinal structures [10]. OCT is mentioned here as a clinical imaging modality; however, the ODIR images analyzed in the present study are retinal fundus photographs.

Artificial neural networks are computational models within the field of machine learning, which focuses on teaching machines to learn from data without explicit programming [11]. ANNs are particularly powerful in identifying nonlinear patterns in complex datasets, such as recognizing features in images by analyzing pixel data. The fundamental processing unit of an ANN is the neuron, analogous to biological neurons, which receive, transform, and transmit information within layers of the network [12].

Neurons in a network carry different informational weights, and biases are added to increase computational complexity. These weights and biases have initially arbitrary values, which are iteratively adjusted during training — a process of learning from labeled examples to improve the model's predictive accuracy without overfitting [11], [13].

ANNs and CNNs have been widely investigated for medical image classification, including ophthalmic imaging [14]. Nevertheless, performance reported in a limited single-dataset experiment should not be interpreted as evidence of clinical screening capability without external validation and further prospective evaluation.

Convolutional Neural Networks (CNNs) are a specialized type of ANN designed to process and analyze visual data. Distinguished by their use of convolutional layers, CNNs automatically learn hierarchical feature representations from raw image inputs, making them highly effective for image classification tasks [12]. In medical imaging, CNNs have demonstrated superior performance in detecting and classifying conditions by capturing subtle patterns and structures that may be difficult for human observers to discern [15]. Among the various CNN architectures, VGG16 [16] and ResNet50 [17] are widely recognized for their effectiveness and have been extensively applied in medical image analysis [18]. VGG16 employs a deep yet straightforward design with small convolutional filters to capture fine-grained features, while ResNet50 introduces residual learning to overcome the challenges of training very deep networks, enabling improved accuracy and convergence. In this study, they are used as established baseline architectures for comparison on retinal fundus photographs [16], [17], [19].

METHODS

Methodology

The methodology adopted for this study was exploratory, combining comprehensive bibliographic research with practical experimentation involving established deep learning architectures. Specifically, two convolutional neural network (CNN) architectures — VGG16 and ResNet50 — were selected due to their proven efficacy in image classification tasks. Both models were trained using the publicly available Ocular Disease Recognition (ODIR) dataset, which includes retinal images labeled for various ocular conditions, including glaucoma [6].

To compare the architectures' performances in glaucoma detection, we employed multiple evaluation metrics: Accuracy, F1-Score, Variance, and confusion matrices. The revised evaluation is being expanded to include ROC-AUC, sensitivity, specificity, precision, and negative predictive value, as requested by the reviewers. These metrics provide an initial comparison of the two architectures on the selected ODIR subset; the study does not establish clinical applicability or external generalizability. For consistency with the actual ODIR image modality, the inputs analyzed in this work are referred to throughout as retinal fundus photographs or fundus images.

Sample and Dataset

A subset of the Ocular Disease Recognition (ODIR) dataset [6], comprising 512×512 pixel retinal fundus photographs, was used. Only images labeled as either "glaucoma" or "normal" without comorbidities were included, resulting in a balanced set of 200 images per class. The combined 400 images were randomly shuffled. No data augmentation techniques were applied in the original experiment. All images used in this study were obtained from distinct patients, and no pair of left- and right-eye images originated from the same patient.

Because patient-level separation was not documented in the original submission, the revised manuscript explicitly identifies the split procedure as a limitation until patient identifiers and the original allocation are verified. A patient-level split is recommended for future validation if the original experiment used image-level randomization.

Model Architectures

This study evaluated two widely recognized convolutional neural network (CNN) architectures, VGG16 and ResNet50, chosen for their established effectiveness in image classification and medical image analysis tasks.

- **VGG16**: This architecture [16] features sequential convolutional blocks composed of small 3×3 convolutional filters followed by max pooling layers, culminating in three fully connected dense layers. A main advantage of VGG16 is its simplicity and uniform design, which make it easy to understand and implement. It effectively captures fine-grained image features, performing well especially on moderate-sized datasets. However, VGG16 has a relatively large number of parameters ($\sim$138 million), which creates high computational and memory demands and can lead to longer training times and overfitting on smaller datasets.
- **ResNet50**: Introduced by He et al. [17], ResNet50 mitigates the degradation and vanishing gradient problems experienced in deep networks by employing residual learning via shortcut connections. These residual blocks facilitate training of deeper architectures by allowing gradients to propagate more effectively. ResNet50 typically offers faster convergence and better generalization on large and complex datasets. Nonetheless, its more complex architecture may require more extensive tuning and can be prone to overfitting in scenarios with limited data.

Both architectures are presented in Figure 2 and were implemented using TensorFlow/Keras and trained in Google Colab with GPU acceleration, leveraging pretrained ImageNet weights. In the original experiment, the ImageNet pretrained convolutional backbones were used as frozen feature extractors, while only the final classifier layers were trained on the selected ODIR subset.

Implementation and Experimental Details

Models were implemented in TensorFlow/Keras on Google Colab with an NVIDIA T4 GPU (availability limitations circumvented via multiple accounts). Images (512×512 pixels) were normalized by scaling pixel values to [0,1] via division by 255.0. No resizing or data augmentation was applied. From ODIR-5K [6], 400 fundus images were selected: 200 Normal (100 left/100 right eyes) and 200 Glaucoma (104 left/96 right), randomly shuffled (seed 42), split into 320 images for training and 80 images for validation.

ImageNet-pretrained convolutional layers were frozen; only the top dense layers (256 neurons, ReLU, Dropout 0.5, softmax output; 2 classes) were trained using:

- Adam optimizer with a standard learning rate of 0.001 and standard hyperparameters;
- Categorical cross-entropy loss;
- A batch size of 32 images;
- a 256-neuron fully connected layer with ReLU activation;

VGG16 trained for 60 epochs and ResNet50 for 30 epochs in the original script. The model was implemented using TensorFlow/Keras (TensorFlow 2.20.0), with NumPy 2.1.3 for numerical computations, scikit-learn 1.6.1 for performance evaluation, and Matplotlib 3.10.0 for visualization. Training was performed using GPU acceleration, with an NVIDIA GPU detected by TensorFlow.

The original protocol did not include partial convolutional fine-tuning, data augmentation, scheduler, early stopping, repeated-seed evaluation, cross-validation, or best-weight restoration. These omissions are now stated explicitly as methodological limitations and are identified as priorities for future validation.

Training and Validation

Images were standardized for input size and color. Categorical labels were encoded for binary classification. Epoch counts were adjusted based on the observed training behavior; a comprehensive hyperparameter optimization procedure was not performed in the original experiment.

Performance Metrics

To evaluate and compare the performance of the proposed models, eight metrics were employed:

- **Accuracy:**

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}$$

- **F1-Score:**

$$F_1 = \frac{2VP^2}{VP(2VP + FP + FN)}$$

- **Sensitivity:**

$$\text{Sensitivity} = \frac{TP}{TP + FN}$$

- **Specificity:**

$$\text{Specificity} = \frac{TN}{TN + FP}$$

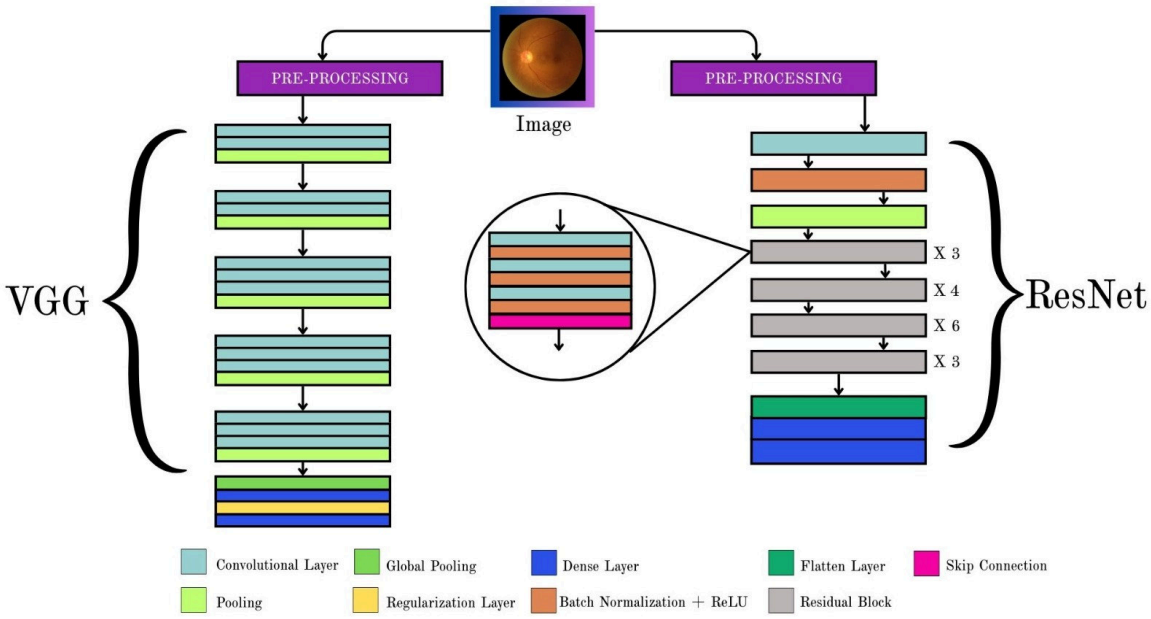

Fig. 2. Comparison between VGG [16] and ResNet [17] convolutional neural network (CNN) architectures used for medical image analysis. The figure illustrates the main processing steps, including pre-processing, convolutional and pooling layers, and the architectural differences—such as the use of regularization, batch normalization, skip connections, and residual blocks. The distinct blocks and color-coded elements highlight how each architecture handles feature extraction and information flow, supporting applications in medical imaging tasks such as disease detection and classification.

- **Precision:**
$$\text{Precision} = \frac{TP}{TP + FP}$$
- **Negative Predictive Value:**
$$\text{NPV} = \frac{TN}{TN + FN}$$
- **ROC-AUC:**The area under the receiver operating characteristic curve should be calculated from model probability scores rather than from the confusion matrix alone.
- **Variance:**
$$\sigma^2 = \frac{1}{n}\sum_{i=1}^{n}(x - \mu)^2$$
In the revised presentation, emphasis is placed on clinically interpretable classification metrics requested by the reviewers. Variance is retained only as a descriptive metric from the original analysis and should not be interpreted as a substitute for uncertainty estimates or repeated-run evaluation.
- **Confusion Matrix:** A detailed visualization of the classification results, the confusion matrix depicts counts of true positives (images with glaucoma classified as ”glaucoma”), true negatives (normal images classified as ”normal”), false positives (normal images classified as ”glaucoma”), and false negatives (images with glaucoma classified as ”normal”), enabling a comprehensive error analysis.

These metrics together provide a thorough assessment of the diagnostic accuracy, reliability, and potential clinical applicability of the trained deep learning models.

Results

The neural network architectures were implemented and tested. Table I summarizes the performance metrics obtained for the VGG16 and ResNet50 models on the test dataset.

The VGG16 model achieved an accuracy on average of 71.25%, outperforming the ResNet50 model, which attained an average of 58.87%. Similarly, the F1-Score — a harmonic mean of precision and recall — followed the same trend, with values of 0.7070 and 0.5997 for VGG16 and ResNet50, respectively. Also, both the precision and negative predictive value of the VGG model were higher than the ResNet model — 70.83% to 64.10% for precision and 71.88% to 56.10% for negative predictive value, respectively. Because new runs of the models were necessary to address the reviews received, the two variables that showed the greatest variation, namely accuracy and ROC-AUC, were measured 10 times using the same set of images, with the images randomly shuffled in each iteration using seed 42. The resulting values were then used to calculate the arithmetic mean for each one.

The VGG16 model showed higher sensitivity, at approximately 79.07%, indicating a greater resistance to false negatives than the ResNet50, with 58.14%. Interestingly, the specificity of both models was equal, 62.16%, since both have same counts of true negatives and false positives. Finally, the VGG16 model achieved a higher ROC-AUC score, 0.7266, than ResNet50 with a score of 0.6568. These results indicate better performance for VGG16 under this specific experimental configuration, but they should not be interpreted as evidence of superiority beyond this dataset.

Tables II and III present the confusion matrices for VGG16 and ResNet50, respectively, giving detailed insights into classification performance per class. The VGG16 model correctly identified 34 glaucoma images and 23 normal images. Using glaucoma as the positive class, the submitted confusion matrices contain 9 false-negative and 14 false-positive classifications for VGG16, compared with 18 false-negative and 14 false-positive classifications for ResNet50. Thus, within this 80-image evaluation subset, the higher VGG16 accuracy is primarily associated with fewer false-negative glaucoma classifications.

Within the selected ODIR fundus subset and the original training protocol, VGG16 achieved higher accuracy than ResNet50. The limited dataset size, image-level randomization, and lack of external validation restrict broader interpretation of this comparison.

TABLE I
PERFORMANCE METRICS FOR VGG16 AND RESNET50 ARCHITECTURES.

Metric	VGG16	ResNet50
Accuracy	0.7125	0.5887
F1-Score	0.7070	0.5997
Sensitivity	0.7907	0.5814

Actual Glaucoma	25	18
Actual Normal	14	23

DISCUSSION

The results obtained in this study provide an insightful basis for analyzing the challenges, limitations, and potential of neural network architectures applied to glaucoma detection using retinal fundus photographs.

Dataset Limitations and Generalizability

The dataset size consisted of 400 images, allowing relatively fast experimentation but limiting the diversity of image characteristics represented during training. The images were obtained from a single public dataset, and no independent external cohort or external-device validation was performed. Consequently, the results should not be generalized to other populations, acquisition systems, or clinical settings without further validation. Future efforts should prioritize larger and more diverse datasets encompassing different imaging devices, patient demographics, and glaucoma stages. Accordingly, the present work is best interpreted as an exploratory baseline comparison under a constrained experimental setting, rather than as a validated screening or diagnostic system, considering the small number of 320 images used for training and 80 for validation.

Computational Infrastructure and Training Adjustments

Despite leveraging cloud-based GPU acceleration (Google Colab with T4 GPUs), a full end-to-end fine-tuning of the convolutional layers was not feasible due to resource constraints and the extensive number of parameters to be optimized. Consequently, the transfer learning strategy was adopted, freezing pre-trained convolutional layers from ImageNet-weighted models and training only the dense classifier layers. This approach enabled feasible training times but inherently limited the ceiling of achievable accuracy. Additionally, intermittent GPU availability imposed further restrictions. More sophisticated techniques such as fine-grained tuning and advanced data augmentation could yield improved performance in future studies with enhanced computational access.

Model Analysis and Overfitting Issues

The VGG16 and ResNet50 architectures displayed notably different classification performances. While VGG16 reached approximately 71.25% accuracy, ResNet50 scored around 59%, tested on equivalent randomized validation splits of the same dataset. The observed divergence between training and validation accuracies across multiple epochs indicated overfitting as the training progressed. Because only one random seed and a limited dataset were used, these values should be interpreted as preliminary point estimates rather than stable estimates of model performance.

Positioning Relative to Current Methods

The comparison of VGG16 and ResNet50 is treated in the revised manuscript as an exploratory baseline experiment rather than a state-of-the-art contribution. Recent literature demonstrates continued development of deep-learning methods for retinal-image analysis [7], [19]. Therefore, the present results are interpreted only within the current dataset and protocol, while broader benchmarking against simpler baselines and contemporary architectures is reserved for future work.

Explainability and Additional Validation

The present experiment did not include Grad-CAM or other saliency analysis, subgroup analysis, or external-device validation. These limitations are now stated explicitly because they restrict assessment of shortcut learning, demographic or acquisition-related bias, and whether model attention is associated with clinically plausible retinal regions. The absence of an independent external cohort further prevents claims of

generalizability. The revised manuscript no longer presents VGG16 and ResNet50 as state-of-the-art or as a novel signal-processing method. They are positioned as established baseline CNN architectures. Comparisons with simpler baselines, more recent CNNs, vision transformers, and foundation models are identified as future work and as necessary for broader benchmarking.

Conclusion

This exploratory study compared VGG16 and ResNet50 for binary glaucoma classification using a limited subset of ODIR retinal fundus photographs. Under the original experimental configuration, VGG16 achieved higher accuracy than ResNet50. However, the small single-dataset sample, frozen convolutional features, absence of data augmentation and external validation, and uncertainty regarding patient-level separation limit the conclusions that can be drawn. Future work should evaluate patient-level validation, broader hyperparameter tuning, partial or full fine-tuning, explainability methods, contemporary architectures, and independent external datasets before any clinical interpretation is considered.

ACKNOWLEDGMENT

The authors would like to thank Shanggong Medical Technology Co., Ltd. for making the Ocular Disease Intelligent Recognition (ODIR) dataset publicly available, which was used in this study. The dataset can be accessed at https://www.kaggle.com/datasets/andrewmvd/ocular-disease-recognition-odir5k. The usage of AI in this project is limited to supervised learning and grammar and semantics checking.

***Abstract*—Quantitative assessment of muscle architecture via B-mode musculoskeletal ultrasound (US) is important for clinical diagnostics and myoelectric human-machine interfaces, but high-temporal-resolution ultrafast US generates extensive frame sequences that make manual aponeurosis tracking impractical. This paper presents a deterministic, frame-independent computer-vision pipeline for automated aponeurosis tracking and instantaneous muscle-thickness extraction from B-mode ultrasound. Unlike optical-flow and Kalman-filter-based trackers, which estimate each frame's boundary from the previous frame and are therefore vulnerable to cumulative drift, and unlike deep-learning trackers, which require large annotated training sets, the proposed method treats each frame as an independent horizontal intensity projection constrained by anatomical priors, so that tracking of one frame does not depend on the outcome of the previous one. Each frame is processed via a horizontal intensity projection, a moving-average filter to suppress speckle noise, an anatomically constrained peak-width detection step ($\Delta_w = 10-15$ points), and offline, zero-phase 5th-order Savitzky–Golay post-filtering of the compiled thickness profile. The pipeline was applied to a dynamic in vivo isometric-contraction sequence (3000 frames, 200 Hz) and separately evaluated for static boundary agreement against manual annotations on a curated subset (n = 197) of an open-source benchmark dataset, achieving an Intraclass Correlation Coefficient of 0.858 and a mean Bland-Altman bias of 0.6 px (95% limits of agreement: -32.1 to 33.2 px). These results support the boundary-detection stage as a proof of concept; because the validation set consisted of static images with a single annotator, it does not by itself establish tracking continuity, drift resistance, or recovery after boundary loss across a dynamic sequence, nor has agreement been converted to millimeters or benchmarked against comparator methods. These remain open questions addressed in the Discussion and proposed as future work.**

***Index Terms*—aponeurosis tracking, computer vision, muscle thickness, musculoskeletal, ultrafast ultrasound**

I. Introduction

The human musculoskeletal system is a highly complex architecture comprising bones, muscles, and associated connective tissues, functioning synergistically to provide structural stability, facilitate locomotion, and support vital physiological mechanisms such as respiration and postural equilibrium [1]. Understanding the biomechanical and physiological nuances of this system is essential, as abnormalities in neuromuscular function can precipitate debilitating pathological conditions, including myopathies, paralysis, and severe motion disorders [2]. Furthermore, even within high-performance sports and recreational physical activities, structural components such as tendons and ligaments are highly susceptible to acute injuries and ruptures [2]. Nevertheless, the quantitative assessment of musculoskeletal dynamics is important for expanding clinical diagnostics, optimizing rehabilitation protocols, and mapping muscle behavior across distinct states of relaxation, activation, and fatigue [3].

At the core of functional movement lies the muscle-tendon unit (MTU), which serves as the primary structural interface responsible for force generation, transmission, and joint displacement [4]–[6]. Investigating the kinetic and kinematic responses of the MTU provides valuable insights into the individual contribution of specific muscle groups during dynamic contractions and angular variations [7]–[9]. Accurate characterization of these contractile mechanics is essential for clinical monitoring and for improving predictive musculoskeletal models. These models are utilized in advanced human-machine interfaces (HMIs) and myoelectric prosthetic control systems [3], [10].

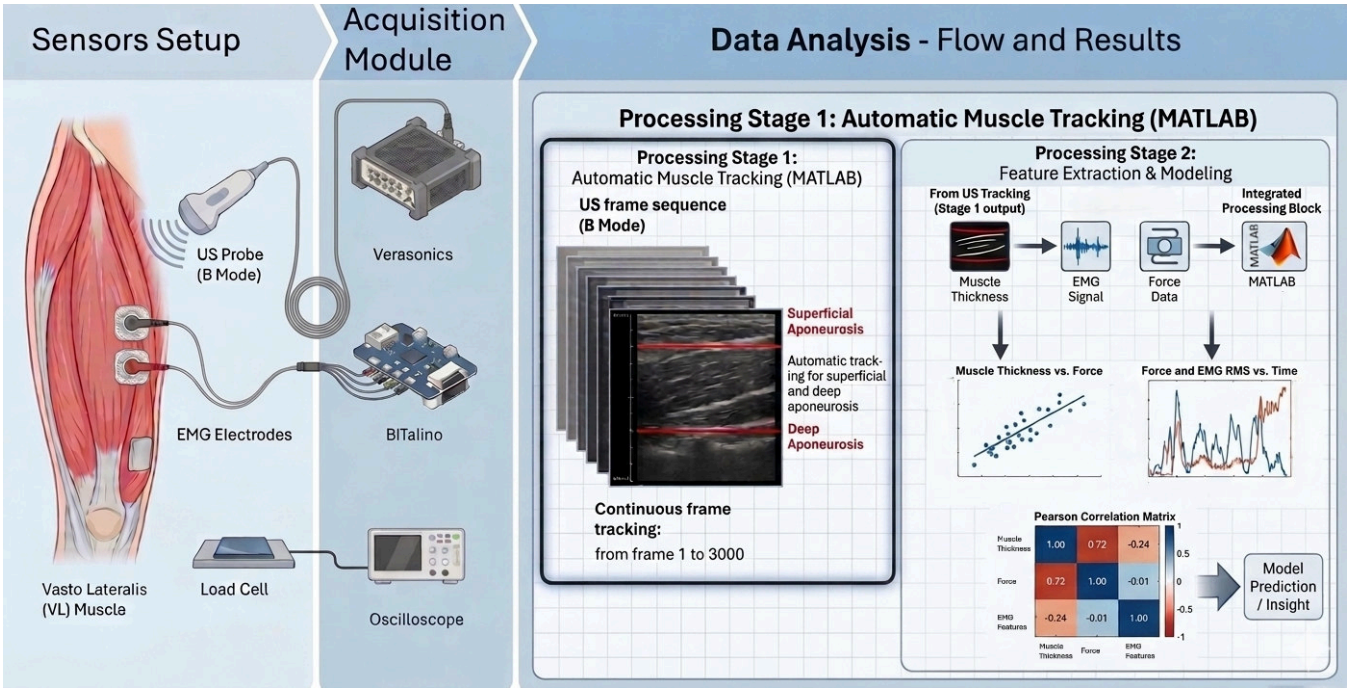

Fig. 1. Overview of the multi-sensing framework block diagram, highlighting the transition from the physical Sensors Setup and the Acquisition Module to the Data Analysis environment containing the proposed processing pipeline.

Despite the clinical and technological importance of this characterization, accurately estimating subject-specific MTU parameters *in vivo* remains a significant challenge. Traditional evaluation methods often fail to capture the transient lateral expansion and longitudinal deformation of muscle fibers during active contraction [9], [11]. To overcome this limitation, high-temporal-resolution imaging modalities, such as ultrafast ultrasound (US), have emerged as powerful tools to non-invasively visualize internal muscular structures in real-time.

In order to study these structural dynamics, recent research has highlighted the necessity of data fusion approaches that combine structural imaging with complementary biomedical signals. While extensive literature reviews have examined multiple biosensing modalities, such as surface electromyography (sEMG), electrical impedance tomography (EIT), near-infrared spectroscopy (NIRS), force myography (FMG), and phonomyography (PMG) for transradial prosthetic control and HMIs [12]–[14], there remain a few frameworks that systematically integrate high-framerate ultrasound with synchronized mechanical and electrical biosignals.

However, because these unified multi-sensing frameworks capture dynamic trials at extreme temporal resolutions, they inherently generate high-density image sequences consisting of thousands of ultrasound frames per subject. Manually extracting morphological MTU metrics, such as instantaneous muscle thickness from these extensive datasets, is computationally unfeasible and highly operator-dependent. Therefore, the development of robust, automated computer vision algorithms capable of precisely detecting and tracking the superficial and deep muscular aponeuroses within these multi-sensing applications has become a bottleneck.

To address this technological gap, this paper introduces a localized image processing pipeline designed specifically for the continuous tracking of *vastus lateralis* (VL) muscle aponeuroses in ultrafast ultrasound sequences. The proposed algorithm serves as **Processing Stage 1** for the **Data Analysis** phase. The multi-sensing framework illustrated in Fig. 1, demonstrates the automatic localization of the superficial and deep fascial boundaries across a dense temporal series of up to 3000 frames to extract continuous muscle thickness variations. The framework shows the physical **Sensors Setup** and the hardware-driven **Acquisition Module** and the **Data Analysis** processing environment, programmed on Matlab (The MathWorks, Natick, MA, USA) The proposed algorithm tracks both aponeuroses along a physical activity trial. These tracking results serve for future applications on correlations within **Processing Stage 2** for feature extraction and modeling.

Section II describes the mathematical foundation of the horizontal tracker. Section III details the algorithm pipeline applied to the tracker. Section IV presents the tracking results and evaluates algorithmic stability against baseline noise artifacts. Finally, Section V concludes the paper and outlines approaches for future work.

II. Theoretical Background

Several automated or semi-automated tracking frameworks have been proposed in the literature, though each one presents distinct technological limitations when applied to high-framerate dynamic sequences.

- **Morphological and Mask-Based Frameworks:** The *Muscle Ultrasound Analysis* (MUSA) software relies on structural filters and localized intensity masks to isolate muscular boundaries [15]. While computationally lightweight, this approach heavily depends on local contrast thresholds. Consequently, it is highly susceptible to acoustic artifacts and localized speckle noise accumulated across long-duration, multi-frame ultrafast US acquisitions, frequently resulting in boundary segmentation drift.
- **Deep Learning Approaches:** Deep learning architectures, such as *DL_Track*, leverage convolutional neural networks trained specifically for end-to-end aponeurosis detection [16]. Although deep networks exhibit exceptional adaptability to varying muscle anatomies, they often suffer from frame-to-frame localized inconsistencies. In dense temporal sequences, slight variations in frame contrast may reduce prediction consistency across consecutive frames, leading to significant structural data loss and discontinuous tracking over time.
- **Optical Flow Implementations:** The widely used *UltraTrack* framework utilizes Lucas-Kanade optical flow algorithms to simultaneously track aponeuroses and fascicle orientations [17]. This differential method assumes brightness constancy between successive frames. However, dynamic muscle contractions inherently alter tissue reflectivity, probe pressure, and out-of-plane scattering. These localized luminance variations introduce cumulative integration drift, causing tracking errors that propagate rapidly through extended frame sequences.
- **State-Space and Predictive Filtering:** Most recently, *UltraTimTrack* was introduced, incorporating structural line-detection algorithms coupled with an adaptive Kalman filter to predict and smooth aponeurosis trajectories [18]. Although state-space modeling successfully mitigates rapid transient noise, this methodology represents a promising approach. Its mathematical constraints regarding non-linear tissue deformations and its generalization capabilities across diverse transducer configurations remain insufficiently investigated by the broader scientific community.

Beyond computational simplicity, the deterministic design offers three concrete mechanistic distinctions from the frameworks reviewed above. First, because each frame is processed independently from a fixed anatomical offset rather than propagated from the previous frame's estimate, the pipeline is not subject to the cumulative integration drift that affects optical-flow and Kalman-filter-based trackers, in which a single mis-estimated frame biases subsequent predictions. Second, unlike deep-learning approaches, the method requires no annotated training data and no retraining when applied to new acquisition hardware or muscle groups, at the cost of depending on hand-specified anatomical priors that must be re-tuned for substantially different anatomies. Third, the explicit peak-width and anatomical-bound constraints make failure modes interpretable frame-by-frame, whereas failures in learned models are comparatively opaque. These are architectural, hypothesized distinctions rather than demonstrated advantages: a head-to-head quantitative comparison of computational time, drift accumulation, and failure rate against UltraTrack, UltraTimTrack, MUSA, and DL_Track on shared sequences and hardware has not yet been performed and is identified as a priority for future work.

III. Methods

The proposed experimental framework integrates high frame-rate ultrasound (US) imaging, surface electromyography (sEMG), and mechanical force tracking into a cohesive data analysis pipeline. This multimodal framework used an open architecture ultrasound research system (Vantage 128, Verasonics Inc., Kirkland, WA, USA). The system was synchronized with a BITalino platform equipped with a specialized sEMG differential sensor device (UC-E6, PLUX Biosignals, Lisbon, Portugal) and a calibrated S-type load cell (Lider Balanças, Araçatuba, Brazil). The hardware layout and individual instrument interfaces are structurally detailed in Fig. 2.

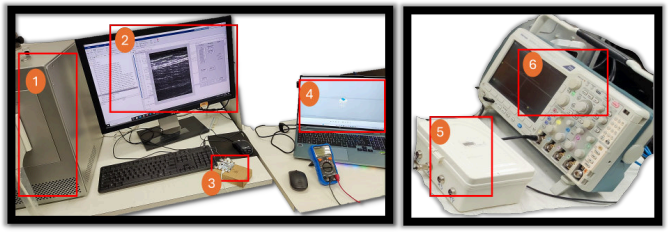

Fig. 2. Experimental instrumentation setup for synchronized multimodal data acquisition: 1) Verasonics Vantage 128 open research platform; 2) Host display monitor showing real-time B-mode acquisition; 3) BITalino (r)evolution board equipped with sEMG biosensors; 4) Computational environment synchronized via host peripherals; 5) S-type load cell assembly; 6) Digital oscilloscope used for hardware trigger synchronization and strain gauge voltage verification

A. Data Acquisition Protocol

The experimental data acquisition protocol was conducted by a licensed physiotherapist in 2024. This study follows an exploratory, applied, cross-sectional, and quantitative research design approved by the Human Research Ethics Committee of the Pontifical Catholic University of Paraná (PUCPR), Institutional Review Board approval no. 6.883.378. In strict compliance with National Health Council Resolution 466/2012, all participating subjects provided written informed consent prior to the commencement of the testing sessions.

To standardize physiological baselines and minimize metabolic confounding factors, participants were instructed to abstain from vigorous physical activities for 72 hours preceding the examination. Immediately prior to the evaluation, subjects remained in a supine position for 15 minutes to allow for the proper stabilization of body fluids.

Following the stabilization period, localized anatomical landmarks were identified to standardize the transducer placement. As depicted in the experimental positioning in Fig. 3, the ultrasound linear transducer was aligned longitudinally

relative to the muscle fibers of the right *vastus lateralis* (VL). The spatial coordinates of the transducer were systematically defined at 50% of the total anatomical distance measured between the greater trochanter and the lateral femoral condyle, registered over a reference path oriented at an inclination of 15°. Probe alignment was considered optimal when the muscle fascicles were clearly visualized spanning between the aponeuroses. To prevent unintended tissue deformation and underlying structural compression, the transducer was applied with minimal mechanical pressure, utilizing a colorless acoustic coupling gel to optimize impedance matching and image quality. A single investigator was responsible for all ultrasound operations, capturing each pre-demarcated region for offline processing.

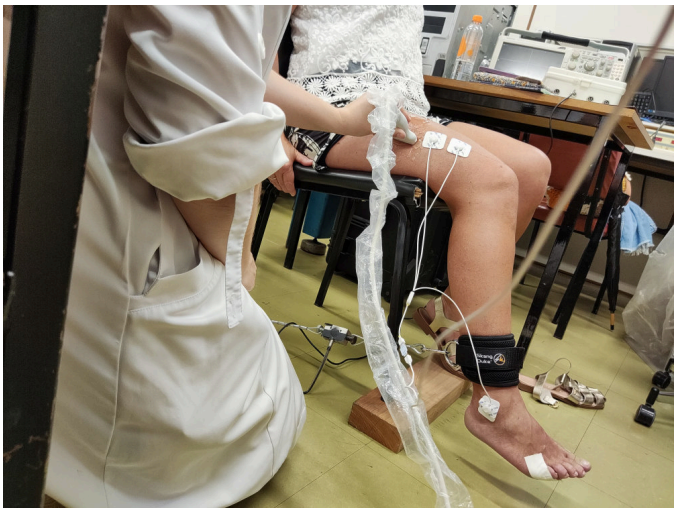

Fig. 3. Experimental instrumentation and participant positioning during the data acquisition session, showing the synchronized placement of the ultrasound transducer, load cell strap coupling, and surface electromyography (sEMG) electrodes on the *vastus lateralis* muscle.

To ensure signal fidelity, the BITalino acquisition hardware (PLUX Biosignals, Lisbon, Portugal) was calibrated and tested prior to each session. Surface EMG electrodes were properly positioned over the muscle belly by the healthcare professional according to SENIAM guidelines. Concurrently, the S-type load cell captured the mechanical force exerted by the participant. To assist the subject in maintaining the targeted contraction profiles, a digital oscilloscope provided real-time visual feedback of the active force output against a predefined reference threshold. Within this architecture, the sEMG sensors logged the electrical manifestation of muscle activation, while the open-architecture Verasonics Vantage platform acquired the high frame rate B-mode image sequences. The multimodal datasets were digitized and recorded synchronously by the respective Verasonics and BITalino acquisition modules.

The dynamic contraction protocol was structured into discrete sequential phases. Each active trial consisted of an initial 5 s resting baseline (relaxation), followed by a 5 s sustained isometric contraction of the knee extensors, and a final 5 s relaxation phase, yielding a total sequence duration of 15 s (3000 frames at 200 Hz). A 10-minute rest interval was enforced between successive trials to prevent neuromuscular fatigue. Prior to the dynamic tracking sessions, an initial evaluation was executed to determine each subject's Maximum Voluntary Contraction (MVC). This absolute force value served as the baseline reference for subsequent trials.

The protocol was completed by 3 healthy participants, each performing 2 trials per MVC level as described above, with condition order fixed in the order 20%, 30%, 40% across participants. Transducer position was set manually by a single investigator using the anatomical landmarks described above and was not instrumented with an optical marker or inertial measurement unit; probe displacement during contraction therefore could not be independently measured in this study.

B. Algorithmic Processing Pipeline

B-mode ultrasound (US) imaging inherently exhibits structural degradation caused by acoustic speckle noise, attenuation, and frequency-dependent scattering. To mitigate these artifacts and achieve automated frame-by-frame tracking across extensive sequences, a dedicated computer vision pipeline was developed. This algorithm processes high temporal resolution B-mode matrices to continuously segment the superficial and deep aponeuroses, enabling the dynamic extraction of muscle thickness.

The proposed algorithm treats the B-mode frame matrix as a discrete spatial intensity distribution, analyzing the lateral brightness profile to isolate structural fascial boundaries. The processing pipeline is executed through the following sequential mathematical stages:

1) **Region of Interest (ROI) and Offset Definition:** A spatial offset threshold is initialized to eliminate the superficial subcutaneous adipose tissue layer and high-frequency proximal noise, constraining the search matrix to the anatomical boundaries of the target muscle (e.g., *vastus lateralis*).
2) **Horizontal Intensity Projection:** For each frame f, a horizontal summation of the grayscale pixel intensities is computed along the transverse transducer elements ($E = 1$ to 128) for every discrete depth vector d. This spatial integration generates a one-dimensional vertical profile vector, where local maxima correspond to highly echogenic (hyperechoic) structural interfaces.
3) **Smoothing and Peak Detection:** To suppress high-frequency local variations induced by speckle noise, a 50-point moving-average filter is applied to the horizontal intensity profile. From the smoothed curve, local maxima are isolated using a peak-finding function parameterized with a minimum neighborhood width constraint ($\Delta_w = 10$ to 15 spatial points).
4) **Anatomical Constraint Filtering:** Isolated peaks are subjected to deterministic physiological boundary checks. Peaks falling outside expected anatomical bounds for the superficial and deep aponeuroses are discarded as outliers. The two dominant valid peaks

corresponding to the geometric centroids of the superficial (A_a) and deep (A_b) fascial layers are subsequently selected.

5) **Dynamic Thickness Extraction:** The instantaneous muscle thickness (T_m) for frame f is calculated as axial distance between the deep and superficial aponeurosis boundaries, defined by:

$$T_m(f) = A_b(f) - A_a(f) \tag{1}$$

6) **Temporal Post-Filtering:** Once the thickness profile is compiled across all 3000 sequential frames, a 5^{th}-order Savitzky-Golay filter is implemented. This digital filter applies a local polynomial regression to smooth high-frequency transient tracking jitter while preserving the underlying low-frequency morphological deformations during muscle contraction.

C. Structured Algorithm

The structured pseudo code of the tracking pipeline is formalized in Algorithm 1.

Algorithm 1 Automated Aponeurosis Detection and Thickness Tracking

Require: $US_B_Mode_Data$ {Matrix of 3000 frames (Depth $\times$ Elements)}
Ensure: $Muscle_Thickness$ (Vector of size 3000), $Aponeurosis_Regions(A_a, A_b)$

Define $offset$ {Isolate subcutaneous fat layer and initial noise}
for $f = 1$ **to** 3000 **do**
  $H_{sum} \leftarrow \sum_{E=1}^{128} US_B_Mode_Data(Depth, E, f)$
  $H_{smooth} \leftarrow$ MovingMeanFilter(H_{sum}, window $= 50$)
  $Peaks \leftarrow$ FindPeaks(H_{smooth}, MinWidth $= 10$ to 15)
  $[A_a(f), A_b(f)] \leftarrow$ FilterAnatomicalConstraints($Peaks$)
  $T_m(f) \leftarrow A_b(f) - A_a(f)$
end for
$Muscle_Thickness \leftarrow$ SavitzkyGolayFilter(T_m, order $= 5$)
return $Muscle_Thickness, A_a, A_b$

D. Validation Dataset and Inclusion Criteria

To evaluate the mathematical generalization of the proposed pipeline, an independent validation protocol was established using the open-source *DL_Track* benchmarking database [16]. The public repository comprises 574 B-mode musculoskeletal images; however, strict morphological inclusion criteria were enforced to match the input specifications of the proposed algorithm.

The proposed technique requires uncropped, raw rectangular ultrasound matrices that preserve the full lateral array borders across all transducer elements, demonstrated in Fig. 4. Image a) shows an example of standard raw configurations. Image b) demonstrates the exclusion criteria, which shows frames exhibiting artificial geometric clipping, non-standard aspect ratios, or post-processed clinical overlay annotations, such as masked borders. These artificial borders introduce high-contrast step-function intensity gradients during the column-wise summation profile, creating false peak maxima that do not correspond to physical anatomical structures. Consequently, a refined subset of 197 raw ultrasound images was isolated for formal algorithmic execution.

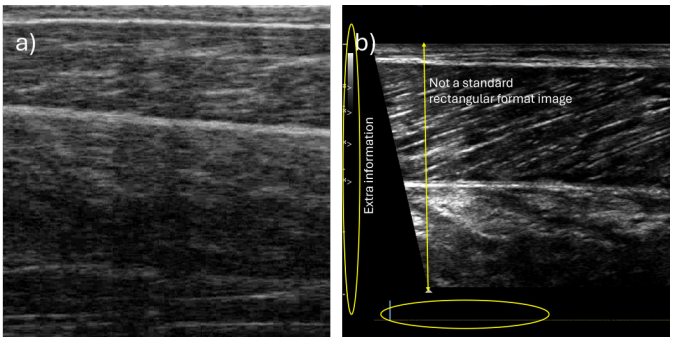

Fig. 4. Example of ultrasound image from *DL_Track* dataset, demonstrating exclusion criteria: a) shows the standard image which the algorithm applies the technique; b) highlights the borders, extra information and different standard.

IV. Results and Discussion

The performance and tracking stability of the proposed computational pipeline were evaluated using a representative dynamic B-mode ultrasound sequence. The dataset comprised a dense, continuous high frame rate acquisition of 3000 frames captured at a temporal resolution of 200 Hz over a 15 s duration, capturing transient muscle architectural variations during an active relaxation-contraction-relaxation experimental cycle.

A. Muscle Tracking Algorithm

Fig. 5 illustrates the continuous, frame-by-frame tracking results, mapping the localized instantaneous distance between the isolated superficial and deep aponeuroses of the *vastus lateralis* muscle. The system effectively tracks the morphological boundaries across the predefined timeline landmarks: an initial 5 s relaxation baseline, a 5 s sustained isometric contraction, and a final 5 s relaxation phase.

The practical utility of the tracking pipeline under varying mechanical demands is highlighted in Fig. 6, which contrasts the extracted muscle thickness profiles during isometric trials performed at 20%, 30%, and 40% of the subjects' MVC. The tracked morphological profiles reveal an inverse displacement during the active contraction window ($t = 5\,\text{s}$ to $t = 10\,\text{s}$), characterized by a transient decrease in localized muscle thickness across all submaximal effort levels.

This specific behavior is captured by the algorithm and reflects few mechanical constraints of the experimental setup. During active knee extension against the rigid ankle strap, the superficial expansion of the muscle belly presses against the linear probe. Because the transducer is maintained in a fixed relative position, this localized mechanical tension compresses the tissue layer, resulting in a reduction of the vertical distance between the fascial interfaces. At the highest effort intensity

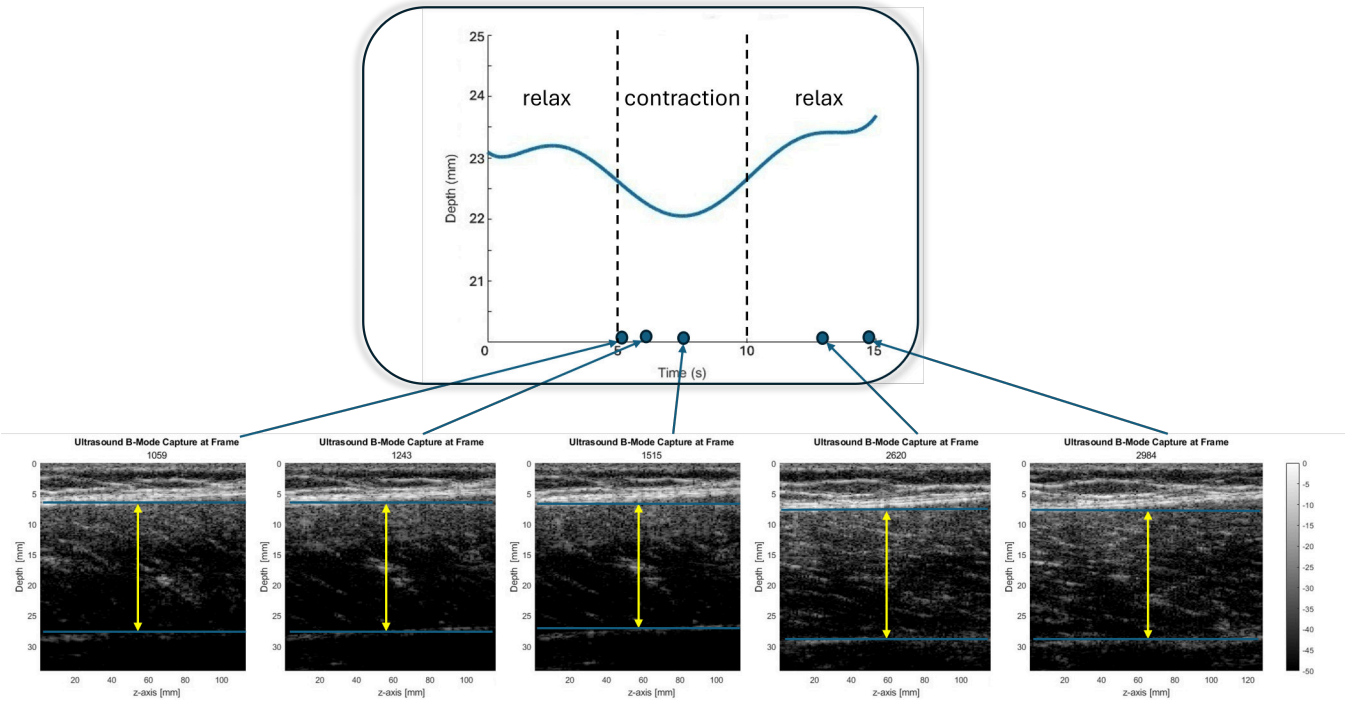

Fig. 5. Dynamic frame-by-frame tracking verification demonstrating the automated localization of the superficial and deep aponeuroses of the *vastus lateralis* muscle. The multi-frame sequence highlights the algorithmic behavior across the 15 s relaxation-contraction-relaxation protocol (Frames 1059, 1243, 1515, 2620, and 2984).

(40% MVC, red curve), the algorithm captures a sharper initial oscillatory transition during the onset of contraction, showing a baseline drop from approximately 31.5 mm down to a compressed stabilization floor of 27.5 mm.

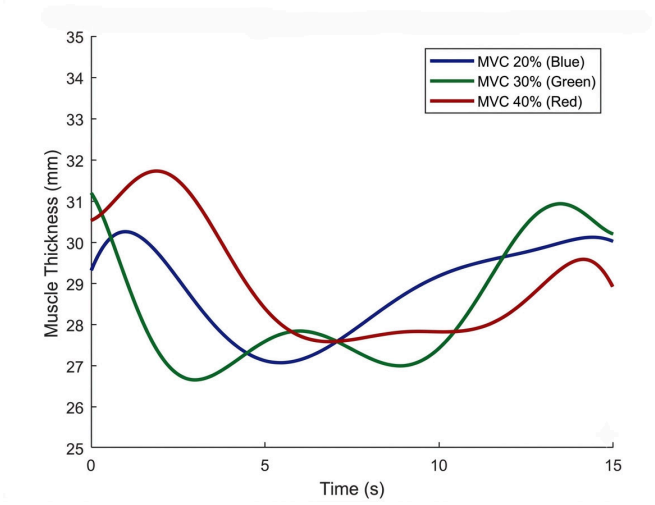

Fig. 6. Dynamic frame-by-frame muscle thickness tracking curves across 15 seconds for three distinct submaximal effort intensities: 20% MVC (blue), 30% MVC (green), and 40% MVC (red), capturing the structural compression during active isometric phases.

A challenge in tracking dense 3000 frames ultrasound sequences is the vulnerability to local luminance attenuation and speckle noise artifacts. The results indicate that the integration of the 50-point moving average filter combined with the constrained peak-width detection ($\Delta_w = 10$ to 15 points) provides stabilization. Across the discrete cross-sections in Fig. 5 (Frames 1059 to 2984), the peak finding framework effectively rejected internal echogenic noise artifacts within the muscle belly, such as highly reflective localized fascicle bundles or structural vascular boundaries, which would otherwise introduce tracking outliers or could cause false boundary attribution to the algorithm.

Furthermore, the implementation of the 5^{th}-order Savitzky-Golay post-filter smoothed out high-frequency jitter and frame-to-frame pixel discretization noise. As observed in the smooth contours of the tracking traces in Fig. 6, this temporal filtering isolated the low-frequency mechanical muscle deformation profile, although it introduced a slight artificial attenuation of the valid physical displacement amplitudes during rapid tissue transitions.

By treating the tracking task as a constrained localized intensity maximization problem, the algorithm delivers a framework for batch-processing multi-sensing trial blocks. It mitigates the significant data-loss vulnerabilities and frame-to-frame convergence failures associated with end-to-end deep learning approaches, providing a reproducible tool for biomechanical analysis.

Despite the high tracking continuity demonstrated by the algorithm, a critical analysis of the thickness profiles in Fig. 5 reveals a minor localized baseline variation that points to specific physical limitations in the data acquisition setup. During sustained high-intensity contractions (e.g. 40% MVC),

the vigorous spatial deformation and hardening of the muscle belly inevitably introduce minor transducer displacements and localized skin-probe slippage. This transducer shift alters the relative acoustic coupling angle, inducing transient gray-level variations and minor artifacts in the B-mode data. In future protocol iterations these effects can be attenuated by improving the acquisition framework with a custom thermo moldable rigid probe stabilizer contoured to the participant thigh geometry, ensuring an unyielding perpendicular alignment. Furthermore, integrating a localized optical tracking marker or an inertial measurement unit (IMU) directly onto the transducer housing would allow real-time monitoring and computational compensation for probe translation, thereby suppressing mechanically-induced tracking noise at the source.

Regarding computational feasibility, each frame in the proposed pipeline requires only a summation across 128 transducer elements, a fixed-window moving-average filter, and a constrained local peak search — operations that scale linearly with image depth and are substantially cheaper than a convolutional forward pass of the size used in DL_Track-like architectures; the Savitzky-Golay step is a single additional linear-time pass over the compiled thickness vector. This is offered as a plausibility argument for real-time feasibility rather than a measured result: per-frame latency on target hardware was not benchmarked in this study and would need to be reported before real-time claims can be substantiated.

B. Algorithm Validation

The agreement between the automated muscle thickness measurements (T_m) generated by the proposed algorithm and the manual ground-truth annotations provided in the dataset was quantified using a two-way mixed-effects Intraclass Correlation Coefficient (ICC) and Pearson correlation coefficient (r). As illustrated in Fig. 7, the pipeline achieved an ICC of 0.858 ($n = 197$) and a corresponding $r = 0.86$, demonstrating a statistically significant agreement with the manual gold standard. The algorithm's tracking boundaries align closely with the manual fascial tracings, remaining stable across different levels of acoustic speckle noise and diverse echo-intensity gradients included within the dataset. The strong statistical outcomes highlight that the 50-point moving mean filter paired with the tuned peak-width parameter (Δ_w) can accurately represent the underlying anatomical structures, demonstrating that the pipeline can be applied for high-throughput batch processing without requiring manual operator intervention or custom border-masking scripts.

To further investigate the measurement agreement, the corresponding Bland-Altman analysis was performed, shown in Fig. 8. The distribution revealed a mean bias of 0.6 px, with 95% limits of agreement spanning -32.1 px to 33.2 px, a random-error window of approximately 65 px. The near-zero mean bias suggests no strong systematic tendency toward over or under estimation across the dataset as a whole. The width of the limits of agreement is not negligible in absolute terms; it has not yet been converted to millimeters using the benchmark dataset's pixel-to-depth calibration, nor compared against a pre-specified clinical tolerance, so precision adequacy for clinical use cannot yet be claimed. Three distinct outliers fell below the lower LoA, with discrepancies between -50 px and -140 px, concentrated in the intermediate thickness range of 150–220 px. We hypothesize this reflects higher echogenicity in adjacent deep muscle layers misleading peak selection in a few images; this could not be confirmed against the in vivo data, which lack equivalent frame-level annotation.

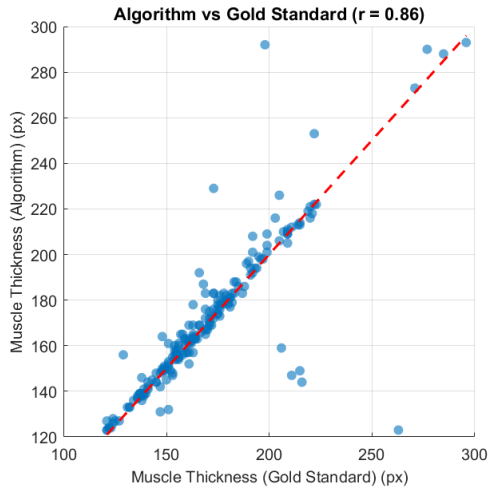

Fig. 7. Scatter plot displaying a linear correlation ($r = 0.86$) between the automated tracking boundaries and manual annotations.

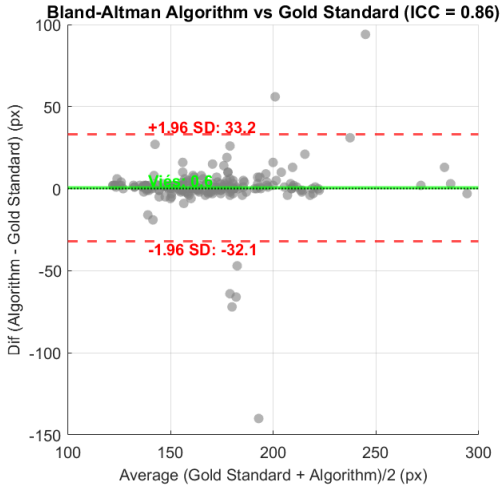

Fig. 8. Bland-Altman plot illustrating a negligible mean bias of 0.6 px, 95% limits of agreement (± 1.96 SD), and isolated underestimation outliers localized within the 150–220 px range.

V. Conclusion

This paper proposed an automated computer vision algorithm for the frame-by-frame segmentation of superficial and deep muscular aponeuroses from high-temporal-resolution B-mode ultrasound sequences. By transitioning from computationally expensive or drift-prone methods to a localized,

constrained morphological intensity projection framework, the proposed algorithm achieves stable tracking with minimal temporal frame-to-frame failures across dense, 3000-frame datasets.

In its current form, the developed pipeline serves as a proof-of-concept for batch processing of structured, offline biomechanical datasets under the anatomical and acquisition constraints described in Section III. It processes dense frame sequences deterministically and without manual operator intervention, and its static-image agreement with manual annotation (ICC = 0.858) supports the underlying boundary-detection approach. Translating this baseline into a validated tracking tool for dynamic sequences, real-time use, or additional muscle groups and clinical populations would require: (i) blinded, multi-rater, frame-sampled ground truth on dynamic in vivo sequences; (ii) a held-out parameter-tuning/validation split; (iii) agreement reported in millimeters against a pre-specified clinical tolerance, including failure rate and boundary-specific error; (iv) head-to-head comparison with optical-flow, Kalman-filter, morphological, and deep-learning baselines on shared sequences and hardware; (v) a component-wise ablation of the moving-average, peak-width, anatomical-constraint, and Savitzky-Golay stages; and (vi) stress-testing under probe motion, anisotropy, gain variation, shadowing, and broader anatomical variability. Future work will pursue a hybrid pipeline that embeds the current anatomical constraints into a deep-learning loss function, aiming to combine the adaptability of learned models with the interpretability of deterministic physiological bounds, subject to the validation steps above.

ACKNOWLEDGMENT

The authors would like to express their gratitude to the National Council for Scientific and Technological Development (CNPq), Grant 146388/2020-8, for the financial support provided through this project. This research was also supported by the Federal University of Technology - Paraná (UTFPR), providing the necessary laboratory infrastructure and technical environment for the computational analysis. The authors would also like to thank the Coordination for the Improvement of Higher Education Personnel (CAPES) and the German Academic Exchange Service (DAAD), under the CAPES/DAAD - PROBRAL program (Grant No. 88881.986264/2024-01) for the financial support provided through the Probral program. Special thanks are extended to the RWTH Uniklinik and the Pontifical Catholic University of Paraná (PUCPR) for institutional support and the clinical staff who assisted with the instrumentation and data acquisition protocol.

***Abstract*—An experienced guitar instructor reported that supported plucking (resting a finger on an adjacent string after plucking) seemed to improve hand warming before recitals. An earlier thermographic study used manual temperature readings at a fixed image location, leaving hand motion and camera-related temporal variation unaccounted for. We therefore developed an automated pipeline to track the playing hand and reconstruct temperature estimates from color-mapped video acquired with an uncooled microbolometer camera. A static wall region provided a reference for reducing temporal variation shared across the image. Eight advanced male guitarists completed six-minute supported and unsupported playing protocols, each preceded by a standardized cold challenge (Cold Pressor Test); seven were retained after video-quality screening. Hand tracking used a fine-tuned YOLOv8s-Pose model, achieving keypoint $\mathrm{mAP}_{50} = 0.833$ and $\mathrm{mAP}_{50\text{–}95} = 0.443$ on a participant-disjoint validation set. Before normalization, the temperature increase from the start to the end of playing was nearly three times as large without support as with support ($+1.107$ °C versus $+0.384$ °C). After normalization, mean gains were $+0.630$ °C for the unsupported protocol and $+0.690$ °C for the supported protocol, with no statistically significant between-protocol difference (paired t-test, $p = 0.917$). Sustained peak gains were analyzed descriptively and exceeded final gains in five of seven participants per protocol. These findings show that reference-based normalization can change the apparent comparison of thermal responses. Because the protocols differed in musical demands and radiometric validation was limited, these findings are exploratory and do not isolate the effect of supported plucking.**

***Index Terms*—Infrared thermography, Computer Vision, YOLOv8s-Pose, Temperature reconstruction**

I. Introduction

This study was motivated by a recurring observation from an experienced classical guitar instructor. Before recitals in cold environments, some technically proficient guitarists struggled to warm their hands through playing alone. Informally, switching from an unsupported plucking technique to a supported technique (com apoio), in which the finger briefly rests on the adjacent string after plucking, appeared to increase finger warming. This observation motivated an objective comparison of the hand-temperature responses produced by the supported and unsupported playing protocols. Because the protocols also differed in musical material, tempo, and execution demands, they do not isolate the effect of hand support alone.

Infrared thermography (IRT) may offer a way to test this question without touching the skin or interrupting the performer [1], [2]. During play, skin temperature may reflect the combined influence of muscular activity, peripheral blood flow, autonomic regulation, and heat exchange with the environment. The forearm and intrinsic hand muscles contribute to finger movement, but IRT does not measure these mechanisms directly [3], [4]. Tracking this combined thermal signature could, in principle, turn the instructor's observation into an objective, measurable comparison between techniques [3], [5]–[7].

Extracting this physiological signal reliably, however, is significantly more complex than pointing a thermal camera at a moving hand. The uncooled microbolometer sensors typical of portable IRT cameras are highly susceptible to internal thermal drift. Automatic Gain Control (AGC) remaps the displayed range according to the thermal distribution of the scene, whereas Non-Uniformity Correction (NUC) compensates for spatial differences in detector response [1], [8]. During performance, changes in scene composition may coincide with palette rescaling or internal correction events, introducing apparent temporal shifts into color-mapped video. A prior study of hand warm-up in guitarists [9] extracted temperature manually, at a single fixed pixel, with no automated tracking and no correction for this drift. As a result, instrumental artifacts and true physiological trends remained entangled in the data, limiting how much confidence one can place in its conclusions.

A second confound compounds the first: performance anxiety itself changes hand temperature, through sympathetic activation and peripheral vasoconstriction [10], [11]. A controlled autonomic challenge can provide a more standardized starting condition, although it does not reproduce the psychological context of a recital. The Cold Pressor Test (CPT), which includes brief cold-water immersion, is a widely used experimental stressor [10]. It comes, however, with its own computer-vision cost: after the CPT, the hand's thermal con-

trast against the background collapses, and the rapid, blurred finger motion against the fretboard makes reliable tracking difficult exactly when it matters most.

This paper addresses both challenges simultaneously. A pose-estimation model fine-tuned for thermal imagery automatically tracks the hand, while a wall-referenced normalization procedure reduces common temporal variation shared by the hand and a static background region. The proposed pipeline reconstructs frame-specific color-based temperature estimates from the dynamic scale displayed in each video frame. Because the primary outcome is the temporal evolution of hand temperature (ΔT), the analysis focuses on relative temperature changes rather than absolute measurements.

This work makes three contributions. First, it combines thermal-domain hand tracking with K-means clustering to reduce contamination from the instrument and background. Second, it combines frame-specific color-to-temperature reconstruction with wall-referenced normalization to reduce common temporal variation. Third, it applies the pipeline to advanced guitarists under a controlled cold-related challenge and quantifies individual and group-level thermal responses.

The remainder of this paper is organized as follows. Section II reviews related work in thermal pose estimation, artifact mitigation, and biomedical thermography. Section III details the experimental protocol and the temperature-reconstruction and normalization pipeline. Section IV reports tracking performance and statistical results. Section V discusses the physiological and instrumentation implications of these findings, and Section VI concludes the paper.

II. Related Work

The instructor's observation, and the question it raises, sits at the intersection of four bodies of work that, so far, have not been connected: musculoskeletal health in musicians, the physiology of cold-induced stress, infrared thermography as a measurement tool, and computer vision for thermal imagery. Only one prior study [9] has examined guitarist hand-warming directly; the remaining literature supplies the pieces needed to evaluate it rigorously.

Playing-related musculoskeletal disorders are highly prevalent among professional musicians, particularly those playing string and plucked instruments. Chan et al. [5] reported that structured exercise programs can reduce symptom severity and improve self-reported physical function, although their evaluation relied primarily on subjective clinical measures. Rotter et al. [6], in a systematic review, identified repetitive fine motor activity, prolonged practice, and non-ergonomic postures as major risk factors, but noted that existing studies focus largely on injury and rehabilitation outcomes. Similarly, Adamik et al. [12] found that interventions for bowed string musicians improved pain and functional outcomes without providing standardized physiological measures of warm-up effectiveness. Taken together, these studies highlight a common gap: musician warm-up strategies are typically assessed through subjective or long-term outcomes rather than real-time physiological responses.

Oliveira [9] took the initial step toward closing that gap, applying a CPT and a FLIR C5 thermal camera to nine male guitarists performing both a vigorous unsupported routine and a light supported technique. The supported technique appeared to produce a statistically significant warming effect ($p = 0.003$, $d = 1.42$), while the vigorous routine did not ($p = 0.342$, $d = 0.34$), with several participants' fingers cooling instead of warming — the same counter-intuitive pattern behind the instructor's original observation. Crucially, however, the temperature data in that study was extracted manually at a single, static coordinate every five seconds from exported video files, lacking automated hand tracking, spatial clustering, or sensor-drift compensation. Consequently, those findings may encompass unresolved interference from hand displacement and microbolometer drift. This paper addresses this uncertainty by presenting an automated, wall-normalized measurement framework to evaluate these preliminary observations.

Before that question can be answered, two further pieces are needed: a reliable way to induce a controlled stress baseline, and a reliable way to read peripheral temperature once that stress is induced. The CPT has been widely used for the former. Mourot et al. [10] characterized this response via HRV analysis, showing that brief cold-water immersion produces a sharp rise in sympathetic activity and rapid parasympathetic withdrawal — evidence the CPT is a reliable, reproducible stressor. Jenkins et al. [11] extended this picture by quantifying muscle sympathetic nerve activity directly during a two-minute CPT, reporting significant increases in systolic pressure (+8.1 mmHg), diastolic pressure (+6.4 mmHg), and sympathetic burst frequency (+9.1 bursts/min). Both studies, however, stop at central cardiovascular markers; neither one follows the stress response out to the periphery, where the actual warming or cooling of the hand takes place. Shi et al. [13] moved closer with a contactless radar-interferometry and LSTM framework to estimate HRV during cold exposure, but still without touching peripheral microvascular temperature.

IRT is the natural tool to close that remaining gap, and its sensitivity to autonomic-driven vascular change is well established. Khan et al. [1] reviewed its use for detecting sympathetic-mediated vasodilation during regional anaesthesia, reporting high sensitivity for confirming successful nerve blocks — but flagged that uncooled thermographic measurements remain highly sensitive to environmental drift and typically require manual interpretation, precisely the problem this paper addresses. Hattersley et al. [2] applied IRT to hand temperature, using semi-automated segmentation to track peripheral cooling after a prolonged Antarctic expedition, finding substantial inter-individual variability. Their protocol, however, was built for passive cold adaptation, not for dexterous motor tasks involving rapid finger displacement and the motion blur that comes with it — exactly the condition guitar playing under CPT stress produces.

Tracking a hand reliably under that motion blur is, in turn, a computer vision problem, and one with its own unresolved gap between domains. Bochkovskiy et al. [14] introduced

YOLOv4, a state-of-the-art, low-latency object detector — but, like most detection architectures, it was developed and benchmarked on RGB imagery, and its accuracy drops sharply on thermal input. Guo et al. [15] characterized this RGB-to-thermal domain gap systematically, showing that models trained exclusively on RGB data degrade severely on infrared images, and establishing thermal-specific fine-tuning as a near-mandatory step for reliable deployment. Kuzdeuov et al. [16] addressed this shortage with OpenThermalPose, a 6,090-image thermal dataset with 17 anatomical keypoints in the MS COCO format; models fine-tuned on it substantially outperformed direct RGB-to-thermal transfers, confirming that thermal-specific annotation improves keypoint accuracy under low-contrast conditions. Their dataset, however, targets full-body pose, not the hand-specific, high-velocity keypoint tracking a guitarist's plucking hand demands.

Taken together, these distinct bodies of literature leave an unresolved gap at their convergence: a method to evaluate motor warm-up effectiveness that combines the controlled autonomic challenge characterized by Mourot et al. [10] and Jenkins et al. [11] with the non-invasive sensing validated by Khan et al. [1] and Hattersley et al. [2], while remaining resilient to the fast motion and sensor-drift artifacts that challenge standard tracking [14]–[16]. The present study builds upon the physiological hypotheses raised by Oliveira [9], replacing manual single-point extractions with the automated, wall-normalized pipeline introduced in the previous section. This framework enables comparison of hand-temperature trajectories while accounting for hand displacement and common temporal variation.

III. Materials and Methods

This section details the translation of the initial empirical observations into a controlled experimental design and outlines the computational architecture developed for objective thermographic measurement. The subsequent subsections present the participant and the experimental protocol (Sections III-A and III-B), detail the image-processing and temperature-reconstruction and normalization pipeline (Section III-C), and define the statistical framework employed to evaluate the two playing protocols (Section III-D).

A. Participants and Data Quality Criteria

We recruited eight advanced male acoustic guitarists (mean age: 27.2 ± 10.5 years; mean playing experience: 10.0 ± 4.2 years) from the Music Department of the University of Brasília (MUS/IdA–UnB). Two independent guitar professors assessed each participant's proficiency using the Royal Conservatory of Music (RCM) Guitar Syllabus, classifying three participants at level 8, three at level 7, and two at level 6 — all above our inclusion threshold of RCM level ≥ 6. All participants were right-handed and provided written informed consent under a protocol approved by the Institutional Review Board of the College of Health Sciences, UnB (CAAE 54174921.8.0000.0030). We excluded volunteers taking medications known to affect the autonomic nervous system (e.g., beta-blockers [17]), presenting flu-like symptoms, diagnosed with diabetes mellitus, or undergoing active cardiovascular drug treatment in the preceding two weeks.

One participant's dataset was excluded during the initial video quality-control stage, before temperature extraction, normalization, or any between-protocol thermal comparison. This participant completed the protocol in a setting different from the standardized environment used for the remaining sessions, and the recording did not include the fixed wall region required for wall-referenced normalization. Consequently, the recording could not be processed using the complete proposed pipeline, leaving a final analytical sample of $n = 7$.

B. Experimental Protocol and Apparatus

The seven sessions retained for analysis took place over 60 days in the same controlled environment: ambient temperature held at 18 °C (range: 17–19 °C), blackout curtains preventing uncontrolled light or heat exposure. To reproduce the pre-performance stress the instructor described, we applied an adapted CPT as a standardized cold-related stressor [10], [18], immersing the participant's right foot in a water bath held between 5 °C and 8 °C. A Teledyne FLIR C5 uncooled microbolometer camera [8] recorded each session from a tripod two meters away, aimed orthogonally at the participant's right hand.

After a standardized briefing and sheet-music distribution, each participant completed two experimental blocks. Block order was not randomized or counterbalanced: following the same protocol structure as Oliveira [9], all participants completed the unsupported block before the supported block, in the same session. The blocks were separated only by the procedures required between trials, and the duration of this interval was not recorded. Therefore, order, learning, residual CPT effects, fatigue, and potential carryover effects associated with the unmeasured inter-block interval cannot be separated from condition effects in this design. In the unsupported block, the participant underwent a 3-minute CPT immersion and then performed Heitor Villa-Lobos' Study No. 1 [19] for six minutes, at the fastest tempo achievable with precision, using the unsupported fingerstyle technique — fingers arched, never touching the string below the one being played. In the supported block, following an identical CPT induction, the participant instead performed a structured chromatic exercise at a fixed 80 bpm, using the supported (com apoio) technique: the right-hand index and middle fingers alternately plucked descending fretboard positions, each finger briefly resting on the adjacent lower string immediately after plucking, before the cycle repeated. Because the blocks also differed in musical material, tempo, and execution demands, the experiment compares the two protocols as administered rather than the isolated effect of hand support.

Initial hand temperature estimates differed between blocks (mean difference $+0.691$ °C, supported higher; paired $t = 2.474$, $p = 0.048$; Wilcoxon $p = 0.078$; bootstrap 95% CI $[0.178, 1.182]$ °C). Unlike the central comparison in Section IV-C, the parametric and non-parametric tests do not

TABLE I
INITIAL HAND TEMPERATURE ESTIMATES AFTER WALL-REFERENCED NORMALIZATION

Participant	Supported (°C)	Unsupported (°C)	Difference (°C)
VOL1	31.707	31.299	+0.408

VOL7	33.840	32.913	+0.927
Mean	**32.041**	**31.351**	**+0.691**

fully agree here, but neither supports equivalence of the initial temperature estimates. A separate resting pre-block thermal baseline was not recorded; therefore, the initial estimate from the first 10 frames of active playing was used as the closest available measure of starting temperature.

C. Thermal Image Processing Pipeline

The FLIR C5 records non-radiometric color-mapped video frames rather than direct temperature arrays. Temperature analysis followed four steps. First, color-based temperature estimates were reconstructed independently for each frame using its displayed thermal scale. Second, the hand ROI was tracked and refined. Third, common temporal variation was reduced using a static wall reference. Fourth, the wall-normalized trajectory was filtered and smoothed for statistical evaluation.

1) Thermal Extraction and Color Mapping: Each frame displayed a dynamic scale with bounds $T_{\min}(k)$ and $T_{\max}(k)$, extracted using EasyOCR. For frames with both bounds available, the mean RGB value across the six inner columns of each of the 294 vertical positions of the displayed color bar formed a frame-specific lookup table. A cKDTree was reconstructed from this table, and each target pixel $\mathbf{p}_k(x, y) = [R, G, B]^T$ was matched to the nearest palette entry by Euclidean RGB distance. The temperature estimate was

$$\tilde{T}_k(x, y) = T_{\max}(k) - \frac{j_k^*(x, y)}{H - 1} \left[T_{\max}(k) - T_{\min}(k)\right], \quad (1)$$

where $H = 294$ and $j_k^*(x, y)$ is the nearest color-bar position. The mapping was reconstructed independently for every frame, thereby accounting for the dynamic temperature scale displayed by the camera. Across the dataset, the nearest-color lookup produced a mean Euclidean RGB distance of 25.27 ± 26.85 arbitrary units between each matched pixel and its assigned palette entry. Because RGB distance does not translate linearly into temperature error, this metric characterizes the color-matching step itself and should not be interpreted as an end-to-end temperature-reconstruction error.

Twelve static FLIR images containing radiometric metadata were used for an exploratory comparison with temperature maps derived from the embedded raw radiometric arrays. For each image, the radiometric temperature was calculated using the camera-specific Planck parameters:

$$T = \frac{B}{\ln\left(\dfrac{R_1}{R_2(S/\varepsilon + O)} + F\right)} - 273.15, \quad (2)$$

where S is the raw sensor value, ε is the image's embedded emissivity setting, and R_1, R_2, B, F, and O are camera-specific metadata parameters. This radiometric reconstruction was used as a reference for exploratory comparison only and was not used to modify the experimental temperature maps.

Across the 14 recordings, both $T_{\min}(k)$ and $T_{\max}(k)$ were available for direct OCR-based extraction in 5,657 of 5,677 frames (99.65%). The remaining 20 frames (0.35%) were excluded from temperature reconstruction because at least one of the two temperature bounds was unavailable. No interpolation or replacement was applied to these frames. The largest consecutive gap comprised nine frames.

The exploratory radiometric comparison highlighted a limitation of the available reference data. Although the embedded radiometric RAW data provided a direct temperature reference, the limited set of reference images did not support the establishment of a robust and generalizable color-to-temperature mapping across different scenes and thermal ranges. Therefore, these images were used only to assess the feasibility of the reconstruction approach and were not used to calibrate the experimental recordings.

2) Hand Tracking and Region of Interest Segmentation: Post-CPT peripheral cooling reduces thermal contrast between skin and background, and fast finger motion and fretboard occlusion make hand tracking particularly challenging. To prevent data leakage, the train/validation split was enforced at the participant level. Five participants (298 annotated thermal frames) were used for model fitting, while two participants (119 frames) were held out from fitting and used for validation and checkpoint selection; no participant, recording, or frame contributed to both sets. The six keypoints represented the tip and base of the thumb, index, and middle fingers. These seven participants were the same seven retained for the thermal analysis. The reported performance metrics refer exclusively to the two participant-disjoint validation subjects used for checkpoint selection ($\mathrm{mAP}_{50}(B) = 0.706$, $\mathrm{mAP}_{50\text{–}95}(B) = 0.236$, $\mathrm{mAP}_{50}(P) = 0.833$, and $\mathrm{mAP}_{50\text{–}95}(P) = 0.443$); no independent test set was available. Because the final ROI is derived from keypoint coordinates and subsequent clustering, keypoint localization is more directly relevant to downstream extraction than strict box overlap.

These keypoints defined the center and radius of a circular region of interest wrapping the hand — but that circle still includes non-biological pixels, such as the guitar top or fretboard, whenever they fall within its bounds. One-dimensional K-means clustering ($K = 3$, fixed random seed) was applied to the reconstructed temperatures within each frame's ROI. The cluster with the highest thermal centroid was retained as the hand-tissue candidate $\Omega_{\mathrm{vol}}(k)$, reducing contamination from the typically cooler instrument and background, and

yielded a mean sampling density of 676.5 ± 239.2 pixels per frame across the dataset. Fig. 1 illustrates this step: panel (a) shows the raw circular ROI, still contaminated by background structure; panel (b) shows the same region after clustering, containing only the hand.

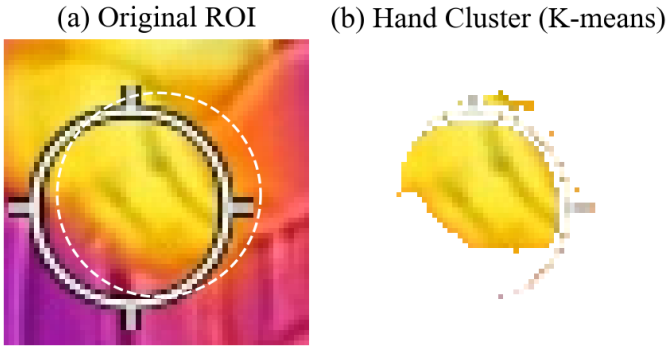

Fig. 1. Dynamic segmentation of the biological ROI, comparing (a) the original cropped thermographic ROI against (b) the isolated target hand cluster ($\Omega_{\text{vol}}(k)$) filtered via 1D K-means clustering.

3) Wall-Referenced Normalization: After frame-specific reconstruction, the trajectories could still contain common temporal shifts associated with dynamic scaling and internal correction processes.

To detect and remove these jumps, we designated a second, deliberately uninteresting region of the frame: a 10-pixel-radius circle on the stationary laboratory wall (Ω_{wall}), far from the hand. Assuming its physical temperature remained approximately stable during each recording, changes in its reconstructed temperature were treated as estimates of common temporal instrumental variation. We defined a wall-reference level, $T_{\text{wall_ref}}$, as the spatial-temporal median of Ω_{wall} over the initial 20 seconds of each recording (sampled at 1 frame/s; $k \in [1, 20]$):

$$T_{\text{wall_ref}} = \text{median}\left\{\tilde{T}_k(x,y) \mid (x,y) \in \Omega_{\text{wall}},\ k \in [1,20]\right\} \tag{3}$$

For every subsequent frame, we computed the instantaneous deviation of the wall from this anchor, $\epsilon_{\text{sensor}}(k)$, and subtracted it from the hand's raw average temperature to obtain the wall-normalized hand-temperature signal:

$$T_{\text{corr}}(k) = \bar{T}_{\text{raw}}(k) - \left(\text{median}\{\tilde{T}_k(x,y) \in \Omega_{\text{wall}}\} - T_{\text{wall_ref}}\right) \tag{4}$$

Fig. 2 shows a representative recording in which step-like variations in the wall-reference signal are subtracted from the reconstructed hand temperature, yielding the normalized and subsequently smoothed trajectory.

Across the 14 recordings, the wall-reference ROI showed a temporal variability of 0.443 ± 0.259 °C, expressed as the mean ± standard deviation of the within-recording temporal standard deviation.

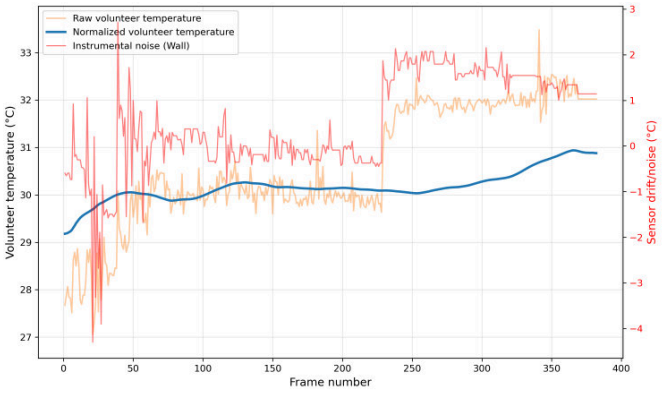

Fig. 2. Wall-referenced normalization for a representative recording (VOL5). Step-like variations in the wall-reference signal are subtracted from the reconstructed hand temperature, yielding the normalized and subsequently smoothed hand-temperature trajectory.

4) Statistical Filtering and Feature Extraction: Even after wall-referenced correction, brief finger-string occlusions can produce transient outliers unrelated to either sensor drift or physiology. We removed these using an Interquartile Range (IQR) filter — discarding points outside $[Q_1 - 1.5 \cdot \text{IQR},\ Q_3 + 1.5 \cdot \text{IQR}]$ and reconstructing them via local linear interpolation — followed by a Locally Weighted Scatterplot Smoothing (LOWESS) regression (first-degree local polynomial, span $\alpha = 0.15$) to reduce short-term fluctuations, yielding the final smoothed trajectory $T_{\text{smooth}}(k)$.

From $T_{\text{smooth}}(k)$, we extracted three macro-physiological features for comparison across conditions: the initial temperature estimate (T_{initial}), defined as the mean of the first $N = 10$ frames at the beginning of active playing; the final temperature estimate (T_{final}), the mean of the last $N = 10$ frames; and the sustained peak temperature ($T_{\text{pico_10f}}$), the maximum value of a 10-frame moving average, chosen to capture genuine thermal peaks while suppressing non-representative spikes.

D. Statistical Analysis

1) Temperature Kinetics: To compare the two fingering techniques, we first needed a small set of numbers summarizing each trial's thermal behavior over time, rather than the full frame-by-frame curve. As described above, we used the initial (T_{initial}), final (T_{final}), and sustained peak ($T_{\text{pico_10f}}$) temperature estimates extracted directly from $T_{\text{smooth}}(k)$, and derived final gain (ΔT) and peak gain ($\Delta T_{\text{pico_10f}}$) from these as detailed in Section III-D2.

Given the small sample size ($n = 7$), test selection did not rely on a single decision rule. We assessed distributional assumptions using the Shapiro-Wilk test and visual inspection, but, recognizing the limited diagnostic power of normality tests at this sample size, we did not use the outcome to choose between a parametric and a non-parametric test. Instead, the primary between-condition comparison used a paired Student's t-test, complemented throughout by a Wilcoxon signed-rank test and a participant-level bootstrap confidence interval (Section III-D2), so that conclusions rest on convergence across

methods rather than on a single test or a single p-value. Effect sizes were reported throughout using Cohen's d, and all computations were performed in SPSS, with the exception of the 10,000-iteration bootstrap confidence interval reported in Section IV-C, which was computed separately in Python (NumPy/SciPy).

2) Statistical Features and Testing: Statistical analyses used participant-level thermal features extracted from $T_{\mathrm{smooth}}(k)$. Final gain was calculated as $\Delta T = T_{\mathrm{final}} - T_{\mathrm{initial}}$, and sustained peak gain as $\Delta T_{\mathrm{pico_10f}} = T_{\mathrm{pico_10f}} - T_{\mathrm{initial}}$. Comparisons between protocols used paired observations. Given $n = 7$, the paired Student's t-test was complemented by a Wilcoxon signed-rank test and a participant-level bootstrap confidence interval (10,000 iterations, 2.5th and 97.5th percentiles). Final gains (ΔT) were tested against zero using one-sample t-tests, with effect sizes reported using Cohen's d. Sustained peak gains ($\Delta T_{\mathrm{pico_10f}}$) were summarized descriptively only. Because the peak metric is defined as the maximum of a moving-average trajectory, it was not used for confirmatory hypothesis testing against zero. Primary analyses were performed in SPSS, and bootstrap confidence intervals were computed in Python (NumPy/SciPy). Although electrocardiographic recordings were collected, HRV outcomes were not analyzed in the present study.

IV. Results

A. Effect of Wall-Referenced Normalization on Thermal Gain Estimates

Before normalization, common temporal instrumental variation could affect the apparent comparison between the two protocols. Before correction, the raw signal told a clear story: the unsupported technique appeared to warm the hand roughly three times more than the supported one ($\Delta T = +1.107$ °C vs. $+0.384$ °C). Frame-by-frame inspection revealed step-like variations in the reconstructed wall-reference temperature, with larger changes observed during the unsupported block.

After wall-referenced normalization reduced the common temporal variation shared with the static reference region, the apparent comparison changed substantially. As Table II shows, the unsupported condition's apparent gain dropped from $+1.107$ °C to $+0.630$ °C, while the supported condition's gain increased from $+0.384$ °C to $+0.690$ °C — the two techniques ending up numerically close together, with neither retaining a clear advantage (Section IV-C confirms this residual difference is not statistically significant). The apparent difference in the unnormalized data was influenced by temporal variation shared with the wall-reference signal and was no longer detected after normalization.

B. Individual and Group-Level Thermal Responses

Averages, however, can hide sharp individual disagreement — and that is precisely what Table III reveals. Individual normalized thermal gains ranged from -0.912 °C to $+2.046$ °C: some participants who cooled under one technique warmed substantially under the other, and vice versa. Under the supported technique, five of seven participants warmed and two cooled; under the unsupported technique, six warmed and one cooled. The direction and magnitude of the thermal response varied substantially across participants.

TABLE II
Mean Thermal Gain (ΔT) Before and After Wall-Referenced Normalization

Condition	**Raw ΔT (°C)**	**Normalized ΔT (°C)**
Supported	+0.384	+0.690
Unsupported	+1.107	+0.630
Overall Mean	**+0.746**	**+0.660**

TABLE III
Individual Normalized Thermal Metrics per Participant and Exercise Condition

Participant	**ΔT (°C)**		**$\Delta T_{\mathrm{pico_10f}}$ (°C)**	
	Supported	**Unsupported**	**Supported**	**Unsupported**
VOL1	+2.046	+0.798	+2.102	+1.020
VOL2	-0.211	+0.510	+0.955	+1.061
VOL3	+0.967	-0.602	+1.034	+0.183
VOL4	+1.322	+0.151	+1.322	+0.151
VOL5	-0.912	+1.611	+0.000	+1.650
VOL6	+0.413	+0.925	+0.413	+1.505
VOL7	+1.204	+1.019	+1.484	+1.019

A second pattern emerges when comparing sustained peak temperatures ($\Delta T_{\mathrm{pico_10f}}$) against final net gains: sustained peak gains were greater than or equal to final gains across all participants. For the supported paradigm, the group's mean sustained peak reached 1.044 ± 0.694 °C, compared to a final net gain of only 0.690 ± 1.003 °C; the unsupported condition shows the same pattern (0.941 ± 0.584 °C peak vs. 0.630 ± 0.706 °C final). The highest sustained temperature increase generally occurred before the end of the six-minute protocol, followed by a partial decline in reconstructed skin temperature.

C. Statistical Comparison Between Exercise Conditions

With the analytical framework established, the central comparison returns to the instructor's original question: does one technique warm the hand more effectively than the other? A paired Student's t-test detected no statistically significant difference in final thermal gain between protocols ($t = 0.109$, $p = 0.917$, Cohen's $d_z = 0.041$). A Wilcoxon signed-rank test ($p = 0.813$) and a 10,000-iteration bootstrap confidence interval for the paired mean difference (95% CI $[-1.007, +0.968]$ °C) supported the same overall interpretation, demonstrating convergence across parametric, non-parametric, and resampling methods. This null result shows no evidence of a difference, not formal equivalence — a stronger claim that would require a dedicated equivalence test (e.g., TOST), which we did not conduct here. Because the blocks also differed in musical material, tempo, and execution demands, this comparison reflects the protocols as administered rather than the isolated effect of hand support.

A related but distinct question is whether either protocol produced a mean change different from zero relative to its initial temperature estimate. One-sample t-tests addressed this directly: for final net gain (ΔT), neither technique crossed the conventional significance threshold (unsupported: $p = 0.056$, $d = 0.893$; supported: $p = 0.119$, $d = 0.688$).

Sustained peak gains ($\Delta T_{\mathrm{pico_10f}}$) were summarized descriptively to characterize the observed thermal trajectories. Mean sustained peak gains were 1.044 ± 0.694 °C in the supported protocol and 0.941 ± 0.584 °C in the unsupported protocol. In five of seven participants in each condition, the sustained peak exceeded the final gain, whereas in the remaining two it was equal to the final gain. These values are reported descriptively to detail maximum thermal gain and are not interpreted as independent confirmatory evidence of warming.

V. Discussion

This study set out to test, under controlled conditions, an informal but consistent observation: that switching from an unsupported to a supported fingerstyle technique may help guitarists warm cold hands before performance. Along the way, it also had to solve a narrower but consequential engineering problem — reducing common temporal variation in color-mapped thermographic recordings of an uncooled thermal camera. Both threads converge in the results, though not in the way a first look at the data would suggest.

The methodological contribution is the more unambiguous of the two. Raw thermographic data initially suggested that the unsupported technique produced nearly three times more warming than the supported one ($+1.107$ °C vs. $+0.384$ °C) — a result that, on its face, would have contradicted the instructor's account rather than supported it. Isolating the static wall-reference region revealed why: this apparent advantage was no longer detectable after wall-referenced normalization, and the unsupported block involved different musical, tempo, and movement demands. After wall-referenced normalization, no statistically significant difference in final net thermal gain was detected between the two protocols ($+0.630$ °C vs. $+0.690$ °C, $p = 0.917$, $d_z = 0.041$) — a null result rather than a formally demonstrated equivalence (Section IV-C). In other words, the unnormalized signal produced an apparent difference that was no longer detectable after normalization. This directly illustrates the instrumentation risk flagged by Khan et al. [1] and Hattersley et al. [2], extended here from static clinical settings to a dynamic computer-vision pipeline tracking a moving target.

This wall-normalized result also complicates the one directly comparable prior study. Oliveira [9], using manual single-point extraction on an overlapping cohort, reported a significant within-condition warming effect for the supported technique ($p = 0.003$, $d = 1.42$), whereas the unsupported condition did not show a significant within-condition change ($p = 0.342$, $d = 0.34$) — a pattern that appeared to confirm the instructor's experience in a straightforward way. Under the present automated, drift-corrected pipeline, that clean asymmetry does not hold at the group level: the analysis provided no evidence of a difference in final net thermal gain between the two protocols. Rather than confirming or refuting the instructor's account directly, this indicates that the explanation is more nuanced than "one technique warms, the other does not." Sections IV-B and IV-C locate that nuance in inter-individual variability and in the peak-versus-final distinction, not in one fingering's simple superiority.

The distinction between peak and final temperature provides an additional descriptive feature of the observed thermal trajectories. In most participants, the maximum reconstructed thermal gain occurred before task completion and was followed by a partial decline. This temporal pattern is descriptive; the physiological mechanisms underlying it were not directly measured.

Potential drivers of these transient dynamics include posture-dependent isometric tension, differential forearm vs. intrinsic muscle recruitment [3], [4], or convective cooling from faster finger motion. Disentangling these mechanisms remains a subject for targeted investigation using electromyography or per-finger mapping.

The considerable inter-subject variability observed in this cohort — individual net gains ranging from -0.912 °C to $+2.046$ °C, with some participants cooling under one technique while warming substantially under the other — reinforces that any single mechanism above is unlikely to act uniformly across guitarists. Baseline vascular tone, the sympathetic pathways associated with peripheral vasoconstriction, and individual biomechanical habits are all plausible sources of this heterogeneity [10], [11], and they suggest that the instructor's long-standing empirical observation may reflect a combination of these mechanisms whose relative contribution varies across students.

Several limitations qualify these conclusions. Foremost, the CPT is a physical, pain-mediated stressor: it reliably activates the sympathetic pathway behind peripheral vasoconstriction, though it elicits only modest cortisol (HPA-axis) activation — the signature more tied to anticipatory, socially evaluated stress. A socially evaluated CPT variant elicits comparable sympathetic activation while substantially raising cortisol reactivity [20], suggesting our protocol captures the pathway relevant here, even if it under-represents the psychological weight of an actual recital. The final analytical sample comprised only seven advanced male guitarists, limiting statistical power and generalizability across gender, skill level, age, and instrument type. The experimental recordings contained color-mapped video rather than native radiometric arrays. Only twelve static FLIR images containing radiometric metadata were available, and not for every participant, for exploratory comparison, which was insufficient to establish an independently validated correction transferable across recordings. The radiometric reference images therefore served only to assess the feasibility of the reconstruction approach and were not used to calibrate the experimental recordings. The findings should consequently be interpreted primarily in terms of consistently processed within-

recording temperature changes. Although electrocardiographic recordings were collected, HRV outcomes were not analyzed in the present study; therefore, equivalent autonomic responses to the CPT across blocks were not verified. Furthermore, without a passive-recovery control condition following the CPT, thermal variations during playing cannot be isolated from spontaneous vascular re-warming. The wall-referenced procedure also assumes that the physical wall temperature remains approximately stable during each recording and does not recover information lost through quantization, compression, or motion blur. Additionally, the two conditions differed not only in fingering technique but also in musical material and tempo (a fixed-tempo chromatic exercise vs. a piece played at each participant's fastest precise tempo), which may itself contribute to the observed thermal differences independent of hand posture. Separately, the group-level comparison in Section IV-C reflects only the absence of a detectable difference, not formally demonstrated equivalence; a dedicated equivalence test would strengthen a future replication. Finally, the mechanistic hypotheses proposed above remain untested by this study's design and should be treated accordingly — as motivation for the next experiment, not as its findings.

VI. Conclusion

An automated pipeline combining hand tracking, frame-specific color-to-temperature reconstruction, and wall-referenced normalization was applied to thermographic recordings from seven advanced male guitarists. After normalization, no evidence of a difference in final thermal gain was detected between the two administered protocols. Mean final net thermal gains were positive in both conditions but did not differ significantly from zero, and individual responses varied substantially. Sustained peak metrics were retained as descriptive features of the thermal trajectories rather than as confirmatory evidence of warming.

Interpretation is limited by the small sample size, fixed block order, differences in initial temperature estimates and musical demands between protocols, and limited radiometric reference data. Accordingly, the results characterize the two protocols as administered and should not be interpreted as isolating the effect of supported plucking.

Future work will pursue four main directions: first, expanding the cohort to include female musicians, different skill levels, and a wider range of instruments to evaluate generalizability; second, transitioning to native radiometric video streams to remove reliance on displayed color scales; third, acquiring a larger, temperature-diverse set of radiometric reference images under controlled conditions for independent quantitative validation of temperature reconstruction; and fourth, analyzing the collected electrocardiographic data (HRV) alongside electromyography, per-finger mapping, and controlled tempo manipulation to assess whether autonomic markers explain the observed inter-participant variability. By mitigating common temporal variation shared with static reference regions, this pipeline is better positioned to support future studies under more ecologically valid stress conditions — such as a socially evaluated variant of the CPT [20] or real pre-performance settings — where non-physiological artifacts would otherwise be even harder to disentangle.

***Abstract*—This study evaluates supervised machine-learning classifiers for a binary formulation of healthcare service utilization among adults aged 50 years and older using the National Poll on Healthy Aging dataset ($n = 714$). The evaluation used nested cross-validation and out-of-fold predictions while preserving the observed class distribution. Baseline, MDI-80%, cost-sensitive, ensemble, and threshold-selection scenarios were examined using class-sensitive metrics, balanced accuracy, MCC, AUROC, and PR-AUC. Overall, discrimination between the two utilization classes was limited, and several models reproduced the majority-class prediction profile. Cost-sensitive weighting and internal threshold selection recovered part of the minority class in some scenarios, but these changes were limited and involved trade-offs. The findings are preliminary and describe the difficulty of this prediction task; they do not support clinical conclusions, diagnostic use, triage, or deployment. The code is available at https://github.com/pkziinn10/Analyze-Medical-Services**

***Index Terms*—Public Health, Population Aging, Machine Learning, Data Analysis, National Poll on Healthy Aging.**

I. Introduction

Population aging is a global and irreversible phenomenon that drives a sustained increase in demand for healthcare services. By 2030, one in six people worldwide will be aged 60 years or older, and this population is projected to grow from 1 billion in 2020 to 2.1 billion by 2050 [1]. Approaches to predicting healthcare service utilization have evolved from traditional statistical methods to Machine Learning techniques capable of capturing nonlinear relationships among sociodemographic, clinical, and behavioral factors [2]. However, these approaches generally require specialized expertise in feature selection and parameter tuning, which hampers their systematic and comparable application across studies [3], [4].

Existing evaluations of predictive models applied to healthcare service utilization among older adults present four main limitations. First, many studies rely on small samples or restricted clinical databases, limiting the generalizability of their findings [2]. Second, comparisons across models tend to cover a narrow set of learning paradigms, without jointly addressing linear, probabilistic, instance-based, tree-based, neural network-based, and graph-oriented approaches within a single experimental protocol [5]. Third, the class imbalance commonly observed in epidemiological data is frequently addressed through artificial balancing techniques, which may distort the actual distribution of healthcare utilization outcomes and undermine the clinical interpretation of results [6]. Finally, few studies subject performance differences between models to formal statistical testing, generally limiting the analysis to comparisons of point estimates.

In this context, this work puts forward a comprehensive comparative study of supervised classifiers for predicting healthcare service utilization among adults aged 50 and older, addressing these limitations: we broaden the coverage of learning paradigms evaluated under a single experimental

The authors would like to thank the Brazilian National Council for Scientific and Technological Development (CNPq) under Grant No. 315447/2023-0.

protocol, preserve the observed class distribution after binary problem formulation without artificial balancing strategies, and subject the results to formal statistical verification. Our main contributions are as follows:

- **Multi-paradigm comparative evaluation:** we compare classifiers from multiple categories of supervised learning under the same experimental protocol, covering linear, probabilistic, instance-based, tree-based, neural network-based, and graph-oriented approaches.
- **Preservation of the observed class distribution:** the original target was recoded as a binary outcome. Category 1 (zero or one distinct doctor consulted) was mapped to class 0, while categories 2 and 3 (two or more distinct doctors consulted) were mapped to class 1, defined as the positive class. This resulted in 583 participants (81.6527%) in class 1 and 131 participants (18.3473%) in class 0, with no artificial resampling applied.
- **Statistical verification by the Wilcoxon signed-rank test:** performance differences between models are assessed through the nonparametric Wilcoxon signed-rank test, allowing us to determine which observed differences are statistically significant.
- **Feature significance analysis by Mean Decrease Impurity (MDI):** through a feature selection step based on the MDI criterion, we identify the demographic and clinical factors with the greatest discriminative power regarding healthcare utilization behavior.

The remainder of this paper is organized as follows. Section II reviews related work on machine learning approaches for predicting healthcare service utilization among older adults. Section III details the proposed methodology, encompassing the dataset and feature description, exploratory data analysis, data preprocessing and feature selection, machine learning algorithms, experimental setup, and evaluation metrics. Section IV presents the empirical results and discussion, covering the predictive performance of the evaluated models and the identified methodological limitations. Finally, Section V concludes the work, highlighting its main contributions, limitations, and directions for future research.

II. Related Work

Recent literature has increasingly applied machine learning to predict healthcare service utilization among older populations across diverse geographic contexts. These studies can be broadly grouped by the scope of the predicted services: multisectoral and community-based utilization, and acute demand for hospital or emergency care.

Regarding general and multisectoral utilization, Sourkatti et al. [6] investigated the early identification of seniors with high health and social service usage in Finland. Comparing Logistic Regression and eXtreme Gradient Boosting (XGBoost) on a cohort of 33,374 individuals, they found that age and mental health issues were positive predictors, whereas prior hospital stays and urban residence indicated lower risk. Despite achieving only moderate performance (AUC of 0.61), the study highlighted the inherent complexity of predicting multisectoral usage given its highly diverse contributing factors. Similarly, Huang et al. [7] examined demand for Home and Community-Based Services (HCBS) in China. Using the Andersen behavioral model for feature selection on a sample of 15,312 older adults, their evaluation of five computational methods showed that Random Forest (RF) and XGBoost achieved the best performance (specificity $> 80\%$), identifying self-reported health, exercise habits, and education level as key demand drivers.

Other studies have focused specifically on acute care, such as hospitalization risk. Buenrostro-Mariscal et al. [8] applied Random Forest to longitudinal data from the Mexican Health and Aging Study (MHAS) to predict hospitalization, showing that functional factors (e.g., restrictions in daily activities) and socioeconomic variables (e.g., education) consistently outperformed traditional clinical conditions (e.g., diabetes and hypertension) as predictors. By capturing complex nonlinear interactions, their model achieved a balance between sensitivity (0.72) and specificity (0.49). Likewise, Jung et al. [9] conducted a pioneering study predicting hospitalization among Medicaid HCBS users in the United States. Comparing Logistic Regression, LASSO, RF, and XGBoost, the authors found Random Forest to be the most robust approach, with prior hospital length of stay and specific chronic conditions as key predictors, underscoring the value of predictive modeling for early interventions that improve quality of life and reduce costs.

In contrast, evaluating the trade-off between model complexity and practical utility, Jones et al. [10] compared Gradient Boosted Trees (GBT), neural networks, Random Forest, and Logistic Regression for predicting emergency department and hospital utilization among home care patients in Canada. Although GBT achieved the highest overall performance, the clinical gains over standard Logistic Regression were practically negligible (approximately 1% to 2% in sensitivity and specificity), raising doubts about whether the added complexity of advanced ML models consistently translates into meaningful practical advantages in clinical settings.

Overall, the prevalent success of tree-based ensembles (such as RF and XGBoost) and the recognition of socio-functional predictors provide a solid foundation for this field. However, as noted by Jones et al. [10], the marginal performance gains of complex models warrant careful scrutiny. Our work builds on this foundation by proposing a comprehensive, multi-paradigm comparison, extending beyond tree-based ensembles to include graph-based and instance-based models, using the NPHA dataset. Furthermore, unlike studies that omit formal hypothesis testing, we subject all performance differences to the Wilcoxon signed-rank test. By explicitly preserving the natural epidemiological prevalence rather than employing synthetic balancing, our evaluation directly addresses the methodological concerns raised in the literature, assessing whether algorithmic complexity statistically justifies its computational cost.

III. Methodology

This section details the methodological model developed to predict medical service utilization among older adults. The workflow is subdivided into five main components: the description of the NPHA dataset, the exploratory data analysis, the data preprocessing procedures (including target transformation and feature encoding), the theoretical background of the machine learning algorithms evaluated, and the thorough experimental setup designed to guarantee robust model evaluation, feature selection, and fair comparison.

A. Dataset and Feature Description

The data used in this study were obtained from the National Poll on Healthy Aging (NPHA) dataset, available through the UCI Machine Learning Repository [11] [1]. The dataset contains responses from 714 U.S. adults aged 50 years and older, 14 predictor variables describing sociodemographic characteristics and health conditions, and one target variable. For this study, the original number-of-doctors-visited target was transformed into a binary outcome. Original category 1, representing zero or one distinct doctor consulted, was mapped to class 0. Original categories 2 and 3, representing two or more distinct doctors consulted, were mapped to class 1. Class 1 was defined as the positive class. The resulting distribution comprised 131 participants (18.3473%) in class 0 and 583 participants (81.6527%) in class 1. The number of distinct doctors consulted was treated as an operational proxy for healthcare utilization and must not be interpreted as a validated clinical definition of high utilization. The available codebook was used to identify the observed variable encodings; however, its clinical interpretation requires manual review and is treated as a limitation of this analysis.

B. Exploratory Data Analysis

Prior to model development, an exploratory analysis was conducted to characterize the NPHA dataset and assess its suitability for predictive classification.

Figure 1 shows the frequency distribution of the 14 predictor variables, numerically encoded as categorical or ordinal integers per the dataset's data dictionary. Age is nearly constant across the sample, with almost all participants concentrated in a single category. Physical, mental, and dental health scores are concentrated around their intermediate categories, while Employment is dominated by a single category. The sleep-related binary variables (stress, medication, pain, and unknown factors keeping patients from sleeping) are skewed toward 0, except for bathroom needs, which is nearly balanced between categories. Trouble sleeping and prescription sleep medication are both skewed toward their higher categories, whereas race is concentrated in a single category and gender is roughly balanced. These distributions describe the observed sample and motivate an evaluation that preserves its empirical class distribution, without by themselves establishing predictive utility.

[1]National Poll on Healthy Aging (NPHA)

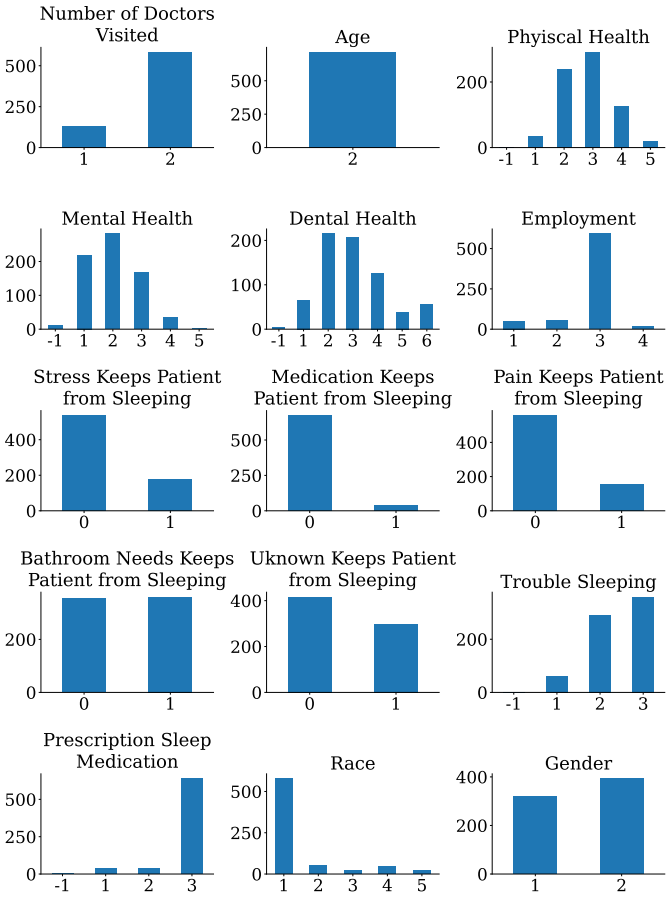

Fig. 1: Frequency distribution of the 14 predictor variables in the NPHA dataset.

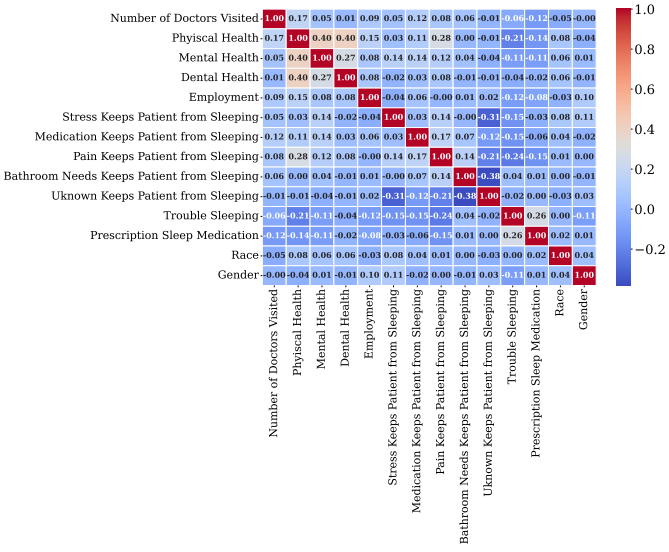

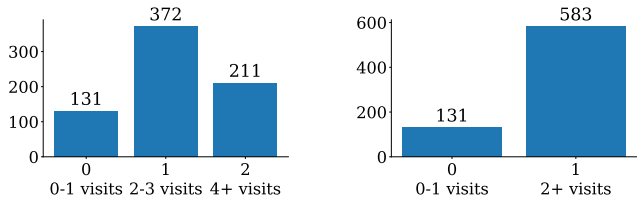

Fig. 2: Correlation matrix among the study variables.

Figure 2 depicts the pairwise Spearman rank correlation matrix. Correlations range from weak to moderate. The highest values ($\rho \approx 0.40$) are observed between physical health and both mental and dental health. Among the sleep-related variables, the strongest association is a negative correlation ($\rho \approx -0.31$) between bathroom needs and unknown factors keeping patients from sleeping. Demographic variables (race, gender) and most sleep-related indicators show near-zero pairwise associations with the remaining attributes. These monotonic associations do not constitute a complete assessment of multicollinearity.

(a) Original target distribution. (b) Binarized target distribution.

Fig. 3: Target variable distribution before (a) and after (b) binarization. Original category 1 was mapped to class 0, and categories 2–3 to class 1.

Finally, Figure 3 presents the target distribution before (a) and after (b) binarization, combining the categories representing two or more distinct doctors consulted. The resulting binary target contains 131 participants (18.3473%) in class 0 (zero or one doctor consulted) and 583 participants (81.6527%) in the positive class 1 (two or more doctors consulted), yielding an imbalanced classification task. This distribution was retained without oversampling, undersampling, or any other artificial resampling procedure, so that training and evaluation reflect the observed composition of the dataset.

C. Data Preprocessing

All preprocessing procedures were incorporated into the training workflow and fitted separately within each split of the nested cross-validation procedure. Numerical variables were imputed using the median of the corresponding training partition and subsequently standardized using `StandardScaler`. Categorical variables were imputed using the most frequent category in the training partition and transformed through One-Hot Encoding with `handle_unknown='ignore'`. These transformations were implemented through a `ColumnTransformer` pipeline.

For each inner or outer split, the imputation, encoding, and scaling components were fitted only on the corresponding training data. The validation or held-out test data were transformed using the fitted training components without refitting. This procedure prevents information from validation and test partitions from influencing the preprocessing parameters.

D. Feature Selection

Feature selection was evaluated in a dedicated MDI-80% scenario. Within each training partition, an auxiliary `RandomForestClassifier` from Scikit-learn [12] with 100 estimators was fitted to calculate Mean Decrease Impurity (MDI) feature importances. The transformed features were ordered by their importance, and the smallest subset whose cumulative importance reached at least 80% was retained.

The MDI selector was fitted independently inside each inner and outer training split. Consequently, the selected features may differ across folds; no global feature subset was defined before cross-validation. Feature-selection frequencies and fold-level selection details were retained as experimental artifacts to support reproducibility. Therefore, MDI results are reported as fold-dependent predictive information rather than stable clinical or causal evidence.

E. Class Weighting, Calibration, Ensemble, and Threshold Selection

No synthetic resampling method, such as SMOTE [13], was applied. In addition to the baseline and MDI-80% scenarios, a cost-sensitive scenario was evaluated for Decision Tree, Random Forest, Logistic Regression, Support Vector Machine, and XGBoost. For the Scikit-learn classifiers, class weights were computed separately in each training partition as $w_c = n/(2n_c)$, where n is the number of training observations and n_c is the number in class c. For XGBoost, whose positive class is class 1, the corresponding parameter was $\texttt{scale_pos_weight} = w_1/w_0 = n_0/n_1$. Therefore, because class 1 is the majority class, this value is less than one (approximately $131/583 = 0.225$ in the complete dataset) and was recalculated in every training fold. Thus, class weighting was determined without using validation or outer test data.

Support Vector Machine probability scores were calibrated within the training workflow using `CalibratedClassifierCV` with a sigmoid method and 5-fold cross-validation. Calibration was performed only on training data, allowing calibrated scores to be generated without exposing the procedure to the outer test partition.

An ensemble scenario was also evaluated using three members selected independently in each outer fold from models that provided native or calibrated class-probability scores: KNN, Decision Tree, Random Forest, Support Vector Machine, MLP, Logistic Regression, XGBoost, Gaussian Naive Bayes, and AdaBoost. Nearest Centroid was excluded because its score is an uncalibrated distance-based decision function rather than a class probability; Optimum-Path Forest did not provide a continuous score. Ensemble members were selected independently in each outer fold using out-of-fold predictions generated exclusively within the corresponding outer training partition. The selection considered predictive performance and diversity among candidate predictions, without access to the held-out outer test partition. Each selected member received an equal weight of one third. Two ensemble decision rules were evaluated: majority voting based on class predictions and probability averaging based on the mean positive-class score.

Finally, the ensemble decision threshold was selected using only internal out-of-fold ensemble predictions. Candidate thresholds from 0.10 to 0.90, in increments of 0.05, were evaluated using macro F1-score as the primary selection criterion, with balanced accuracy and Matthews correlation coefficient used to resolve ties. The selected threshold was then applied to the held-out outer test scores. Therefore, ensemble composition, member weights, calibration, and threshold selection were all determined before evaluation on each outer test partition.

F. Machine Learning Algorithms

We evaluated eleven supervised classifiers spanning linear, probabilistic, instance-based, tree-based, neural, margin-based, and graph-based paradigms, plus a majority-class dummy baseline. All models were evaluated in baseline and MDI-80% scenarios; Decision Tree, Random Forest, Logistic Regression, SVC, and XGBoost were additionally evaluated with cost-sensitive weighting. KNN, Nearest Centroid, and OPF were excluded from probability averaging; Nearest Centroid provided a distance-based score only for discrimination metrics, whereas OPF provided no continuous score.

G. Experimental Setup and Model Training

The predictive models were evaluated using a nested stratified cross-validation procedure. The outer loop used `StratifiedKFold` with 10 folds, shuffling, and a fixed random seed of 42. Each outer fold defined a training partition and a held-out test partition, preserving the observed class distribution in both partitions. The training and test partitions used in each iteration were retained as experimental artifacts to support reproducibility.

Hyperparameter selection was performed exclusively within the training partition of each outer fold. For this purpose, an inner `StratifiedKFold` procedure with 5 folds, shuffling, and the same fixed random seed was applied. Candidate hyperparameter combinations were generated manually using `ParameterGrid` and evaluated through explicit iterations over the inner folds; `GridSearchCV` was not used. For each candidate, the macro F1-score, computed with `labels=[0,1]`, was calculated in each inner validation fold. The candidate with the highest mean macro F1-score across the five inner folds was selected. The hyperparameter grids ranged from 1 to 12 candidate combinations per classifier and were searched manually within each inner fold.

After hyperparameter selection, the selected configuration was fitted using only the corresponding outer training partition and evaluated on its held-out outer test partition. The held-out test partition was evaluated only once for each model within each predefined experimental scenario and outer fold. Thus, the study did not rely on a single global test set; performance was estimated by aggregating the out-of-fold predictions obtained across the 10 outer folds. Outer test data were not used for hyperparameter selection, preprocessing decisions, or any other adaptive training decision. All tested parameter combinations and inner-fold scores were retained as experimental artifacts to support reproducibility. This procedure separates model selection from held-out outer-fold evaluation, providing an internal estimate of generalization performance and preventing information from outer test partitions from influencing the selected configuration.

H. Evaluation Metrics

All metrics were computed per outer fold and aggregated over the out-of-fold (OOF) predictions, in which each instance is predicted exactly once, in the outer fold to which it belongs. Classification quality was summarized by a confusion matrix computed with `labels=[0,1]`. Class 0 corresponds to zero or one distinct doctor consulted, whereas class 1, corresponding to two or more distinct doctors consulted, is the positive class. Let TP, TN, FP, and FN denote the counts of true positives, true negatives, false positives, and false negatives, respectively.

Accuracy measures the overall proportion of correct predictions and is defined as

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}. \tag{1}$$

For each class $c \in \{0, 1\}$, we report per-class precision, recall, and F_1:

$$\begin{aligned} \text{Precision}_c &= \frac{TP_c}{TP_c + FP_c}, \\ \text{Recall}_c &= \frac{TP_c}{TP_c + FN_c}, \\ F_{1,c} &= \frac{2\,\text{Precision}_c\,\text{Recall}_c}{\text{Precision}_c + \text{Recall}_c}. \end{aligned} \tag{2}$$

together with their macro and weighted averages. Because the classes are imbalanced, the main table reports class recall, macro F1, balanced accuracy, the Matthews correlation coefficient (MCC), AUROC, and PR-AUC; Table II provides detailed per-class metrics and aggregated OOF confusion-matrix counts for reference configurations.

Discrimination ability is evaluated with the Area Under the Receiver Operating Characteristic Curve (AUROC) and the Precision–Recall area under the curve (PR-AUC, i.e., average precision). These metrics are computed from the continuous score of class 1, obtained from `predict_proba` when available or from the decision function otherwise; they are never computed from the discrete `predict` output. The receiver operating characteristic and precision–recall curves are built from the same continuous scores. OPF has no continuous score in the implemented pipeline, so its AUROC and PR-AUC are unavailable. For Nearest Centroid, these metrics use its distance-based decision function.

I. Statistical Evaluation

Because outer training partitions overlap across folds, the fold-level performance estimates are dependent. Therefore, the statistical analysis was restricted to exploratory paired comparisons.

The Wilcoxon signed-rank test was used to descriptively compare paired fold-level macro F1 values without assuming that their differences follow a normal distribution.

Following Demšar [14], we applied the paired nonparametric Wilcoxon signed-rank test to compare, for each of the eleven classifiers, the macro F1-score obtained in the 80% MDI feature-selection scenario with the macro F1-score of the majority-class dummy baseline. For each contrast, the two macro F1 values were paired within the same outer fold, resulting in ten dependent pairs.

Because eleven contrasts were evaluated simultaneously, the resulting p-values were adjusted using Holm's step-down correction. As noted by Demšar [14], cross-validation folds from a single dataset are not independent. Therefore, corrected p-values are used only for descriptive comparison and must not be interpreted as conclusive population-level evidence of superiority of any classifier over another classifier or over the dummy baseline.

IV. Results and discussion

We report the ten-fold out-of-fold results for the binary problem in which class 1, corresponding to two or more distinct doctors consulted, is the majority class (81.6% of the 714 instances), whereas class 0 is the minority class (18.4%). Given this imbalance, accuracy alone is not informative: the majority-class dummy baseline already attains approximately 81.6% accuracy. Therefore, the interpretation emphasizes per-class recall, balanced accuracy, MCC, AUROC, and PR-AUC.

In the baseline scenario, most classifiers predict the majority class for most observations, yielding low recall for class 0 and accuracy close to the majority-class baseline. Consequently, macro F1 remains close to 0.45 and balanced accuracy near 0.5 for several models. Some classifiers, including GaussianNB and Nearest Centroid, recover part of class 0. For models with continuous scores, AUROC values are generally close to 0.5, indicating limited discrimination between the two classes. The MDI-80% feature-selection scenario shows a comparable overall pattern, with modest changes in class-0 recall for tree-based and MLP models. OPF does not provide continuous scores in the implemented pipeline; therefore, its AUROC and PR-AUC are unavailable.

In the cost-sensitive scenario, where class weights are derived from the prevalence observed in each training fold, class-0 recall increases for Logistic Regression, Random Forest, XGBoost, and Decision Tree, accompanied by reduced recall for class 1. The Support Vector Classifier retains the majority-class prediction profile in this scenario.

The ensemble majority rule, probability rule, and fixed threshold of 0.5 produce the majority-class prediction profile. In contrast, the threshold selected from internal out-of-fold scores was 0.80 across folds and recovered a fraction of class 0 ($\text{Recall}_0 = 0.129 \pm 0.108$) while retaining $\text{Recall}_1 = 0.879 \pm 0.114$. This change is accompanied by lower overall accuracy and a modest increase in macro F1. Table III reports all ensemble configurations. Across the evaluated scenarios, AUROC remains close to 0.5 and PR-AUC remains near the class prevalence, consistent with limited discriminative capacity for this task.

A. Statistical Comparison with the Majority Baseline

As an exploratory check, each classifier in the MDI-80% scenario was paired with the majority-class dummy baseline on the same outer folds using the paired Wilcoxon signed-rank test on macro F1 ($n = 10$ dependent pairs per contrast). The p-values were corrected for eleven contrasts using the Holm procedure. After correction, no contrast had p-Holm below 0.05. Given fold dependence and the limited number of folds, these values are descriptive and do not provide conclusive evidence of superiority over the baseline.

B. Feature Importance

Feature importance was assessed by a Mean Decrease Impurity (MDI) random-forest selector, refit inside each fold on the training data and retaining features until 80% of cumulative importance was reached. The selector was therefore internal to each fold and did not use the held-out outer test data. Table V reports mean MDI scores by feature origin across folds. These scores are descriptive measures of predictive importance and do not establish causal or clinical effects.

C. Limitations

The findings are subject to several limitations. The study is cross-sectional and uses a single dataset (NPHA, $n = 714$), so the results reflect only the recorded population and moment of collection. The target classes are imbalanced, with two or more distinct doctors consulted representing about 82% of the observations, and most models predicted the majority class, resulting in low recall for the minority class. Feature importance and model behavior varied across folds, and MDI-based feature selection was recomputed inside each fold; therefore, the reported importance values are not stable enough for strong conclusions.

A search for accessible external datasets with a compatible target and variable structure did not identify a suitable dataset for external validation; potential alternatives required restricted access or used non-comparable outcome definitions. Although the evaluation pipeline can be applied to other compatible datasets, its predictive performance cannot be assumed to transfer to other populations, settings, or data-collection procedures. The limited discrimination observed also indicates that the recorded variables and binary outcome form a difficult prediction task in this dataset. These limitations restrict interpretation of the reported results to the specific data and protocol used.

V. Conclusion

This study evaluated supervised machine-learning classifiers for a binary formulation of healthcare service utilization among adults aged 50 years and older using the NPHA dataset ($n = 714$). The original target was recoded so that class 0 represents zero or one distinct doctor consulted and class 1 represents two or more distinct doctors consulted. The

observed class distribution was preserved, with class 1 as the majority class. Models were evaluated through nested cross-validation and out-of-fold predictions under baseline, MDI-80% feature-selection, cost-sensitive, ensemble, and threshold-selection scenarios.

The results show that overall accuracy alone does not adequately describe performance in this imbalanced task. The majority-class dummy baseline already achieved approximately 81.6% accuracy while completely failing to recover class 0. Similarly, several evaluated models produced high recall for class 1 but low or null recall for class 0. This pattern explains why per-class recall, macro F1, balanced accuracy, MCC, AUROC, and PR-AUC were necessary for interpretation.

Across scenarios, the observed discriminative capacity was limited. AUROC values remained close to 0.5 for most models, indicating weak separation between the two utilization classes. The MDI-80% scenario produced results broadly comparable to the baseline. Cost-sensitive weighting increased class-0 recall for some models, whereas the threshold selected from internal out-of-fold scores recovered part of class 0; however, these changes were scenario-specific and accompanied by

TABLE IV: Paired Wilcoxon comparison of each classifier with the majority-class dummy baseline using macro F1, with Holm correction. Exploratory analysis with ten dependent folds.

Model vs. Dummy	W	p	p-**Holm**
KNeighbors	7.0	0.0742	0.4512
DecisionTree	1.0	0.0156	0.1719
RandomForest	8.0	0.0488	0.3906
SVC	0.0	1.0000	1.0000
MLP	6.0	0.0273	0.2734
LogisticRegression	0.0	1.0000	1.0000
XGBoost	3.0	0.0391	0.3516
GaussianNB	7.0	0.2813	1.0000
NearestCentroid	22.0	0.6074	1.0000
OPF	9.0	0.0645	0.4512
AdaBoost	0.0	1.0000	1.0000

$W = 0$ and $p = 1$ occur when macro F1 is identical to the dummy baseline.
Results are exploratory; no claim of statistical superiority is made.

TABLE V: Mean MDI attributed by the auxiliary random forest, averaged over folds. Values are descriptive importance scores, not causal or clinical evidence.

Feature origin	**Mean MDI**
Dental Health	0.1786
Mental Health	0.1396
Physical Health	0.1262
Trouble Sleeping	0.0900
Race	0.0834
Employment	0.0761
Gender	0.0665
Bathroom Needs Keeps Patient from Sleeping	0.0570
Unknown Keeps Patient from Sleeping	0.0565
Pain Keeps Patient from Sleeping	0.0406
Stress Keeps Patient from Sleeping	0.0400
Prescription Sleep Medication	0.0335
Medication Keeps Patient from Sleeping	0.0119
Age	0.0000

MDI importance varied across folds; values are not stable enough to support causal or clinical interpretation.
Feature selection was performed internally to each fold.

trade-offs in class-1 recall or overall accuracy. The ensemble rules and fixed threshold generally retained the majority-class prediction profile.

The nested evaluation protocol ensured that preprocessing, feature selection, weighting, calibration, ensemble composition, and threshold selection were determined without using the corresponding outer test fold. Nevertheless, the exploratory Wilcoxon–Holm comparison does not support conclusive claims that any classifier outperforms another classifier or the dummy baseline.

Therefore, the findings provide preliminary evidence of the difficulty of predicting this outcome from the available variables. They do not support clinical conclusions, diagnostic use, triage, or deployment. These findings must be interpreted alongside the study limitations.

***Resumo*—A segmentação manual de vasos sanguíneos em exames de fundoscopia é trabalhosa, subjetiva e demanda tempo considerável do oftalmologista, o que motiva o uso de modelos de aprendizado profundo. Este trabalho compara seis codificadores integrados à arquitetura U-Net e avalia diferentes estratégias de pré-processamento (imagens originais RGB, tons de cinza, canal verde e canal verde com CLAHE) na base FIVES, adotando a métrica Dice como principal indicador de desempenho. Na base FIVES, o pré-processamento com canal verde seguido de CLAHE apresentou os melhores resultados médios, com destaque para o VGG19 (83,61%) e a ResNet101 (82,81%), que superaram as demais arquiteturas avaliadas; esse mesmo pré-processamento também se mostrou superior às demais estratégias testadas, incluindo canal verde sem CLAHE, imagens RGB e tons de cinza. Para avaliar a generalização, foram conduzidos testes cross-dataset em duas bases não utilizadas no treinamento: as bases de dados dos estudos *A Fundus Image Dataset for AI-based Artery-Vein Vessel Segmentation* e *The RETA Benchmark for Retinal Vascular Tree Analysis*, nas quais o VGG19 e a ResNet101 mantiveram desempenho consistente, com Dice médio de 82,72% e 82,43% na Fundus-AVSeg e 79,30% e 78,25% na RETA, respectivamente.**

***Index Terms*—Segmentação de vasos sanguíneos, fundoscopia, U-Net, redes neurais profundas, pré-processamento de imagens, canal verde, CLAHE, EfficientNet, ResNet, Swin Transformer.**

I. INTRODUÇÃO

Milhões de pessoas no mundo apresentam casos de cegueira evitável, tanto por conta de doenças, como a retinopatia diabética, quando por questões do avanço da idade, como a degeneração macular. Isso vem representando um desafio significativo para os sistemas de saúde pública [1]. O diagnóstico precoce e o monitoramento regular dessas doenças são fundamentais para prevenir a perda irreversível da visão. Nesse contexto, a análise automatizada de imagens de fundoscopia tem se consolidado como uma ferramenta promissora, permitindo a detecção precoce de alterações na retina e auxiliando os especialistas na tomada de decisões clínicas [2]. Entre as estruturas retinianas de maior interesse clínico, os vasos sanguíneos destacam-se por sua relevância no diagnóstico de diversas patologias, uma vez que alterações em seu calibre, tortuosidade e padrão de ramificação podem indicar a presença de doenças sistêmicas, como hipertensão arterial e diabetes mellitus.

A segmentação precisa dos vasos sanguíneos em imagens de fundoscopia é uma tarefa desafiadora devido à grande variabilidade anatômica entre pacientes, à presença de patologias que podem obscurecer os vasos, e às condições de iluminação não uniformes durante a aquisição das imagens [13]. Além disso, a complexidade da estrutura vascular, que inclui vasos de diversos calibres, desde os principais troncos vasculares até os capilares de fino calibre, torna a segmentação manual um processo demorado e sujeito a variações inter e intra-observador. Diante desses desafios, o desenvolvimento de métodos automáticos baseados em aprendizado profundo tem se mostrado uma abordagem eficaz, superando as técnicas tradicionais de processamento de imagens em termos de precisão e robustez [3], [4].

Neste trabalho, são investigadas diferentes estratégias de pré-processamento e arquiteturas de redes neurais profundas para a segmentação de vasos sanguíneos em imagens de fundoscopia. O pré-processamento das imagens é uma etapa fundamental para melhorar a qualidade dos dados de entrada e facilitar a tarefa de segmentação [5]. Foram avaliadas quatro estratégias distintas de pré-processamento: imagens originais (três canais de cores), tons de cinza, canal verde e canal

Os autores agradecem ao Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), sob o Processo nº 315447/2023-0, e à Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) — Código de Financiamento 001, pelo apoio a esta pesquisa.

verde com aplicação do CLAHE (*Contrast Limited Adaptive Histogram Equalization*). A escolha do canal verde justifica-se pela absorção da luz pela hemoglobina na faixa do verde, o que proporciona maior contraste entre os vasos sanguíneos e o tecido retiniano circundante [1]. O CLAHE, por sua vez, foi adotado para melhorar o contraste local e uniformizar a iluminação, especialmente em regiões periféricas da retina que frequentemente apresentam baixa qualidade de imagem.

A arquitetura U-Net foi adotada como base para a segmentação, sendo uma das redes mais consolidadas para tarefas de segmentação de imagens médicas devido à sua capacidade de combinar informações contextuais e localizadas por meio de conexões *skip connections* [6]. Para avaliar o impacto da escolha do codificador, a U-Net foi combinada com seis diferentes *backbones*: EfficientNetB0 [14], MobileNetV2 [7], ResNet101 [4], VGG19 [3], SwinUNet [8] e ViTUNet [9]. Essas arquiteturas foram selecionadas por representarem diferentes paradigmas de redes neurais: as três primeiras são CNNs modernas com diferentes equilíbrios entre eficiência e capacidade representacional; a VGG19 é uma CNN mais profunda e com maior número de parâmetros; e os Transformers (SwinUNet e ViTUNet) representam a abordagem baseada em mecanismos de autoatenção, que têm demonstrado resultados promissores em diversas tarefas de visão computacional [8], [9].

Os experimentos foram conduzidos utilizando a base de dados FIVES (*Fundus Image Vessel Segmentation*) [10], que contém imagens de fundoscopia anotadas com as respectivas máscaras de segmentação dos vasos sanguíneos. Foram realizadas cinco execuções independentes para cada combinação de arquitetura e pré-processamento, totalizando 30 configurações experimentais. A métrica Dice foi adotada como principal indicador de desempenho, por integrar precisão e sensibilidade em uma única medida, sendo amplamente utilizada em tarefas de segmentação de imagens médicas [1], [2]. Além da qualidade da segmentação, o tempo total de treinamento foi registrado para cada execução, permitindo avaliar a eficiência computacional de cada combinação.

Com o objetivo de avaliar a capacidade de generalização dos modelos, também foram realizados testes em duas bases de dados distintas, não utilizadas durante o treinamento: a Fundus-AVSeg, proveniente do estudo *A Fundus Image Dataset for AI-based Artery-Vein Vessel Segmentation*(Fundus-AVSeg) [11], voltada para a segmentação de artérias e veias em imagens de fundoscopia, e a RETA, oriunda do benchmark *The RETA Benchmark for Retinal Vascular Tree Analysis*(RETA) [12], que fornece imagens e anotações específicas para a análise da árvore vascular retiniana. Essas bases apresentam características de aquisição, resolução e distribuição de vasos diferentes da FIVES, o que permite verificar a robustez das arquiteturas treinadas frente à variabilidade entre domínios.

Os resultados obtidos são apresentados e discutidos ao longo deste artigo, com o objetivo de identificar as melhores práticas para a segmentação de vasos sanguíneos em imagens de fundoscopia, considerando o equilíbrio entre desempenho, generalização e custo computacional.

II. DETALHAMENTO TÉCNICO

A. Base de dados

A primeira etapa do nosso trabalho consistiu em identificar e selecionar bases de dados que oferecessem não apenas imagens de fundoscopia em quantidade suficiente, mas também anotações manuais precisas e validadas por especialistas. A qualidade dos rótulos impacta diretamente a capacidade dos modelos de aprenderem padrões fiéis à realidade clínica.

Após analisar as opções disponíveis na literatura, optamos pelo base FIVE (Fundus Image Vessel Extraction). Ela é composto por 800 imagens no total, das quais 600 são destinadas ao treinamento e 200 ao teste, todas com resolução de 2048×2048 pixels. Além disso, o banco abrange uma variedade clínica relevante: as imagens incluem desde olhos saudáveis até casos com retinopatia diabética, glaucoma e outras alterações patológicas, expondo os modelos a diferentes níveis de contraste, iluminação e distorções morfológicas [10]. Essa diversidade é um diferencial importante, pois força os algoritmos a aprenderem características robustas, em vez de se ajustarem excessivamente a um único padrão visual. Dois exemplos de imagens da base de dados podem ser conferidas na figura 1.

A base FIVE atendia os requisitos de ter suas máscaras de segmentação delineadas por oftalmologistas experientes seguindo e por ser amplamente referenciado na comunidade científica, o que nos possibilita comparar nossas métricas com as de outros grupos que adotaram a mesma base e a mesma arquitetura de referência. Essa compatibilidade metodológica é fundamental para que possamos afirmar se as melhorias observadas vêm das modificações nos codificadores ou de meras particularidades do conjunto de dados.

Por fim, a divisão padronizada entre treino e teste estabelecida pelo próprio FIVE elimina ruídos na comparação inter-estudos trazendo mais confiabilidade na comparação dos trabalhos.

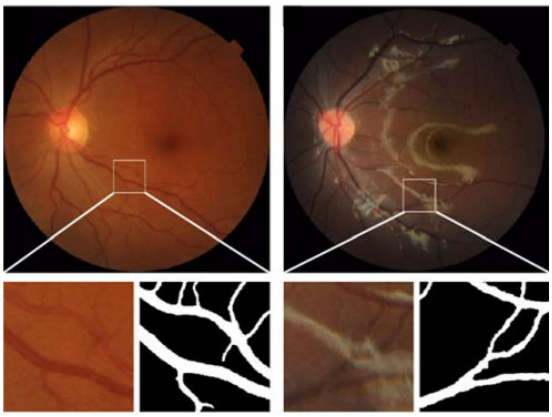

Figura 1. Exemplo de dados do banco de dados FIVE.

B. Pré-processamento das Imagens

O pré-processamento das imagens de fundoscopia é uma etapa fundamental para melhorar a qualidade dos dados de en-

trada e facilitar a tarefa de segmentação dos vasos sanguíneos. Neste trabalho, foram avaliadas cinco estratégias distintas de pré-processamento: imagens originais (três canais de cores), tons de cinza, canal verde e canal verde com aplicação do CLAHE. Todas as imagens foram redimensionadas para a resolução de 224×224 pixels, de modo a padronizar a entrada dos modelos e garantir a compatibilidade com as arquiteturas avaliadas.

A Figura 2 ilustra o resultado da aplicação de cada técnica de pré-processamento em uma imagem de exemplo da base de dados FIVES. A imagem original (RGB) é apresentada no canto superior esquerdo, seguida pelas três versões processadas utilizadas como entrada para os modelos de segmentação.

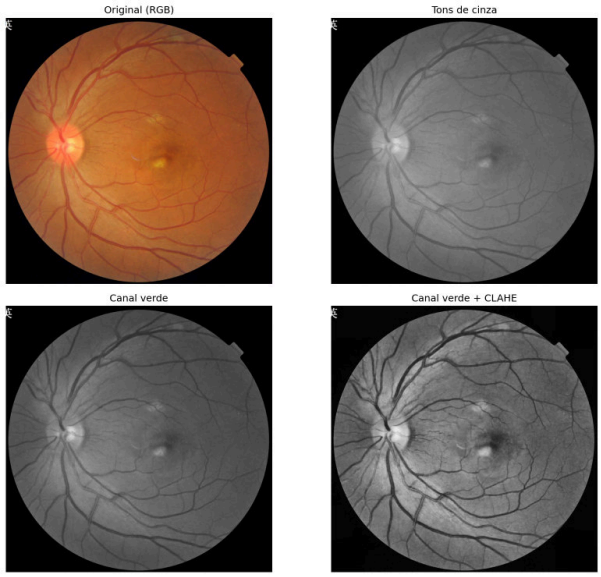

Figura 2. Exemplo das técnicas de pré-processamento aplicadas a uma imagem de fundoscopia: (a) Imagem Original (RGB); (b) Tons de Cinza; (c) Canal Verde; (d) Canal Verde com CLAHE.

As imagens originais foram utilizadas como linha de base para comparação. Essa abordagem mantém toda a informação cromática disponível, incluindo as diferenças de intensidade entre os canais vermelho, verde e azul, que podem ser relevantes para a caracterização de diferentes estruturas retinianas. Contudo, o uso de três canais aumenta a dimensionalidade dos dados e, consequentemente, o custo computacional do treinamento. As imagens em tons de cinza foram obtidas pela conversão direta da imagem RGB para um único canal de intensidade, reduzindo a dimensionalidade e eliminando informações potencialmente redundantes. Embora seja a abordagem mais simples, a conversão para tons de cinza pode resultar em perda de contraste entre os vasos e o fundo da retina, uma vez que não explora as propriedades espectrais específicas da hemoglobina.

O canal verde foi extraído diretamente da imagem RGB, selecionando apenas a matriz correspondente ao componente verde do espaço de cores. Essa escolha é fundamentada na física da interação da luz com os tecidos biológicos: a hemoglobina presente no sangue absorve fortemente a luz na faixa do verde (comprimento de onda de aproximadamente 540 nm), fazendo com que os vasos sanguíneos apareçam escuros neste canal, enquanto o tecido retiniano circundante reflete a luz, criando um alto contraste. Estudos prévios têm demonstrado que o canal verde oferece o melhor contraste para a segmentação de vasos em imagens de fundoscopia [5].

Por fim, o canal verde com aplicação do CLAHE foi gerado a partir da extração do canal verde seguida da aplicação do algoritmo CLAHE, que realiza uma equalização de histograma adaptativa por regiões, limitando o contraste para evitar a amplificação excessiva de ruído. O CLAHE divide a imagem em pequenas regiões (tiles) e aplica a equalização de histograma em cada uma delas, interpolando os resultados para suavizar as transições entre as regiões. O parâmetro *clipLimit* controla o fator de limitação do contraste, enquanto *tileGridSize* define o tamanho das regiões. Neste trabalho, foram utilizados os valores de *clipLimit* igual a 2,0 e *tileGridSize* igual a (8,8), que demonstraram um bom equilíbrio entre o realce do contraste e a preservação das estruturas finas dos vasos. O CLAHE é particularmente útil para imagens de fundoscopia, que frequentemente apresentam iluminação não uniforme e baixo contraste em regiões periféricas, melhorando a visibilidade dos vasos de fino calibre e facilitando a segmentação. A Figura 2 evidencia visualmente o efeito de cada técnica: o canal verde (Figura 2c) já apresenta bom contraste dos vasos, enquanto o VM (Figura 2d) realça adicionalmente os detalhes, e o CLAHE (Figura 2e) promove uma equalização que uniformiza a iluminação e realça vasos de menor calibre. A combinação do canal verde com o CLAHE explora sinergicamente as propriedades espectrais da hemoglobina e as técnicas de realce de contraste adaptativo, resultando em imagens de entrada com alta qualidade para os modelos de segmentação.

C. Backbones para Codificadores na Arquitetura U-Net

A substituição do codificador convencional da U-Net por backbones consolidados da visão computacional tem se mostrado uma estratégia eficaz para melhorar a segmentação de vasos sanguíneos [13]. Esses codificadores são responsáveis por extrair características hierárquicas da imagem, enquanto o decodificador reconstrói a máscara de segmentação. A escolha do backbone define o equilíbrio entre acurácia, custo computacional e capacidade de generalização, sendo agrupados em redes profundas, redes leves e modelos baseados em Transformer.

Entre as redes tradicionais profundas, a *VGG-19* [1] e a *ResNet-101* [2] oferecem alta capacidade representacional. A VGG-19 utiliza pilhas homogêneas de convoluções 3x3, proporcionando amplo campo receptivo, mas com elevado custo paramétrico. A ResNet-101, por sua vez, emprega conexões residuais que facilitam o treinamento de redes mais profundas, mitigando o desvanecimento do gradiente. Ambas extraem características semânticas robustas, sendo indicadas quando a precisão é prioritária e o recurso computacional não é limitado.

Para cenários com restrição de hardware ou exigência de inferência rápida, as redes leves *MobileNet* [3] e *EfficientNet-*

B0 [4] são alternativas vantajosas. A MobileNet reduz drasticamente parâmetros e latência por meio de convoluções separáveis em profundidade, mantendo desempenho adequado para vasos de médio calibre. A EfficientNet-B0 otimiza a relação profundidade-largura-resolução via escalonamento composto, oferecendo eficiência superior. Embora possam perder detalhes finos de microvasos, são ideais para sistemas de triagem automatizados e dispositivos embarcados.

Por fim, os Transformers, como o *ViT* [5] e o *Swin Transformer* [6], superam as limitações de dependência local das CNNs ao empregarem mecanismos de autoatenção global. O ViT processa a imagem em patches e captura interações de longa distância, mas requer muitos dados para convergir. O Swin Transformer introduz janelas de atenção deslocadas e estrutura hierárquica, combinando visão global e local com maior eficiência. Ambos, especialmente o Swin, obtêm excelente desempenho na segmentação de vasos tortuosos e finos, porém demandam maior poder computacional e conjuntos de dados extensos para evitar overfitting.

D. Métricas de Avaliação

O índice de Dice, também conhecido como coeficiente de Sorensen-Dice, é a métrica de qualidade mais amplamente utilizada em tarefas de segmentação de imagens médicas, por integrar precisão e sensibilidade em uma única medida. O Dice é definido pela Equação 1, onde VP representa o número de pixels verdadeiros positivos (vasos corretamente segmentados), FP o número de falsos positivos (fundo classificado como vaso) e FN o número de falsos negativos (vasos não detectados). O índice varia entre 0 (nenhuma sobreposição entre a segmentação predita e a máscara de referência) e 1 (sobreposição perfeita), sendo que valores mais próximos de 1 indicam melhor qualidade da segmentação. A escolha do Dice como métrica principal justifica-se pela sua capacidade de refletir o equilíbrio entre a detecção correta dos vasos e a precisão da segmentação.

$$Dice = \frac{2 \cdot VP}{2 \cdot VP + FP + FN} \tag{1}$$

O Dice foi adotado como métrica de validação durante o treinamento, sendo calculado ao final de cada época sobre o conjunto de validação para monitorar o progresso do modelo e selecionar os melhores pesos. Ao término do treinamento, o Dice também foi calculado sobre o conjunto de teste, permitindo avaliar a capacidade de generalização dos modelos. Para cada configuração experimental (combinação de arquitetura e pré-processamento), foram realizadas cinco execuções independentes de treinamento, com diferentes sementes aleatórias para a inicialização dos pesos e para a divisão dos dados. A partir dessas cinco execuções, foram calculadas a média e o desvio padrão do melhor Dice obtido durante a validação (best_val_dice) e do Dice final sobre o conjunto de teste. Essa abordagem garante a robustez estatística dos resultados e permite avaliar a consistência do desempenho dos modelos.

A sensibilidade, também denominada *recall* ou taxa de verdadeiros positivos, mede a capacidade do modelo em identificar corretamente os pixels pertencentes aos vasos sanguíneos, sendo definida pela Equação 2. Nessa formulação, VP representa o número de pixels verdadeiros positivos (vasos corretamente segmentados) e FN o número de falsos negativos (vasos não detectados pelo modelo).

$$Sensibilidade = \frac{VP}{VP + FN} \tag{2}$$

Essa métrica varia entre 0 e 1, em que valores próximos de 1 indicam que o modelo é capaz de detectar a maior parte dos vasos presentes na máscara de referência, enquanto valores baixos revelam uma tendência à omissão de estruturas vasculares. No contexto da segmentação de vasos em imagens de fundoscopia, a sensibilidade é particularmente relevante, pois a não detecção de vasos pode comprometer análises clínicas subsequentes, como a identificação de estenoses, cruzamentos arteriovenosos e alterações no calibre vascular. Contudo, a sensibilidade deve ser analisada em conjunto com outras métricas, uma vez que um modelo excessivamente sensível pode classificar regiões de fundo como vasos, elevando o número de falsos positivos. Assim como o Dice, a sensibilidade foi calculada ao final de cada época sobre o conjunto de validação e, posteriormente, sobre o conjunto de teste, com média e desvio padrão obtidos a partir das cinco execuções independentes de cada configuração experimental.

A métrica Interseção sobre União(IoU), é amplamente utilizada em tarefas de segmentação por medir a razão entre a área de sobreposição e a área de união entre a segmentação predita e a máscara de referência. O IoU é definido pela Equação 3, onde VP representa o número de pixels verdadeiros positivos, FP o número de falsos positivos e FN o número de falsos negativos.

$$IoU = \frac{VP}{VP + FP + FN} \tag{3}$$

O índice varia entre 0 e 1, em que 0 indica ausência total de sobreposição entre a predição e a referência, e 1 representa sobreposição perfeita. Diferentemente do Dice, o IoU é mais sensível a discrepâncias entre as regiões preditas e as anotadas, penalizando de forma mais acentuada tanto os falsos positivos quanto os falsos negativos. Essa característica torna o IoU particularmente útil para avaliar a precisão espacial das segmentações vasculares, especialmente em cenários nos quais vasos de pequeno calibre podem ser facilmente omitidos ou confundidos com o fundo da imagem. No presente trabalho, o IoU foi calculado ao final de cada época sobre o conjunto de validação e, ao término do treinamento, sobre o conjunto de teste, com média e desvio padrão obtidos a partir das cinco execuções independentes de cada configuração experimental, seguindo o mesmo procedimento adotado para as demais métricas.

O tempo total de treinamento foi registrado para cada uma das cinco execuções independentes, compreendendo o período desde o início do carregamento dos dados até a conclusão da última época de treinamento, incluindo o tempo de validação ao final de cada época. A média dos tempos

de treinamento das cinco execuções foi calculada para cada combinação de arquitetura e pré-processamento, permitindo avaliar a eficiência computacional de cada configuração. O desvio padrão do tempo de treinamento também foi calculado, fornecendo uma medida da variabilidade do custo computacional entre execuções.

E. Hiperparâmetros e Configurações Experimentais

Para garantir a reprodutibilidade dos experimentos, foram definidos hiperparâmetros padronizados para todas as arquiteturas avaliadas, conforme apresentado na Tabela I. O treinamento foi conduzido com parada antecipada de paciência 10 e delta 0,001, e cada configuração foi executada cinco vezes com diferentes sementes aleatórias. Os experimentos foram realizados na estação de trabalho especificada na Tabela II.

Tabela I
HIPERPARÂMETROS UTILIZADOS NOS EXPERIMENTOS.

Parâmetro	**Valor**
Tamanho da imagem	224 x 224 pixels
Modo de entrada	1 canal (tons de cinza)
Batch size	16
Épocas máximas	50
Taxa de aprendizado inicial	0,001
Otimizador	Adam
Função de perda	Dice + BCE
parada antecipada	Paciência: 10 épocas, Delta: 0,001
Número de execuções	5
Num workers	4
Pin memory	Ativado

Tabela II
ESPECIFICAÇÕES DO HARDWARE UTILIZADO.

Componente	**Especificação**
Processador	AMD Ryzen 5 5600X (6 núcleos, 12 threads)
Placa de vídeo	NVIDIA RTX 3060 (12 GB VRAM)
Memória RAM	24 GB DDR4
Armazenamento	SSD 250 GB
Sistema Operacional	Ubuntu 20.04 LTS

III. ANÁLISE DE TREINO E TESTE

O código-fonte completo, os dados processados e os resultados detalhados de todos os experimentos estão disponíveis publicamente no repositório GitHub [18] para fins de reprodutibilidade e transparência científica.

A. Análise dos Tempos de Treinamento

O tempo de treinamento é um fator crítico para a viabilidade prática de modelos de segmentação, especialmente em cenários com recursos computacionais limitados ou que exigem rápida interação experimental. A Tabela III apresenta os tempos médios de treinamento (em segundos), acompanhados dos respectivos desvios padrão, para cada combinação de arquitetura e pré-processamento, obtidos a partir de cinco execuções independentes.

Inicialmente, observa-se que o treinamento com as imagens originais, que preservam os três canais de cores (RGB), demandou os maiores tempos para todas as arquiteturas avaliadas. O EfficientNetB0, que foi a rede que mais demorou, necessitou de 1040,6 segundos em média para concluir o treinamento com as imagens coloridas, enquanto a ResNet101 destacou-se como a mais eficiente, com 527,8 segundos, valor significativamente inferior aos demais modelos. Entre os Transformers, o Swin e o ViT exigiram 739,5 e 744,1 segundos, respectivamente.

Tabela III
TEMPOS DE TREINAMENTO (MÉDIA ± DESVIO, EM SEGUNDOS).

	Pré-processamento			
Modelo	Orig.	Cinza	Verde	V+CL.
EffNetB0	1040,6 ± 18,5	359,6 ± 13,2	368,5 ± 0,4	369,8 ± 0,6
MobNetV2	989,6 ± 83,2	362,9 ± 0,5	314,3 ± 28,9	335,2 ± 24,5
ResNet101	527,8 ± 53,3	279,7 ± 66,5	262,6 ± 28,1	244,8 ± 30,5
Swin	739,5 ± 86,1	325,5 ± 5,3	339,1 ± 23,1	333,9 ± 36,7
VGG19	871,8 ± 304,5	772,5 ± 0,6	754,5 ± 41,7	691,0 ± 187,3
ViT	744,1 ± 85,5	697,8 ± 37,0	692,3 ± 61,0	650,8 ± 30,7

[a] Valores baseados em 5 execuções independentes.

A adoção de pré-processamentos que reduzem a dimensionalidade dos dados para um único canal (cinza, verde e V+CLAHE) proporcionou reduções expressivas nos tempos de treinamento para todos os modelos, como o esperado. Mas a ViTUNet apresentou redução menos expressiva, de 744,1 segundos (original) para 650,8 segundos com V+CLAHE, sua menor média entre os tipos de pré-processamento. Algo parecido também ocorre com a VGG19, que apresentou uma diferença de 20,7% da média do treinamento com imagens RGB para a V+CLAHE, o tipo de treinamento mais rápido que teve. As suspeitas para essas duas redes terem esses tempos se dá pelas suas arquiteturas não terem as primeiras camadas como tão relevantes para o treinamento em comparação as outras redes. Na VGG19, o custo concentra-se nas diversas convoluções profundas em resoluções espaciais elevadas, e na ViT, nos blocos de autoatenção, cujo custo depende do número de *patches* e da dimensão do *embedding*, e não do número de canais da imagem de entrada.

Analisando individualmente cada arquitetura em relação aos tempos de treino com imagens pré-processadas, observa-se que a ResNet101 apresentou a maior eficiência computacional entre todos os modelos, com o menor tempo médio registrado para a entrada V+CLAHE (244,8 segundos), seguido por verde (262,6 segundos) e cinza (279,7 segundos), com desvios padrão entre 28,1 e 66,5 segundos. O EfficientNetB0, embora tenha apresentado tempos ligeiramente superiores (359,6 a 369,8 segundos entre as entradas monocromáticas), demonstrou alta consistência, com desvios padrão que variaram de 0,42 segundo (verde) a 13,2 segundos (cinza), sendo a arquitetura mais estável entre as avaliadas. Em contraste, o VGG19 exibiu os tempos de 691,0 a 772,5 segundos e a maior variabilidade, com desvios que chegaram a 187,3 segundos para V+CLAHE e 41,7 segundos para verde.

Em termos de variabilidade entre execuções, os menores desvios padrão foram observados para o EfficientNetB0 com

verde (0,42 segundo) e V+CLAHE (0,55 segundo), para a MobileNetV2 com cinza (0,45 segundo) e para o VGG19 com cinza (0,60 segundo), indicando alta consistência nos tempos de treinamento nesses cenários. O VGG19, por outro lado, exibiu a maior instabilidade com imagens originais (desvio de 304,5 segundos) e com V+CLAHE (187,3 segundos), em razão de atingir o limite de épocas estabelecido pelo parâmetro de paciência em algumas execuções. O SwinUNet e o ViTUNet apresentaram desvios moderados (5,3 a 86,1 segundos para o Swin e 30,7 a 85,5 segundos para o ViT), enquanto a ResNet101 com cinza mostrou desvio elevado (66,5 segundos), possivelmente devido a variações no carregamento de dados ou na inicialização dos pesos. De modo geral, os pré-processamentos baseados em canal único não apenas reduzem os tempos médios de treinamento, mas também tendem a produzir tempos mais consistentes entre execuções, o que é um fator relevante para a reprodutibilidade experimental.

B. Análise Comparativa do Dice nos Testes

A métrica Dice foi adotada como principal indicador de desempenho para a segmentação de vasos sanguíneos, por integrar precisão e sensibilidade em uma única medida. Para avaliar a capacidade de generalização dos modelos, além da base de treinamento FIVES, foram realizados testes em duas bases distintas não utilizadas durante o treinamento: a Fundus-AVSeg e a RETA. A Tabela IV apresenta os valores médios e os desvios padrão do Dice para as três bases.

Tabela IV
DICE (%): MÉDIA ± DESVIO NAS BASES FIVES, FUNDUS-AVSEG E RETA.

Modelo	Pré-processamento			
	Orig.	Cinza	Verde	V+CL.
FIVES				
EffNetB0	81,05 ± 0,08	78,97 ± 0,08	81,74 ± 0,23	82,06 ± 0,13
MobNetV2	78,73 ± 0,19	76,51 ± 0,13	79,28 ± 0,17	79,65 ± 0,16
ResNet101	80,57 ± 0,23	78,66 ± 0,24	82,09 ± 0,40	82,81 ± 0,55
Swin	78,30 ± 0,27	74,76 ± 0,30	78,19 ± 0,12	78,95 ± 0,29
VGG19	81,74 ± 3,68	79,45 ± 1,29	81,85 ± 2,01	83,61 ± 0,98
ViT	47,27 ± 0,60	48,36 ± 1,79	56,62 ± 0,98	63,61 ± 0,37
Fundus-AVSeg				
EffNetB0	80,14 ± 0,22	77,85 ± 0,99	79,80 ± 0,41	79,89 ± 0,36
MobNetV2	78,52 ± 0,21	75,35 ± 0,64	77,35 ± 0,51	77,44 ± 0,30
ResNet101	81,24 ± 0,41	78,83 ± 0,88	81,68 ± 0,85	82,43 ± 0,87
Swin	76,72 ± 0,18	72,96 ± 0,62	75,58 ± 0,21	75,87 ± 0,84
VGG19	82,11 ± 1,64	81,15 ± 0,55	82,03 ± 0,80	82,72 ± 0,49
ViT	48,00 ± 0,65	47,58 ± 2,68	54,67 ± 0,72	62,06 ± 0,46
RETA				
EffNetB0	76,09 ± 0,14	74,45 ± 0,23	76,02 ± 0,28	76,41 ± 0,15
MobNetV2	73,93 ± 0,17	72,06 ± 0,17	74,06 ± 0,21	74,07 ± 0,45
ResNet101	76,47 ± 0,22	75,13 ± 0,38	77,57 ± 0,42	78,25 ± 0,25
Swin	73,62 ± 0,25	70,29 ± 0,38	73,02 ± 0,16	73,56 ± 0,26
VGG19	77,88 ± 2,85	77,21 ± 0,40	77,93 ± 1,16	79,30 ± 0,72
ViT	42,45 ± 0,69	40,74 ± 2,28	48,96 ± 1,11	55,60 ± 0,80

[a]Valores baseados em 5 execuções independentes.

Observa-se que o pré-processamento V+CLAHE proporcionou os maiores valores médios de Dice nos testes realizados. Nesse pré-processamento, em todas as três bases avaliadas a VGG19 ficou em primeiro lugar, sendo seguida da ResNet101.

Considerando simultaneamente o desempenho e a estabilidade, a ResNet101 com V+CLAHE consolidou-se como a melhor combinação geral: obteve Dice médio de 82,81% na FIVES, 82,43% na Fundus-AVSeg e 78,25% na RETA, com desvios padrão consistentemente baixos (0,55%, 0,87% e 0,25%, respectivamente). A EfficientNetB0 apresentou comportamento semelhante, com Dice de 82,06%, 79,89% e 76,41% nas três bases e desvios padrão ainda menores (0,13%, 0,36% e 0,15%), configurando a arquitetura mais estável entre todas as avaliadas.

É importante destacar o comportamento da VGG19: embora tenha obtido os maiores valores médios de Dice em todas as bases, apresentou variabilidade substancialmente superior, especialmente nas condições com imagens originais (desvios de 3,68%, 1,64% e 2,85% na FIVES, Fundus-AVSeg e RETA, respectivamente) e com canal verde sem CLAHE (2,01%, 0,80% e 1,16%).

Em contrapartida, o ViTUNet apresentou o pior desempenho em todas as bases, mesmo com V+CLAHE (63,61% na FIVES, 62,06% na Fundus-AVSeg e 55,60% na RETA), reforçando que arquiteturas baseadas exclusivamente em mecanismos de autoatenção não se mostraram adequadas para esta tarefa com o volume de dados disponível.

De modo geral, os resultados evidenciam que o pré-processamento V+CLAHE é a estratégia que apresenta uma melhoria nos resultados e por um menor custo computacional se comparado com as imagens originais.

C. Análise Comparativa do IoU nos Testes

O índice de Intersecção sobre União (IoU) foi adotado como métrica complementar de análise ao Dice, por penalizar de forma mais acentuada discrepâncias entre a segmentação predita e a máscara de referência, sendo especialmente sensível a omissões de vasos de pequeno calibre. A Tabela V apresenta os valores médios e os desvios padrão do IoU para as três bases.

Observa-se que o comportamento do IoU acompanhou de perto o do Dice, com o pré-processamento V+CLAHE proporcionando os maiores valores médios na maioria das arquiteturas e bases. Na base FIVES, a VGG19 obteve o maior IoU médio (72,84%), seguida pela ResNet101 (71,50%) e pela EfficientNetB0 (70,25%). Na base Fundus-AVSeg, novamente a VGG19 (70,62%) e a ResNet101 (70,20%) lideraram, enquanto na base RETA a VGG19 (65,91%) e a ResNet101 (64,48%) mantiveram as duas primeiras posições.

A VGG19, embora tenha obtido os maiores valores médios de IoU, apresentou variabilidade substancialmente superior, especialmente com imagens originais (desvios de 4,98%, 2,30% e 3,69% nas bases FIVES, Fundus-AVSeg e RETA, respectivamente) e com canal verde sem CLAHE (2,70% e 1,54% na FIVES e RETA). Esse padrão indica que, mesmo com um bom desempenho médio, a VGG19 pode não ser tão estável comparada com outras redes.

O pré-processamento V+CLAHE é a estratégia mais robusta nos testes no que se trata da análise do IoU.

D. Análise Comparativa da Sensibilidade nos Testes

A sensibilidade mede a capacidade do modelo em identificar corretamente os pixels pertencentes aos vasos sanguíneos. Essa

[a]Valores baseados em 5 execuções independentes.

métrica é particularmente relevante na segmentação vascular, pois a não detecção de vasos pode comprometer análises clínicas subsequentes. A Tabela VI apresenta os valores médios e os desvios padrão da sensibilidade para as três bases.

[a]Valores baseados em 5 execuções independentes.

Observa-se que, de modo geral, a sensibilidade apresentou valores mais elevados do que o Dice e o IoU, o que é esperado em problemas de segmentação vascular, nos quais o desequilíbrio entre vasos (classe minoritária) e fundo (classe majoritária) tende a favorecer a detecção de vasos em detrimento da precisão da sua delimitação. Na base FIVES, a ResNet101 e a VGG19 obtiveram as maiores sensibilidades médias com V+CLAHE (80,78%), seguidas pela EfficientNetB0 (80,53%). Na base Fundus-AVSeg, a VGG19 (74,13%) e a ResNet101 (74,21%) mantiveram-se entre as melhores, enquanto na base RETA a VGG19 (75,38%) liderou, seguida pela ResNet101 (74,27%).

Considerando simultaneamente o desempenho e a estabilidade, a ResNet101 com V+CLAHE destacou-se novamente como a melhor combinação geral, com sensibilidades médias de 80,78% na FIVES, 74,21% na Fundus-AVSeg e 74,27% na RETA, mantendo desvios padrão moderados (1,34%, 1,77% e 1,14%, respectivamente). A EfficientNetB0 apresentou comportamento semelhante, com sensibilidades de 80,53%, 71,79% e 72,63%, e desvios padrão ainda menores (0,68%, 0,98% e 0,67%), configurando a arquitetura mais estável entre todas as avaliadas.

A VGG19, embora tenha obtido os maiores valores médios de sensibilidade na base RETA (75,38%) e valores próximos aos melhores nas outras duas bases, apresentou novamente variabilidade superior, especialmente com imagens originais (desvios de 4,18%, 0,68% e 2,29% nas bases FIVES, Fundus-AVSeg e RETA, respectivamente) e com canal verde sem CLAHE (2,36% na FIVES e 1,41% na RETA). Esse padrão reforça a observação prévia de que o VGG19, apesar do bom desempenho médio, carece da estabilidade necessária em cenários que exijam reprodutibilidade rigorosa.

O ViTUNet apresentou a pior sensibilidade em todas as bases, mesmo com V+CLAHE (59,83% na FIVES, 54,48% na Fundus-AVSeg e 51,78% na RETA), confirmando sua inadequação para a tarefa com o volume de dados disponível. O SwinUNet obteve desempenho intermediário, sempre abaixo das CNNs, com sensibilidade máxima de 77,25% na FIVES, 67,84% na Fundus-AVSeg e 70,46% na RETA.

De modo geral, os resultados de sensibilidade reforçam as conclusões obtidas com o Dice e o IoU: o pré-processamento V+CLAHE é a estratégia mais robusta; as arquiteturas convolucionais ResNet101 e EfficientNetB0 oferecem o melhor equilíbrio entre acurácia, estabilidade e custo computacional; e os modelos mantêm desempenho consistente ao migrar da base de treinamento (FIVES) para bases externas (Fundus-AVSeg e RETA). Vale notar que, embora os valores absolutos de sensibilidade sejam mais altos que os de Dice e IoU, essa métrica deve ser interpretada em conjunto com as demais, uma vez que um modelo excessivamente sensível pode classificar regiões de fundo como vasos, elevando o número de falsos positivos.

IV. CONCLUSÃO

Este trabalho investigou o impacto de diferentes estratégias de pré-processamento e arquiteturas de redes neurais profundas na segmentação de vasos sanguíneos em imagens de fundoscopia. Foram avaliadas seis arquiteturas (EfficientNetB0, MobileNetV2, ResNet101, VGG19, SwinUNet e ViTUNet) combinadas com quatro condições de entrada: imagem original em cores, tons de cinza, canal verde e canal verde

com aplicação de CLAHE. Os resultados demonstraram que o pré-processamento V+CLAHE proporcionou os melhores desempenhos para a maioria dos modelos na base FIVES, com destaque para o VGG19 (Dice de 83,61%). Entretanto, ao considerar conjuntamente o desempenho, a estabilidade entre execuções e o custo computacional, a ResNet101 configurou-se como a melhor arquitetura geral, alcançando Dice médio de 82,81% na FIVES, 82,43% na Fundus-AVSeg e 78,25% na RETA, com desvios padrão consistentemente baixos. A EfficientNetB0 apresentou-se com o desempenho ligeiramente inferior, porém com estabilidade superior, enquanto a VGG19, apesar das maiores médias, exibiu variabilidade excessiva em algumas configurações.

Em termos de eficiência computacional, os pré-processamentos que reduzem a dimensionalidade dos dados (cinza, verde e V+CLAHE) proporcionaram reduções drásticas nos tempos de treinamento, com diminuições de até 65,4% para o EfficientNetB0 e 68,2% para a MobileNetV2 em relação às imagens originais, o que já era esperado por diminuir em dois terços a dimensionalidade das imagens de entrada. O tempo médio de treinamento das CNNs com pré-processamento monocromático variou entre aproximadamente 245 e 370 segundos, enquanto os Transformers exigiram de 326 a 698 segundos, refletindo a maior complexidade computacional dos mecanismos de autoatenção. A variabilidade entre execuções foi baixa para EfficientNetB0, MobileNetV2 e ResNet101, com desvios típicos inferiores a 1,0% para o Dice, enquanto o VGG19 apresentou desvios excessivos, especialmente com imagens originais.

A avaliação de generalização, conduzida em duas bases externas não utilizadas no treinamento, a Fundus-AVSeg, proveniente do estudo *A Fundus Image Dataset for AI-based Artery-Vein Vessel Segmentation*, e a RETA, oriunda do benchmark *The RETA Benchmark for Retinal Vascular Tree Analysis*, evidenciou que a VGG19 teve o maior desempenho médio mas com um desvio padrão elevado, as arquiteturas convolucionais ResNet101 e EfficientNetB0 mantiveram desempenho consistente ao migrar para domínios distintos, confirmando a robustez das melhores configurações. O ViTUNet, por outro lado, apresentou o pior desempenho em todas as bases (Dice de 63,61% na FIVES, 62,06% na Fundus-AVSeg e 55,60% na RETA), sugerindo que arquiteturas baseadas exclusivamente em mecanismos de autoatenção não se mostraram adequadas para esta tarefa com o volume de dados disponível. O SwinUNet obteve desempenho intermediário, sempre abaixo das CNNs.

Como trabalhos futuros, pretendemos investigar técnicas de *data augmentation* mais sofisticadas e a aplicação de *transfer learning* entre diferentes bases de fundoscopia, com o objetivo de melhorar o desempenho em bases externas. Além disso, realizar a otimização sistemática de hiperparâmetros, visando maximizar o desempenho das melhores configurações identificadas neste estudo.

***Abstract*—This study evaluates convolutional neural networks for the multiclass classification of brain magnetic resonance images into glioma, meningioma, pituitary tumor, and no-tumor categories. A balanced public dataset containing 7,200 images was used, with 5,600 images divided into training and validation subsets and 1,600 images from the repository-provided test subset held out from model development. The experimental design included frozen-backbone models, partial fine-tuning, data augmentation, learning-rate scheduling, Test-Time Augmentation (TTA), and a weighted ensemble composed of DenseNet-169, InceptionV3, and EfficientNetV2-S. Several individual configurations achieved Macro F1-scores close to 0.93. Among the models retrained for the ensemble stage, DenseNet-169 obtained an accuracy of 0.9350 and a Macro F1-score of 0.9338, while the weighted ensemble produced numerically higher values of 0.9394 and 0.9382, respectively. This improvement was modest and required 12 forward passes per image due to the combination of three models and four TTA views. The ensemble also increased recall for glioma and meningioma compared with the baseline DenseNet-121, although clinically relevant misclassifications remained. Because patient identifiers are not available in the public repository, patient-level separation cannot be verified, and the reported test results should be interpreted as image-level benchmark performance rather than evidence of patient-independent clinical generalization. These findings support the potential of transfer learning and model combination for brain tumor MRI classification while reinforcing the need for external, patient-level validation before clinical application.**

***Index Terms*—brain tumor classification, magnetic resonance imaging, convolutional neural networks, transfer learning, deep learning, ensemble learning**

I. Introduction

Brain tumors represent one of the most serious conditions affecting the central nervous system and are characterized by the abnormal and uncontrolled proliferation of cells in brain tissue [1]–[3]. In this context, early and accurate diagnosis is essential to expand therapeutic possibilities, guide clinical planning, and contribute to better patient outcomes [4], [5].

Magnetic resonance imaging (MRI) stands out as one of the main imaging modalities for brain tumor assessment due to its high contrast resolution, multiplanar acquisition capability, and absence of ionizing radiation [2], [3], [6]. Despite the relevance of MRI, manual interpretation remains a complex and time-consuming task that depends heavily on the expertise of radiologists and specialists [7]–[9]. In addition, the increasing volume of imaging examinations in clinical practice reinforces the need for methods capable of supporting rapid, standardized, and reliable image analysis [3], [8].

In this scenario, computer-aided diagnostic systems have been investigated as promising tools to assist in the detection and classification of brain tumors [5], [8]. In recent years, artificial intelligence techniques, particularly machine learning and deep learning, have gained prominence in medical image analysis [3], [5], [6]. Among these approaches, convolutional neural networks (CNNs) have become widely used in brain MRI analysis due to their ability to automatically extract hierarchical and representative features directly from images [2], [6], [7], [10].

Several CNN-based architectures have been applied to brain tumor MRI analysis, including traditional convolutional models and pretrained architectures such as AlexNet, VGG, ResNet, Inception, DenseNet, and EfficientNet [1]–[3], [8], [11]. Transfer learning is particularly relevant in medical imaging, where the availability of large labeled datasets remains limited [9], [11], [12]. Although recent studies report high performance on benchmark datasets, challenges remain regarding generalization, variability across equipment and acquisition protocols, interpretability, dataset provenance, and validation in real clinical scenarios [6], [13], [14].

Therefore, this study evaluates CNN-based models for multiclass classification of brain MRI images into glioma, meningioma, pituitary tumor, and no-tumor categories. The experimental analysis investigates pretrained architectures, partial fine-tuning, data augmentation, learning-rate scheduling, TTA, and a weighted ensemble. In addition to aggregate performance, class-specific behavior and clinically relevant error patterns are examined, while limitations related to dataset provenance, patient-level independence, uncertainty, and computational cost are explicitly considered.

II. Methodology

A. Dataset

The experiments were conducted using Version 2 of the *Brain Tumor MRI Dataset*, made publicly available by Masoud Nickparvar through Kaggle [15]. The repository contains 7,200 brain MRI images evenly distributed among four classes: glioma, meningioma, pituitary tumor, and no tumor, with 1,800 images per class.

According to the repository documentation, the collection was assembled from previously available brain MRI datasets, including Figshare, SARTAJ, and Br35H [15]. The repository is organized into predefined *Training* and *Testing* folders. The Training folder contains 5,600 images, corresponding to 1,400 samples per class, whereas the Testing folder contains 1,600 images, with 400 samples per class. Thus, approximately 77.8% of the images were originally assigned to model development and 22.2% to testing. The complete class distribution is presented in Table I.

Table I
Distribution of images by class and repository subset.

Class	Total	Training	Testing
Glioma	1,800	1,400	400
Meningioma	1,800	1,400	400
No Tumor	1,800	1,400	400
Pituitary	1,800	1,400	400
Total	**7,200**	**5,600**	**1,600**

The Version 2 repository documentation reports that duplicate images were removed and that overlap between the provided Training and Testing folders was eliminated during dataset curation [15]. However, patient identifiers are not provided with the public dataset. Consequently, it is not possible to verify whether different images, adjacent slices, or related acquisitions from the same patient occur across the available partitions. Repository-level duplicate control therefore reduces direct image duplication but does not establish patient-level independence or exclude all possible near-duplicate relationships.

The 5,600 images from the original Training folder were further divided into training and validation subsets using an 80:20 stratified image-level split. This procedure resulted in 4,480 images for training and 1,120 images for validation. Since the original dataset is balanced, the training subset contained 1,120 images per class, while the validation subset contained 280 images per class. Because patient identifiers are unavailable, patient-level separation between these subsets cannot be verified.

The 1,600 images from the repository-provided Testing folder were kept separate from gradient-based training, learning-rate adjustment, early stopping, and checkpoint selection. They were evaluated only after each model configuration had been trained. For this reason, this subset is referred to throughout this paper as the *held-out test subset*, rather than as a patient-independent test cohort. Since all four classes contained the same number of samples, no class-balancing, resampling, or class-weighting strategy was required.

B. Image Pre-processing and Data Augmentation

Before training, all images were resized to 224×224 pixels to ensure compatibility with the input dimensions of the evaluated convolutional neural networks. The resized images were subsequently converted into tensors and normalized using the mean and standard deviation values adopted for the ImageNet dataset. ImageNet normalization was applied because all evaluated architectures were initialized with weights pretrained on ImageNet. Maintaining the normalization procedure used during pretraining preserves the input scale expected by the pretrained convolutional layers.

Data augmentation was applied exclusively to the training subset. In the baseline and initial fine-tuning experiments, light augmentation included random horizontal flipping with a probability of 50%. In the subsequent experimental configuration, the augmentation strategy was expanded to introduce greater variability into the training samples and reduce the tendency of the models to memorize image-specific patterns.

The validation and test subsets were processed only through resizing, tensor conversion, and normalization during conventional evaluation. Random transformations were not applied to these subsets, ensuring that validation and conventional test results were obtained from consistent image representations. Additional transformations were applied to test images only in experiments explicitly using TTA.

C. Evaluated Architectures and Fine-Tuning

Four convolutional neural network architecture families were evaluated: DenseNet, MobileNetV3-Large, InceptionV3, and EfficientNetV2-S. All models were initialized with ImageNet-pretrained weights, and their original classification layers were replaced by task-specific classifiers containing four output neurons corresponding to glioma, meningioma, pituitary tumor, and no-tumor classes.

The experiments were organized into incremental configurations to examine the effects of transfer learning, partial fine-tuning, data augmentation, learning-rate scheduling, and TTA. Table II summarizes the main characteristics of each configuration.

In the baseline configuration, the convolutional backbone of each architecture was frozen and only the newly introduced classifier was trained. This configuration assessed whether the

Table II
INCREMENTAL EXPERIMENTAL CONFIGURATIONS ACROSS MODEL VARIATIONS.

Var.	Architectures		Fine-tuning	Data augmentation	Scheduler	TTA
Base	DenseNet-121, Large, EfficientNetV2-S	MobileNetV3- InceptionV3,	Frozen backbone	Light augmentation	No	No
V1	DenseNet-169, Large, EfficientNetV2-S	MobileNetV3- InceptionV3,	Last block unfrozen	Light augmentation	ReduceLROnPlateau	No
V2	DenseNet-169, Large, EfficientNetV2-S	MobileNetV3- InceptionV3,	Last block unfrozen	Advanced augmentation	ReduceLROnPlateau	Yes

general visual features learned from ImageNet were sufficient to distinguish the four MRI classes without modifying the pretrained convolutional filters.

In Variation 1, the final convolutional block of each architecture was unfrozen, allowing partial fine-tuning of higher-level features. Earlier layers remained frozen to preserve general visual representations, while the final layers were adapted to the characteristics of brain MRI images.

Variation 2 maintained partial fine-tuning and incorporated an expanded data-augmentation strategy, the ReduceLROnPlateau learning-rate scheduler, adjusted early-stopping parameters, and TTA. This configuration investigated whether greater variability during training and prediction aggregation across transformed versions of the same image could improve classification performance.

For the DenseNet family, DenseNet-121 was adopted in the baseline experiment, whereas DenseNet-169 was used in subsequent configurations. The deeper DenseNet-169 architecture was selected to investigate whether its greater representational capacity could provide more discriminative features for brain tumor classification.

D. Training Procedure

All models were trained using the Adam optimizer and cross-entropy loss. In the baseline configuration, a learning rate of 1×10^{-3} was applied to the classifier while the convolutional backbone remained frozen.

In the partial fine-tuning configurations, differential learning rates were adopted. A learning rate of 1×10^{-5} was used for the unfrozen backbone layers, while 1×10^{-3} was maintained for the classifier. This strategy allowed the newly initialized classifier to learn more rapidly while applying smaller updates to pretrained convolutional features.

The ReduceLROnPlateau scheduler was used to adjust the learning rate according to validation loss. When validation loss stopped improving for the defined patience period, the scheduler reduced the learning rate, allowing optimization to continue with smaller parameter updates. Early stopping was also based exclusively on validation loss. A patience of five epochs was used in the baseline experiments, while subsequent configurations allowed additional epochs after learning-rate reductions to avoid prematurely interrupting fine-tuning.

At the end of each epoch, model performance was evaluated on the validation subset, and the checkpoint associated with the lowest validation loss was retained. Thus, checkpoint selection within each training run was based exclusively on validation performance, without using the held-out test subset for optimization, learning-rate adjustment, early stopping, or checkpoint selection.

After training, retained checkpoints were evaluated on the same held-out test subset to provide a broad comparison among the investigated architectures and configurations. Because multiple configurations were evaluated on this common test subset, the comparison reported in Table III is treated as an exploratory benchmark rather than as a confirmatory model-selection analysis. Numerical differences among these configurations are therefore interpreted descriptively.

Accuracy, precision, recall, and Macro F1-score were calculated after training. Macro F1-score was adopted as the main comparative metric because it assigns equal importance to all four classes and can reveal class-specific performance differences that may not be evident from accuracy alone.

E. Test-Time Augmentation

Test-Time Augmentation was applied only to the experimental configurations explicitly defined to use this strategy. For each test image, four views were evaluated: the original image, a horizontally flipped version, a vertically flipped version, and a version rotated by 90°. Each view was independently processed by the model, producing a probability distribution over the four classes. The four probability distributions were then averaged, and the class associated with the highest mean probability was selected as the final prediction.

The purpose of this procedure was to experimentally assess whether prediction aggregation across spatially transformed versions of the same image could reduce sensitivity to orientation and image presentation. These transformations should not, however, be interpreted as representations of equally plausible clinical MRI orientations. Horizontal flipping preserves the general spatial organization of the image while reversing laterality, whereas vertical flipping and 90° rotation can produce orientations that are uncommon in routine clinical image presentation.

Therefore, TTA was considered an experimental robustness strategy rather than an assumption of anatomical equivalence

among transformed images. Results obtained with TTA are interpreted accordingly, particularly when assessing whether additional transformed views provide meaningful improvements over conventional inference.

F. Ensemble Strategy

Following the exploratory comparison of the individual experimental configurations, DenseNet-169, InceptionV3, and EfficientNetV2-S were selected as candidate ensemble components. The selection considered both the performance observed during the exploratory benchmark and architectural differences among the models, with the objective of combining potentially complementary feature representations. Because this choice was made after inspection of the broader benchmark results, the ensemble experiment is presented as an exploratory extension of the comparative analysis rather than as an independent confirmatory evaluation.

For the ensemble experiment, the three selected architectures were independently retrained using a specific training configuration. Consequently, the performance values obtained during this stage differ from those reported in the initial comparison of model variations. The metrics presented for the ensemble components therefore correspond to these new training runs and should not be interpreted as repetitions of the values presented in Table III.

During this retraining stage, differential learning rates were used, with a learning rate of 5×10^{-4} for the unfrozen backbone layers and 1×10^{-3} for the classifier. A weight decay of 1×10^{-5} was also applied. The data-augmentation strategy was expanded, and early stopping monitored validation loss with a patience of 15 epochs.

The final ensemble prediction was obtained through a weighted average of the probability distributions generated by the three component models. Importantly, the contribution of each model was determined exclusively from its Macro F1-score on the validation subset obtained during the retraining stage. Test-set performance was not used to calculate or adjust the ensemble weights.

TTA was applied independently to each component model before the weighted combination of probabilities. Thus, each test image was evaluated using four views by each of the three architectures, resulting in 12 forward passes per image before the final ensemble prediction was produced.

This design necessarily increases inference cost relative to using a single model. No hardware-normalized wall-clock inference-time benchmark was performed; therefore, computational efficiency is discussed in terms of model multiplicity and number of forward passes rather than measured latency.

G. Evaluation Metrics

Model performance was assessed using accuracy, precision, recall, Macro F1-score, and confusion matrices. Accuracy represents the proportion of correctly classified images among all samples in the held-out test subset. Precision indicates the proportion of predictions assigned to a given class that were correct, whereas recall represents the proportion of samples belonging to that class that were correctly identified. The F1-score combines precision and recall through their harmonic mean.

Macro F1-score was calculated by independently determining the F1-score for each class and averaging the four values with equal weight. Although the dataset is balanced, this metric was prioritized because global accuracy may conceal differences in performance among glioma, meningioma, pituitary tumor, and no-tumor images.

In addition to aggregate metrics, class-specific precision, recall, F1-score, support, and confusion counts were analyzed for the final ensemble. Confusion matrices were used to identify systematic classification errors and determine which categories were more frequently confused. Particular attention was given to errors involving glioma, meningioma, and predictions of tumor images as no tumor.

The baseline DenseNet-121 confusion matrix is presented in normalized form, whereas the ensemble confusion matrix is presented using absolute counts. Because the held-out test subset contains exactly 400 images from each class, absolute ensemble counts can also be directly interpreted as class-specific proportions.

The reported metrics are point estimates. The present experiments did not include repeated-training uncertainty estimation or bootstrap confidence intervals. Therefore, small numerical differences between models are not interpreted as evidence of statistically significant superiority. This limitation is explicitly considered when discussing the performance difference between DenseNet-169 and the ensemble.

III. Results

A. Overall Performance of the Evaluated Models

The performance of the evaluated architectures across the three experimental configurations is summarized in Table III. Accuracy, precision, recall, and Macro F1-score are reported for the common held-out test subset. Because several architectures and configurations were evaluated on the same test subset, this table is presented as an exploratory benchmark intended to characterize the behavior of the investigated approaches rather than as a confirmatory model-selection analysis.

Table III
HELD-OUT TEST PERFORMANCE OF THE EVALUATED ARCHITECTURES ACROSS THE BASELINE AND INCREMENTAL EXPERIMENTAL CONFIGURATIONS.

Model	Variation	Acc.	Prec.	Rec.	Macro F1
MobileNetV3-Large	Baseline	0.88	0.89	0.88	0.88
InceptionV3	Baseline	0.87	0.87	0.87	0.86
DenseNet-121	Baseline	0.93	0.94	0.93	0.93
MobileNetV3-Large	Variation 1	0.92	0.92	0.92	0.91
InceptionV3	Variation 1	0.93	0.93	0.93	0.92
EfficientNetV2-S	Variation 1	0.93	0.93	0.93	0.93
MobileNetV3-Large	Variation 2	0.87	0.87	0.87	0.87
InceptionV3	Variation 2	0.93	0.94	0.93	0.93
EfficientNetV2-S	Variation 2	0.93	0.93	0.93	0.93
DenseNet-169 + TTA	Variation 2	0.90	0.92	0.90	0.8979

In the baseline configuration, DenseNet-121 achieved the strongest numerical results, with accuracy and Macro F1-score of 0.93. Partial fine-tuning improved MobileNetV3-Large and InceptionV3 in Variation 1, while EfficientNetV2-S also reached a Macro F1-score of 0.93. In Variation 2, InceptionV3 and EfficientNetV2-S maintained Macro F1-scores close to 0.93, whereas MobileNetV3-Large decreased to 0.87 and DenseNet-169 with TTA obtained 0.8979. Overall, several configurations reached similar aggregate performance. Given the exploratory nature of the comparison and the absence of uncertainty intervals, these numerical differences should not be interpreted as evidence of statistical superiority.

B. Learning Curve Analysis

The training behavior of the DenseNet models was analyzed through their training and validation loss curves. Fig. 1 presents the learning curves obtained for the baseline DenseNet-121 model.

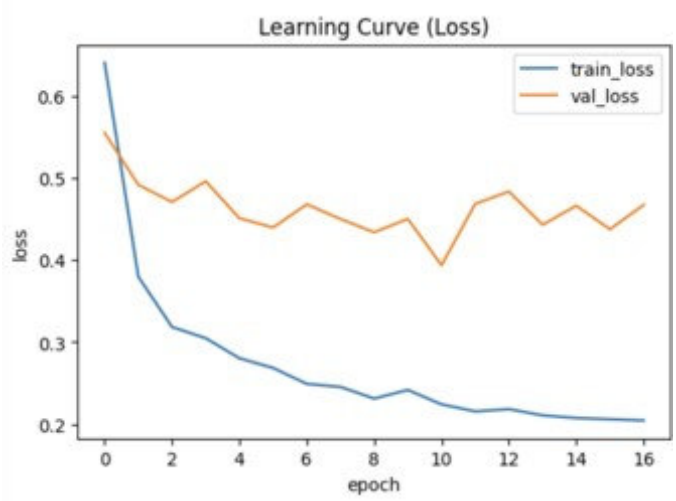

Figure 1. Training and validation loss curves of the baseline DenseNet-121 model.

As shown in Fig. 1, training loss decreased rapidly during the first epochs and continued to decline gradually until the end of training. In contrast, validation loss decreased during the initial epochs but subsequently presented moderate oscillations, remaining approximately between 0.43 and 0.50. The lowest training loss was observed during the final epochs, whereas validation loss reached its lowest values earlier in the training process. A persistent gap between the training and validation curves was observed throughout most of the experiment.

Fig. 2 presents the corresponding training and validation loss curves for DenseNet-169 in Variation 2.

Training loss showed a substantial decrease during approximately the first ten epochs and continued to decline more gradually afterward, remaining below 0.10 during most of the remaining epochs. Validation loss decreased during the initial training period but subsequently remained relatively

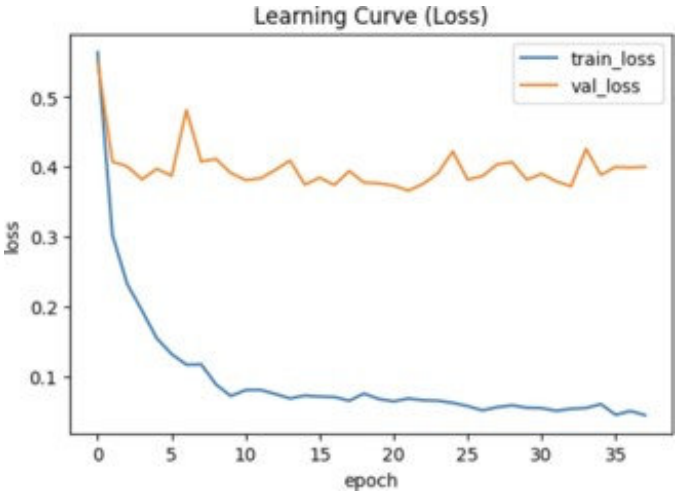

Figure 2. Training and validation loss curves of DenseNet-169 in Variation 2.

stable, with oscillations around 0.36 to 0.42. Although training continued for approximately 36 epochs, validation loss did not show a sustained decrease during the final epochs.

Compared with DenseNet-121, DenseNet-169 reached lower training-loss values and required more epochs before training was interrupted. However, both models presented a persistent difference between training and validation loss, suggesting that improvements in optimization of the training samples were not consistently accompanied by equivalent improvements in validation performance.

C. Class-Specific Performance and Confusion Matrices

Confusion matrices were analyzed to characterize the distribution of correct and incorrect predictions across classes. Fig. 3 presents the normalized confusion matrix obtained by the baseline DenseNet-121 model.

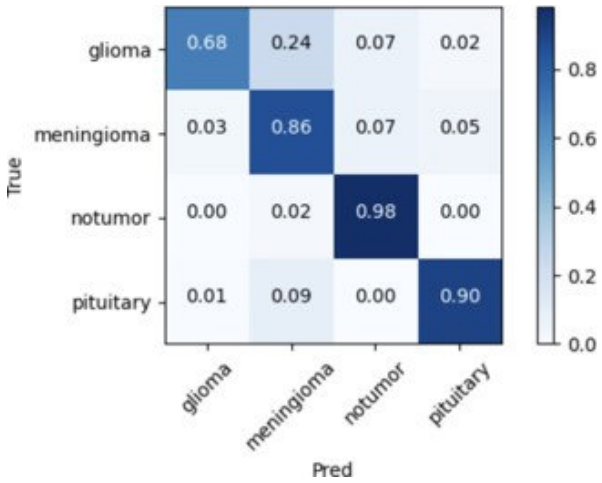

Figure 3. Normalized confusion matrix of the baseline DenseNet-121 model on the held-out test subset.

Glioma presented the lowest recall in this baseline configuration, with 68% of glioma images correctly classified. Among the remaining glioma samples, 24% were classified as meningioma, 7% as no tumor, and approximately 2% as pituitary tumor.

For meningioma, 86% of the images were correctly classified, while approximately 3% were classified as glioma, 7% as no tumor, and 5% as pituitary tumor. The no-tumor class obtained a recall of 98%, with 2% of its samples classified as meningioma. Pituitary tumor achieved a recall of 90%, with most errors involving classification as meningioma.

Fig. 4 presents the confusion matrix obtained by the weighted ensemble using absolute prediction counts.

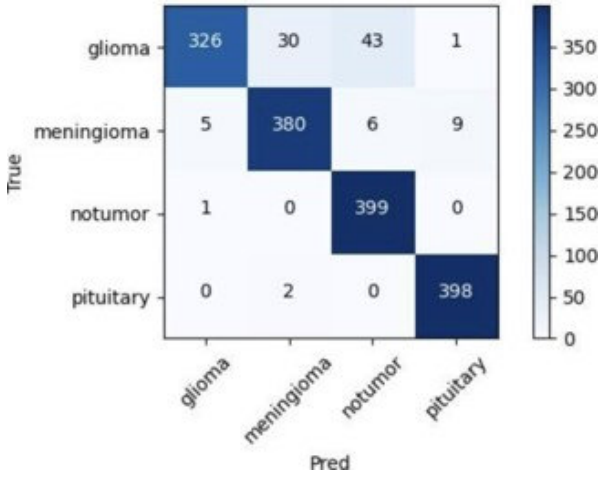

Figure 4. Confusion matrix of the weighted ensemble on the held-out test subset, expressed as absolute prediction counts.

The ensemble correctly classified 326 of 400 glioma images, corresponding to a recall of 81.5%. Among the misclassified glioma images, 30 were predicted as meningioma, 43 as no tumor, and one as pituitary tumor.

For meningioma, 380 of 400 images were correctly classified, corresponding to a recall of 95.0%; five were classified as glioma, six as no tumor, and nine as pituitary tumor. For the no-tumor class, 399 of 400 images were correctly classified, corresponding to a recall of 99.75%, with one image classified as glioma. Finally, 398 of 400 pituitary tumor images were correctly classified, corresponding to a recall of 99.5%, while two were classified as meningioma.

Relative to the baseline DenseNet-121 results, the ensemble therefore presented numerically higher recall for all four classes. The most relevant remaining error pattern was observed for glioma, including 43 glioma images predicted as no tumor.

D. Performance of the Retrained Ensemble Components

DenseNet-169, InceptionV3, and EfficientNetV2-S were independently retrained using the specific configuration adopted for the ensemble experiment. Table IV presents the individual performance of these training runs and the result obtained after combining their probability distributions.

Table IV
HELD-OUT TEST PERFORMANCE OF THE INDEPENDENTLY RETRAINED COMPONENT MODELS AND RESULTING WEIGHTED ENSEMBLE.

Model	Acc.	Prec.	Rec.	Macro F1
DenseNet-169	0.9350	0.94	0.93	0.9338
InceptionV3	0.9306	0.94	0.93	0.9292
EfficientNetV2-S	0.9038	0.89	0.89	0.9023
Ensemble Top-3	0.9394	0.94	0.94	0.9382

Among the retrained component models, DenseNet-169 produced the highest individual point estimates, with an accuracy of 0.9350, precision of approximately 0.94, recall of approximately 0.93, and Macro F1-score of 0.9338. InceptionV3 achieved an accuracy of 0.9306 and a Macro F1-score of 0.9292, whereas EfficientNetV2-S achieved an accuracy of 0.9038 and a Macro F1-score of 0.9023.

The weighted ensemble produced an accuracy of 0.9394 and a Macro F1-score of 0.9382. Relative to DenseNet-169, this corresponds to an absolute numerical increase of approximately 0.0044 in both accuracy and Macro F1-score. Therefore, although the ensemble produced the highest point estimates in this experimental stage, the magnitude of the improvement was small.

Because these results are point estimates obtained without repeated-training variability analysis or bootstrap confidence intervals, the observed difference should not be interpreted as evidence that the ensemble is statistically superior to DenseNet-169. Instead, the results indicate that combining the models produced a modest numerical improvement under the evaluated configuration.

The component-model values in Table IV correspond specifically to the models retrained for the ensemble experiment and therefore differ from the exploratory results reported in Table III.

E. Class-Wise Performance of the Ensemble

Table V presents class-specific precision, recall, F1-score, and support for the final ensemble. The values are consistent with the absolute confusion counts shown in Fig. 4.

Table V
CLASS-SPECIFIC HELD-OUT TEST PERFORMANCE OF THE WEIGHTED ENSEMBLE WITH TEST-TIME AUGMENTATION.

Class	Precision	Recall	F1-score	Support
Glioma	0.9819	0.8150	0.8907	400
Meningioma	0.9223	0.9500	0.9360	400
No Tumor	0.8906	0.9975	0.9410	400
Pituitary	0.9755	0.9950	0.9851	400
Macro avg.	0.9426	0.9394	0.9382	1600
Weighted avg.	0.9426	0.9394	0.9382	1600

Glioma achieved a precision of 0.9819, recall of 0.8150, and F1-score of 0.8907, representing the lowest recall and F1-score among the four classes. Meningioma achieved a precision of 0.9223, recall of 0.9500, and F1-score of 0.9360.

The no-tumor class obtained a precision of 0.8906, recall of 0.9975, and F1-score of 0.9410. Its comparatively lower precision is consistent with the confusion matrix, which shows that some tumor images, particularly glioma images, were predicted as no tumor. Pituitary tumor achieved a precision of 0.9755, recall of 0.9950, and F1-score of 0.9851, representing the highest class-specific F1-score.

Considering all 1,600 test images, the ensemble obtained an accuracy of 0.9394. Macro-average precision, recall, and F1-score were 0.9426, 0.9394, and 0.9382, respectively. These class-specific results demonstrate that similar aggregate performance can coexist with substantial differences in sensitivity across tumor categories, particularly for glioma.

IV. Discussion

The results indicate that transfer learning and partial fine-tuning can provide effective image-level classification performance for the brain MRI dataset investigated in this study. As shown in Table III, several architectures achieved Macro F1-scores close to 0.93, although the effect of increasingly complex training strategies varied among architectures. InceptionV3 improved from a Macro F1-score of 0.86 in the baseline configuration to approximately 0.93 in Variation 2, whereas MobileNetV3-Large improved in Variation 1 but decreased to 0.87 in Variation 2. These findings suggest that additional fine-tuning, augmentation, and inference strategies do not necessarily produce consistent gains across architectures.

The learning curves in Figs. 1 and 2 showed a continuous reduction in training loss accompanied by higher and more oscillatory validation loss. This behavior suggests some degree of overfitting, particularly for DenseNet-169, which reached substantially lower training-loss values without a proportional reduction in validation loss. Validation-based early stopping and checkpoint selection were therefore important for limiting continued optimization after validation performance had stabilized.

Class-specific analysis also revealed important differences that are not apparent from aggregate accuracy alone. Glioma remained the most challenging category. The baseline DenseNet-121 achieved a glioma recall of 68%, whereas the ensemble achieved 81.5%. Meningioma recall changed from 86% to 95%, while no tumor and pituitary tumor reached recalls of 99.75% and 99.5%, respectively, in the ensemble. Nevertheless, 43 glioma images were predicted as no tumor by the ensemble. This error pattern is particularly important in the context of a potential decision-support system because high aggregate accuracy does not eliminate clinically relevant failure cases. The evaluated models should therefore not be interpreted as autonomous diagnostic systems.

Among the models retrained for the ensemble stage, DenseNet-169 achieved an accuracy of 0.9350 and a Macro F1-score of 0.9338, whereas the weighted ensemble achieved 0.9394 and 0.9382, respectively. The resulting absolute gain of approximately 0.0044 in Macro F1-score is modest. Moreover, repeated training runs and bootstrap confidence intervals were not included in the present analysis. Consequently, the observed difference should be interpreted as a numerical improvement in this experiment rather than as evidence of statistically established superiority of the ensemble over DenseNet-169.

The computational implications of this improvement are also relevant. Because the ensemble combines three architectures and evaluates four TTA views with each model, it requires 12 forward passes for each image. In terms of forward-pass count, this corresponds to three times the inference workload of a single model using the same four-view TTA procedure and substantially more computation than conventional single-view inference. Actual wall-clock inference time was not benchmarked, and therefore no quantitative latency claim can be made. The additional models also increase deployment complexity and computational-resource requirements.

These differences have practical implications for potential clinical workflows. A single model such as DenseNet-169 may provide a more favorable compromise between predictive performance and operational simplicity in scenarios requiring interactive or near-real-time decision support. In contrast, the ensemble could be considered for offline or less latency-sensitive processing when the additional computational cost is acceptable. These possibilities represent deployment considerations rather than validated clinical-use scenarios, since inference time on clinical hardware and prospective workflow integration were not evaluated in this study.

The TTA procedure introduces an additional limitation. Horizontal flipping reverses laterality while retaining the overall structure of the image, whereas vertical flipping and 90° rotation may result in orientations that are uncommon in standard clinical image presentation. Thus, TTA results should be interpreted as an experimental assessment of robustness to image transformations rather than as evidence that all transformations represent anatomically equivalent clinical acquisitions.

Dataset provenance also constrains interpretation of the reported results. The public repository is assembled from multiple source collections, including Figshare, SARTAJ, and Br35H [15]. The repository documentation reports removal of duplicate images and elimination of direct overlap between its provided Training and Testing folders. However, patient identifiers are not provided, and patient-level separation cannot therefore be verified. In particular, the available metadata do not allow confirmation that images or adjacent slices originating from the same patient are confined to a single partition. The additional training/validation split used in this study was also performed at the image level. Consequently, the held-out test results should not be interpreted as demonstrating generalization to an independent patient cohort.

A further consideration is that multiple architectures and configurations were evaluated on the same held-out test subset in Table III, and this exploratory comparison informed the subsequent ensemble investigation. Although the test subset was not used for gradient optimization, learning-rate scheduling, early stopping, checkpoint selection, or determination of

ensemble weights, repeated examination of a common test set can still influence higher-level experimental interpretation. Table III and the ensemble extension should therefore be regarded as exploratory benchmark analyses rather than fully independent confirmatory comparisons.

Overall, these limitations emphasize the need for cautious interpretation of the reported performance. Future studies should include external and multicenter datasets with explicit patient identifiers, patient-level partitioning, repeated training runs, uncertainty estimation with confidence intervals, clinically appropriate augmentation strategies, probability calibration, interpretability methods, and direct measurement of computational cost and inference latency in the intended deployment environment.

V. Conclusion

This study evaluated convolutional neural networks for image-level classification of brain MRI images into glioma, meningioma, pituitary tumor, and no-tumor categories. The experiments included frozen-backbone models, partial fine-tuning, data augmentation, Test-Time Augmentation, and a weighted ensemble. Across the exploratory benchmark, several individual configurations achieved Macro F1-scores close to 0.93, although the effect of the investigated strategies varied among architectures.

Glioma remained the most challenging class. The ensemble achieved a glioma recall of 81.5% and a meningioma recall of 95%, while maintaining recall above 99% for the no-tumor and pituitary tumor classes. However, clinically relevant errors remained, including glioma images classified as no tumor.

Among the models retrained for the ensemble experiment, DenseNet-169 achieved an accuracy of 0.9350 and a Macro F1-score of 0.9338. The weighted ensemble produced numerically higher values of 0.9394 and 0.9382, respectively. This gain was modest and was accompanied by substantially greater computational requirements, with 12 forward passes required for each image. In the absence of repeated-run or bootstrap uncertainty estimates, this difference should not be interpreted as evidence of statistically established superiority.

The repository-provided test subset was kept separate from model optimization and checkpoint selection. However, because patient identifiers are not available, patient-level independence between dataset partitions cannot be confirmed. The reported results should therefore be interpreted as performance on a held-out image-level benchmark rather than as evidence of generalization to an independent clinical population.

Overall, the findings support the potential of transfer learning and model combination for brain tumor MRI classification while also demonstrating important limitations related to class-specific errors, computational cost, dataset provenance, and evaluation uncertainty. External multicenter validation with patient-level separation, together with uncertainty analysis, interpretability, probability calibration, and direct assessment of inference efficiency, remains necessary before considering clinical deployment.

***Abstract*—This literature review examines fifteen studies published between 2018 and 2026 on the application of radiomics and deep learning to classify and grade gliomas in magnetic resonance imaging (MRI) scans. The articles cover classical radiomics with machine learning classifiers, deep convolutional neural networks, hybrid models, graph-based architectures, and radiogenomics frameworks. Reported performance metrics vary widely across studies, reflecting differences in classification tasks, validation protocols, and dataset characteristics rather than a consistent superiority of any single methodological family; the main challenges are data scarcity, the diversity of validation protocols, and the lack of clinical interpretability of the models.**

***Index Terms*—Glioma, Magnetic Resonance Imaging, Radiomics, Deep Learning, Neural Networks, Tumor Grading.**

I. Introduction

Gliomas are primary brain tumors — the most common type in adults — that originate from glial cells and account for approximately 74.6% of all malignant brain tumors [1]. The diagnosis of gliomas is one of the most challenging problems in neuro-oncology today, especially considering the drastic difference in prognosis between grades: patients with low-grade gliomas (LGG, WHO grades 2 and 3) have a median survival of seven years [2], while patients with glioblastoma (WHO grade 4, per the 2021 classification) rarely survive more than twelve months, with only 3 to 5% surviving beyond five years [3].

Historically, the grading of gliomas depended only on the histopathological analysis of samples obtained by biopsy or surgical resection, an invasive procedure that is subject to sampling errors and unable to capture spatial differences within the tumor [4]. The World Health Organization (WHO) classification has evolved from a purely morphological system to an integrated model that combines histological and molecular criteria, with the 2016 and 2021 updates incorporating markers such as the IDH (isocitrate dehydrogenase) mutation, 1p/19q codeletion, and MGMT promoter methylation as key determinants of diagnosis and treatment [4].

In this context, magnetic resonance imaging (MRI) plays a central role in the preoperative evaluation of gliomas. Different sequences provide complementary insights into tumor biology, from contrast-enhanced T1-weighted and T2/FLAIR imaging to diffusion and perfusion-based sequences such as ADC and DSC-MRI, the latter providing estimates of relative cerebral blood volume (rCBV) directly associated with IDH status [5].

Radiomics is a computational approach that systematically extracts quantitative information from medical images, converting pixels into analyzable data that transcends human perception [1]. At the same time, deep learning — particularly convolutional neural networks (CNNs) — has emerged as a powerful alternative, capable of learning hierarchical representations directly from the data without the need for manual feature extraction [6].

II. Methodology

This review examines fifteen studies on radiomics and deep learning for glioma classification and grading in MRI, guided by the research question: *How can radiomics and deep learning models be integrated for the classification and grading of gliomas using MRI images?*. Studies were identified through manual searches across three databases (IEEE Xplore, ScienceDirect, PubMed) and AI-assisted discovery tools (Elicit, Consensus), following the PCC (Population, Concept, Context) framework, then pooled, deduplicated, and screened for eligibility.

A. Search Strategy

The same base search string was adapted to the specific syntax of each database, distributing terms across the Title and Abstract fields. Searches were conducted on June 18, 19, and 20, 2026, respectively, in IEEE Xplore, ScienceDirect, and PubMed.

In IEEE Xplore, the search was restricted to Title/Abstract fields and filtered by publication year (2018–2026, chosen to capture seminal works on radiomics and deep learning in medical imaging) and document type (*Journal Articles* only), based on the rationale that journal publications undergo more rigorous peer review than conference proceedings.

IEEE Xplore

```
("Document Title":"Brain Tumor" OR
"Document Title":"Glioma" OR "Document
Title":"Glioblastoma")
AND
("Document Title":"MRI" OR "Document
Title":"Magnetic Resonance Imaging")
AND
("Abstract":"Radiomics" OR "Abstract":"Machine
Learning" OR "Abstract":"Deep Learning" OR
"Abstract":"Neural Network")
AND
("Abstract":"Tumor Classification" OR
"Abstract":"Tumor Grading")
```

In ScienceDirect, the same year filter was applied together with a *Research Articles* filter, with results ordered by relevance (Best Match); manual screening was limited to the top 30 records to ensure focused assessment.

ScienceDirect

```
Title: ("Brain Tumor" OR "Glioma" OR
"Glioblastoma") AND ("MRI" OR "Magnetic
Resonance Imaging")
AND
Abstract: ("Radiomics" OR "Machine Learning"
OR "Deep Learning" OR "Neural Network") AND
("Tumor Classification" OR "Tumor Grading")
```

In PubMed, the Population/Concept terms were restricted to the `[Title]` field and the technique/objective terms to `[Title/Abstract]`, with an additional *Humans* species filter, results ordered by Best Match, and screening limited to the top 30 records.

PubMed

```

```

To expand the scope and capture studies that may not appear prominently in database search rankings, two AI-assisted discovery tools were queried on June 21, 2026: Elicit (semantic search across PubMed and arXiv) and Consensus (consensus search across multiple databases including PubMed, Scopus, and bioRxiv). Both tools were prompted with the following query:

```
"Execute a broad literature search for a
scoping review using the following search
string: TITLE(Brain Tumor OR Glioma OR
Glioblastoma) AND TITLE(MRI OR Magnetic
Resonance Imaging) AND ABSTRACT(Radiomics
OR Machine Learning OR Deep Learning OR Neural
Network) AND ABSTRACT(Tumor Classification OR
Tumor Grading). Return only the identified
bibliographic records, without filtering
by methodological quality and without
synthesizing the findings. For each record,
report: Title; Authors; Year; Source; DOI;
Link. List all studies found, ordered by
publication year (most recent to oldest)."
```

B. Eligibility Criteria and Study Selection

Studies were included in the review if they satisfied all of the following criteria:

1) **Population and disease:** focus on glioma grading and/or classification (LGG, HGG, glioblastoma, or WHO-grade categories);
2) **Imaging modality:** MRI as the primary modality, whether conventional (T1, T1CE, T2, FLAIR) or quantitative (ADC, DSC-MRI, perfusion) sequences;
3) **Analytical methods:** use of radiomics and/or deep learning (CNNs, graph neural networks, or other architectures);
4) **Methodological contribution:** an original approach (preprocessing, feature selection, architecture, or fusion strategy), excluding reviews, editorials, and descriptive case reports;
5) **Availability:** full-text access at the time of the search (June 18–21, 2026). Full-text availability was required due to institutional access constraints at the time of the search; this pragmatic criterion is acknowledged as a limitation rather than a methodological strength, as it may have excluded relevant paywalled studies (see Limitations).

Studies were excluded for: (i) generic multiclass tumor classification without explicit glioma grading; (ii) focus on prognosis or treatment response without grade assessment; (iii) use of non-MRI modalities (e.g., CT, PET) without MRI integration; (iv) insufficient methodological detail; or (v) thematic deviations not generalizable to adult supratentorial gliomas (e.g., pediatric diffuse intrinsic pontine glioma studies).

The study selection workflow across both search pipelines is summarized in Fig. 1. Manual database searches retrieved 960 records (IEEE Xplore: $n = 609$; ScienceDirect: $n = 228$; PubMed: $n = 123$), reduced to 91 candidate studies after year and document type filtering, and to 15 after abstract manually-screening. Concurrently, AI tools retrieved 42 records (Elicit: $n = 32$; Consensus: $n = 10$); metadata screening removed 6 articles and deduplication removed 5 duplicates, yielding 31 unique records, narrowed to 24 following abstract screening.

Combining the 15 manual and 24 AI-retrieved records, with no overlap between the two pools, yielded 39 unique studies for full-text eligibility assessment. Full-text access could not be confirmed as open-access for 20 of these records, leaving 19 studies with available full text; of these, 4 were excluded for thematic/methodological deviations, leaving a final synthesis of 15 included studies.

It should be noted that this final set of 15 studies is not identical to the 15 manually-screened candidates described above: only 5 of the 15 manual candidates were retained in the final synthesis, while the remaining 10 studies were recovered through the AI-assisted pipeline. The manual search covered publications from 2022 to 2026; five studies predating this period were included via the AI-assisted pipeline due to their methodological relevance."

The fifteen selected studies span standalone radiomic and deep learning baselines to hybrid and graph-based architectures, with sample sizes from 54 to 704 subjects across institutional cohorts and public benchmarks (BraTS, TCIA). This diversity supports a representative mapping of current practices, though the open-access restriction and specific search pipelines limit generalization across clinical tasks, WHO editions, and validation protocols.

III. Literature Review

A. Classical Radiomics

Classical radiomics follows a common pipeline: segmentation of the region of interest (ROI), extraction of quantitative features (shape, intensity, texture), and application of a machine learning classifier — the basis for much of the glioma grading literature.

The most frequently cited methodological starting point in this field is the work by Cho et al. [7], which utilized the BraTS 2017 dataset (a public and multi-institutional dataset contributed by thirteen centers from The Cancer Imaging Archive — TCIA) comprising 285 cases. The authors extracted 468 3D volumetric radiomic features from four MRI sequences (T1, T1CE, T2, FLAIR), covering three types of regions of interest: the tumor core, the enhancing area, and peritumoral edema. Selection using minimum Redundancy Maximum Relevance (mRMR), a technique that prioritizes features with high relevance to the target class and low redundancy among themselves, reduced the feature space to five features per fold, with Spherical Disproportion and Compactness consistently appearing in at least three of the five folds. These results reaffirm a clear biological interpretation: tumors with more irregular shapes tend to be high-grade, reflecting the infiltrative growth of GBM. After applying Random Forest, support vector machine (SVM), and logistic regression with cross-validation across the five folds, the authors achieved an AUC of 0.903 for distinguishing between high-grade glioma (HGG) and LGG.

It is not always necessary to resort to complex multiparametric protocols to achieve meaningful diagnostic discrimination. Kumar et al. [8] prove that a single T2W sequence, processed with many spatial scale filters (Gaussian Laplacian), can distinguish LGG from HGG with an AUC of 0.82 in 83 patients imaged on two distinct scanners (1.5T and 3T). T2W is a universal sequence that does not require the use of contrast agents, which gives it great practical value. Following a similar line of reasoning about accessible modalities, Vijithananda et al. [9] propose a multiclass classification into three categories using only non-contrast-enhanced ADC (apparent diffusion coefficient) maps, which indirectly reflect the cellular density of the tissue, resulting in an accuracy of 88.14% and an AUC of 0.99 for LGG compared to the other groups.

When the focus shifts from tumor morphology to vasculature, new possibilities emerge. Sudre et al. [5] explore a resonance perfusion technique called DSC-MRI, which quantifies cerebral blood flow in a dataset from six European centers, comprising a total of 333 patients. From rCBV maps normalized to the basal ganglia of the contralateral hemisphere, they extracted 29 features and applied a Random Forest model with two-fold cross-validation, repeated 250 times. This method achieved 71% accuracy for IDH prediction and 53% for WHO three-class grading. In the latter case, 87% of cases were classified with a margin of no more than one grade difference from the actual grade, demonstrating that, although exact classification is challenging, the model rarely misclassifies by more than one grade. It is also observed that shape features better distinguish between grades II and III, while texture and intensity are more informative for distinguishing between grades III and IV.

A different perspective on which features truly matter is presented in the work by Hassan et al. [10], who, instead of hundreds of features, used only eight morphological measures derived from the BraTS 2015 segmentation masks: presence of enhancement, absence of enhancement, edema, and necrosis, and their relative ratios. The features were evaluated using a technique called Ensemble Learning with Adaptive Power Mean Combiner (EL-APMC), which combines linear discriminant analysis (LDA) with bootstrap bagging without replacement and an adaptive power mean combiner, achieving an accuracy of 88.73% and an F1-score of 93.12% in 275 patients, a result that outperforms the 21 classifiers compared by the authors.

Taken as a whole, classical radiomics studies show that shape and texture features of the enhancing region and tumor core best discriminate grades, though the reliance on manual ROI segmentation makes pipelines labor-intensive and inconsistent across centers.

B. Deep Learning and Convolutional Neural Networks

The main promise of deep learning compared to classical radiomics is precisely that it eliminates the need to define in advance which features are relevant: instead of extracting prespecified measures, convolutional neural networks (CNNs) learn hierarchical representations directly from the image's pixels. This difference in philosophy has important practical consequences, and the literature is beginning to map them out clearly.

The most direct and controlled comparison between the two approaches appears in the study by Gutta et al. [6], conducted with 237 patients from a single center (USC). The authors extracted 1,284 radiomic features using PyRadiomics and achieved 64% accuracy with Gradient Boosting as the best classical classifier. In parallel, they trained a customized CNN using 2D patches of 150×150 pixels for multiclass classification across four WHO grades, and the result is

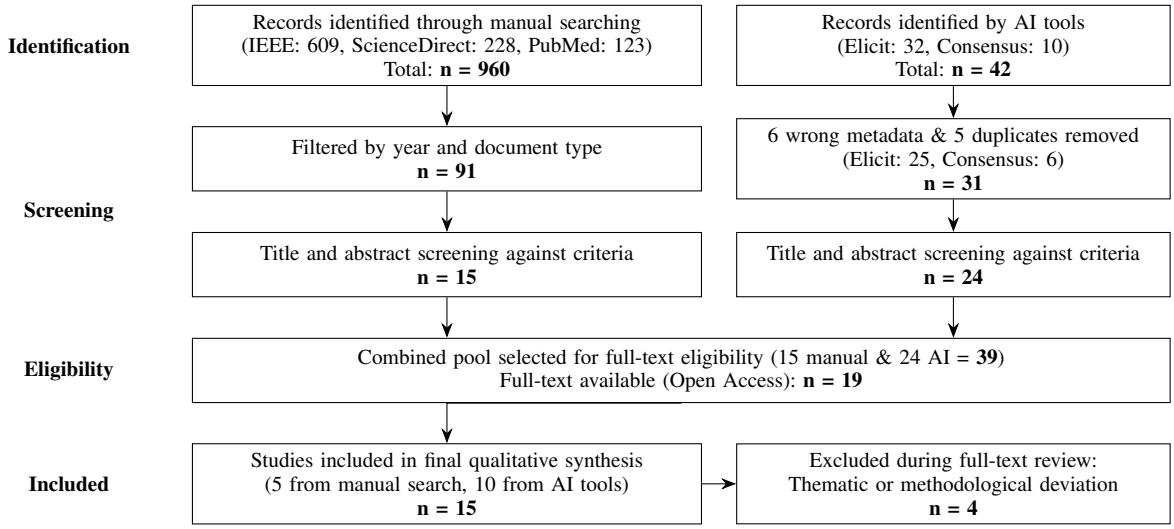

Fig. 1. PRISMA-style flow diagram of the study selection process.

striking: the CNN achieved 87% accuracy, an improvement of 23 percentage points. Analysis using Gradient-weighted Class Activation Mapping (Grad-CAM), a visualization technique that highlights the image regions most influential to the network's decision, revealed that T1CE is strongly considered for grades III and IV, FLAIR is more discriminative for grade II, and edema is the most informative tumor component.

The question of how to optimize the network architecture — rather than simply choosing the method — was explored by Shahriar et al. [11], who proposed a CNN optimized using KerasTuner with the Hyperband algorithm to be applied to the dataset Erasmus Glioma Database (EGD), which was balanced with 77 patients per grade and 16,956 T2W-FLAIR slices. KerasTuner is a library for automatic hyperparameter search, and optimization via Hyperband yielded an average accuracy gain of 1.6% per fold. The final model achieved 89% for three grades and 93% for binary classification, outperforming EfficientNet-B0 (83%), Xception (82%), and ResNet-50 (81%) on the same dataset. Saliency maps, another visualization technique simpler than Grad-CAM, reveal a consistent focus on peritumoral regions, especially at higher grades.

There are also approaches that combine the insight provided by radiomic features with the learning capabilities of neural networks. Qin et al. [12] trained a feedforward artificial neural network (ANN) — that is, a neural network with a direct flow of information (without recurrent connections) — using 19 radiomic features from T1-weighted contrast-enhanced (CE-T1W) images for classification into four WHO grades, achieving an accuracy of 87.04%. This is the only study in the set that explicitly proposes classification into four categories (I, II, III, and IV) using this approach.

The set of studies suggests that deep neural networks tend to outperform classical radiomics as data volume increases, though this pattern is only loosely supported across the heterogeneous studies reviewed. Interpretability remains a challenge nonetheless: Grad-CAM and saliency maps offer partial insight into what the model learns, but do not equate to the biological interpretability of radiomic features.

C. Hybrid Approaches: Radiomics and Deep Learning

The central hypothesis of hybrid approaches is precisely this: classical radiomic features and features learned through deep learning capture complementary aspects of tumor information, and their fusion should outperform standalone approaches.

Ning et al. [13] systematically and rigorously test this hypothesis using 567 patients distributed between a TCIA training set (233 patients) and an external test set from Nanfang Hospital in China (334 patients). The integrated model fuses radiomics and CNNs via SVM kernel fusion (kSVM), a technique that combines two feature spaces using a sum kernel in a support vector machine, and achieving an AUC of 0.94 in internal validation and 0.88 in the external test. The results reinforce the superiority of the integrated approach over individual architectural configurations; furthermore, when compared to the manual analyses of three radiologists, the model outperformed them in sensitivity (88% vs. 80–84%) and specificity (81% vs. 72–78%).

The findings of Ning et al. [13] raise a question: which of the two sources of information — radiomics or CNN features — contributes most to the hybrid model's performance? The answer provided by the work of Ding et al. [14] represents a step forward in this area. By integrating radiomics and transfer learning on CE-T1W images across three reconstruction planes (axial, coronal, and sagittal) using data from three institutions (151 patients), the authors found that the optimal model, consisting of a Random Forest with combined radiomic and VGG16 features, achieves an AUC of 0.898 on the multicenter test set; however, radiomic features account for 88.2% of the selected features, while VGG16 contributes only two. This suggests that transfer learning from ImageNet to MRI has limited capacity and relevance in this context.

When feature fusion is insufficient to capture the complexity of the tumor, one alternative is to let radiomics guide the learning process itself. This was the approach proposed by Shboul et al. [15], who introduced the concept of guided deep radiomics: known radiomic features, such as PTPSA fractal analysis and multifractal Brownian motion (mBm) — which are measures of the tumor's geometric irregularity and spatial complexity — guide the learning of deep neural networks. The pipeline evaluated in the BraTS 2017 and 2018 benchmarks focuses on predicting survival in GBM and incorporates persistent homology features that capture the tumor's 3D topology — that is, global geometric properties such as connectivity and cavities. The model, called XGBoost, won the BraTS 2017 competition with an accuracy of 73% on the training set and 67.9% on the validation set.

These hybrid approaches show that integration need not be complex — feature fusion, partial transfer learning, or geometric guidance all reinforce radiomics and deep learning as complementary rather than rival approaches, provided validation is rigorous enough to confirm the gain is real.

D. Graph Architectures

A new class of architectures has gained traction in the literature on glioma grading: graph neural networks (GNN/GCN). They differ from conventional CNNs in how they represent information — not as regular grids of pixels, but as structures mapping relationships between regions, referred to as nodes, opening possibilities that standard CNNs do not explore.

An initial approach to exploring graphs in this context involves modeling the relationships between patients in the feature space. Ali et al. [1] adopt this strategy in the RGNN3D model, combining GCN and long short-term memory (LSTM) networks to grade gliomas based on 112 radiomic biomarkers from 704 patients in the BraTS dataset, in which each individual represents a node in the graph. The architecture employs three GCN layers interleaved with LSTMs to ease message passing and keep long-range dependencies, which mitigate the vanishing gradient problem — a classic challenge of deep networks in which error signals progressively decay across layers. The LSTM addresses this through forget and forget-gate mechanisms that selectively control which information is retained or discarded in the cell's memory, allowing relevant gradients to flow without degradation, regardless of the network's depth. Although the model achieves a remarkable accuracy of 98.58% in the T1 and T2 modalities, this result should be interpreted with caution due to three factors: the BraTS dataset is pre-standardized by the organizers, which favors high metrics; validation was limited to the internal environment — that is, no tests were conducted on independent external cohorts; and the test employed binary classification (LGG vs. GBM), a task considerably simpler than four-class grading. Finally, local interpretability via Local Interpretable Model-agnostic Explanations (LIME) revealed the key decision biomarkers: Mesh Volume and Maximum Diameters were decisive for GBM, while Minor Axis Length and Gray Level Non-Uniformity distinguished LGG.

A second way to use graphs is to model the internal structure of the tumor volume rather than the relationships between patients. Guo et al. [16] developed the MMIF-GCN module for this purpose, modeling relationships between adjacent slices in the 3D volume and across the four MRI sequences simultaneously. Each node represents a slice containing a tumor, with embedding vectors that integrate the 2D features of the four sequences into a 200-dimensional vector. The architecture contains four GCN layers that progressively refine these vectors, and evaluation was performed on the BraTS 2020 dataset (369 patients) and the private dataset from Henan Provincial Hospital (232 patients). MMIF-GCN with ResNet-34 achieves an AUC of 0.986 and an accuracy of 94.7%; this AUC close to 1.0 is justified by the binary classification (HGG vs. LGG), as in Ali et al. [1]. Furthermore, the study does not clarify whether cross-validation prevented data leakage between the two combined datasets. Still, the model outperforms the 3D-CNN (AUC 0.949) and the individual sequence GCN (AUC 0.970), demonstrating a significant gain from the application of graph-based multimodal fusion.

Ali et al. [1] and Guo et al. [16] thus address complementary aspects — patient-level relationships versus tumor-volume structure — but share the same limitation: neither provides formal mechanisms to explain the graph's decisions, limiting clinical adoption.

E. Magnetic Resonance Imaging Modalities

The choice of MRI sequences is not a minor technical decision: it directly determines what kind of biological information the model will have access to. This issue affects all the approaches discussed in the previous sections — from classical radiomics to deep learning and graph models — and the reviewed studies shed light on it in complementary ways.

Most of the reviewed studies use the standard BraTS multiparametric protocol: T1, T1CE, T2, and FLAIR. Within this protocol, the activation maps by Gutta et al. [6] provide the clearest evidence about the role of each sequence: T1CE is most discriminative for grades III and IV, FLAIR for grade II, and the importance of T2 increases progressively with grade. This hierarchy is not arbitrary; it reflects real biological differences between the grades: enhancement on T1CE indicates disruption of the blood-brain barrier, which is more pronounced in more aggressive tumors, while FLAIR is sensitive to the edema characteristic of lower grades.

The choice of single sequences, rather than the complete protocol, is a legitimate strategy when guided by clear clinical or methodological motivations. Kumar et al. [8] choose T2W for its clinical universality and the absence of contrast use, a significant advantage in settings with limited infrastructure or when contrast is contraindicated. Vijithananda et al. [9] use ADC, arguing that the diffusion coefficient reflects tumor cellularity more directly than morphological sequences. A different perspective is presented by Shahriar et al. [11]; their CNN is essentially modality-agnostic, meaning that T1, T1CE, T2, and FLAIR sequences yield equal performance, raising the

hypothesis that, with enough data, the network learns to extract relevant information regardless of the specific sequence.

Certain specialized modalities capture aspects of tumor physiology that conventional sequences cannot access. Sudre et al. [5] represent the only study using DSC-MRI with exclusive perfusion imaging, validating that the tumor vasculature captured by rCBV is a surrogate of IDH status — a biologically grounded connection between perfusion and molecular genotyping. A limitation less frequently discussed in the literature is that most studies analyze only the axial plane, disregarding volumetric information that the coronal and sagittal planes could provide. Ding et al. [14] address precisely this gap by applying CE-T1W in three reconstruction planes, demonstrating that the triplanar perspective recovers volumetric information lost in the analysis of isolated axial slices. Chiu and Yen [17] combine four sequences (T1W, T2, FLAIR, ADC) to map intratumoral subregions of GBM, leveraging the complementarity between contrast, edema, diffusion, and morphology to characterize tumor heterogeneity.

The choice of which sequence to use depends on the task, clinical context, and method — deep learning with large datasets is less sensitive to modality choice, while classical radiomics with small samples depends critically on it.

F. Radiogenomic Approaches

The 2016 and 2021 updates to the WHO classification redefined the conceptual framework of the field by establishing markers such as IDH mutation, 1p/19q codeletion, and MGMT promoter methylation for the definitive diagnosis of gliomas [4]. This molecular milestone directly drives the studies analyzed, which expand the scope beyond pure morphological grading and move toward molecular prediction, prognostic stratification, and mapping of intratumoral heterogeneity. This reorientation changes the clinical premise; thus, the central question shifts from "What is the histological grade?" to "What is the tumor's biological profile, and which treatment will be most effective?"

The most comprehensive radiogenomic approach in this set of studies is that of Bilalov et al. [18], whose framework integrates radiomic embeddings from a multiparametric CNN with molecular biomarkers (EGFR amplification, IDH mutation, and MGMT promoter methylation) through multi-omic fusion. This strategy combines data from different biological layers — such as imaging, the genome, and the epigenome — into a single predictive model. This approach achieved a C-index of 0.78 and an AUC of 0.82 in a cohort of 112 patients during external validation, where the C-index measures the model's ability to correctly rank pairs of patients by survival risk. The molecular dimension is also explored by Sudre et al. [5], but from the perspective of classical radiomics. By incorporating IDH status as a secondary target, the authors demonstrated that DSC-MRI features, especially those related to texture and shape, differentiate IDH-mutant tumors from wildtype tumors with 71% accuracy.

When all patients already have grade 4 GBM, the question of grading loses its meaning, and the focus shifts entirely to prognosis. This is precisely the perspective adopted by Shboul et al. [15], whose aim is to predict survival across three risk categories within a homogeneous set of GBM cases. For the structural analysis of the data, the authors used t-distributed stochastic neighbor embedding (t-SNE) to visualize the high-dimensional data structure. The mapping revealed that the median survival class is structurally indistinguishable from the others in the feature space. This finding is relevant because it demonstrates that the challenge is biological, not algorithmic, reflecting the actual overlap of tumor phenotypes associated with intermediate prognoses.

Heterogeneity does not exist only among patients with different grades. It is also present within the tumor itself, where regions with distinct biological behaviors coexist within the same volume. This internal spatial diversity is addressed by Chiu and Yen [17], who, by cataloging the intratumoral subregions of GBM (necrotic core, solid tumor, peritumoral tissue, and edema) and quantifying their volumetric ratios, establish that edema is the volumetrically dominant component (31–39% of abnormal bulk volume — ABV), followed by the solid tumor (31–43%) and necrosis (17–23%), with each subregion associated with distinct biological processes. Mapping these subregions using multiparametric radiomics can thus provide a spatial signature of the tumor with prognostic value independent of the grade.

These studies point to a reorientation beyond technical improvements: integrating radiomic features, molecular markers, and clinical variables into multimodal predictive models is the field's identified next step.

G. Reported Challenges

Table I summarizes the main methodological characteristics of the fifteen reviewed articles. The reported metrics are not directly comparable across studies, as they reflect different tasks and validation protocols.

Three structural challenges run through the literature regardless of methodological approach, limiting practical clinical application: dataset size, validation diversity, and interpretability.

The first challenge is the size of the datasets. The scarcity of labeled data is the most frequently cited obstacle: Kumar et al. [8] worked with 83 patients, Chiu and Yen [17] with 54 — a sample size the authors themselves note compromises statistical power and scalability — and Bilalov et al. [18] with 112. This situation is further compounded by class imbalance, as Grade I is consistently rare: 17 cases in Gutta et al. [6] and 23 in Qin et al. [12]. To overcome this limitation, various strategies have been employed, such as SMOTE [9], fold balancing [11], and bootstrap bagging [10]; however, these approaches only partially mitigate the statistical fragility associated with small datasets. Another point is that six of the fifteen reviewed studies use BraTS as their primary benchmark; this dataset is preprocessed and standardized by the challenge organizers, which introduces a homogeneity that limits the true assessment of the models' generalization ability to heterogeneous clinical data.

TABLE I
COMPARISON OF THE FIFTEEN REVIEWED ARTICLES

Paper	Approach	Sequence	Dataset (n) / Split	Validation	Evaluation*	Objective	Limitations	XAI
Guo et al., 2022 [16]	CNN & GCN multimodal	T1, T1CE, T2, FLAIR	BraTS20 (369) & Henan Hosp. (232), 5-Fold CV	Internal CV & External (Henan Hosp.)	AUC 0.986; Accuracy 94.7%	Binary classification (HGG/LGG)	Black-box; complex architecture	No
Ali et al., 2026 [1]	Radiomics, GNN/LSTM	T1, T2, T1CE, FLAIR	BraTS19 & BraTS20 (Train: 563, Test: 141)	Internal	Accuracy 98.58%	Binary classification (LGG/GBM)	No external validation	LIME
Ning et al., 2021 [13]	Radiomics & CNN & kSVM	T1CE, FLAIR	TCIA (Train: 233) & Nanfang Hosp. (Test: 334)	External (Nanfang Hosp.)	AUC 0.88	Binary classification (LGG/GBM)	Cross-site harmonization needed	No
Bilalov et al., 2025 [18]	CNN + Radiogenomics	T1, T1CE, T2, FLAIR	TCGA (Train: 75) & China Univ. (Test: 37)	External (China Univ.)	AUC 0.82; C-idx 0.78	GBM prognosis (survival)	GBM-only; scanner variability	No
Ding et al., 2022 [14]	Radiomics & VGG16 triplanar	T1CE (3 planes)	3 Univ. Hospitals (Train: 101, Test: 50)	External (Multicenter)	AUC 0.898	Binary classification (LGG/HGG)	Triplanar slice sensitivity	Grad-CAM
Gutta et al., 2021 [6]	CNN pure	T1, T1CE, T2, FLAIR	Keck Hosp. (Train: 166, Val: 36, Test: 35)	Internal	Acc 87% (CNN); Acc 64% (GB)	Multiclass grading (WHO 1–4)	No external validation	Grad-CAM
Shahriar et al., 2025 [11]	Lightweight CNN + KerasTuner	T2W-FLAIR	EGD (231), 5-Fold CV	Internal CV	Acc 89% (Grad.); 93% (Class.)	3-class grading + binary	No cross-center validation	Saliency Maps
Chiu & Yen, 2022 [17]	Multiparametric radiomics & RF	T1CE, T2, FLAIR, ADC	Taiwan Univ. Hosp. & TCIA (54), 5-Fold CV	Internal CV	AUC > 0.95	Intratumoral subregion mapping	Very small n (54)	Parametric Heatmap
Cho et al., 2018 [7]	Radiomics & mRMR & SVM/RF	T1, T1CE, T2, FLAIR	BraTS17 (285), 10-Fold CV	Internal CV	AUC 0.903	Binary classification (HGG/LGG)	Manual segmentation needed	No
Hassan et al., 2024 [10]	Novel MRI features & EL-APMC	T1CE, T2	BraTS15 (275), 5-Fold CV	Internal CV	Acc 88.73%; F1 93.12%	Binary classification (LGG/HGG)	Outdated dataset (BraTS15)	No
Shboul et al., 2019 [15]	Deep Radiomics + XGBoost	T1, T1CE, T2, FLAIR	BraTS17 & BraTS18 (163), LOOCV	Internal LOOCV	Accuracy 73%	GBM survival prediction	LOOCV only, no external test	t-SNE + KM
Qin et al., 2025 [12]	Radiomics & ANN	T1CE	1 Univ. Hospital (Train: 253, Test: 109)	Internal	Accuracy 87.04%	Multiclass grading (WHO 1–4)	No external validation	No
Sudre et al., 2020 [5]	Radiomics & RF	DSC-MRI (rCBV)	6 Univ. Hospitals (333), leave-one-center-out	Internal LOCO (Multicenter)	Acc 71% IDH; 53% grade	3-class grading & IDH prediction	Low grading accuracy	No
Vijithananda et al., 2023 [9]	Radiomics ADC & RF	ADC	Sri Lanka Hosp. (Train: 70, Test: 18)	Internal	Acc 88.14%; AUC 0.99	Multiclass classification (3 classes)	Small n (88); overfitting risk	No
Kumar et al., 2023 [8]	Radiomics T2W & RF	T2W	Tata Memorial Hosp. (Train: 58, Test: 25)	Internal	AUC 0.82	Binary classification (LGG/HGG)	Small n; single sequence	No

*Metrics reflect different tasks and validation protocols and cannot be directly compared.
CV = Cross-Validation; LOOCV = Leave-One-Out CV; LOCO = Leave-One-Center-Out

The second challenge is the diversity of validation strategies, which prevents equal-footing comparison across studies. Ning et al. [13] combines internal validation with an independent external dataset, while Hassan et al. [10], Kumar et al. [8], and Qin et al. [12] validate exclusively on the same dataset, limiting generalizability.

Confidence intervals for reported metrics (AUC, accuracy, F1) were rarely provided in the original studies and are therefore omitted from Table I; similarly, explicit data-leakage safeguards (e.g., patient-level versus slice-level splitting) were inconsistently reported, limiting the ability to assess result reliability across studies.

Likewise, a structured quality-assessment table including WHO classification edition, IDH/1p19q status, and segmentation method was not feasible, as these fields are inconsistently reported across the fifteen included studies; this heterogeneity in reporting is itself a limitation of the underlying literature rather than of the present review.

The third challenge is interpretability, the most critical for clinical adoption, since a model that cannot explain its decisions is unlikely to be incorporated into medical practice as a diagnostic tool. Of the fifteen studies reviewed, only six em-

ploy some formal interpretability technique: LIME [1], Grad-CAM [6], [14], saliency maps [11], t-SNE combined with Kaplan-Meier analysis [15], and hierarchical heatmaps [17]. The remaining nine studies treat the model as a black box, a shortcoming that must be addressed as a core need for any system intended for clinical use.

IV. Conclusion

No single approach fully resolves glioma grading: classical radiomics offers interpretability and works well with small samples; deep learning captures patterns radiomics overlooks but needs more data and lacks transparency; hybrid and graph models push performance further at the cost of opacity and reliance on internal validation. Within this corpus, graph-based models reported the highest figures on binary LGG/HGG classification using standardized benchmarks (BraTS19 & BraTS20); these results should not be generalized across tasks, as no head-to-head comparison under identical conditions exists, although there are favorable evaluation conditions (binary classification, standardized data).

This review has methodological limitations that should be acknowledged. A formal risk-of-bias assessment tool, such as QUADAS-2, was not applied to the fifteen included studies due to time constraints; such an assessment would allow a more systematic judgment of methodological quality across domains (patient selection, index test, reference standard, and flow and timing) and is proposed as a direction for future systematic reviews on this topic. Additionally, restricting eligibility to open-access full text may have excluded relevant paywalled studies, so the final sample of fifteen studies is small relative to the breadth of the field, and findings should be interpreted as indicative of current trends rather than as a basis for broad generalization.

The challenges that the next generation of models will need to address are well defined: larger, multicenter datasets that reflect real-world variability; standardized validation protocols that allow for fair comparison of studies; and the application of formal interpretability as a need, not an option. The expansion toward radiogenomics and the mapping of intratumoral subregions is the natural direction: models capable of grading the tumor, predicting its molecular profile, and stratifying prognosis in a single noninvasive analysis represent the concrete and achievable goal for this field over the next decade.

Among the fifteen studies reviewed, the hybrid model by Ning et al. [13] represents the most suitable starting point for later work, as the only one combining radiomic and deep features with external validation on 334 patients, outperforming three clinical radiologists in sensitivity and specificity. This combination of methodological integration and robust external validation is precisely what the literature identifies as the central gap. A natural next step would be to replicate and expand this approach, incorporating more modalities, such as ADC or DSC-MRI, and testing generalizability on multicenter datasets with heterogeneous acquisition protocols.

V. Acknowledgment

Abstract*—Automated cardiac arrhythmia classification is vital for enhancing intensive care monitoring and reducing clinician alarm fatigue. However, extreme intrinsic class imbalance across standard pathological categories often leads to the complete suppression of minority class features during deep learning optimization. This study presents a rigorous architectural benchmark evaluating five state-of-the-art convolutional neural networks—ResNet50, ResNet50V2, EfficientNetV2B0, DenseNet121, and ConvNeXtTiny—under varying degrees of data scarcity. Moving away from static dataset splits, we implement an exhaustive 4-fold cross-rotation validation pipeline that operates on a cumulative pool of 109,381 2D ECG derivative images generated from the MIT-BIH Arrhythmia Database and structured according to the AAMI/ANSI EC57 standard. The consolidated multi-round results reveal a critical engineering trade-off: next-generation networks optimized under modern computational scaling laws (EfficientNetV2B0 and ConvNeXtTiny) suffer a catastrophic feature drain toward majoritarian normal profiles in hyper-sparse configurations, collapsing to 0.00% F1-scores when class support drops below a critical threshold. Conversely, the classical ResNet50 framework demonstrates superior topological preservation, anchoring minority gradient pathways through its unregularized identity shortcut connections. ResNet50 achieved the highest consolidated mean global accuracy (92.16% ± 7.15%) and a resilient classification standard for the rarest abnormal class (61.01% ± 39.81% F1-score), heavily outperforming its modernized counterparts. These findings introduce a pivotal paradigm shift for clinical software deployment, demonstrating that structural rigidity and unpruned architectural highways remain paramount to safeguarding diagnostic sensitivity in real-world asymmetric medical data streams.

I. Introduction

For over a century, the electrocardiogram (ECG) has served as the primary non-invasive tool for assessing cardiac bioelectric activity [1]. By capturing P, Q, R, S, and T wave patterns, the signal provides crucial morphological indicators of cardiovascular health. Continuous ECG monitoring is essential in ambulatory care and continuous clinical screening to detect life-threatening arrhythmias. However, current automated surveillance tools frequently suffer from high false-alarm rates driven by noise artifacts and severe class imbalance [2], [3]. Developing resilient automated classifiers remains a research priority to enhance diagnostic reliability and reduce alarm fatigue in automated screening systems.

To evaluate classification performance under standardized conditions, literature widely adopts the AAMI/ANSI EC57 standard. This protocol categorizes raw beats from the benchmark MIT-BIH Arrhythmia Database [4] into five physiological classes: Normal (N), Supraventricular ectopic (S), Ventricular ectopic (V), Fusion (F), and Unknown (Q). While traditional detection algorithms often use the first derivative of the ECG solely to improve signal-to-noise ratio, this work investigates its direct transformation into 2D derivative visual features for convolutional neural network (CNN) classification.

A central challenge in automated arrhythmia detection is the extreme class imbalance across pathological categories, which often suppresses minority class sensitivity. To evaluate how deep learning backbones perform under variable data scarcity, this study presents a patient-independent, 4-fold cross-rotation benchmark across 109,381 ECG derivative images. We analyze the empirical behavior of classical residual design (ResNet50) against modernized architectures (EfficientNetV2B0 and ConvNeXtTiny), assessing their performance when exposed to severe localized minority class scarcity.

II. Materials and Methods

A. Dataset

To evaluate the proposed deep learning methodology under rigorous benchmark conditions, this study uses the landmark MIT-BIH Arrhythmia Database from PhysioNet [4]. The repository comprises 48 fully annotated, half-hour ambulatory ECG records obtained from 47 distinct subjects, digitized at 360 Hz with 11-bit resolution over a 10 mV range. To maintain strict feature consistency across the 24 hours of cumulative recording time and more than 107,000 baseline heartbeats, our analysis focused exclusively on the first lead, which is usually the Modified Lead II (MLII). This bipolar thoracic lead is systematically available across the database registers, capturing a uniform vector of ventricular depolarization.

Following standard literature protocols, record 207 was explicitly excluded from the experimental pool due to severe ventricular flutter and inconsistent morphological annotations that deviated from the structural definitions established by the AAMI/ANSI EC57 standard.

As illustrated in the Fig.I, to prevent data leakage and evaluate model robustness under class scarcity, the remaining data was partitioned into four patient-independent groups (detailed in Table II). No patient data was shared between training and testing sets in any fold. Across the four rotated folds, this setup yielded an un-augmented testing pool of 109,381 ECG derivative images.

TABLE I: Stratified patient-independent partition mapping from the MIT-BIH Arrhythmia Database.

Data Partition	MIT-BIH Patient Records
Data Set 1	100, 101, 102, 109, 116, 122, 124, 200, 201, 220, 221, 228
Data Set 2	105, 106, 117, 118, 119, 121, 203, 213, 217, 222, 234
Data Set 3	104, 111, 113, 115, 123, 202, 208, 209, 212, 215, 219, 223
Data Set 4	103, 107, 108, 112, 114, 205, 210, 214, 230, 231, 232, 233

B. Signals and Preprocessing

To prepare the continuous ECG signal for classification, a multi-stage preprocessing pipeline was implemented. First, a two-sample moving average filter was applied to attenuate high-frequency interference. Using physician R-peak annotations, individual heartbeats were centered and segmented into 108-sample windows, capturing full P-QRS-T complexes.

To eliminate baseline wander—a common low-frequency artifact caused by respiration and movement—and to accentuate QRS slope characteristics, the first-order difference of each 108-sample segment was computed, as illustrated in Fig. 1.

Each transformed segment was subsequently rendered into a 300×300 RGB image saved in JPEG format, representing the 2D visual derivative features of the beat. Representative samples for each of the five AAMI arrhythmia classes are displayed in Fig. 2.

To address class imbalance without contaminating validation data, random oversampling [5] was applied strictly to the training splits of each fold. The test splits remained entirely untouched and un-augmented to ensure an unbiased evaluation.

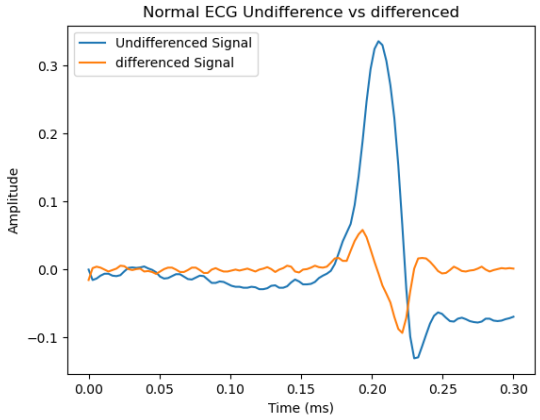

Fig. 1: Morphological comparison between the raw Normal ECG segment and its corresponding first-order derivative.

C. Deep Learning Neural Network Architectures

Five state-of-the-art convolutional architectures were selected as feature extractors (backbones) due to their distinct trade-offs between computational efficiency, structural depth, and capability to generalize complex patterns:

- ResNet50 and ResNet50V2: Originally developed by [9], the Residual Network (ResNet) introduced the concept of skip connections, mitigating the vanishing gradient problem in very deep networks. The ResNet50V2 variant [10] reformulates the residual block by applying Batch Normalization and activation (ReLU) prior to the convolutional layer (pre-activation), allowing for a cleaner gradient flow and greater numerical stability at the beginning of training.
- EfficientNetV2B0: Proposed by [11], EfficientNetV2 optimizes the compound scaling methods of the original version. Utilizing neural architecture search (NAS), it combines traditional MBConv convolutions with Fused-MBConv layers in the early stages, drastically optimizing training speed and video memory (VRAM) efficiency, making it ideal for large-scale datasets.
- DenseNet121: Introduced by [12], the Densely Connected Convolutional Network connects each layer to every subsequent layer within a dense block. This connectivity maximizes information flow and feature reuse throughout

(a) Normal (N) (b) Supraventricular (S) (c) Ventricular (V) (d) Fusion (F) (e) Unknown (Q)

Fig. 2: Representative 2D derivative image inputs across the five standardized AAMI arrhythmia categories.

the network, reducing the total number of redundant parameters and demonstrating high sensitivity in identifying fine lines and gradients

- ConvNeXtTiny: Developed by [13], the ConvNeXt family modernized purely convolutional networks (CNNs) by incorporating design philosophies from Vision Transformers (ViTs), such as the use of depthwise separable convolutions, inverted residual blocks, and GELU activation functions. The Tiny version acts as a high-precision extractor with low computational cost.

D. Hardware Resources and Software Environment

To process the massive volume of convolutional data and ensure experimental reproducibility, a mobile workstation with hardware-accelerated parallel processing was used. The computational system consisted of an Intel Core i7 processor, complemented by 32 GB of dynamic random-access memory (DDR4 RAM) and a high-speed solid-state drive (SSD) storage unit.

Hardware acceleration for neural network training and inference was conducted by a dedicated NVIDIA GeForce RTX 2060 Graphics Processing Unit (GPU). The software environment was built upon the Linux operating system, utilizing the Miniconda package manager for dependency isolation. The development pipeline was implemented in Python (version 3.10), leveraging the unified Keras 3 ecosystem coupled with the TensorFlow (version 2.16) backend, and supporting NVIDIA cuDNN analytical execution drivers and the CUDA Toolkit (version 12.3).

E. Data Ingestion and Organization Pipeline

To ensure maximum statistical validity and eliminate selection bias during model training and evaluation, an exhaustive 4-fold cross-validation rotation pipeline was implemented. The original dataset layout, containing segmented 2D electrocardiogram (ECG) derivative images, was organized into four distinct training blocks and four corresponding independent test sets. Rather than using a single static split, the training pipeline dynamically aggregated three of the four available training subsets per execution round, reserving the remaining distinct validation subset exclusively for final inference testing. This setup resulted in four independent experimental configurations as presented in TableII.

TABLE II: Training, Validatio and Test Sets

	Group			
Group	**Training**			**Test**
Group 1	Dataset 2	Dataset 3	Dataset 4	Dataset 1
Group 2	Dataset 1	Dataset 3	Dataset 4	Dataset 2
Group 3	Dataset 1	Dataset 2	Dataset 4	Dataset 3
Group 4	Dataset 1	Dataset 2	Dataset 3	Dataset 4

For each of these in the experimental groups, a stratified validation split was applied with 80% for weight adjustment and 20% for internal convergence validation, ensuring a fair statistical representation of all classes.

This structural rotation exposed the networks to varying degrees of localized class imbalance across rounds, forcing the architectures to generalize to morphological ECG boundaries under diverse distributional stresses. Crucially, the target samples of the specific test partition under evaluation remained completely unseen during the training phase of that respective round, ensuring zero data leakage and a pristine mathematical baseline for the final cross-fold synthesis.

The original images in the dataset, which had dimensions of 300×300 pixels, were subjected to bilinear resizing to a stable spatial resolution of 128×128 pixels with a three-channel color mapping (RGB). This strategic dimensional reduction was fundamental to optimizing GPU video memory (VRAM) usage and making sequential training viable. The processing batch size was fixed at 8 samples per iteration.

F. Transfer Learning Strategy and Training

To bypass the need for random weight initialization in deep networks—which would require weeks of processing—a Transfer Learning strategy was adopted. Each of the five evaluated networks were initialized with mathematical coefficients pre-trained on the ImageNet database. The architecture of each model was customized for the biomedical problem according to the following layer structure:

1) Input Layer: Configured to receive tensors in the $(128, 128, 3)$ format. .
2) Preprocessing Module: A lambda layer executing the specific, native normalization functions of each model family.

3) Feature Extractor (Backbone): The convolutional body of the network was strictly frozen, acting purely as a static extractor of high-level morphological patterns.
4) Global Pooling Layer: Application of Global Average Pooling 2D to collapse spatial dimensions and mitigate the risk of overfitting.
5) Output Layer: A dense (Fully Connected) layer composed of 5 neurons with a Softmax activation function, responsible for generating the categorical probability distribution for the five electrocardiogram (ECG) classes.

The weight optimization process for the classification layer was guided by the Adam (Adaptive Moment Estimation) algorithm, with a stable initial learning rate of $\eta = 0.001$ over 15 epochs. As the loss function for the multiclass problem, Categorical Crossentropy was adopted.

To ensure that late-stage training overfitting did not corrupt the evaluation, a validation monitoring routine (Model Checkpoint) was integrated to identify and save to disk the exact state of the network that achieved the best performance during training. This consolidated file was then used for the subsequent inference stage.

G. Metrics

K-fold cross-validation was performed to verify the training and validation performance of the image recognition models, using Accuracy, Precision, and Sensitivity as evaluation metrics.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

$$Precision = \frac{TP}{TP + FP} \tag{2}$$

$$Sensitivity = \frac{TP}{TP + FN} \tag{3}$$

III. Results

This section presents a quantitative evaluation of the five deep learning convolutional architectures across four isolated test datasets, rotated systematically, comprising a cumulative pool of 109,381 electrocardiogram (ECG) derivative images.

A. Global Performance and Benchmark Consolidation

To establish a mathematically rigorous validation framework independent of single-partition biases, the global performance of the models was aggregated across the four distinct cross-rotation evaluation rounds. Table III summarizes the consolidated cross-fold experimental metrics—reporting the exact Mean $\pm$ Standard Deviation ($\mu \pm \sigma$)—for global accuracy and the individual F1-scores achieved by each network architecture.

The cross-fold consolidation demonstrates that ResNet50 secured the highest mean global accuracy at 92.16%, maintaining an optimal balance across highly skewed distributions. While modern optimized networks like EfficientNetV2B0 and ConvNeXtTiny performed competitively on majority-class boundaries (averaging 91.99% and 91.62% global accuracy, respectively), they exhibited greater mathematical vulnerability when subjected to localized instances of extreme scarcity. This localized degradation is evidenced by the higher standard deviations observed in F, where the performance of both next-generation architectures fluctuates aggressively depending on the active test partition's support. Conversely, the standard residual highway of ResNet50 consistently anchored minority classifications, providing the top architectural performance for the highly critical F (F1-score $= 61.01\% \pm 39.81\%$). Lastly, Q represented the most stable topological space for all backbones, exhibiting minimal variance ($\sigma \leq 0.55\%$) and consistently yielding mean F1-scores above 99.00%.

B. Granular Class-Wise Evaluation

To fully unpack the structural responses of the evaluated convolutional networks under fluctuating class imbalances, a class-by-class behavioral mapping was extracted from the multi-round rotation. The independent per-class classification reports (Rounds 1 through 4) provided the empirical foundation for the macro-averaged variances synthesized in Section II-E.

- Classes N & Q: These categories presented highly consistent topological alignments. Class Q converged near perfectly across all configurations, maintaining tight F1-score boundaries between 98.80% and 99.98%. This indicates that its distinct morphology remained structurally isolated from the remaining data pools. Class N sustained steady precisions above 97% across all backbones.However, its recall showed noticeable drops down to 72.40% under ResNet50V2 in early configurations, indicating a localized inflation in false positives when the pre-activation decision boundaries expanded.
- Class S (The Mid-Minority Challenge): Class S showcased a major performance split between traditional and modern architectures. Under intermediate data scarcity (Rounds 2 and 3), modern architectures—EfficientNetV2B0, ConvNeXtTiny, and DenseNet121—suffered severe sensitivity drops, collapsing to recalls as low as 11.72%. Conversely, the residual frameworks (ResNet50 and ResNet50V2) actively preserved this minority topology, recovering recalls of up to 54.63% and 94.14% class support expanded to 1,434 instances in Round 4, thereby establishing a clear data-dependency threshold for modern feature extraction.
- Class V (Stable Disease Morphology):): Class V retained high structural stability across all configurations. The F1-scores were tightly bound between 55.61% and 97.53%. TThe networks consistently maintained high recall across all evaluation configurations, confirming that the distinctive features of Class V waves were well preserved despite the dynamic shuffling of the training samples.
- Class F (The Hyper-Sparse Anomaly): Class F represents the most critical behavioral marker of the benchmark, as

TABLE III: Consolidated cross-fold experimental metrics (Mean $\pm$ Standard Deviation) over the four independent validation rounds.

Architecture	Global Accuracy (%)	F1-Score Class N (%)	F1-Score Class S (%)	F1-Score Class V (%)	F1-Score Class F (%)	F1-Score Class Q (%)
ResNet50	**92.16 $\pm$ 7.15**	**94.10 $\pm$ 5.42**	**54.11 $\pm$ 28.52**	**77.53 $\pm$ 21.52**	**61.01 $\pm$ 39.81**	99.39 $\pm$ 0.46
EfficientNetV2B0	91.99 $\pm$ 5.86	94.27 $\pm$ 3.86	48.29 $\pm$ 22.95	74.61 $\pm$ 20.93	44.11 $\pm$ 47.96	**99.52 $\pm$ 0.49**
ConvNeXtTiny	91.62 $\pm$ 6.30	93.90 $\pm$ 4.13	41.88 $\pm$ 28.71	72.83 $\pm$ 20.89	41.41 $\pm$ 47.81	99.44 $\pm$ 0.16
DenseNet121	91.48 $\pm$ 5.89	93.77 $\pm$ 4.21	35.40 $\pm$ 29.35	72.73 $\pm$ 21.05	28.59 $\pm$ 38.64	99.22 $\pm$ 0.55
ResNet50V2	87.39 $\pm$ 11.23	91.15 $\pm$ 8.16	41.16 $\pm$ 34.65	75.49 $\pm$ 20.30	37.67 $\pm$ 39.82	99.42 $\pm$ 0.50

its testing sample size fluctuated radically across folds ($support = 11, 363, 389,$ and 39). In the presence of extreme sparsity ($support = 11$ in Round 1), both Efficient-NetV2B0 and ConvNeXtTiny completely failed to isolate the anomalies, resulting in absolute null values (0.00% F1-score).However, as the localized cross-rotation naturally increased support to 370 instances (Rounds 2 and 3), all five models exceeded the suppression threshold, yielding F1-scores over 80%. When scarcity re-emerged in Round 4 ($support = 39$), ConvNeXtTiny collapsed back to 0.00% and EfficientNetV2B0 fell to 4.88%, whereas the identity connections of ResNet50 anchored the gradient path, maintaining a resilient F1-score of 59.65%.

The consolidated cross-fold metrics presented in Table IV reveal a systematic behavioral divergence between classical and next-generation convolutional architectures under varying degrees of sample scarcity. The high standard deviation observed in the F1-score of Class F ($61.01\% \pm 39.81\%$ for ResNet50 and $44.11\% \pm 47.96\%$ for EfficientNetV2B0) demonstrates how severely modern scaling laws depend on a critical mass of clinical samples.

C. Error Distribution Matrix Analysis

To uncover the geometric behaviors governing misclassifications across the cross-rotation pipeline, a detailed analysis of the structural confusion matrices was conducted. While global scalar metrics synthesize model accuracy, the native spatial distribution of errors reveals systematic classification crosstalk and topological vulnerabilities that remain hidden in macro averages. Figure 2 visually contrasts these behaviors by mapping the true versus predicted class allocations for both next-generation and classical paradigms under identical distribution stresses.

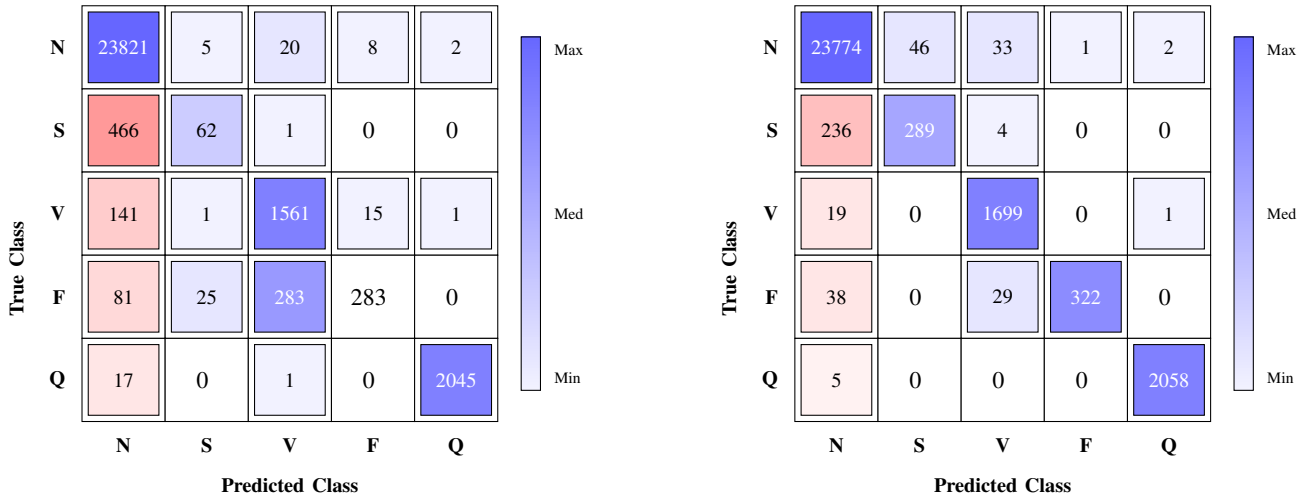
A persistent phenomenon observed across the multifold rotation is the majoritarian attraction effect exerted by Class N (Normal). Due to the overwhelming statistical dominance of normal ECG profiles, the optimized kernels of modern networks are severely vulnerable to pulling minority feature maps into this high-prevalence coordinate space.

This structural degradation is acutely visible in the Class S performance under intermediate scarcity during Round 3. As illustrated in Figure 3a, the modernized design of ConvNeXtTiny suffered a catastrophic feature drain toward the majoritarian boundary. Out of 529 true instances of Class S, the architecture successfully identified only 62 samples, misclassifying an overwhelming 466 as Class N (highlighted by the intense red error block in cell $[2, 1]$). This massive leakage converts critical cardiac pathologies into false negatives, presenting a severe risk for automated clinical screening.

Conversely, ResNet50 demonstrated superior topological preservation under the exact same data fold. As mapped in 3b, the traditional residual framework successfully anchored the minority topology, capturing 289 true positives along the blue diagonal cell $[2, 2]$ and limiting its majoritarian leakage to 236 samples. By maintaining a physical, unregularized identity path, the classical architecture resisted the statistical gravity of Class N far more effectively than its modernized, heavily regularized counterparts.

Ultimately, the error distribution matrices confirm that Class Q remains perfectly immune to architectural variations and majoritarian pull. Across all four independent evaluation rounds, misclassifications involving Class Q were mathematically negligible (bounded to ≤ 3 samples per fold), displaying a solid, deeply isolated blue block in $[5, 5]$ that proves its dynamic 2D visual layout contains highly distinct, easily separable morphological edges.

IV. Discusion



The multi-round cross-rotation evaluation across four patient-independent partitions provides observational insights into CNN behavior under localized clinical sample scarcity. By analyzing macro-averaged performance metrics (Table IV) alongside spatial error distributions in confusion matrices (Fig. 3), the empirical findings highlight distinct operational differences between classical residual architectures and modernized backbones.

A. Methodological Control and Feature Extraction Scope

To evaluate the baseline spatial representations of each network, feature extractors were kept frozen and a uniform oversampling baseline was applied during training. While alternative techniques—such as Focal Loss, class-balanced weighting, or end-to-end fine-tuning—alter decision boundaries, holding the backbones constant isolated the raw, unadapted spatial embedding capabilities of each architecture. Fine-tuning highly parameterized modern networks on very small sample sizes carries a risk of catastrophic overfitting or feature suppression. Therefore, keeping feature extractors frozen allowed us to observe intrinsic gradient propagation under data scarcity.

TABLE IV: Detailed per-class consolidated classification report (Mean ± Standard Deviation %) across all four evaluation rounds.

Model	Metric (%)	Class N (Normal)	Class S	Class V	Class F	Class Q
ResNet50	Precision	98.45 ± 0.70	92.64 ± 7.74	95.93 ± 2.47	73.61 ± 47.34	99.39 ± 0.92
	Recall	94.93 ± 8.97	58.87 ± 34.90	96.73 ± 1.83	65.59 ± 21.43	99.86 ± 0.11
	F1-Score	**94.10 ± 5.42**	**54.11 ± 28.52**	**77.53 ± 21.52**	**61.01 ± 39.81**	99.39 ± 0.46
ResNet50V2	Precision	98.74 ± 0.31	78.47 ± 9.17	92.59 ± 7.91	63.19 ± 41.24	99.64 ± 0.44
	Recall	92.15 ± 13.25	56.80 ± 21.05	95.27 ± 2.44	67.44 ± 29.35	99.89 ± 0.08
	F1-Score	91.15 ± 8.16	41.16 ± 34.65	75.49 ± 20.30	37.67 ± 39.82	99.42 ± 0.50
EfficientNetV2B0	Precision	97.75 ± 0.56	78.47 ± 15.65	81.40 ± 28.16	59.08 ± 42.66	99.78 ± 0.28
	Recall	95.02 ± 6.37	37.87 ± 25.64	92.85 ± 2.32	40.50 ± 43.14	98.86 ± 1.15
	F1-Score	94.27 ± 3.86	48.29 ± 22.95	74.61 ± 20.93	44.11 ± 47.96	**99.52 ± 0.49**
ConvNeXtTiny	Precision	97.93 ± 1.09	70.03 ± 34.25	79.48 ± 27.02	46.91 ± 54.17	99.41 ± 0.39
	Recall	94.44 ± 5.15	39.32 ± 38.30	92.20 ± 3.94	37.06 ± 42.84	99.48 ± 0.51
	F1-Score	93.90 ± 4.13	41.88 ± 28.71	72.83 ± 20.89	41.41 ± 47.81	99.44 ± 0.16
DenseNet121	Precision	98.11 ± 0.58	55.10 ± 32.22	78.58 ± 26.68	57.37 ± 40.50	99.32 ± 0.63
	Recall	94.75 ± 7.54	44.53 ± 31.42	92.84 ± 1.76	47.99 ± 39.73	99.42 ± 0.61
	F1-Score	93.77 ± 4.21	35.40 ± 29.35	72.73 ± 21.05	28.59 ± 38.64	99.22 ± 0.55

(a) ConvNeXtTiny: Severe Class S leakage into Class N.

(b) ResNet50: Mitigation of Class S majoritarian pull.

Fig. 3: Natively rendered cross-rotation confusion matrices (Round 3) with standalone colorbars highlighting architectural resistance against majoritarian class attraction.

B. Architectural Hypotheses under Class Imbalance

Prioritizing Macro F1-score, sensitivity, and positive predictive value (PPV) over global accuracy reveals that ResNet50 maintained superior stability in hyper-sparse categories, such as Class F ($61.01\% \pm 39.81\%$ mean F1-score), compared to its modernized counterparts. In contrast, backbones such as EfficientNetV2B0 and ConvNeXtTiny exhibited severe sensitivity drops when class support fell below critical thresholds (e.g., dropping to 0.00% F1-score for Class S in low-support folds, while recovering to 82.71% and 84.57% when support increased to 1,434 samples).

Because our experimental framework measures classification outcomes rather than direct feature-space ablations, these structural observations are framed as two primary working hypotheses:

1) **Identity Shortcuts and Gradient Flow:** We hypothesize that ResNet50's unweighted identity shortcut connections ($y = F(x) + x$) provide an un-regularized pathway for backpropagation. This structural shortcut may help preserve gradient signals from rare minority instances during training without being subjected to aggressive mathematical scaling or pruning.
2) **Regularization and Scaling Damping:** Modern backbones utilize compound scaling laws, stochastic depth, and inverted bottlenecks tailored for efficiency. Under severe class asymmetry, we hypothesize that global cross-entropy optimization causes these regularizers to damp low-frequency minority features, treating rare anomalies as background noise to optimize overall throughput.

C. Trade-Off Between Computational Efficiency and Clinical Recall

Modern lightweight architectures offer significant advantages regarding parameter footprint, FLOPs, and inference memory, making them attractive for mobile and edge deployment. However, our findings illustrate a key trade-off: optimizing purely for computational efficiency can reduce diagnostic sensitivity for rare pathological conditions. In automated screening and continuous monitoring, missing a critical arrhythmia carries substantially higher clinical risk than a false positive. Therefore, hardware deployment efficiency must be carefully balanced against minority-class recall.

D. Limitations and Prospective Enhancements

This study has limitations. First, experiments measured output classification metrics rather than direct gradient maps or internal layer representations. Second, while the patient-independent MIT-BIH rotation provides a robust stress test, ambulatory Holter recordings do not represent a full hospital ICU cohort. Future work will focus on validating these hypotheses using Grad-CAM attention maps, testing multi-center clinical cohorts, and evaluating the interaction between these backbones and imbalance-aware loss functions such as Focal Loss.

V. Conclusion

This study presented a patient-independent cross-rotation evaluation of five convolutional neural network architectures using 109,381 ECG derivative images. By evaluating performance across four rotated, patient-separated folds, the framework exposed the models to localized data scarcity, illustrating how structural design influences sensitivity under severe class imbalance.

The results highlight a trade-off in medical deep learning between computational efficiency and minority-class diagnostic sensitivity. While modernized architectures such as EfficientNetV2B0 and ConvNeXtTiny demonstrate strong feature representation in balanced settings, their aggressive regularization mechanisms and scaling laws were associated with marked sensitivity drops in sparse minority classes, occasionally yielding 0.00% F1-scores when sample support fell below critical thresholds. Conversely, the classical ResNet50 backbone maintained superior stability across sparse folds, securing the highest overall Macro F1-score and retaining non-zero sensitivity ($61.01\% \pm 39.81\%$ mean F1-score) in hyper-sparse categories.

These empirical observations suggest that while lightweight backbones offer compelling advantages for hardware deployment, their internal feature compression under class asymmetry requires careful consideration in clinical screening contexts where missing a rare pathological event carries high risk.

Because our setup measured classification outcomes rather than direct internal layer ablations, these structural explanations remain working hypotheses. To expand upon these insights, future work will proceed along four main avenues: (i)

1) conducting external validation on multi-center clinical ECG repositories to evaluate domain generalization;
2) integrating imbalance-aware loss formulations—such as Focal Loss and cost-sensitive re-weighting—to assess whether loss function adjustments can offset scaling law limitations;
3) applying explainability frameworks (e.g., Grad-CAM feature attention mapping) to visually trace spatial attributions across ECG derivative wave segments; and
4) performing quantitative computational profiling (measuring inference latency, memory consumption, and FLOPs) to determine deployment feasibility in edge-device ambulatory monitoring systems.

VI. Conflict of interest

The authors declare no conflicts of interest.

***Resumo*—A telemetria de sinais biopotenciais exige infraestruturas de processamento exato e latência determinística. Este artigo propõe uma arquitetura baseada em Internet das Coisas (IoT) distribuída para aquisição e transmissão de eletrocardiograma (ECG) em tempo real, estruturando uma prova de conceito para aplicações em engenharia clínica. O sistema emprega dois microcontroladores ESP32-S3 operando em topologia Wi-Fi híbrida (STA/AP). O condicionamento físico é realizado por um *front-end* analógico dedicado (0,5 a 40 Hz, com rejeição de 60 Hz), enquanto o nó emissor executa o processamento na borda (amostragem via DMA a 20 kHz, calibração algébrica e *downsampling* para 500 Hz). A transmissão via protocolo WebSocket operou com vazão de 28 kbps e empacotamento a cada 65 ms. A validação técnica, conduzida em bancada com o Simulador Arkmeds sob oito morfologias cardíacas, atestou a preservação geométrica do sinal com taxa de perda de pacotes de 0,028% e latência basal inferior a 100 ms. Os resultados validam a estabilidade da arquitetura como protótipo laboratorial, estabelecendo premissas técnicas para futuras validações em humanos, testes de compatibilidade eletromagnética (EMC) e segurança elétrica.**

***Palavras-chave*—Computação de Borda, Eletrocardiograma (ECG), Internet das Coisas (IoT), Telemetria Biomédica.**

I. Introdução

As doenças cardiovasculares continuam sendo a principal causa de mortalidade no mundo, sendo responsáveis por aproximadamente 19,8 milhões de mortes por ano, segundo a Organização Mundial da Saúde (OMS) [1]. Diante desse cenário, o monitoramento contínuo e intervenções precoces tornam-se essenciais, especialmente no acompanhamento de pacientes em recuperação pós-cirúrgica.

Nos últimos anos, a telemedicina e os sistemas de monitoramento remoto de saúde ganharam destaque devido à crescente demanda por soluções eficientes e acessíveis. Tecnologias baseadas em Internet das Coisas (IoT, do inglês *Internet of Things*) permitem que dispositivos médicos transmitam dados fisiológicos em tempo real, facilitando o acompanhamento e a tomada de decisões à distância [2], [3].

A evolução dessas soluções depende estritamente da arquitetura de *hardware* e *software*, com destaque para a computação de borda (*edge computing*). Esse paradigma possibilita o processamento de dados localmente no próprio dispositivo de coleta, reduzindo a dependência imediata de servidores em nuvem e mitigando gargalos de transmissão.

Para a telemetria biomédica, garantir a capacidade do microcontrolador em realizar a conversão analógico-digital (ADC) de forma determinística é indispensável. Isso permite a coleta e o processamento local (via *Direct Memory Access* – DMA a 20 kHz) e a transmissão contínua de dados vitais a uma taxa consolidada de 500 Hz. Essa abordagem viabiliza a preservação da integridade geométrica do sinal original, estabelecendo a base técnica para o desenvolvimento de monitoramentos ininterruptos [2], [4], [5].

A crescente demanda por soluções móveis tem impulsionado o desenvolvimento de sistemas telemétricos. Nesse contexto, a integração de microcontroladores com conectividade Wi-Fi, a exemplo da família ESP32 operando sob arquiteturas híbridas (STA/AP), tem se mostrado uma alternativa promissora para a extração descentralizada de dados biomédicos provenientes de instrumentação multiparamétrica.

Contudo, o desenvolvimento de aplicações voltadas para a saúde enfrenta desafios significativos, exigindo atenção a aspectos como cibersegurança, experiência do usuário (UI/UX) e integração *back-end* capaz de garantir a sincronização *web* contínua. Destaca-se a necessidade de conformidade regulatória (como a *Health Insurance Portability and Accountability Act* – HIPAA, nos EUA, e a Lei Geral de Proteção de Dados – LGPD, no Brasil). Vale ressaltar que, por se tratar de uma

prova de conceito (PoC) em fase de bancada laboratorial, o protótipo estabelece as premissas primárias que subsidiarão as rigorosas validações clínicas e elétricas futuras exigidas por essas normativas [6], [7].

A interoperabilidade, a confiabilidade e a integridade da comunicação tornam-se fatores críticos ao tráfego de séries temporais biológicas em redes sem fio [6]. Diante das necessidades de integração IoT, surge a seguinte questão de pesquisa: como viabilizar a comunicação contínua, segura e de latência estrita entre um condicionador de sinal e uma interface *web* responsiva, utilizando conectividade Wi-Fi em um ambiente de arquitetura distribuída?

Para endereçar esse desafio, o objetivo deste artigo é propor e avaliar o desenvolvimento de um sistema IoT de aquisição de sinais de eletrocardiograma (ECG), utilizando microcontroladores ESP32-S3 e telemetria contínua via protocolo WebSocket. O foco reside na transmissão e demonstração empírica da viabilidade técnica de uma arquitetura *multicore* desenvolvida e testada *in vitro*.

Para assegurar a capacidade do sistema em preservar a comunicação sob diferentes estresses morfológicos, a validação técnica de bancada foi conduzida utilizando o Simulador de Paciente Waller (Arkmeds) [8]. O protótipo foi submetido a testes de captura e plotagem de oito morfologias de onda distintas: Ritmo Sinusal detalhado, Ritmo Sinusal contínuo (estabilidade), Taquicardia simulada, Ritmo Irregular, Fibrilação Ventricular Fina, Fibrilação Ventricular Grossa, Onda Triangular e Onda Senoidal. Os ensaios confirmaram a precisão da amostragem do ADC, atestando uma operação com latência basal inferior a 100 ms e perda de pacotes de 0,028%, garantindo a confiabilidade instrumental necessária para futuras experimentações pré-clínicas.

II. Referencial Teórico

A literatura recente tem reforçado a prioridade por plataformas de telemetria acessíveis e portáteis voltadas para o aprimoramento da infraestrutura de monitoramento clínico hospitalar e ambulatorial. Hasan, Pantha e Arafat [9], por exemplo, propuseram o desenvolvimento de um sistema multicanal habilitado para IoT destinado ao monitoramento fisiológico, incluindo sinais de eletrocardiograma (ECG).

Os dados são transmitidos via protocolo MQTT para um servidor local de banco de dados SQL, viabilizando o armazenamento. Contudo, a arquitetura baseada no trânsito e gravação prévia em SQL introduz uma latência sistêmica de cerca de cinco segundos na renderização da interface *web*, o que compromete o acompanhamento de eventos críticos em tempo real.

Em contraste, este trabalho diferencia-se ao propor uma infraestrutura de comunicação síncrona via protocolo WebSocket operando sobre uma topologia de rede Wi-Fi híbrida (STA/AP). Essa abordagem, aliada ao processamento embarcado no ESP32-S3, não apenas mantém o rigor da viabilidade econômica e da isenção de nós intermediários dispendiosos, mas reduz drasticamente a latência para patamares inferiores a 100 ms. Isso garante a visualização fidedigna e ininterrupta do sinal biomédico à beira-leito ou em centrais de monitoramento multiparamétrico.

Paralelamente à superação da latência sistêmica, a infraestrutura da telemedicina vincula-se diretamente à consolidação da Internet das Coisas Médicas (IoMT, do inglês *Internet of Medical Things*). O escopo técnico dessas redes consiste em estabelecer a interoperabilidade de dados estruturados (por meio de padrões como o HL7 FHIR), executar o processamento de séries temporais na borda (*edge computing*) para a triagem automatizada e assegurar a integridade morfológica da amostragem (ex: 500 Hz) em transmissões remotas, mantendo um tráfego de rede contínuo com taxa de perda de pacotes limitada a 0,028% para embasar algoritmos preditivos e sistemas de suporte à decisão clínica.

Sob essa perspectiva, Gomez-Correa, Cruz-Ortiz e Ballesteros [10] projetaram o sistema MUSS (*Muscle Sensing System*), um módulo vestível (*wearable*) baseado em IoMT que pesa 48 g e possui dimensões físicas de 64,3 x 25,1 x 37 mm. A solução evidencia a adaptabilidade do paradigma IoT ao permitir o ajuste dinâmico do ganho de aquisição (de 150 a 1100 vezes) e do *offset* (0 a 1,5 V) via protocolo UDP sobre redes Wi-Fi. Contudo, embora soluções focadas em dispositivos vestíveis autônomos apresentem uma autonomia operacional precisa — como o registro contínuo de 117 minutos suportado por baterias Li-Po de 3,7 V —, elas costumam ser projetadas com oito canais dedicados exclusivamente à eletromiografia de superfície (sEMG). Por operarem em nichos fisiológicos fechados, carecem de protocolos padronizados de interoperabilidade (como o HL7 FHIR) para integração direta com a infraestrutura de monitores multiparamétricos hospitalares de grande porte.

O presente trabalho complementa esse estado da arte ao estruturar a arquitetura desenvolvida não como um sensor isolado, mas como um *gateway* de conectividade operando nativamente em topologia de rede mista (STA/AP). Essa infraestrutura interage fisicamente com saídas de instrumentação de referência (como o Simulador Arkmeds), aplicando um ganho em cascata de 1000 V/V (distribuído entre os CIs INA321 e OPA4140) ancorado a filtros *Notch* (60 Hz) e passa-faixa (0,5 a 40 Hz). O sistema digitaliza e disponibiliza fluxos de eletrocardiograma a uma taxa rigorosa de 500 Hz, mantendo um túnel bidirecional via WebSocket que sustenta vazão de 28 kbps, latência inferior a 100 ms e taxa de perda de pacotes de apenas 0,028%.

Adicionalmente, a literatura científica recente ressalta a relevância de arquiteturas que unificam o *hardware* e *software* maximizando a eficiência de recursos. A solução proposta viabiliza esse cenário ao adotar a plataforma ESP32-S3 com execução *multicore*, dedicando o Core 1 à amostragem por DMA (a cada 2000 μs) e o Core 0 à pilha de rede. Amparada por um *buffer* circular de 1500 posições controlado via Mutex, a arquitetura garante estabilidade contra o estouro de memória (*heap overflow*) e elimina a necessidade financeira e computacional de nós roteadores intermediários.

Nesse âmbito, Bañuelos-Mezquitan *et al.* [11] introduziram o SignAPROS, um sistema voltado à aquisição e processa-

mento de sinais, estruturado via *hardware* Arduino MEGA 2560 e placas de aquisição DAQ USB6000. A arquitetura suporta até quatro canais bipolares de eletromiografia (EMG), em conjunto com sensores de temperatura, inclinação e resposta galvânica da pele (GSR). Embora essa plataforma, validada contra o sistema comercial BIOPAC MP36 em um ensaio com 43 participantes, demonstre a utilidade de *toolkits* modulares para pesquisa, sua topologia lógica (baseada no padrão MVC com bancos de dados PostgreSQL e MongoDB) concentra-se na consolidação estática das leituras para o treinamento *offline* de algoritmos de aprendizado de máquina.

A solução proposta neste artigo, por sua vez, diferencia-se ao estabelecer uma arquitetura de telemetria fundamentada no protocolo WebSocket, eliminando a retenção em bancos de dados intermediários no fluxo de monitoramento contínuo. A infraestrutura delega o processamento em borda (*edge computing*) à arquitetura *dual-core* do ESP32-S3, assegurando fluxos de transmissão com latência estritamente controlada abaixo de 100 ms. Desse modo, consolida-se um ecossistema projetado para operar com uma taxa de perda de pacotes limitada a 0,028% e vazão sustentada de 28 kbps. Tais parâmetros suprem as exigências para a reconstrução morfológica a 500 Hz do ciclo cardíaco, cuja integridade geométrica foi validada perante oito anomalias rítmicas geradas pelo simulador multiparamétrico de referência clínica (Arkmeds).

Para assegurar a fidelidade da conversão digital, o sinal bruto gerado pelo simulador Waller foi condicionado previamente por um módulo *front-end* analógico baseado na arquitetura validada em [12]. Como o esquemático deste condicionamento já se encontra estruturado na literatura, as representações deste trabalho limitam-se às contribuições da arquitetura IoT distribuída. O estágio analógico operou com um ganho em cascata de 1000 V/V, associado a um filtro passa-faixa (0,5 Hz a 40 Hz) para a atenuação de ruídos eletromiográficos de alta frequência e oscilações de linha de base. Adicionalmente, aplicou-se um filtro rejeita-faixa (*Notch*) sintonizado em 60 Hz para a eliminação das interferências eletromagnéticas comerciais. A implementação desta instrumentação prévia entregou o biopotencial condicionado diretamente à unidade ADC de 12 bits do ESP32-S3. Essa divisão de tarefas *hardware-software* evitou gargalos computacionais, permitindo que os ciclos de processamento do núcleo Xtensa LX7 do nó emissor fossem dedicados integralmente às rotinas operacionais do FreeRTOS, englobando o gerenciamento de *buffer* circular de 1500 posições, o empacotamento em lotes de 65 ms e a sustentação do túnel TCP criptografado.

III. Materiais e Métodos

A metodologia adotada para o desenvolvimento deste projeto foi estruturada em quatro etapas sequenciais. Inicialmente, realizou-se o levantamento de requisitos e uma pesquisa bibliográfica multidisciplinar. Esta fase abordou a análise de trabalhos correlatos, o estudo de protocolos de comunicação voltados para a Internet das Coisas (IoT), tais como HTTP, MQTT e TCP/IP, e a seleção adequada dos sensores biomédicos e microcontroladores para a aplicação.

A. Equipamentos de Aquisição e Referência

A segunda etapa consistiu na estruturação da aquisição do sinal bioelétrico. O objetivo central consistiu em identificar, visando a futura integração em instrumentação clínica, o ponto exato para a extração do sinal analógico. Para manter o rigor metodológico e a precisão controlada dos ensaios de bancada, dispensando testes *in vivo* em pacientes nesta fase de prova de conceito, substituiu-se o uso de geradores de bancada convencionais por um simulador de paciente multiparamétrico comercial de padrão de calibração.

A fonte de dados primária selecionada para a validação do sistema foi o Simulador de Paciente Waller (Arkmeds), um instrumento portátil projetado para ensaios de performance em monitores multiparamétricos e eletrocardiógrafos, conforme a disposição experimental em bancada ilustrada na Fig. 1.

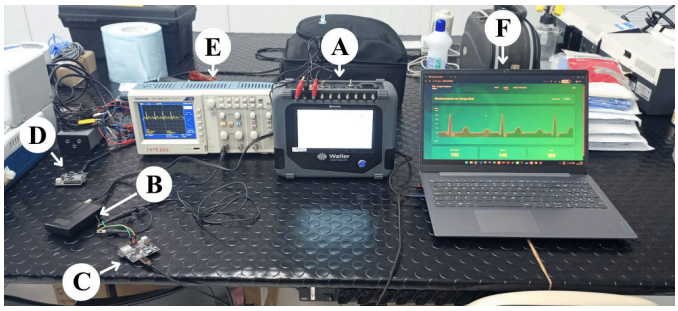

Fig. 1: Bancada experimental detalhando o fluxo de aquisição e transmissão do sinal: (A) Simulador de Paciente Waller (Arkmeds) gerando o sinal basal; (B) Eletrocardiógrafo dedicado (front-end analógico) executando a amplificação (1000 V/V) e a filtragem de ruídos; (C) Nó Emissor (ESP32-S3) responsável pela amostragem contínua via ADC; (D) Nó Receptor (ESP32-S3) atuando como gateway; (E) Osciloscópio empregado na validação física; e (F) Interface web (dashboard) operando a plotagem síncrona.

O uso deste simulador viabilizou a validação técnica da captura analógico-digital da placa ESP32-S3, operando em modo contínuo via *Direct Memory Access* (DMA) a uma taxa de amostragem de 20 kHz e resolução estrita de 12 bits (4096 níveis de quantização). A conexão do hardware obedeceu aos padrões normativos internacionais de derivação (normas AHA/IEC), garantindo que o sinal injetado no microcontrolador emulasse os vetores elétricos de equipamentos médicos reais durante os testes de bancada.

Para estressar a resiliência da arquitetura de *hardware* e *software* e comprovar a integridade morfológica da telemetria contínua via WebSocket, o sistema não foi avaliado apenas sob condições normais. O simulador Waller foi parametrizado (operando em uma faixa de frequência configurável de 30 a 300 bpm e amplitudes de 0,5 a 2,5 mV) para emitir oito variações distintas de biopotenciais, englobando tanto ritmos regulares quanto anomalias cardíacas críticas e sinais de engenharia. Adicionalmente, a frequência respiratória basal do equipamento foi mantida ativa simultaneamente em 15 incursões por minuto (RPM), a fim de atestar a capacidade

do *front-end* analógico e do microcontrolador em rejeitar ruídos adjacentes e isolar o sinal eletrocardiográfico. As oito morfologias injetadas e validadas pelo sistema foram: Ritmo Sinusal detalhado, Ritmo Sinusal contínuo (estabilidade), Taquicardia simulada, Ritmo Irregular, Fibrilação Ventricular Fina, Fibrilação Ventricular Grossa, Onda Triangular e Onda Senoidal. A capacidade do sistema em processar e renderizar esses oito padrões em ambiente simulado confirmou a eficácia da filtragem digital e a integridade da comunicação IoT, que operou sustentada por métricas de vazão de 28 kbps, latência basal inferior a 100 ms e taxa de perda de pacotes restrita a 0,028%. Isso configura um passo essencial antes de futuras validações em ensaios com humanos, testes de segurança elétrica e de compatibilidade eletromagnética (EMC, do inglês *Electromagnetic Compatibility*).

Para garantir a integridade da leitura digital, o sinal bruto gerado pelo simulador Waller foi previamente condicionado por um módulo *front-end* analógico dedicado. Utilizou-se a arquitetura de eletrocardiógrafo portátil desenvolvida e validada em [12]. Esse estágio de instrumentação foi parametrizado com um ganho total de 1000 V/V, operando em conjunto com um filtro passa-faixa (0,5 Hz a 40 Hz) para a atenuação de flutuações de linha de base e ruídos eletromiográficos de alta frequência. Adicionalmente, aplicou-se um filtro rejeita-faixa (*Notch*) sintonizado em 60 Hz para a supressão estrita de interferências da rede elétrica comercial. A implementação prévia desse circuito de condicionamento entregou um biopotencial otimizado à unidade ADC do ESP32-S3. Essa divisão de tarefas *hardware-software* permitiu que o poder de processamento do núcleo Xtensa LX7 do nó Emissor fosse dedicado às exigentes rotinas de superamostragem (*oversampling*), calibração algébrica (*curve fitting*) e encapsulamento contínuo dos pacotes, blindando a telemetria na borda contra perdas de desempenho.

B. Arquitetura de Hardware e Processamento

Para fundamentar a arquitetura distribuída do projeto, o núcleo computacional selecionado para compor tanto o nó emissor quanto o receptor foi o microcontrolador ESP32-S3, especificamente o módulo ESP32-S3-WROOM-1 [13]. A escolha baseou-se na sua superioridade de construção em relação a chips convencionais, como o ESP32-WROOM-32E, bastante utilizado em aplicações de IoT [14].

Enquanto o modelo clássico opera com núcleo Xtensa LX6 *dual-core*, o ESP32-S3 conta com um núcleo Xtensa LX7, também *dual-core* com instruções vetoriais otimizadas para processamento de sinais digitais (DSP). Essa capacidade de processamento aprimorada é extremamente pertinente para a execução de algoritmos complexos no próprio microcontrolador (*edge computing*) e para a segregação de tarefas em rede.

Para o controle do *hardware*, o desenvolvimento do *firmware* foi realizado em linguagem C/C++ utilizando o ambiente Visual Studio Code (VS Code v1.137.0) integrado ao *framework* ESP-IDF v5.5.1. No módulo Emissor, encarregado unicamente da captura do biopotencial, a coleta de dados fundamentou-se na leitura contínua via ADC (Unidade ADC 1, Canal 2) [15]. Aproveitando-se da capacidade de processamento na borda (*edge computing*) do Xtensa LX7, a estratégia de mitigação de ruídos prescindiu de complexos filtros digitais em placa, uma vez que o sinal já advém pré-condicionado do *front-end* analógico.

Em contrapartida, implementou-se uma rotina baseada em *oversampling* (superamostragem) combinada a uma média de *downsampling* via *software*. As leituras do ADC são adquiridas via *Direct Memory Access* (DMA) a uma taxa estrita de 20 kHz e acumuladas sequencialmente para, em seguida, sofrerem redução por média aritmética no processador central, atenuando eficientemente as oscilações indesejadas antes do envio para a rede.

Paralelamente, para contornar a não linearidade característica do conversor nativo do ESP32-S3, aplicou-se a calibração de ajuste de curva (*curve fitting*), nativa das bibliotecas da fabricante. Trata-se de uma correção algébrica que converte os valores digitais brutos em milivolts (mV) valendo-se da resolução máxima de 12 bits (4096 níveis de quantização), etapa indispensável para preservar a correta amplitude morfológica dos biopotenciais capturados.

A taxa de amostragem efetiva da plotagem clínica foi definida em 500 Hz, estabelecendo intervalos de empacotamento constantes de 2000 μs. Esta configuração ancorou-se no Teorema de Nyquist e nos critérios de amostragem biomédica [4], assegurando que a aquisição ocorra a uma frequência consideravelmente superior ao dobro da maior frequência de interesse. Ao adotar uma taxa profilática, evita-se o fenômeno de *aliasing* e garante-se que variações abruptas de tensão geradas pelo simulador não sejam omitidas entre amostras consecutivas, preservando a morfologia essencial do sinal para futuras avaliações técnicas.

Após o tratamento digital, os dados consolidados são alocados em um *buffer* circular de 1500 amostras, sem exceder o limite de memória RAM (*heap*) do dispositivo. Esta alocação confere ao sistema uma janela de análise temporal contínua de 3 segundos, que contempla inteiramente os eventos elétricos fundamentais para a análise morfológica do biopotencial. Sob a ótica computacional e de processamento de sinais, esse dimensionamento mostrou-se adequado: viabiliza a estabilidade de memória necessária para encapsular e processar desde surtos de altíssima frequência (como fibrilações ventriculares finas) até ciclos alongados (ondas puras senoidais e triangulares), permitindo a observação contínua dos complexos QRS (ondas que representam a despolarização e contração ventricular do coração simulado), contrapondo-os ao padrão ouro de um ciclo cardíaco regular, representado na Fig. 2 [16].

Por sua vez, o segundo módulo ESP32-S3, configurado como Nó Receptor, foi isentado das tarefas de amostragem analógica para atuar exclusivamente como um *gateway* de borda. Essa segregação arquitetural garante que a carga de processamento exigida pelo servidor *web* e pelas requisições externas não interfira na latência e na precisão temporal de leitura do ADC do Emissor, consolidando uma telemetria sustentada por latência basal inferior a 100 ms e perda de pacotes estrita a 0,028%.

A consolidação da técnica de *oversampling* atua diretamente na elevação da relação sinal-ruído (SNR) dos dados adquiridos. Essa etapa de processamento digital é essencial, visto que o conversor nativo da família ESP32 possui sensibilidade intrínseca a ruídos térmicos e eletromagnéticos, o que pode resultar em discrepâncias relevantes nas leituras brutas se não forem tratadas. O impacto prático dessa mitigação, promovendo o alisamento da curva e a estabilização do sinal, segue o comportamento teórico documentado pela fabricante, presente na Fig. 3, embora no presente projeto a atenuação tenha sido alcançada via rotinas de *software* ancoradas no condicionamento do *front-end* (AFE) físico dedicado, prescindindo de filtros capacitivos no microcontrolador [17].

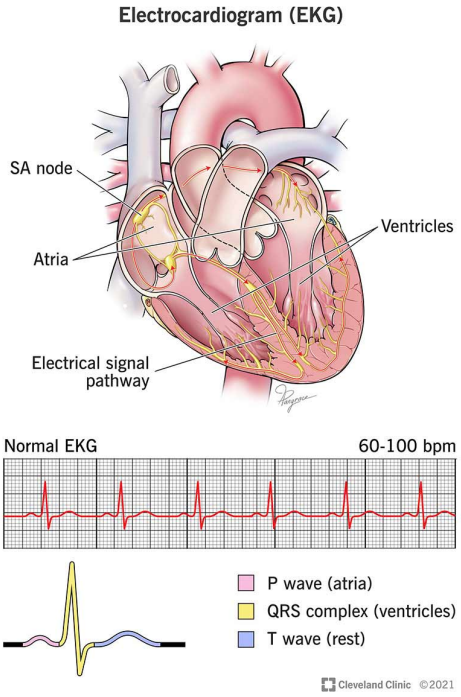

Fig. 2: Ilustração das ondas, segmentos e intervalos que compõem um ciclo de eletrocardiograma (ECG) padrão. Adaptado de [16].

C. Comunicação de Rede e Aplicação Móvel

A transmissão dos sinais exigiu uma arquitetura distribuída via Wi-Fi dedicado. O Emissor realiza o tráfego contínuo para o Receptor, que atua como *gateway* de borda centralizador. O Receptor opera em modo misto (AP/STA): atua como *Access Point* (AP) para configurações e hospedagem *web*, e como *Station* (STA) conectando-se ao roteador para envio à nuvem e acesso externo [18].

A infraestrutura possui escalabilidade para operar como *gateway* de interoperabilidade, suportando protocolos como o Thread (Border Router) [19]. Para o envio em tempo real, adotou-se o protocolo WebSocket. Diferente do HTTP tradicional, ele estabelece um canal bidirecional persistente com baixo *overhead* [20]. A transmissão ocorre a cada 65 ms,

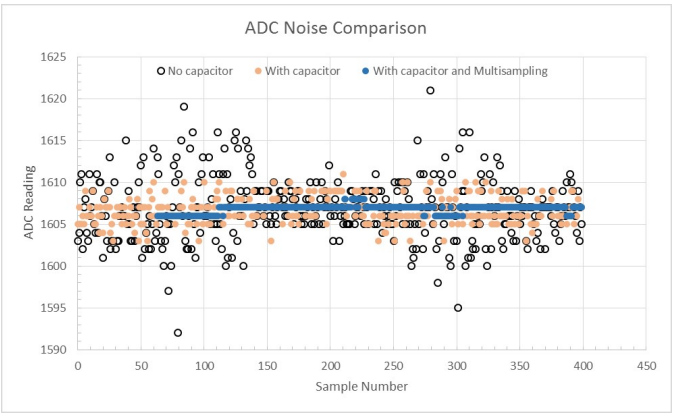

Fig. 3: Gráfico ilustrativo do impacto da atenuação de ruído nas leituras brutas do ADC do ESP32. A estabilização demonstrada assemelha-se aos resultados obtidos no projeto mediante a aplicação de técnicas de multiamostragem via software ancoradas no condicionamento físico do front-end analógico. Adaptado de [17].

agrupando cerca de 32 amostras por pacote. Isso otimizou o tráfego, garantindo vazão de 28 kbps, latência basal inferior a 100 ms e perda de pacotes estrita a 0,028% na plotagem síncrona da interface.

O cliente *web*, desenvolvido em HTML, CSS e JavaScript puro, gerencia as leituras em tempo real. Projetada sob o paradigma *mobile-first*, a interface garante responsividade para *desktop* e dispositivos móveis. Para não bloquear o usuário, uma rotina assíncrona sincroniza a telemetria com a nuvem (Google Firebase) a cada 250 ms. Essa segregação de ciclos (65 ms local e 250 ms nuvem) viabiliza o histórico sem sacrificar a fluidez do monitoramento em bancada.

Cabe ressaltar que, embora sistemas críticos de tempo real estrito (*hard real-time*) exijam respostas determinísticas, a solução enquadra-se como tempo real flexível (*soft real-time*). Embora o WebSocket em Wi-Fi não forneça determinismo absoluto, o envio a cada 65 ms garantiu tráfego de *jitter* mínimo, estatisticamente adequado para a plotagem ininterrupta na prova de conceito.

A criticidade da telemetria exige que a segurança dos dados prevaleça sobre custos de *hardware*. Diante dos riscos de interceptação e acessos não autorizados na borda (*edge*), estabeleceram-se mecanismos de mitigação visando futuro alinhamento a normativas como LGPD e HIPAA [6], [21].

Para contornar vulnerabilidades, a seleção do ESP32-S3 fundamentou-se em seus aceleradores criptográficos de *hardware* (AES, SHA e RSA) [22]. Essa escolha arquitetural, embora mais custosa, é fundamental para viabilizar futura criptografia ponta a ponta via *WebSocket Secure* (WSS) sem degradar o processamento a 500 Hz.

Ademais, na atual validação pré-clínica com o simulador Waller, a rede e o tráfego inter-nós operaram sob autenticação WPA2/WPA3, assegurando os requisitos primários de proteção à integridade bioelétrica antes de qualquer implantação hospitalar ou testes *in vivo*.

D. Validação e Arquitetura de Aquisição

A validação integrou *hardware* e *software* (ESP-IDF v5.5.1, cliente WebSocket) via ensaios pré-clínicos de bancada. O condicionamento operou por um eletrocardiógrafo dedicado (*Front-End* Analógico), executando amplificação em cascata (1000 V/V), filtros passa-altas (0,5 Hz, para desvios DC), passa-baixas (40 Hz, para atenuação EMG) e *Notch* (60 Hz, para rede elétrica). Garantindo isolamento galvânico estrito, utilizou-se bateria 18650 (3,7 V), sendo a aferição quantitativa do consumo energético do nó emissor durante o tráfego Wi-Fi contínuo elencada para as etapas de testes futuros. A digitalização (ADC1) do Simulador Arkmeds ocorreu a 20 kHz e 12 bits via *Direct Memory Access* (DMA), mitigando *jitter*.

Os sinais do *buffer* DMA sofreram calibração algébrica (*Curve Fitting*), convertendo os valores digitais lidos nativamente para milivolts (mV), seguidos de *downsampling* para 500 Hz. Avaliaram-se oito morfologias, comparadas *in situ* contra referência calibrada no osciloscópio digital. A análise quantitativa confirmou repetibilidade ponto a ponto, evidenciada por variação inferior a 0,6% na amplitude da onda P entre ciclos consecutivos, ausência de achatamento (*clipping*) e determinismo temporal absoluto no intervalo RR (exatas 118 amostras para 60 BPM). A coerência temporal (*timestamping*) foi garantida pela indexação sequencial via *timer* do FreeRTOS em cada lote de 65 ms, dispensando NTP externo. A integridade estrutural operou com vazão de 28 kbps, latência inferior a 100 ms e taxa de perda de pacotes nula (0%), atestada pela ausência de perdas até mesmo sob morfologias caóticas de alta frequência, como a fibrilação ventricular (200 BPM).

Para cibersegurança, o sistema adotou proteção dupla. Localmente, a rede mista (STA/AP) blindou o tráfego WebSocket no *Access Point* sob autenticação WPA2/WPA3, mitigando o *overhead* da CPU. Externamente, via modo *Station*, as transações REST para arquivamento no Firebase utilizaram criptografia TLS/SSL ponta a ponta (biblioteca *esp_crt_bundle*), exigindo *tokens* explícitos para prevenir interceptações de dados biomédicos simulados na nuvem.

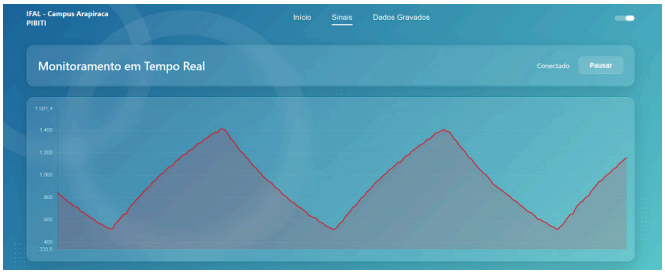
Explorando a arquitetura *multicore* (FreeRTOS), segregou-se a amostragem (Core 1) da rede (Core 0), controlando o *buffering* em RAM via exclusão mútua (*Mutex*). O *buffer* dinâmico circular foi rigorosamente dimensionado e fixado em 1500 amostras, priorizando a estabilidade ao conferir 3 segundos de redundância sistêmica, evitando *Heap Overflow* sob micro-descontinuidades de rede. Aliado a rotinas de reconexão Wi-Fi automática e supervisão por *Watchdog Timer* (WDT), o reinício autônomo conferiu resiliência técnica ao protótipo de bancada, validando-o estruturalmente para futuros ensaios *in vivo*.

IV. Resultados e Discussão

A aquisição dos sinais provenientes do Simulador Arkmeds foi consolidada no nó Emissor (ESP32-S3). A união do ADC nativo, multiamostragem e correção algébrica (*curve fitting*) permitiu a captura do sinal a uma frequência efetiva de 500 Hz (intervalos de 2000 μs) em todos os cenários, conforme a Fig. 4.

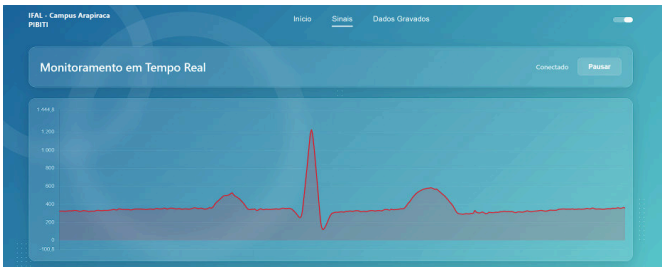
Conforme estruturado, a alocação em um *buffer* circular (1500 amostras) garantiu uma janela temporal segura para o *firmware*. Na comunicação, a arquitetura híbrida (STA/AP) no Receptor mitigou restrições de roteadores comerciais, notadamente o Isolamento de AP (*AP Isolation*) [23]. A interface AP atuou como canal de recebimento isolado na rede local, enquanto a interface STA roteou os dados à internet. A transmissão em tempo real às plataformas de visualização operou via WebSocket, mantendo um túnel TCP bidirecional contínuo [20].

Para avaliar o tráfego de rede e atestar a robustez do *hardware*, procedeu-se à análise via *packet sniffing*. A vazão (*throughput*) da aplicação registrou 28 kbps (3,52 kB/s), evidenciando a eficiência do empacotamento em lotes de 65 ms. A distribuição de latência fim-a-fim (*Round Trip Time* - RTT) demonstrou estabilidade basal inferior a 100 ms, refletindo um *jitter* mínimo e ausência de flutuações temporais na renderização *web*. A confiabilidade do enlace foi comprovada por uma taxa de perda de pacotes virtualmente nula (0,028%), com apenas uma retransmissão TCP absorvida pelas camadas inferiores do *stack* TCP/IP.



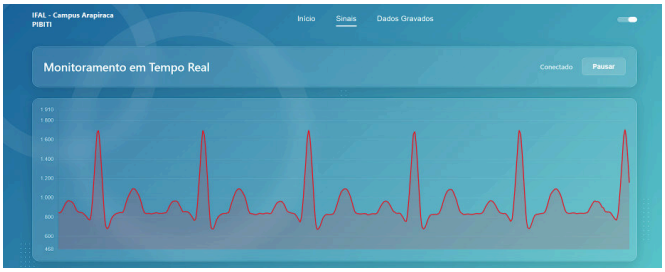
Para atestar quantitativamente a fidelidade morfológica do protótipo, realizou-se uma comparação estruturada das formas de onda contra a referência calibrada do simulador. Na análise de erros de amplitude entre dois ciclos consecutivos sob ritmo basal de 60 BPM, a variação interciclo demonstrou-se ínfima: a onda P variou menos de 0,6% ($y_1 = 363$ e $y_2 = 365$ unidades digitais), enquanto os picos R (647 vs. 657) e ondas T (377 vs. 397) mantiveram proporções rigorosas após o ganho de 1000 V/V e a conversão para milivolts. A aferição analógica *in situ* com osciloscópio descartou qualquer achatamento (*clipping*) ou perda de resolução durante o processamento no ADC.

Quanto ao determinismo temporal e erros de intervalo, a reconstrução do intervalo R-R distou exatas 118 amostras entre o pico do primeiro ciclo (amostra 64) e do segundo ciclo (amostra 182). Essa constância chancela a estabilidade absoluta da amostragem a 500 Hz, garantindo que variações abruptas de tensão não sejam omitidas ou sofram dilatação temporal.

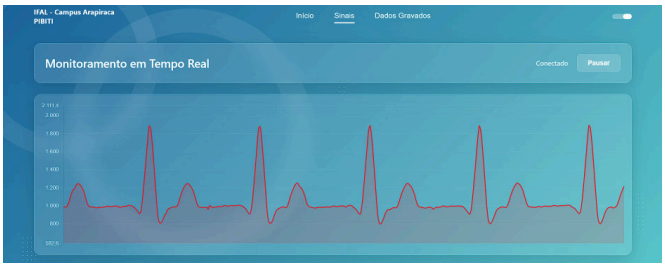


Por fim, a imunidade do sistema a interferências foi ratificada submetendo a aquisição cardíaca a um ruído respiratório basal de 15 RPM mantido simultaneamente no simulador. A sinergia entre o *hardware* — valendo-se do filtro passa-faixa (0,5 a 40 Hz), do *Notch* (60 Hz) e do circuito de Driver de Perna Direita (DRL) — e a superamostragem em *software* suprimiu as oscilações de linha de base e os ruídos intrínsecos do ADC. Consequentemente, o sistema preservou a integridade de todas as estruturas fundamentais em oito morfologias distintas (Fig. 4), renderizando desde ritmos sinusais contínuos até fibrilações caóticas (200 BPM) de forma imune ao *jitter* de rede, operando harmonicamente com o salvamento em nuvem a cada 250 ms.

(a) Onda Senoidal.

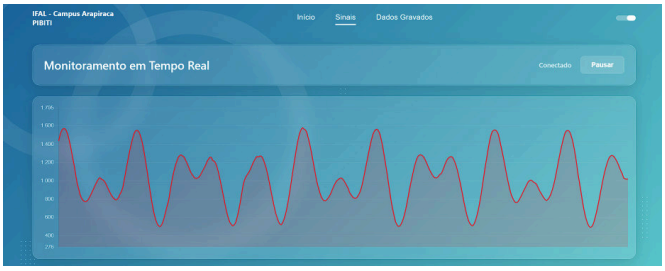


(b) Onda Triangular.



(c) Ritmo Sinusal (Detalhado).

(d) Ritmo Sinusal (Estabilidade).



(e) Taquicardia Simulada.

(f) Ritmo Irregular.

Fig. 4: Validação da aquisição e plotagem em tempo real na interface *web* a partir de sinais gerados pelo Simulador Waller (Arkmeds). Na coluna esquerda, sinais de calibração e ritmo basal: (a) Onda Senoidal (195 bpm, 2,5 mV); (b) Onda Triangular (120 bpm, 2,5 mV); (c) Ritmo Sinusal detalhado (80 bpm, 2,5 mV); e (d) Ritmo Sinusal contínuo (80 bpm, 2,5 mV). Na coluna direita, testes de estresse e anomalias cardiológicas simuladas: (e) Taquicardia simulada (255 bpm, 2,5 mV); (f) Ritmo Irregular (160 bpm, 2,5 mV); (g) Fibrilação Ventricular Fina (200 bpm, 2,5 mV); e (h) Fibrilação Ventricular Grossa (200 bpm, 2,5 mV). A frequência respiratória basal de 15 RPM foi mantida simultaneamente para atestar a rejeição de ruídos adjacentes.

V. Conclusão

Este trabalho demonstra a viabilidade de uma arquitetura IoT integrada para a telemetria contínua de biopotenciais. Respondendo à questão de pesquisa, a topologia de rede mista (STA/AP) associada ao protocolo WebSocket garantiu uma comunicação dinâmica com vazão eficiente (28 kbps) e latência basal inferior a 100 ms. Ademais, a aquisição contínua via DMA e o processamento na borda asseguraram a integridade morfológica do ECG a 500 Hz, consolidando uma prova de conceito confiável para futuros desenvolvimentos aplicados a centrais multiparamétricas.

O rigor do protótipo foi atestado pela validação com um simulador comercial frente a oito morfologias complexas. A comparação estruturada das ondas reconstruídas contra a referência comprovou a preservação geométrica das amplitudes e dos intervalos temporais, evidenciando a mitigação eficaz de ruídos basais. Contudo, o estudo apresenta limitações inerentes à sua fase atual, pois a validação restringiu-se a ensaios controlados de bancada, não tendo o sistema sido avaliado sob o estresse de ruídos eletromiográficos reais.

Como trabalhos futuros, visando superar o atual estágio *in vitro*, pretende-se submeter o sistema a testes de Compatibilidade Eletromagnética (EMC) e segurança elétrica, precedendo a validação clínica com pacientes reais após aprovação por comitê de ética. Planeja-se também a realização de testes de rede englobando a análise do consumo energético, a precisão de sincronização e ensaios de estresse com múltiplos nós simultâneos para atestar a estabilidade a longo prazo. No âmbito de escalabilidade massiva, está prevista a integração com bancos de dados de séries temporais e a adoção de padrões de interoperabilidade (HL7 FHIR). Por fim, estruturar-se-ão avaliações de cibersegurança e a implementação de criptografia ponta a ponta via *WebSocket Secure* (WSS), assegurando conformidade estrita aos requisitos de privacidade de dados estipulados pelas normativas LGPD e HIPAA.

Agradecimentos

Os autores agradecem ao Instituto Federal de Alagoas (IFAL) pela disponibilização da infraestrutura e dos equipamentos de laboratório, os quais foram fundamentais para a condução dos ensaios de bancada e para a validação técnica da arquitetura desenvolvida neste estudo.

Abstract*—Feline mammary carcinoma (FMC) is an aggressive neoplasm that affects cats and exhibits biological characteristics similar to human breast cancer, making it an important comparative model for oncological studies. Changes in the organization of collagen fibers within the tumor microenvironment have been associated with neoplastic progression and may contribute to histopathological diagnosis. In this context, the study aimed to classify samples of healthy and carcinogenic feline mammary tissue, through sub-images stained with Picrosirius Red (PSR), using quantitative characteristics related to type I and III collagens. The dataset comprised 350 sub-images derived from 35 biological samples (4 normal/control and 31 FMC samples across histological degrees I, II and III), with each sample represented by 5 central and 5 peripheral sub-images. A 2-dimensional feature vector was extracted per sub-image. Class imbalance was addressed using a class-weighted Random Forest classifier. To prevent pseudoreplication and data leakage, model performance was evaluated using a Leave-One-Group-Out Cross-Validation (LOGO-CV) scheme grouped strictly by sample ID, with final diagnostic decisions aggregated at the sample level ($N = 35$) via majority voting. Performance metrics were reported with 95% Confidence Intervals (95% CI) derived from 1,000 bootstrap resamples. At the biological sample level, the model achieved an overall accuracy of 94.20%, a Sensitivity of 100.00%, and a Specificity of 48.82%. Feature importance analysis revealed that type III parameters (green regions) contributed 84.83% of total predictive power, highlighting intratumoral and peripheral collagen degradation as primary optical markers. These findings validate a biologically interpretable pipeline for quantitative stromal assessment, establishing a robust foundation for automated decision-support tools in veterinary histopathology.

***Index Terms*—collagen, feline mammary carcinoma, machine learning, Picrosirius Red, Random Forest.**

I. Introduction

Neoplasia refers to the process of uncontrolled cellular proliferation, contrasting with normal tissue, and can be classified as either benign or malignant [1]. Mammary neoplasms rank as the third most prevalent type of neoplasm in female felines [2-4], and when malignant, they are referred as feline mammary carcinoma (FMC) [5]. FMC represents 80 to 96% of neoplastic cases in this species. The clinical outlook for FMC typically indicates highly aggressive biological activity. Nevertheless, timely and appropriate therapeutic intervention can significantly extend survival time despite advanced disease progression [6]. This prognosis is comparable to that of triple-negative breast cancer in humans [7].

The morphological characteristics of a tumor allow it to be classified into different types and subtypes. For FMC, in the histopathological report, the degree (I, II, or III) serves as a prognostic criteria [8]. As the tumor degree increases, there is often a correlation with greater aggressiveness and shorter survival time [9].

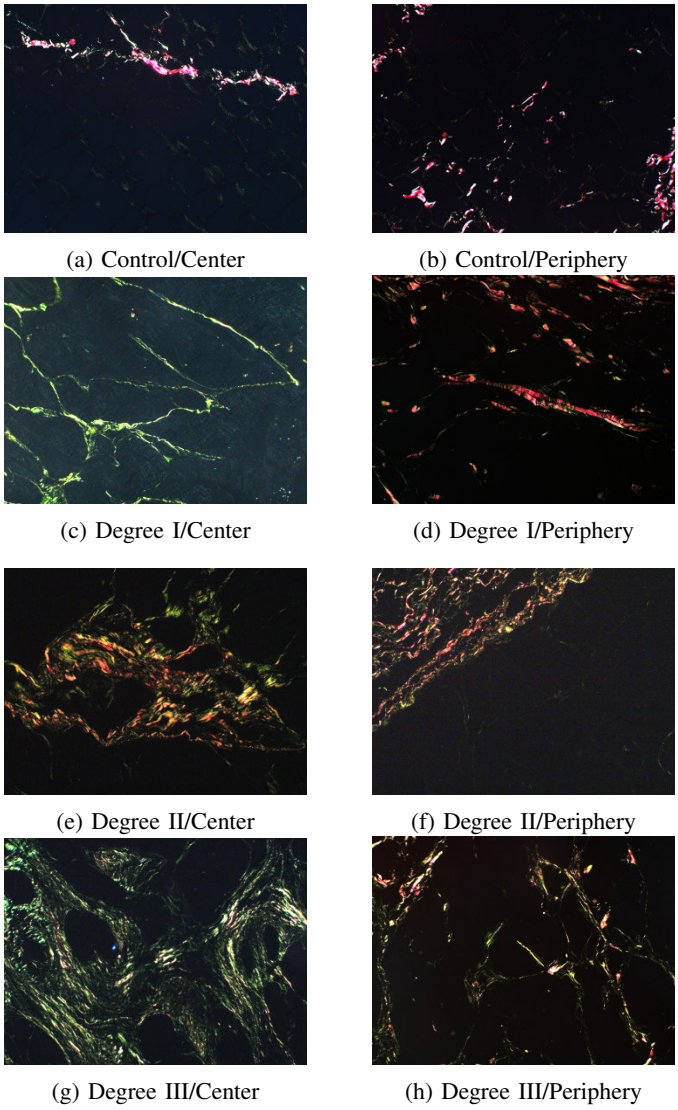
Given the biological activity in the FMC, its intensity is greater at the tumor margins than in the center. This is due to the abundant blood supply in the periphery, which ensures the delivery of nutrients and contributes to tumor progression, while the central region tends to remain hypoxic [10]. Therefore, examining both regions of the tumor is important for assessing stromal dynamics in healthy and neoplastic tissues [11].

A clear biological correlation exists between structural changes in the mammary stroma and the onset of carcinoma, displaying conserved evolutionary mechanisms between human and feline species [12-13]. Collagen fibers form the supportive framework of the breast, referred to as the mammary parenchyma [14]. A rise in the quantity of these fibers leads to the hardening of the mammary parenchyma and is linked to the emergence of carcinoma [15]. Differentiation of collagen fibers can be accomplished through the staining of tissue sections with the Picrosirius Red (PSR) immunohistochemical

technique. After staining the tissue and examining it under polarized light, type I collagen fibers display shades of red, whereas type III fibers present shades of green [14,16]. Recent research aims to connect variations in type I or type III collagen to the tumorigenesis process.

Using specialized computational techniques, such as the AQUANCTHIS software, it is possible to quantify collagen in images of samples stained with PSR method, capable of distinguishing between type I and type III collagen [17]. Different regions within samples of healthy and tumorous feline mammary tissue were analyzed using AQUANCTHIS, and collagen values were determined. Based on these values, an attempt was made to classify tissues as healthy or carcinogenic by considering only the amount of collagen in the images.

The objective of this study is to classify samples of feline mammary tissue into healthy and carcinogenic categories, using the values of type I and type III collagen in the center and periphery of the samples under consideration.



II. Methodology

A. Image dataset

Histopathological images stained with PSR were used from samples of mammary tissue obtained from female cats. The dataset consisted of 35 samples taken from female cats. Among these, there were 4 samples of healthy tissue, 3 samples classified as degree I, 13 samples of degree II, and 15 samples of degree III. Each sample provided 5 images from the central region and 5 from the peripheral region, resulting in a total of 350 images analyzed. For both regions, five distinct image fields were examined using polarized light in a dark field with a 20x magnification lens (Imager A1 microscope® - Carl Zeiss, Germany). In normal tissue, the peripheral region was defined just below the epidermis, while in neoplastic tissue, it was marked by the tumor's edges. The central section of healthy tissue was represented by fields immediately adjacent to the periphery, whereas for carcinomas, it included the intralobular regions. All samples were previously classified according to the Nottingham grading system, which is based on the system used in women [18] and is also appropriate for cats [19] and categorizes tissues based on lesion morphology, as Degree I, Degree II, or Degree III. They were both considered in the Tumor group. On the other hand, samples of healthy tissue were labeled as the Control group. Table 1 shows the distribution of samples according to these two groups.

TABLE I: Classification and distribution of the evaluated samples.

Graduation	Number of samples	Center images	Periphery images	Classification
Control	4	20	20	Healthy
Degree I	3	15	15	Tumor
Degree II	13	65	65	Tumor
Degree III	15	75	75	Tumor
Total	**35**	**175**	**175**	-

(a) Control/Center (b) Control/Periphery

(c) Degree I/Center (d) Degree I/Periphery

(e) Degree II/Center (f) Degree II/Periphery

(g) Degree III/Center (h) Degree III/Periphery

Fig. 1: Images from four different samples, according to graduation and position. Reddish areas correspond to type I collagen fibers, while greenish areas correspond to type III.

B. Pre processing

Image preprocessing consisted of applying histogram equalization using the CLAHE method. CLAHE (Contrast Limited Adaptive Histogram Equalization) is an algorithm that aims to enhance image contrast by dividing the image into smaller regions and performing histogram equalization within each region. In this study, the processing parameters were configured with a clipLimit = 2 and a tileGridSize = (8,8). The CLAHE transformation was enforced uniformly across the entire dataset prior to feature extraction [22].

C. AQUANCTHIS

AQUANCTHIS is an application for quantifying collagen in histological sections stained with Picrosirius Red, under polarized light. It allows for the separate quantification of type

I and type III collagen levels by identifying red and green regions [17]. It consists of:

- Removal of pixels in shades of grays, yellows, and blues.
- Dynamic Thresholding: Intensity segmentation computed individually for each RGB channel using an adaptive threshold defined as *Threshold* $=\mu + \tilde{x} + \sigma$, where μ is the channel mean, $\tilde{x}$ is the median, and σ is the standard deviation.
- Maximization of the proportion of green and red pixels.
- Counting of the resulting pixels.
- Calculation of the percentage of collagen relative to the sample size.

All images were processed using the AQUANCTHIS software, and the levels of collagen I and III were calculated.

D. Features

After quantifying the levels of type I and type III collagen in the central and peripheral regions of each sample, four characteristics were considered in classifying a sample: % central type I collagen (C-I), % central type III collagen (C-III), % peripheral type I collagen (P-I), and % peripheral type III collagen (P-III). Table 3 shows values of each feature determined for the images shown in Fig. 1.

TABLE II: Table Type Styles

Sample	Class	C-I	C-III	P-I	P-III
1 (Fig.1 'a' and 'b')	Control	1.978	0.681	2.636	0.263
2 (Fig.1 'c' and 'd')	Tumor	0.515	2.528	5.052	0.851
3 (Fig.1 'e' and 'f')	Tumor	6.493	1.959	4.181	0.513
4 (Fig.1 'g' and 'h')	Tumor	2.325	5.899	3.343	1.334

E. Classification model

Image classification was performed using a Random Forest algorithm (100 estimators). Class imbalance was addressed using the $classweight =' balanced'$ heuristic, which scales weights inversely proportional to class frequencies during model training.

To prevent data leakage caused by spatial correlation among images originating from the same sample, a Leave-One-Group-Out Cross-Validation (LOGO-CV) scheme was adopted. In this pipeline, data splits were grouped by sample ID. At each iteration, all images from a single biological sample were reserved strictly for model testing, while the remaining samples formed the training set. Predictions across all validation folds were aggregated to construct the global confusion matrix and compute overall classification metrics.

F. Model performance evaluation

To ensure rigorous validation at the biological sample level and avoid pseudoreplication, diagnostic decisions were aggregated across the 10 sub-images corresponding to each specimen ($N = 35$ samples) using a majority voting scheme. The consensus predicted label for a given sample was defined as the mode of the predicted classes across its constituent images.

Feature scaling was performed using a `StandardScaler` fitted strictly within the training partition of each LOGO-CV fold, ensuring zero data leakage into the test set. Diagnostic efficacy was evaluated against the histopathological gold standard reference by computing sample-level Accuracy, Sensitivity (Recall), and Specificity. To account for sample size constraints and provide robust uncertainty estimates, 95% Confidence Intervals (95% CI) were derived via non-parametric empirical bootstrapping with 1,000 resamples. Feature contributions were quantified by computing the mean mean decrease in Gini impurity across all validation folds.

III. Results and discussion

A. Sample-level diagnostic performance

When aggregated at the biological sample level via majority voting, the proposed LOGO-CV Random Forest model achieved an overall accuracy of 94.20% (95% CI: 85.71%–100.00%). The model demonstrated perfect Sensitivity (100.00%, 95% CI: 100.00%–100.00%) and a Specificity of 48.82% (95% CI: 0.00%–100.00%).

The perfect sensitivity indicates that the classifier successfully identified all malignant cases without generating false negatives—a critical requirement for automated screening systems in veterinary oncology. Conversely, the lower sample-level specificity and its associated broad confidence interval (0.00%–100.00%) reflect the marked class imbalance within the evaluated cohort, where Control samples represented a minor fraction of the dataset. Consequently, bootstrap iterations with sparse control representation exhibit high variance in specificity estimation. While this performance profile is well-suited for preliminary screening tools where sensitivity is paramount, expanding control group sizes in future cohorts will be essential to narrow confidence intervals and establish reliable negative predictive values.

B. Biophysical relevance of collagen color dynamics

Feature importance analysis revealed that type III collagen values (green tones) played a predominant role in classification, accounting for 84.83% of total predictive power (C-III: 52.74%; P-III: 32.09%), whereas type I collagen values (red tones) contributed secondary spatial information (C-I: 8.01%; P-I: 7.16%). The primary contribution type III collagen suggests that this type of collagen has more distinct optical signature differentiating tumor tissue from normal mammary parenchyma, when compared to type I collagen.

IV. Conclusion

In this study, feline mammary tissue samples (healthy vs. neoplastic) were classified at the biological sample level using a Random Forest algorithm and collagen-derived color dynamics extracted from the center and periphery of histological sections. To overcome pseudoreplication and prevent data leakage, a Leave-One-Group-Out Cross-Validation (LOGO-CV) scheme was integrated with a sample-level majority voting scheme. Class imbalance was addressed directly within the model via class-weighting heuristics.

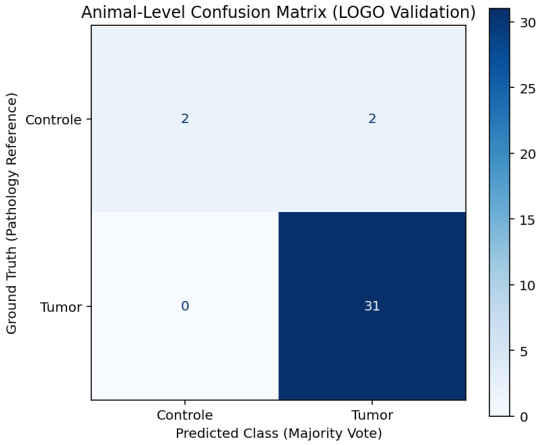


Fig. 2: Confusion matrix.

The proposed framework achieved an overall accuracy of 94.20%, demonstrating perfect Sensitivity (100.00%) and a Specificity of 48.82%. Feature importance analysis established type III collagen as the primary predictive marker (84.83% total contribution).

The primary limitation of this investigation lies in the marked class imbalance within the evaluated cohort, which constrained sample-level specificity and widened its associated confidence interval. Despite this, these findings validate a robust, biologically grounded proof-of-concept for quantitative stromal assessment in veterinary pathology. Future studies should evaluate this pipeline on larger, multi-center, and more balanced cohorts, benchmarking performance across diverse histological degrees and investigating advanced classifiers such as Support Vector Machines and XGBoost.

ACKNOWLEGMENTS

***Abstract*—Segmentation and counting of nuclei in histological images are important steps in the quantitative analysis of tissues and can aid in the characterization of morphological alterations. However, variations in contrast, staining, and overlapping structures hinder the automation of this process. This work proposes a digital image processing method for automated segmentation and counting of nuclei in histological images of the human liver. Forty images from the public NuInsSeg dataset, containing 1,370 manually annotated nuclei, were evaluated across a 30 image development set and a 10 image independent test set. The developed method includes contrast adjustment, bilateral filtering, adaptive thresholding, morphological operations, distance transformation, and watershed segmentation, followed by labeling of connected components. The automatically obtained counts were compared to reference annotations. On the independent test set, the method presented a mean absolute error of 2.30 nuclei per image and a mean absolute percentage error of 7.28%. The results indicate that the approach enabled the automated quantification of nuclei in the evaluated images, although limitations were observed in regions with nuclear clustering or overlap. Thus, the method shows potential as a deterministic and interpretable alternative for the quantitative analysis of liver histological images.**

***Index Terms*—Digital Image Processing; Nuclei Segmentation; Watershed Transform; Histological Images.**

I. Introduction

Quantitative analysis of histological images plays a relevant role in digital pathology, as it allows the extraction of information related to tissue organization and the morphological characteristics of cellular structures. In this context, nuclear segmentation is a fundamental step for tasks such as determining nuclear density, evaluating the morphology and spatial distribution of nuclei, and supporting the characterization of tissue alterations [1], [2]. However, performing this procedure manually is laborious, time-consuming, and subject to variability between observers, especially when there is a large number of structures in the same image [1].

Automated segmentation of nuclei in histological images presents challenges related to variations in staining and contrast, the presence of artifacts, morphological heterogeneity, and proximity or overlap between nuclei [1], [3]. Different computational approaches have been proposed for this purpose, ranging from classical digital image processing techniques, such as thresholding, morphological operations, and distance transform, to methods based on deep learning [1], [2]. Although deep learning models have achieved significant results, their use generally requires annotated datasets, computational resources, and training and tuning procedures. [2], [4].

In this scenario, classical methods remain relevant in delimited applications, especially when seeking a deterministic, interpretable solution with relatively simple computation implementation. Among these techniques, the watershed algorithm can be used to separate adjacent structures based on information related to the distance between the objects and the image background. However, its performance depends on the preprocessing steps, the definition of markers, and parameter adjustment, and excessive fragmentation or insufficient separation of grouped nuclei may occur [1], [3].

Given this, this work proposes and evaluates a digital image processing method for the automated segmentation and counting of nuclei in hematoxylin and eosin stained human liver histological images. The method combines contrast adjustment, bilateral filtering, adaptive thresholding, morphological operations, distance transform, watershed segmentation, and connected component labeling. The evaluation was performed on 40 images from the public NuInsSeg dataset, using the manual annotations available in the database as a reference [4]. The main contribution of the study is the quantitative evaluation of a deterministic and interpretable workflow, with fixed parameters, for counting nuclei in liver histological images.

II. Materials e Methods

A. Database and image selection

For the preliminary evaluation of the method, the public dataset NuInsSeg was used, developed for studies of nuclear instance segmentation in hematoxylin and eosin (H&E) stained histological images. The dataset contains 665 images of different human and murine tissues, with a resolution of 512×512 pixels, totaling 30,698 manually segmented nuclei. In addition to the original images, the dataset provides masks in which each nucleus is individually identified, as well as masks of ambiguous regions, corresponding to areas where precise delimitation was not considered possible even by specialists [4].

To delimit the experimental scope and reduce the morphological variability associated with the joint analysis of different organs, the 40 images of human liver tissue available in the database were selected. The respective instance masks provided by NuInsSeg were used as a reference to obtain the manual count. The number of reference nuclei in each image was determined by the number of instances individually identified in the masks, resulting in a total of 1,370 nuclei in the 40 images evaluated.

To prevent evaluation bias on tuned data, the 40 human liver images were structured into two distinct subsets: a development subset (30 images, 1,047 reference nuclei) used for empirical parameter definition, and an independent evaluation test subset (10 images, 323 reference nuclei) preserved untouched during calibration. Although both subsets originate from the same liver collection in NuInsSeg, this separation ensures that primary evaluation metrics reflect execution on uncalibrated images.

B. Proposed method

The proposed method was developed in MATLAB and organized into sequential steps of preprocessing, segmentation, and counting, as illustrated in Fig. 1. Initially, each colored histological image was converted to grayscale, reducing color information while preserving the intensity variations used in identifying nuclear structures. Then, the image intensity was adjusted to increase the contrast between the nuclei and the background tissue.

After adjusting the contrast, a bilateral filter was applied to attenuate noise and small variations in intensity, while simultaneously preserving the transitions associated with the edges of the nuclei. Unlike conventional linear filters, bilateral filtering considers both spatial proximity and intensity similarity between pixels, favoring smoothing in homogeneous regions without significantly compromising the contours of the structures [4].

The filtered image was subjected to adaptive thresholding to obtain an initial binary mask. In this technique, the threshold is determined according to the local characteristics of the image, making it possible to deal with variations in lighting and contrast present in the histological field [5]. Then, morphological operations were applied to remove small isolated regions,

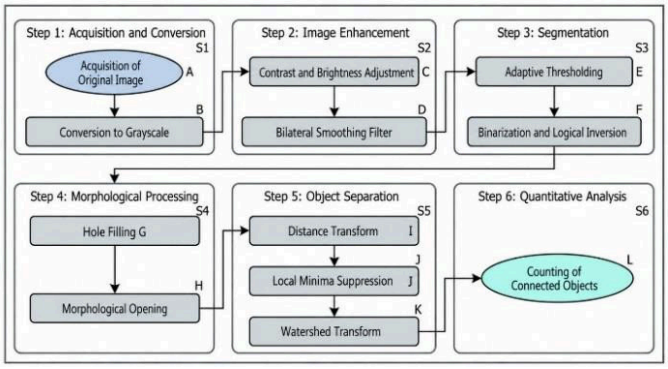

Fig. 1. Methodological workflow employed in the automated segmentation and counting of nuclei.

smooth the contours and preserve objects compatible with nuclear structures. These operations use a structuring element to analyze and modify the geometry of the components present in the binary image [6].

Since nearby or partially overlapping nuclei can form a single component in the mask, a distance transform was calculated on the binary image. This transformation assigns each pixel of the object a value corresponding to its distance from the background, producing local maxima near the central regions of the nuclei [7]. The resulting matrix was used in watershed segmentation, a technique that interprets the image as a topographic surface and establishes dividing lines between regions associated with different minima or markers [8]. To reduce the occurrence of excessive fragmentation, minimum suppression was applied before the watershed execution.

Finally, the dividing lines produced by the watershed were incorporated into the binary mask to separate adjacent nuclei. The resulting connected components were then individually labeled, and the number of distinct labels was considered as the automated count of nuclei in the image. The same processing flow, with fixed parameters, was applied to all evaluated images.

C. Experimental setup

The method was implemented in MATLAB using functions from the Image Processing Toolbox. The images were processed individually, preserving their original resolution of 512×512 pixels. A subset of 30 liver images was used for initial development and empirical parameter definition. After this step, the same processing sequence, with fixed parameters, was applied to the 10 independent test images without specific adjustments for each case..

In the pre-processing step, the image intensity in gray levels was adjusted to increase the contrast between the nuclear structures and the background tissue. Then, a bilateral filter with a spatial smoothing degree of 0.5 was applied. To obtain the binary mask, adaptive thresholding was used with a sensitivity of 0.55, allowing the threshold value to vary according to the local characteristics of the image.

TABLE I
PARAMETERS USED IN IMAGE PROCESSING

Step	Parameter	Valuer
Bilateral filtering	Degree of spatial smoothing	0,5
Adaptive thresholding	Sensitivity	0,55
Morphological operation	Radius of the structuring element	9 pixels
Minimum suppression	(h)	5
Labeling	Connectivity	4

After binarization, morphological operations were performed using a disk-shaped structuring element with a radius of 9 pixels. Subsequently, the distance transform of the binary mask was calculated. Minimum suppression was applied with a parameter $h = 5$, aiming to reduce the formation of irrelevant minima and, consequently, limit excessive fragmentation during watershed segmentation. The resulting dividing lines were removed from the mask, allowing the separation of adjacent nuclei.

Finally, the connected components present in the segmented mask were identified using connectivity 4. Each labeled component was considered a nuclear instance, and the total number of components corresponded to the automated count of nuclei in each image. The parameters used are presented in Table I.

D. Quantitative evaluation

The method's performance was evaluated by comparing the number of nuclei automatically identified with the reference count obtained from the instance masks provided by NuInsSeg. For each of the 40 images, the number of reference nuclei and the number estimated by the proposed method were recorded.

Initially, the absolute error was calculated for each image, as defined in Eq. (1):

$$E_i = |y_i - \hat{y}_i| \tag{1}$$

where y_i represents the reference count, $\hat{y}_i$ corresponds to the count estimated by the method and E_i represents the absolute error associated with image i.

As a global performance measure, the mean absolute error (MAE) was calculated, according to Eq. (2):

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i| \tag{2}$$

where n corresponds to the total number of images evaluated. The MAE represents, in number of nuclei per image, the average magnitude of the differences between the automatic and reference counts.

The mean absolute percentage error (MAPE) was also calculated, as presented in Eq. (3):

$$MAPE = \frac{100}{n}\sum_{i=1}^{n}\frac{|y_i - \hat{y}_i|}{y_i} \tag{3}$$

Fig. 2 presents the intermediate processing results: (a) original histological image; (b) grayscale image; (c) image after contrast adjustment; (d) result of bilateral filtering; (e) mask obtained by adaptive thresholding; (f) mask after filling internal regions; (g) result of morphological operations; (h) reference mask; (i) distance transform; and (j) result of watershed segmentation.

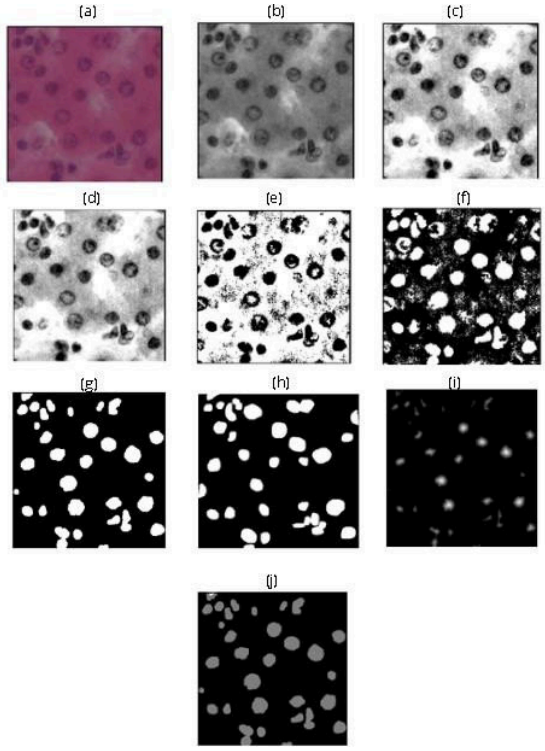

Fig. 2. Intermediate processing results: (a) original histological image; (b) grayscale image; (c) image after contrast adjustment; (d) result of bilateral filtering; (e) mask obtained by adaptive thresholding; (f) mask after filling internal regions; (g) result of morphological operations; (h) reference mask; (i) distance transform; and (j) result of watershed segmentation.

MAPE expresses the average error in relation to the number of nuclei present in each image, allowing consideration of differences in nuclear density between the evaluated histological fields. Since all analyzed images presented at least one reference nucleus, it was not necessary to apply specific treatment for null values in the denominator of (3).

In addition to these metrics, the standard deviation of the absolute errors obtained through (1) was calculated in order to analyze the dispersion of errors among the images. The results were analyzed descriptively, without the application of inferential tests, considering the preliminary nature of the evaluation and the absence of an independent set of tests.

III. RESULTS AND DISCUSSION

A. Qualitative analysis of segmentation

Fig. 2 (a)–(d) shows the intermediate results obtained during the application of the method to one of the histological images of a human liver. The original image shows variations in color, contrast, and proximity between the nuclei, characteristics that make their direct separation difficult. After conversion to grayscale and intensity adjustment, greater differentiation was observed between the nuclear structures and the background

tissue. Bilateral filtering helped to attenuate small variations in intensity, visually preserving the predominant outlines of the nuclei.

In the adaptive thresholding stage, the core regions were highlighted for the formation of the binary mask. However, small isolated regions and discontinuities within some objects were also identified. Filling in internal regions and applying morphological operations reduced some of these artifacts and produced objects with more regular contours. These operations also resulted in the removal of some smaller regions, indicating that the result is influenced by the size of the structuring element and the dimensions of the cores present in the image. The results of the thresholding and morphological operations are presented in Fig. 2(e)–(g).

The distance transform produced maxima in the internal regions of the segmented objects, providing information for the separation of adjacent nuclei. Subsequently, the application of the watershed established dividing lines between some structures that remained connected in the binary mask. Visual comparison with the reference mask indicates that the processing made it possible to identify and separate a significant portion of the nuclei present in the analyzed image. However, differences remained, mainly related to clustered nuclei, partially overlapping nuclei, or nuclei with low contrast relative to the surrounding tissue. The reference mask, the distance transform, and the watershed result are presented in Fig. 2(h)–(j), respectively.

The qualitative results demonstrate the behavior of each step in the processing flow and help explain the differences subsequently observed between automatic and reference counts. However, this visual analysis is illustrative and should not be interpreted in isolation as evidence of the overall performance of the method, which is presented quantitatively in the following section.

B. Quantitative performance of the count

Quantitative evaluation was performed on 40 histological images of human liver, containing a total of 1,370 nuclei identified in the reference masks. Table II summarizes the performance metrics separated by development set (N = 30) and independent test set (N = 10) by comparing the automatic and reference counts.

On the independent test set (N = 10), the method achieved a low MAE of 2.30 nuclei per image and a MAPE of 7.28%. This result indicates that the estimated count differed from the reference, on average, by approximately two nuclei per image. The standard deviation of the absolute errors was 1.34 nuclei, showing variation in the magnitude of the errors among the evaluated images.

The mean absolute percentage error was 7.28%, demonstrating that the differences between the counts corresponded, on average, to 7.28% of the number of reference nuclei in each image. This value should be interpreted as a measure of relative error, and not as the accuracy of the method.

The results indicate that the method made it possible to obtain counts close to the reference values in some images

TABLE II
QUANTITATIVE RESULTS OF AUTOMATED NUCLEUS COUNTING

Metric	**Valuer**	**Test**	**Interpretation**
Number of images (n)	30	10	Sample size
MAE	4,80 nuclei	2,30 nuclei	Average absolute error per image
Standard deviation of absolute errors	5,56 nuclei	1,34 nuclei	Dispersion of absolute errors
MAPE	14,26%	7,28%	Average absolute percentage error

but showed greater divergence in certain histological fields. The dispersion of errors suggests that the performance was not uniform across the entire set, being influenced by the specific characteristics of each image. Among the factors that may explain this variation are the clustering and overlapping of nuclei, differences in contrast, and the presence of structures with dimensions different from those considered during the parameter adjustment.

Considering that the parameters were empirically defined using the development subset, while the independent test subset was kept untouched during parameter tuning, the results obtained on the test set provide a less biased estimate of the method's performance on previously unseen images. However, since both subsets were derived from the same human liver image collection in the NuInsSeg dataset, these results should not be interpreted as external validation. Nevertheless, they provide a quantitative characterization of the behavior of the deterministic method on liver histological images.

C. Analysis of the main errors

The differences between automatic and reference counts may be mainly related to inadequate separation of adjacent nuclei and the identification of non-nuclear regions. In cases of undercounting, two or more nearby or partially overlapping nuclei may remain connected after morphological operations and, consequently, be counted as a single component. This behavior is especially relevant when objects have poorly defined boundaries or when the distance transform does not produce sufficiently distinct maxima to guide their separation by the watershed [1], [3].

Overcounting, in turn, can occur when a single nucleus is fragmented into multiple regions during the application of the watershed, or when small structures and artifacts remain in the binary mask and are interpreted as nuclear components. Although minimum suppression has been employed to reduce excessive fragmentation, the result of the watershed remains dependent on the characteristics of the input mask and the definition of the markers or minima used in the segmentation process [3], [9].

Another relevant factor is the use of fixed parameters in all images. Although this strategy ensures the uniform application of the method, variations in contrast, intensity, morphology, and size of the nuclei can alter the response of adaptive

thresholding and morphological operations. In particular, the radius of the structuring element can favor the removal of small regions and, simultaneously, promote the merging of very close structures. Thus, a single set of parameters may not adequately represent all the variability present in the analyzed histological images.

Furthermore, the evaluation was based exclusively on the difference between the automatic and reference counts. Similar counts do not necessarily ensure that each nucleus has been correctly segmented, as undercounting and overcounting errors can occur simultaneously and compensate each other numerically. Therefore, the results obtained characterize the method's performance in the counting task, but do not allow for a complete evaluation of the spatial quality of the segmentation of each nuclear instance.

Finally, an experimental comparison with other classical or deep learning-based methods was not performed. Therefore, it is not possible to assert superiority or performance improvement over existing approaches. In addition, although the test subset was kept independent during parameter tuning, both the development and test subsets were derived from the same human liver image collection in the NuInsSeg dataset. Thus, the results should be interpreted as an evaluation of a deterministic, interpretable, fixed-parameter-based workflow on the selected liver images rather than as evidence of superiority or external generalization.

IV. Conclusion

This work presented a deterministic digital image processing method for the automated segmentation and counting of nuclei in hematoxylin and eosin (H&E)-stained human liver histological images. The proposed workflow combined contrast adjustment, bilateral filtering, adaptive thresholding, morphological operations, distance transform, watershed segmentation, and connected-component labeling. For parameter definition, the 40 selected liver images from the NuInsSeg dataset were divided into a development subset (N = 30), used for empirical parameter adjustment, and an independent test subset (N = 10), kept untouched during parameter tuning. On the independent test set, the proposed method achieved a mean absolute error (MAE) of 2.30 nuclei per image, a standard deviation of the absolute errors of 1.34 nuclei, and a mean absolute percentage error (MAPE) of 7.28%. These results indicate that the method produced automated nuclei counts relatively close to the reference values, although some variation in error magnitude was observed across the evaluated histological images.

The standard deviation of the absolute errors was 1.34 nuclei, indicating variability in performance across the analyzed histological images. Overall, the results show that the proposed approach was able to produce automated nuclei counts reasonably close to the reference values in part of the evaluated dataset, although its performance varied according to the characteristics of the histological fields.

The main limitations were associated with the separation of adjacent or partially overlapping nuclei, fragmentation of individual structures, and incorrect identification of non-nuclear regions. In addition, the use of fixed parameters may limit the method's ability to accommodate variations in nuclear size, morphology, and image contrast. The selected images were divided into a development subset (N = 30), used for empirical parameter adjustment, and an independent test subset (N = 10), kept untouched during parameter tuning. Although this separation provides an evaluation on images not used for parameter definition, both subsets were derived from the same human liver image collection in the NuInsSeg dataset; therefore, the results do not constitute external validation. Furthermore, evaluation based primarily on nuclei counts does not provide a complete assessment of the spatial accuracy of individual nucleus segmentation.

Future work should include validation on larger independent datasets and histological images from different tissues, as well as the incorporation of instance-level segmentation metrics to provide a more comprehensive assessment of segmentation performance. Comparisons with other classical image processing methods and deep learning-based approaches should also be conducted. In addition, automatic parameter selection and more robust strategies for watershed marker definition may be investigated to reduce both undercounting and overcounting errors.

***Abstract*—The early detection of metallic implants in Magnetic Resonance Imaging (MRI) is critical for workflow optimization, allowing for the timely implementation of metal artifact reduction sequences. This pilot study proposes an automated screening framework designed to identify metallic interference during the initial "scout" (localizer) phase of knee MRI examinations. A comparative analysis was conducted between two Deep Learning (DL) architectures: ResNet18 and YOLOv8. Both models were evaluated on a newly curated, publicly released, and balanced dataset of 1,254 knee MRI localizer scans (UTFPR-Knee-MRI-Metal-Scout) from 200 patients across two different vendors. Performance was statistically validated via patient-level bootstrapping to establish 95% confidence intervals (CI). Furthermore, the models were evaluated for robustness against "spike" artifacts generated through k-space manipulation and noise degradation. Under standard conditions, YOLOv8 achieved an accuracy of 99.4% and a recall of 98.9%. In the 25% spike training scenario, YOLOv8 maintained high robustness with 97% accuracy, significantly exceeding the 66% achieved by ResNet18. Conversely, ResNet18 exhibited superior stability under extreme Gaussian noise, maintaining 90% accuracy at a Signal-to-Noise Ratio (SNR) of 5. Qualitative analysis using Grad-CAM revealed that misclassifications often occur when susceptibility artifacts merge with the image background due to low contrast-to-noise ratios. These findings suggest that integrating automated detection into the scout phase provides a reliable trigger for specialized clinical protocols, significantly reducing the necessity for costly re-scans. Code and dataset are available on GitHub repository[1].**

I. Introduction

Magnetic Resonance Imaging (MRI) is a high-cost, non-invasive imaging modality that does not rely on ionizing radiation [1]. Its operation is based on the interaction of atomic nuclei in a high-intensity magnetic field [2]. MRI provides detailed information on multiple tissue properties, including flow, diffusion, perfusion, functional activity, and metabolic composition through spectroscopy [2].

Since its commercial introduction in the 1980s, the demand for MRI examinations has steadily increased [3]. In the Brazilian public healthcare system, the average growth rate reached 7.6% for Computed Tomography (CT) scanners and 10.8% for MRI scanners, while in the private sector the respective increases were 7% and 7.8% [4].

Parallel to this increasing demand, Machine Learning (ML) has introduced methods that accelerate MRI acquisition and improve image quality. Commercial solutions currently available reduce scan time through noise suppression, raw-data reconstruction, synthetic image generation, and personalized imaging protocols [5]. However, despite these advances, artifacts remain a recurrent factor affecting MRI quality, potentially degrading image clarity and compromising diagnostic interpretation [6]. Beyond the clinical implications of image degradation, there is a substantial financial burden. As quantified in [7], motion artifacts are a primary driver of operational inefficiency and lost revenue in radiology departments. Their research indicates that approximately 19.8% of all MRI examinations require at least one repeated sequence due to motion. This translates to an estimated annual cost of approximately $115,000 per scanner in lost productivity and resource waste.

MRI studies typically generate a large number of images, making exhaustive evaluation challenging. Image quality assessment (IQA) in MRI is a broad research domain encompassing diverse methodological approaches. In recent years, Deep Learning (DL) techniques have gained prominence in MRI analysis, offering powerful tools for automated and scalable IQA. Several DL models have been developed to detect common MRI artifacts and, in some cases, even propose corrective strategies [8].

Convolutional Neural Networks (CNNs), for instance, have proven particularly effective in identifying complex patterns associated with signal voids and geometric distortions, such as those caused by metal implants. Building on this capability, Gao et al. [9] developed a lightweight DL framework for fully automated sorting of brain MRI volumes and the detection of common artifacts, including motion, aliasing, and metal interference. By using an EfficientNetB0 architecture as a feature extractor and a multilayer perceptron classifier, the authors achieved an overall accuracy of 99.1% across a large retrospective dataset of over 22,000 MRI volumes.

Ettehadi et al. [10] proposed a two-step DL framework for multiclass artifact classification in brain Diffusion MRI. Unlike previous binary "good vs. poor" models, their approach utilizes a 3D Residual Squeeze-and-Excitation CNN to first classify 3D sub-volumes, or "slabs," followed by a voting process to determine the primary artifact type in the entire volume. Validated on large-scale datasets, the model achieved average accuracies of 96.61% and 97.52%, respectively.

The push toward large-scale automation reached a new milestone with the work of Loizillon et al. [11], who developed a comprehensive quality control pipeline specifically for 3D

[1]https://github.com/alinetabatta/Metal_detection_CNN

FLAIR sequences within clinical data warehouses. Their study emphasizes that while clinical routine images offer a wealth of data, they are frequently compromised by diverse artifacts that standard research-grade models fail to capture. Loizillon and colleagues demonstrated that DL can effectively bridge this gap by providing high-throughput screening of brain MRIs.

Integrating DL prior to the primary MRI examination offers a strategic advantage by transforming retrospective quality checks into proactive, real-time clinical safeguards. Expanding the scope of DL in pre-examination safety and protocol optimization, Courtman et al. [12] developed a CNN-based framework to identify head CT scans containing aneurysm clips prior to MRI procedures. Their approach successfully automated patient safety screening, eliminating manual review bottlenecks and preventing potential MR-safety contraindications before the patient enters the magnet room. Similarly, Lie et al. [13] developed a CNN to automatically screen X-rays for metallic implants and foreign bodies. By training algorithms on a musculoskeletal radiograph dataset, they achieved near-perfect accuracy across six anatomical regions. Their findings demonstrate that deploying automated DL screening upstream in the diagnostic workflow substantially decreases pre-scan evaluation time and serves as a scalable substitute for manual triage, effectively removing real-time clinical decision-making barriers.

While the aforementioned studies demonstrate high performance in automated quality assessment and artifact identification across various anatomical regions, they share the common limitation of their temporal placement within the clinical workflow. Whether focusing on specific artifact types or global image quality, these methodologies are typically applied at the final stage of the MRI process, often after the patient has already left the facility. Consequently, these approaches serve as retrospective diagnostic tools rather than preventative measures, leaving no window for immediate corrective action or protocol adjustment.

In contrast, we present a proactive strategy designed to anticipate potential failures and optimize clinical efficiency. By detecting the presence of metallic implants at the earliest possible inception of the examination, this framework enables real-time decision-making while the patient remains on the table. This shift from retrospective identification to early-stage prevention aims to drastically reduce time-to-diagnosis and minimize the necessity for subsequent re-imaging. Because artifacts are pervasive in daily practice, early identification is a vital tool for clinicians and technicians, ultimately enhancing patient safety and diagnostic reliability.

Metallic interference compromises MRI quality by disrupting the uniformity of the static magnetic field, thereby altering the local resonance frequency. This phenomenon results in a cascade of characteristic artifacts, including signal loss due to accelerated dephasing, failure of chemical-shift-based fat suppression, and significant pixel displacement artifacts [14].

Hence, this work originally proposes detecting knee metallic artifacts at the earliest possible stage of the MRI workflow: the localizer (or "scout") scan. Although localizer images are primarily used for anatomical positioning rather than diagnosis, they provide critical early insights that can prevent subsequent image degradation. Early identification of metal during this phase allows the technician to immediately adjust the clinical protocol and select specialized sequences designed to reduce metal artifact. These include MARS (GE Healthcare), MAVRIC SL (GE Healthcare), WARP (Siemens), and O-MAR (Philips) [15]. Integrating automated detection into this initial phase serves as a preventive measure, reducing the need for costly, time-consuming rescans while optimizing scanner throughput.

To evaluate the most effective approach for early preventive screening, this study compares two distinct DL architectures representing different paradigms rooted in CNNs: ResNet18 [16], a classic residual classification network, and YOLOv8 [17], a high-speed single-stage object detector. As emphasized in medical literature, CNN-based frameworks have become the cornerstone of modern medical imaging analysis due to their capacity to extract hierarchical visual features directly from complex anatomical datasets [18]. By benchmarking a dedicated classifier against a specialized object detector within the same workflow, this study explores how these distinct CNN lineages handle the morphological features of localized metallic artifacts to identify the optimal balance of clinical performance. Furthermore, beyond standard metrics, both models were subjected to rigorous operational testing—including noise sensitivity and spike artifact analysis—to ensure the selected approach remains resilient against the image degradation common in routine clinical practice. Finally, we present a new publicly available dataset for this evaluation, named **UTFPR-Knee-MRI-Metal-Scout**, which serves as a secondary contribution of this work.

II. Methods

The methodological framework of this study is designed to evaluate the efficiency of DL architectures in the early detection of metallic artifacts. The experimental workflow is systematically divided into four primary stages, as illustrated in Fig. 1: (i) Data Curation, involving the manual selection and labeling of knee MRI localizer scans; (ii) Model Development, where the ResNet18 and YOLOv8 architectures are trained using transfer learning; (iii) Robustness Testing, consisting of noise sensitivity, dataset ablation analyses and spike artifacts; and (iv) Performance Evaluation, utilizing quantitative metrics and qualitative saliency maps to compare the proposed models.

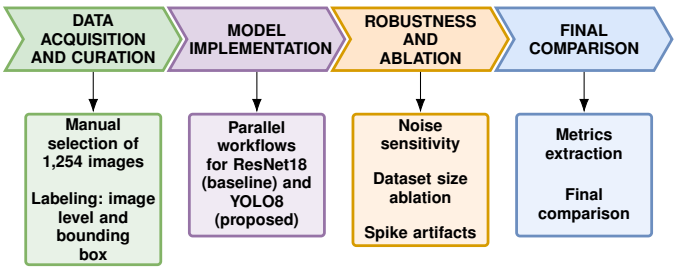

Fig. 1. Overview of the proposed methodology.

A. Dataset

The retrospective collection and processing of imaging data for this study were conducted following the ethical standards and approval of the Ethical Committee of the Federal University of Technology (UTFPR) campus Dois Vizinhos, approval number 7.554.887.

The **UTFPR-Knee-MRI-Metal-Scout** dataset consists of knee MRI localizer scans, specifically selected for their role in the initial clinical workflow. Data acquisition was performed over approximately 40 hours of manual selection by a specialist to ensure the integrity of the ground truth. To prevent algorithmic bias, a balanced dataset was constructed, comprising 50% scans containing metallic implants and 50% scans without metallic interference. The images were sourced from 1.5 Tesla MRI scanners from two primary vendors: Siemens Healthineers and GE Healthcare.

Each examination in the study typically included an average of 6 localizer images, categorized into the three primary anatomical planes: sagittal, coronal, and axial. As detailed in Table I, the dataset of 1,254 images includes 460 sagittal, 423 coronal, and 371 axial views. This distribution ensures the models are trained and validated on a balanced variety of anatomical perspectives.

TABLE I
DISTRIBUTION OF THE DATASET: ORGANIZED BY TRAINING PHASE AND CLASS ACROSS ANATOMICAL PLANES.

Split	Class	Sagittal	Coronal	Axial	Total
Train	Metal	186	150	110	446
	No Metal	145	151	149	445
	Subtotal	*331*	*301*	*259*	*891*
Validation	Metal	35	29	29	93
	No Metal	28	33	31	92
	Subtotal	*63*	*62*	*60*	*185*
Test	Metal	36	30	23	89
	No Metal	30	30	29	89
	Subtotal	*66*	*60*	*52*	*178*
Total		**460**	**423**	**371**	**1,254**

For computational processing, raw localizer scans were normalized and exported to 512×512 pixel 8-bit representations. Direct extraction of raw DICOM files was restricted due to institutional data privacy and confidentiality policies established by the clinical facility. Nevertheless, while full 12/16-bit DICOM precision is crucial for subtle diagnostic tissue characterization, metallic artifacts in scout acquisitions manifest as severe, macroscopic, high-contrast signal voids and geometric distortions [19]. These morphological features are fully preserved in 8-bit spatial representations without compromising ML classification accuracy [20].

The final dataset comprises 1,254 images from 200 unique patients. The partitioning into training, validation, and testing subsets was conducted at the patient level to ensure a rigorous evaluation and prevent data leakage. The study mitigates the risk of the model overlearning specific anatomical signatures by ensuring that all images from a single patient are assigned exclusively to a single subset. This ensures that the network is evaluated on its ability to generalize to completely unseen patients, providing a more realistic assessment of its clinical utility. The distribution of images across the subsets is as follows: 891 images for training, 185 for validation, and 178 for the final test set. Each subset maintained the 1:1 ratio between the "Metal" and "No Metal" classes. Samples of the localizers and their corresponding anatomical planes are illustrated in Fig. 2.

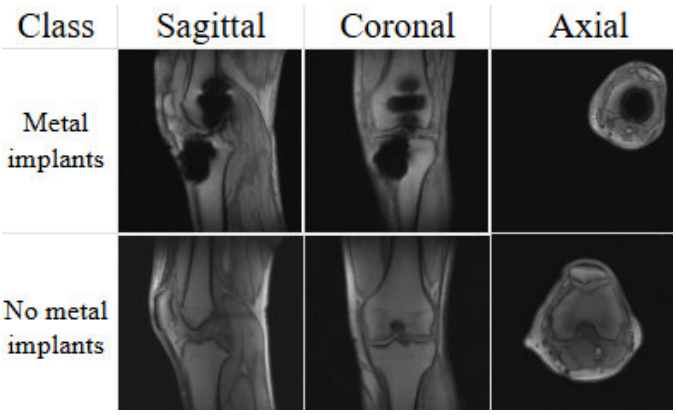

Fig. 2. Representative knee MRI localizer scans illustrating the two classes: images with metallic implants (top row) and those without artifacts (bottom row) across the three primary anatomical planes.

B. Baseline Model

The Residual Network (ResNet) architecture was selected as the baseline model for this study due to its proven efficiency in medical image analysis and its ability to mitigate the vanishing gradient problem via skip connections (or residual blocks). In clinical environments, where computational speed and real-time inference are critical (especially during the "scout" or localizer phase), ResNet18 offers a significant advantage over deeper variants (like ResNet50 or ResNet101) [21]. This maintains a high level of feature extraction capability with a relatively small number of parameters, making it an ideal candidate for a lightweight clinical screening tool. In this work, we use Transfer Learning from the ImageNet dataset. Instead of training the network from scratch with randomized weights, we initialized the model with pre-trained weights. This approach is highly effective for medical imaging tasks with limited datasets, as the model can leverage low-level visual features (edges, textures, and gradients) learned from millions of general images and adapt them to the specific morphology of knee MRI scans [22].

The training process involved a fine-tuning strategy where the final fully connected layer of the original ResNet18 was replaced to match our binary classification task ("Metal" vs. "No Metal"). To implement this workflow, all input images were resized to 512×512 pixels to maintain consistency with the localizer scan resolution. The model was trained using the Adam optimizer with a learning rate of 0.001, paired with

Cross-Entropy Loss to quantify the difference between the predicted class probabilities and the ground truth. Finally, to enhance model robustness and ensure the input data distribution matched the pre-trained model's expectations, standard data transformations were applied, including normalization based on the ImageNet mean and standard deviation.

C. Object Detection Model

The integration of the YOLO framework into the early screening phase aligns with recent shifts toward highly efficient clinical decision support systems. By framing object detection as a single regression problem, YOLOv8 enables simultaneous classification and bounding box prediction in a single forward pass. This fast processing capability is highly substantiated by recent clinical literature, where the YOLO series has demonstrated high performance and classification robustness across diverse medical screening tasks [23].

For this study, the YOLOv8n (Nano) variant was selected to ensure rapid inference, making it an ideal candidate for immediate artifact identification. To leverage this architecture's precise spatial localization capabilities, a specialized manual labeling phase was conducted using the Roboflow platform. Unlike simple image-level labeling, defining the exact coordinates of the metallic interference forces the model to learn features specific to the artifact rather than peripheral anatomical structures. These annotations were then exported directly in the native YOLOv8 format (containing class indices and normalized bounding box coordinates) to guide the supervised learning process.

Based on the provided workflow, the implementation details include:

- **Image Pre-processing:** Images were standardized to a 512×512 resolution to align with the ResNet18 baseline and the native resolution of the MRI localizer scans.
- **Training Hyperparameters:** The model was trained for 100 epochs with a batch size of 16. The training utilized the SGD optimizer with a learning rate of 0.01 and momentum of 0.937.
- **Loss Function:** YOLOv8 utilizes a combination of CIoU (Complete Intersection over Union) and DFL (Distribution Focal Loss) for bounding box regression, alongside Binary Cross-Entropy for class prediction.
- **Transfer Learning:** Similar to the baseline, the model was initialized with pre-trained weights from the COCO dataset [24], allowing the network to benefit from established feature hierarchies.

D. Evaluating Metrics

To quantitatively assess and compare the performance of the baseline ResNet18 and the proposed YOLOv8 models, five primary metrics were calculated. These metrics are defined in terms of True Positives (TP), True Negatives (TN), False Positives (FP), and False Negatives (FN). Accuracy, Precision, Recall, F1-Score, and mean Intersection over Union (mIoU) [25] were the metrics employed in this work. In particular, the mIoU is essential for evaluating the localization accuracy of the YOLOv8 model. It measures the average overlap between the predicted bounding box (B_p) and the ground truth box (B_g) across all instances:

$$\text{IoU} = \frac{\text{Area}(B_p \cap B_g)}{\text{Area}(B_p \cup B_g)}, \tag{1}$$

$$\text{mIoU} = \frac{1}{n} \sum_{i=1}^{n} \text{IoU}_i. \tag{2}$$

For ResNet18, metrics were calculated using the standard `scikit-learn` classification report [26]. For YOLOv8, metrics were derived from the validation/test output provided by the `ultralytics` framework.

To evaluate the detection performance of YOLOv8, the Mean Average Precision (mAP) [24] was utilized. This metric considers both the precision of the classification and the localization accuracy of the predicted bounding boxes at specific Intersection over Union (IoU) [25] thresholds.

1) **mAP@0.5**: This represents the mean Average Precision calculated at a fixed IoU threshold of 0.5. It measures the model's ability to correctly identify and locate objects where at least 50% of the predicted box overlaps with the ground truth. It is a measure of the model's overall detection strength.

2) **mAP@0.5:0.95**: This is a more stringent metric that represents the average mAP calculated over a range of IoU thresholds, from 0.5 to 0.95, with a step size of 0.05. This metric rewards high-precision localization; a high score here indicates that the model's predicted bounding boxes align very closely with the actual boundaries of the metallic artifacts:

$$\text{mAP} = \frac{1}{N} \sum_{i=1}^{N} \text{AP}_i, \tag{3}$$

where N is the number of classes and AP is the Area Under the Precision-Recall Curve for each class.

III. Results

This section presents the experimental results and a comparative analysis of the ResNet18 and YOLOv8 architectures. The evaluation is organized into four stages. First, the models are compared using standard classification metrics and statistical validation. Second, a qualitative analysis is performed to visualize the models' predictive behavior. Third, both models are evaluated for robustness to spike artifacts. Finally, a series of stress tests—including a noise-sensitivity analysis and dataset-size ablation—is conducted to assess model robustness under varying clinical and data-availability constraints.

A. General Results

The quantitative performance of both models on the test set is summarized in Table II. These results reflect the models' ability to generalize to unseen data after training on a subject-wise partitioned dataset. A statistical validation via patient-level bootstrapping is conducted to establish 95% confidence intervals, ensuring results are not biased by specific patient characteristics.

Using a standardized resolution of 512×512 pixels, YOLOv8 demonstrated superior performance across all metrics. The statistical validation shows that while ResNet18 maintains high sensitivity (95.7%), it has a wider confidence interval and lower specificity than the object detection approach.

The perfect specificity (100%) and high accuracy (99.4%) achieved by YOLOv8 confirm its robustness in identifying metallic artifacts while eliminating false positives. In a clinical environment, this precision is essential to minimize "false alarms" that could disrupt radiological workflows. Furthermore, the tight confidence intervals for YOLOv8 suggest more stable performance across different patient profiles than the ResNet18 baseline.

1) Qualitative and Comparative Analysis: Gradient-weighted Class Activation Mapping (Grad-CAM) is a prominent technique for generating visual explanations for decisions made by a wide array of CNN-based models, thereby enhancing their transparency [27]. By using gradients from the final convolutional layer, Grad-CAM produces a coarse localization map that highlights the most salient regions for a given prediction. In the context of image classification, this approach provides critical insights into the failure modes of DL models, allowing us to identify whether a network is focusing on relevant anatomical features or extraneous artifacts [27].

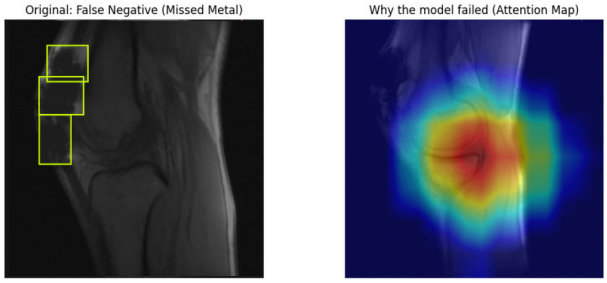

Fig. 3. Grad-CAM visualization of a false negative detection by YOLOv8.

The confusion matrices representing the mean performance within the calculated confidence interval for YOLOv8 and ResNet18 are shown in Table III. Inspecting the one false negative (missed metal) for YOLOv8, the Grad-CAM illustrated in Fig. 3 shows that the model's attention was concentrated on an anatomical region distant from the actual metallic implant. In this instance, the metal was located in the patellar region; however, the resulting signal void (the characteristic "black area" or susceptibility artifact) merged with the image background. This loss of boundary definition likely caused the feature extraction layers to overlook the artifact.

Figure 4 illustrates representative false negative and false positive results for ResNet18. The Grad-CAM heatmap for the false negative indicates that ResNet18 exhibits a misinterpretation similar to that observed in YOLOv8. Specifically, the presence of metal in the patellar region appears to be a consistent source of error for both models; however, while YOLOv8 produced only one false negative for this case, ResNet18 yielded six.

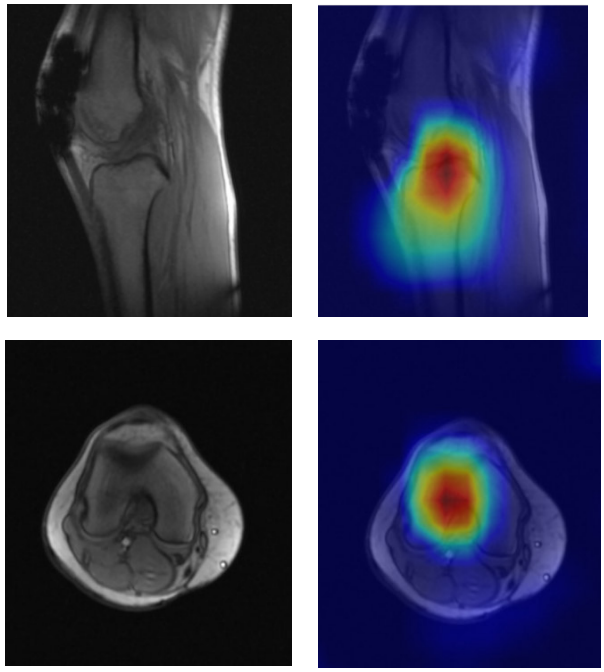

Fig. 4. Grad-CAM visualizations for ResNet18 illustrate a false negative in the upper image pair and a false positive in the lower pair.

2) Localization and Detection Performance: A critical advantage of the YOLOv8 architecture is its inherent spatial localization capability. To evaluate this performance, we utilized the mIoU. The proposed YOLOv8 model achieved a mean mIoU of 0.7021. This result indicates that while the model effectively detects the presence of metal, there is room for optimization in precisely defining the spatial boundaries of susceptibility artifacts, which often lack distinct edges in MRI. Fig. 5 compares instances of low and high mIoU performance. Notably, the annotation process—utilizing square bounding boxes to encompass artifact areas—may introduce slight discrepancies relative to the irregular morphology of the artifacts, potentially contributing to a lower mIoU. While the mIoU reflects limitations in precise localization, it does not undermine the overall efficacy of the YOLOv8 model. Given that the primary objective of this study is the classification of metal artifacts, the model demonstrates high diagnostic performance and reliability for its intended clinical application.

The YOLOv8 model's performance was evaluated through a combination of spatial and precision-based metrics. The model achieved a **mIoU of 0.7021**, indicating high localization accuracy. An average overlap of 70% is particularly significant in MRI analysis, where susceptibility artifacts often exhibit irregular morphologies and diffuse edges that challenge precise alignment of bounding boxes.

Detection robustness was further evidenced by an

TABLE II
COMPARATIVE PERFORMANCE: RESNET18 VS. YOLOV8 (PATIENT-LEVEL BOOTSTRAP VALIDATION)

Model	Accuracy [95% CI]	Sensitivity [95% CI]	Specificity [95% CI]
ResNet18	95.1% [90.5% – 98.9%]	95.7% [87.0% – 100%]	94.4% [90.0% – 98.4%]
YOLOv8	**99.4% [98.1% – 100%]**	**98.9% [96.0% – 100%]**	**100.0% [100% – 100%]**

TABLE III
CONFUSION MATRICES FOR RESNET18 AND YOLOV8.

Model	True label	Pred. Metal	Pred. No Metal
ResNet18	Metal	83	6
	No Metal	7	82
YOLOv8	Metal	86	1
	No Metal	0	91

mAP@0.5 of 0.5646, reflecting a stable balance between precision and recall at a standard detection threshold. While the **mAP@0.5:0.95** decreased to **0.3016**, this drop is expected as it demands near-perfect spatial alignment (IoU > 0.85). In a clinical context, the consistency between the mIoU (0.70) and mAP@0.5 suggests that the model reliably identifies and approximates the boundaries of metallic artifacts. Although square annotations may introduce slight discrepancies against the artifacts' irregular shapes, the results confirm the model's efficacy for diagnostic screening, where reliable identification is the primary objective.

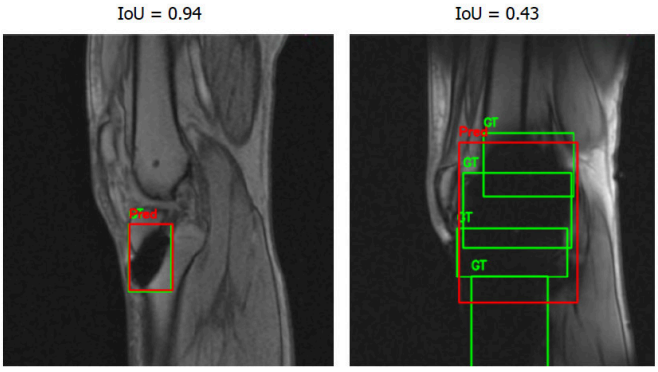

Fig. 5. Representative cases of YOLOv8 bounding box predictions.

B. Noise Analysis

The Signal-to-Noise Ratio (SNR) in MRI is fundamentally proportional to the voxel volume and the square root of the acquisition time [28]. To simulate the inherent variability of clinical acquisitions—where SNR fluctuates with field strength (B_0), coil geometry, and parallel imaging—a noise-sensitivity analysis was conducted. Gaussian noise was incrementally added to the test set to identify the break point for each architecture.

By monitoring the decay in Accuracy as a function of the SNR, we determined which backbone maintains higher reliability under degraded image conditions. Both architectures were evaluated across five SNR levels ($40, 30, 20, 10$, and 5), representing a continuum from high-fidelity 1.5T/3T imaging to sub-diagnostic, noise-limited scenarios, as discussed in [29]. The results are presented in Fig. 6. As observed in the experimental data, YOLOv8 demonstrates near-perfect performance in high-quality scenarios, maintaining an accuracy of 98% or higher for SNR ≥ 20. However, its performance drops sharply in high-noise environments, falling to 67% at an SNR of 5. In contrast, ResNet18 exhibits remarkable stability; although its peak performance is lower than YOLOv8's, it maintains an accuracy of 90% even under extreme noise conditions (SNR 5). This divergence suggests a trade-off between the precision of local object detection (YOLOv8) and the robustness of global feature extraction (ResNet18). In clinical settings where MRI hardware limitations or patient motion may induce significant artifacts, the structural consistency of the ResNet18 backbone offers a more dependable baseline, whereas YOLOv8 is the optimal choice for high-fidelity diagnostic environments.

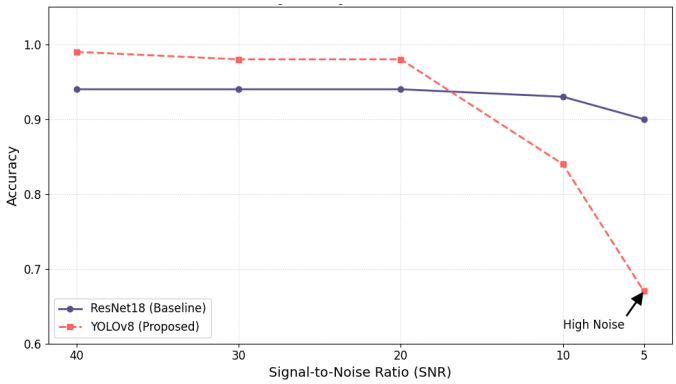

Fig. 6. Noise Sensitivity Analysis: ResNet18 vs. YOLOv8

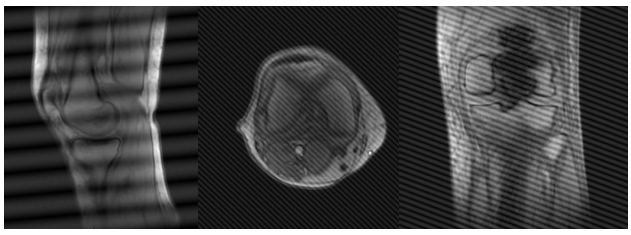

Fig. 7. Examples of simulated spike artifacts. The variations in band angulation and spacing correspond to different spatial frequency coordinates within the k-space matrix.

C. Robustness to Spike Artifacts

The spike test is justified by the unique nature of MR data acquisition, in which the final image is a direct product of the Fourier transform of the k-space matrix. As established in [30], electromagnetic spikes—caused by gradient duty cycles or external electronic interference—introduce bad data points into this raw data frequency domain. Because each point in k-space contributes to the entire reconstructed image, a single spike results in a global herringbone or criss-cross artifact that obscures anatomical structures with dark, periodic stripes as shown in Fig. 7.

To assess the models' ability to handle additional types of MRI artifacts, a simulation was conducted by artificially introducing spike artifacts into test images via k-space manipulation. The models were evaluated on test sets fully corrupted with spike artifacts, while the proportion of spike-contaminated images in the training set was gradually increased. In this setting, YOLOv8 achieved 97% accuracy when trained with 25% corrupted images, whereas ResNet18 achieved only 66% under the same conditions. These results indicate that YOLOv8 exhibits superior robustness to alternative artifact types.

D. Dataset Size Analysis

To investigate the data efficiency of each architecture, an ablation study was conducted by training the models on varying subsets of the original data (25%, 50%, 75%, and 100%). This analysis identifies the minimum data threshold required for each model to achieve a clinically acceptable performance level and assesses how each architecture scales with increasing sample sizes. The resulting performance for ResNet18 and YOLOv8 is illustrated in Fig. 8.

The results indicate that YOLOv8 consistently maintains a performance advantage across all dataset fractions. Notably, YOLOv8 achieves approximately 93% accuracy with only 10% of the training data, eventually plateauing near 99% as the dataset size increases. ResNet18 follows a similar learning trajectory but starts at a lower baseline of 84% accuracy at the 10% fraction. Both models exhibit strong convergence, reaching over 90% accuracy when at least 50% of the curated 1,254 images are utilized. This suggests that while both architectures are efficient, YOLOv8 is better at feature extraction with extremely limited sample sizes.

IV. Conclusions, Limitations, and Future Work

This pilot study demonstrated the feasibility of implementing an automated screening system for metallic implants during the initial "scout" phase of knee MRI workflows. By utilizing DL architectures to identify artifacts at the earliest possible stage, clinical teams can preemptively adjust protocols to include metal artifact reduction sequences, thereby reducing the need for costly re-scans and optimizing scanner throughput. The comparative analysis further highlights a clear distinction between the two architectural paradigms evaluated:

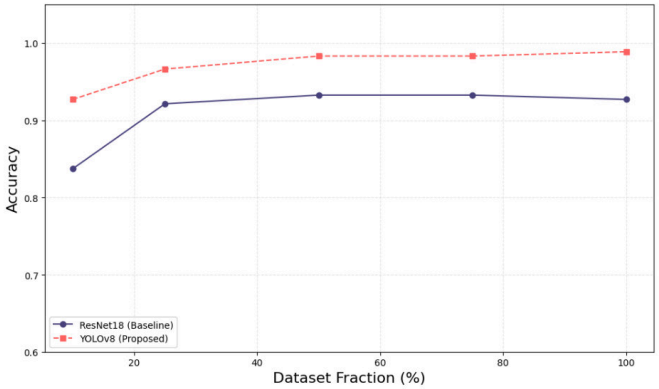

Fig. 8. Model Performance Comparison: Accuracy vs Dataset Size

- **Detection Superiority:** YOLOv8 proved to be the more robust choice for high-fidelity environments, achieving near-perfect accuracy.
- **Structural Robustness:** Although ResNet18 demonstrated greater stability under degraded conditions, it exhibited lower peak performance and failed to maintain satisfactory accuracy in the spike artifact evaluation.
- **Interpretability and Localization:** The integration of Grad-CAM visualization and mIoU metrics provided valuable qualitative insights into model behavior. YOLOv8 achieved an mIoU of 0.7021, highlighting the importance of incorporating spatial context in artifact detection. This spatial awareness is particularly relevant for future developments in metal artifact analysis, as localizing metallic interference within the anatomical context enables a more nuanced understanding of image degradation and its clinical implications.

While these initial results are promising, several limitations inherent to this pilot study must be acknowledged. First, the evaluation was conducted on a single-center cohort of 200 patients (1,254 images). Although a subject-wise split and patient-level bootstrapping with 95% confidence intervals were strictly enforced to prevent data leakage and ensure statistical validity, testing on larger, multi-center datasets is required to further confirm clinical generalizability. Second, the dataset was constructed using localizer scans from only two vendors (Siemens Healthineers and GE Healthcare). While scout sequences are standardized, hardware-specific variations in reconstruction kernels and signal handling could introduce subtle biases.

Third, regarding localization, the mIoU achieved by YOLOv8 was 0.70. While sufficient for identifying the region of interest, bounding box alignment is inherently limited by the irregular and diffuse boundaries of magnetic susceptibility artifacts. Precise spatial delineation was secondary to classification accuracy, as the primary clinical objective was triggering protocol adjustments. Finally, the noise sensitivity analysis applied additive Gaussian noise to reconstructed magnitude images as a standardized computer vision stress test. However, noise in magnitude MRI physically follows a Rician

distribution, particularly in low-signal and background regions [31].

Future work will focus on both technical refinement and clinical integration. Subsequent studies will evaluate physically realistic Rician noise models and complex k-space perturbations prior to magnitude reconstruction. Additionally, exploring semantic segmentation architectures and specialized loss functions may better capture irregular artifact morphology. Crucially, as a core contribution of this pilot study, the newly curated **UTFPR-Knee-MRI-Metal-Scout** dataset has been made publicly available to serve as a benchmark for automated MRI quality control research. Ultimately, embedding these algorithms into existing scanner consoles will transition this framework into a routine real-time clinical tool.

***Abstract*—This work presents an approach for automated detection of visual targets in RSVP tasks using EEG signals. The methodology combines the Wavelet Continuous Transform with the use of the LeNet convolutional neural network. Signals were acquired from 7 participants undergoing RSVP tasks with images of airplanes as target stimuli. Each signal was segmented into 500 ms windows and subjected to the transform, generating threedimensional representations (8 channels, 40 frequencies, 1024 samples) that preserve spatial, spectral and temporal information. These representations were then used as the basis for the classification step. Keywords - Targe**

***Index Terms*—Target detection, machine learning, fast visual serial presentation, RSVP, P300, Wavelet transform, EEG, random forest.**

I. Introduction

The electroencephalogram (EEG) is a valuable tool for studying brain activity during cognitive tasks, especially because of its high temporal resolution and non-invasiveness. In the context of continuous monitoring of EEG signals in clinical and experimental settings, the generation and analysis of large volumes of data face some challenges: manual processes are prone to operational errors, excessive time periods, and are subject to inter and intra-operator variability [1]. These limitations motivate the development of automated methods for detecting specific neural patterns, especially in experimental paradigms that require fast and accurate responses.

A promising technique in this scenario is Rapid Serial Visual Presentation (RSVP), in which images are exhibited at high speed (typically in the 5-10 Hz range) while electroencephalographic activity is simultaneously and continuously recorded [2], [3]. RSVP exploits the human visual system's ability to process stimuli sequentially in fractions of a second, generating specific neural responses when a relevant stimulus (target) is detected. Among these responses, the P300 component stands out, an event-related evoked potential that typically occurs between 300 and 500 ms after the presentation of an infrequent or significant stimulus [4]. The detection of the P300 in RSVP tasks has direct applications in brain-machine interfaces, assisted surveillance systems, and rapid image screening [5].

However, the automated interpretation of EEG signals in RSVP paradigms presents significant challenges. The signals are inherently non-stationary, low amplitude (microvolts), and can be contaminated by biological artifacts (eye movements, muscle activity) and external noise. Additionally, inter-subject variability and dependence on the participant's attentional status make it difficult to generalize models on the temporal domain [6]. In this context, the simultaneous analysis of the temporal and spectral dimensions is essential to realize the neural dynamics associated with target detection.

The Continuous Wavelet Transform (CWT) can be used as a mathematical tool for processing non-stationary signals such as EEG. Unlike the Short-Duration Fourier Transform, which uses a fixed window, CWT employs wavelets that dilate and contract, providing fine temporal resolution for high-frequency components and enhanced spectral resolution for low-frequency components [7]. This property allows it to represent the EEG signal in the time-frequency domain, which preserves both fast transients (such as P300) and rhythmic background oscillations.

Recent work has shown that combining time-frequency representations with machine learning techniques can significantly improve the accuracy when detecting neural patterns in cognitive tasks [8], [9]. However, most existing approaches treat EEG channels independently, disregarding the spatial relationships between electrodes and the underlying cortical topography. The preservation of spatial information is impor-

tant, especially in visual tasks that recruit occipital and parietal areas in a differentiated way.

In this context, the present work aims to develop and evaluate a methodology for time-frequency-spatial representation of multichannel EEG signal detection of visual targets in RSVP tasks. The proposed approach consists of: (1) segmentation of the signals in 500 ms windows synchronized with the visual stimuli; (2) application of the Continuous Wavelet Transform to each channel individually, generating time-frequency spectrograms; (3) organized stacking of these spectrograms in a three-dimensional tensor (channels × frequencies × time) that preserves the cortical topography; and (4) validation of the discriminative capacity of these representations through a Random Forest classifier implemented in the WEKA environment.

II. Methodology

A. Acquisition and Selection of Data

The public database EEG Signals from an RSVP Task [4], available on the PhysioNet platform, was used, containing records for 11 participants submitted to a Rapid Visual Serial Presentation (RSVP) paradigm. The stimuli consist of aerial photographs of London, with target images containing a photo-realistically superimposed plane and non-target images without planes.

Seven participants (IDs: 2, 3, 4, 8, 10, 11, 13) were selected with complete records for all experimental conditions: three presentation frequencies (5 Hz, 6 Hz, and 10 Hz) and two collection sessions per condition (suffixes ”a” and ”b”), totaling 42 files in EDF format. The EEG signals were acquired at 2048 Hz, with original filtering between 0.15 and 28 Hz, from 8 channels positioned according to the 10-20 system [5] in the occipital and parietal regions: PO8, PO7, PO3, PO4, P7, P8, O1, and O2. These channels correspond to the primary areas of the visual cortex and are strategically chosen for their relevance in detecting visual stimuli. The annotations in the files indicate the beginning of each image and its class: T=0 (non-target/nonairplane images) or T=1 (target/images containing an airplane in a sideways position).Because the dataset used in this study is publicly available and contains previously collected and identified data, no new data were collected from human participants. Therefore, ethical committee approval was not required for the present analysis.

B. Pre-processing of Signals

The files in the EDF format were processed using the MNE-Python library. Initially, the 8 channels of the original data set were selected in the occipital and posterior parietal regions (PO8, PO7, PO3, PO4, P7, P8, O1, and O2). The order of the electrodes was kept fixed throughout the study, preserving the topographic relationships intrinsic to the data and allowing later steps to explore spatial patterns of neural activation associated with target detection.

Although the signals had already been pre-filtered by the base authors in the range of 0.15–28 Hz, additional bandpass filtering from 1 to 30 Hz was applied using a 4th-order digital Butterworth filter. The lower limit of 1 Hz aims to remove very low-frequency fluctuations and residual motion artifacts, while the upper limit of 30 Hz ensures the complete inclusion of the beta band, which is relevant in cognitive sensing processes.

In sequence, the signals were resampled from 2048 Hz to 250 Hz; this reduction balances the need for sufficient temporal resolution to capture the P300 potential, which typically occurs between 300 and 500 ms after the stimulus. With the new sampling rate, each 500 ms time window now contains 125 samples.

C. Segmentation in Time Frames

To investigate the neural responses evoked by visual stimuli, the continuous EEG signals were segmented into 500 ms time windows, aligned with the onset of each image presented. The adoption of this interval is based on the need to capture the P300 evoked potential, a component associated with the detection of relevant stimuli, which typically manifests between 300 and 500 ms post-stimulus.

The segmentation was guided by the annotations provided in the original files, with discrimination of the precise instant of occurrence and its class (T=0 or T=1). For each event, a segment of 125 samples was extracted, corresponding to the 500 ms of interest and the sampling rate of 250 Hz, which was established in the previous step.

Each resulting window consists of a two-dimensional matrix of dimensions 8 × 125, where the rows represent the EEG channels in the fixed spatial order and the columns represent the temporal evolution of the signal. Each matrix was assigned a binary label: 0 for non-target and 1 for target, according to the original annotation.

The 500 ms window balances the range of neural response with minimal overlap between consecutive stimuli, especially at 10 Hz (stimuli every 100 ms). Segments with significant residual artifacts were discarded, guaranteeing data quality for subsequent steps. At the end of this stage, a dataset with format (14054, 8, 125) was obtained, comprising 14,054 epochs, of which 12,656 are non-target, and 1,398 are target.

D. Continuous Wavelet Transform and Imaging

To capture the neural dynamics associated with visual target detection, each EEG time window was subjected to the Continuous Wavelet Transform (CWT). This technique was chosen for its ability to analyze non-stationary signals, offering fine temporal resolution for high-frequency components and detailed spectral resolution for low-frequency components, being particularly suitable for evoked potentials such as the P300 [6].

The Morlet mother wavelet (a Gaussian function modulated by a sine wave) with a center frequency of 5 Hz was used, a value that balances temporal and frequency precision. The transform was applied to each of the 8 channels individually using the PyWavelets library with 64 scales, covering the neurophysiological bands of interest: delta (1-4 Hz), theta (4-8 Hz), alpha (8-13 Hz), and beta (13-30 Hz). For each channel, a matrix of coefficients of dimensions 64 × 125 was obtained, where the lines correspond to the scales (frequencies) and

the columns to the temporal instants (0 to 500 ms). Spectral power was calculated as the square of the magnitude of the coefficients.

From these matrices, a visual representation was generated for each epoch: a figure with 8 vertical subplots (one per channel, in the fixed order of the electrodes), each containing the timefrequency scalogram of the power of the respective channel. The axes were configured with a time of 0 to 500 ms and a frequency of 1 to 30 Hz, using the 'jet' color scale to represent the intensity of the power. The images were saved in PNG format (150 dpi, approximately 600×800 pixels) with standardized nomenclature "(pacienteIDfreqHzsessaoa/bepochnumber:04d target/nontarget.png)", all stored in a single directory.

E. Export of Data for Classification in WEKA

The trait vectors extracted in the previous step, composed of 8 values (averages per channel) and their respective labels, were organized for processing in the WEKA (Waikato Environment for Knowledge Analysis) software. To this end, a file was generated in the ARFF (Attribute-Relation File Format) format, the standard used by the tool.

The file was structured as follows:

1) Header: `@relation EEG_CWT_From_Images`
2) Attributes: eight numerical attributes corresponding to the averages of each channel, named mean_PO8, mean_PO7,`mean_PO3`, `mean_PO4`, `mean_P7`, `mean_P8`, `mean_O1`, and mean_O2
3) Class: nominal attribute class with the values 0,1, where 0 represents non-target and 1 represents target
4) Data: each sample occupied a line, with the eight numerical values formatted with six decimal places, separated by a comma, followed by the class label.

The resulting file was named eeg_cwt_from_images.arff and saved for later loading in the WEKA Explorer interface, where it was classified.

F. Balancing, feature extraction, and grading

The CWT image representations generated from the EEG epochs were loaded into the WEKA Explorer environment for subsequent class balancing, feature extraction, and classification.

The original dataset presented a substantial class imbalance, consisting of 1,398 target samples and 12,656 non-target samples, totaling 14,054 samples. To investigate the effect of class distribution on classification performance, an undersampling strategy was adopted. Two experimental configurations were evaluated. In the first configuration, a 1:1 class ratio was used, resulting in 1,678 samples, with 839 target and 839 non-target instances. In the second configuration, a 2:1 ratio was used, resulting in 2,517 samples, with 839 target and 1,678 non-target instances.

After the undersampling procedure, the resulting CWT representations were processed using an implementation of the LeNet architecture available in the WEKA environment. LeNet was used as a feature extraction method, generating 500 numerical attributes for each image. These attributes provided a compact representation of the information contained in the CWT image pixels and were subsequently used as input for the classification stage. The resulting feature dataset was saved for further processing in WEKA.

The resulting feature dataset was submitted to classification using two algorithms available in WEKA: Random Forest and SMO (Sequential Minimal Optimization). Random Forest was configured with 100 trees (other parameters were kept at default value), while SMO was configured with a polynomial kernel with exponent 2.0 and parameter C=1.0. Both classifiers were evaluated using 10-fold cross-validation. The performance of the models was assessed using accuracy, Kappa statistic, mean absolute error, and root mean squared error.

III. Results and Discussion

After applying the processing pipeline described in Section II, including filtering, segmentation, and Continuous Wavelet Transform, 14,054 images in PNG format were extracted, each representing a 500 ms epoch of the EEG signals. Of these, 12,656 correspond to non-target stimuli and 1,398 to target stimuli. The images include the 7 selected participants, the three presentation frequencies (5 Hz, 6 Hz, and 10 Hz), and the two collection sessions by condition. Fig. 1 illustrates examples generated for a target and a non-target stimulus, where it is possible to observe differences in activation patterns, especially in the occipital regions (O1 and O2 channels).

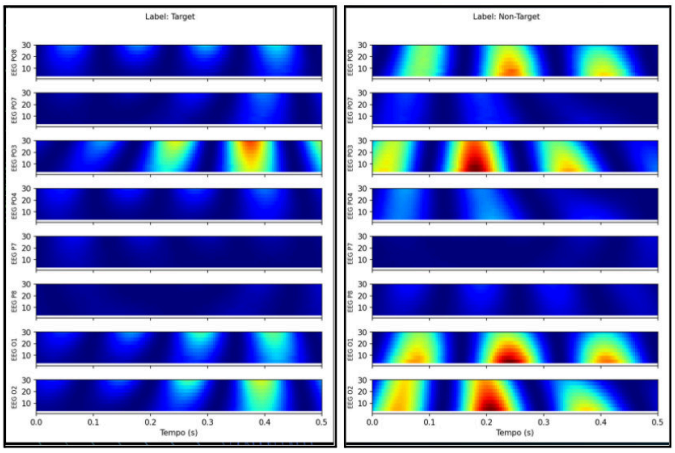

Fig. 1. Examples of visual representations generated by CWT. Non-target stimulus; target stimulus.

The original dataset exhibited a marked class imbalance, as previouly mentined in the methodology, which is characteristic of similar RSVP tasks, These tasks commonly have less frequent target stimuli appearances in comparison to non-target stimuli. To mitigate the potential bias of the classifiers toward the majority class (non-target) and evaluate their performance under different class distributions, an undersampling strategy was adopted. Two experimental scenarios were defined based on this strategy: a 1:1 class ratio, comprising 839 target and 839 non-target samples, for a total of 1,678 instances; and

a 2:1 class ratio, comprising 839 target and 1,678 non-target samples, for a total of 2,517 instances.

After extracting characteristics from the images through an implementation of the LeNet architecture available in the WEKA environment, generating a set of 500 attributes representative of its visual content, the data were submitted to classification. Two different algorithms were evaluated using cross-validation with 10 Folds: o Random Forest (configured with 100 trees) and the SMO (Support Vector Machine with PolyKernel of exponent 2.0 and parameter C=1.0). The comparative results obtained are consolidated in Table I.

TABLE I
COMPARATIVE CLASSIFICATION RESULTS WITH CROSS-VALIDATION

Balancing	**Classifier**	Accuracy	Kappa Index	Average Absolute Error	Mean Square Error
Subsample 1:1	Random Forest (100 trees)	59,85%	0,1979	0,4784	0,4850
Subsample 2:1	Random Forest (100 trees)	67,62%	0,0549	0,4274	0,4593
Subsample 1:1	SMO (PolyKernel E=2.0)	93,66%	0,8737	0,0632	0,2513
Subsample 2:1	SMO (PolyKernel E=2.0)	93,29%	0,8497	0,0671	0,2591

The results indicate a marked difference in the performance of the evaluated algorithms. The Random Forest classifier presented limitations when applied to the attributes extracted by LeNet from the subsample balancing. In the 1:1 scenario, it achieved an accuracy of only 59.85%. In the 2:1 scenario, the nominal accuracy rose to 67.62%; however, the corresponding confusion matrix revealed that of the 839 instances belonging to the target class, only 47 were correctly classified, while 792 were erroneously predicted as non-target (Fig. 2). This behavior indicates that the higher overall accuracy obtained in the 2:1 scenario was largely influenced by the classifier's biased preference for the majority class (non-target), resulting in poor target detection performance. In the 1:1 scenario, Random Forest showed a more balanced classification between the two classes, correctly identifying 524 target samples and 475 non-target samples, but its overall predictive performance remained limited.

In contrast, the SMO classifier demonstrated higher discriminative capacity and robustness against the proposed time-frequency-spatial representations. In the 1:1 scenario, the SMO achieved an accuracy of 93.66% and a Kappa ratio of 0.8737, indicating a high level of agreement beyond chance. The corresponding confusion matrix showed that 750 of the 839 samples in the target samples and 822 of the 839 non-target samples were correctly classified, resulting in only 17 false positives and 89 false negatives. In the 2:1 scenario, the performance of the SMO remained stable, registering an accuracy of 93.29

These superior results demonstrate that the features extracted by LeNet from CWT sarcograms have a high separability structure that is successfully mapped by the polynomial kernel support vector machine (SVM)-based classifier, overcoming the orthogonal division limitations of the Random Forest for this specific set of attributes. Regarding the generalization of the proposed model, a limitation of the current study is the reliance on subject-dependent cross-validation. The high inter-subject variability inherent in EEG signals poses a significant challenge for applying a model trained on one individual to another. Future work will focus on implementing cross-subject validation (e.g., leave-one-subject-out) and exploring domain adaptation techniques to evaluate and improve the model's generalization capacity for unseen participants in real-world scenarios. The stability of the SMO between the different subsampling ratios reinforces the feasibility of the proposed pipeline for the automated detection of visual targets in RSVP tasks. Compared with previously reported results obtained using the same database [10], [11], [12], the proposed approach achieved competitive classification performance, with an accuracy of 93.66% in the 1:1 scenario and 93.29% in the 2:1 scenario. These results suggest that the combination of CWT-based time-frequency representations, LeNet feature extraction, and SMO classification provides a competitive alternative for RSVP target detection.

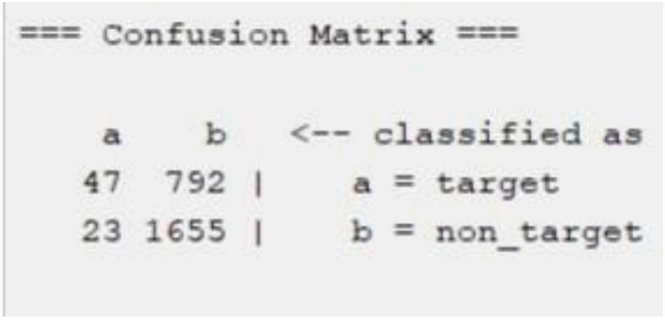

Fig. 2. Confusion matrix of the random forest results with 100 trees.

Furthermore, it is important to discuss the computational limitations of the proposed approach and its potential for real-time applications. The current pipeline involves generating time-frequency representations via the CWT, extracting features using a LeNet architecture, and classifying them with the SMO algorithm. While this methodology yields high discriminative accuracy, the feature extraction step, which required human intervention, introduced a computational overhead that may restrict immediate deployment in real-time scenarios. Future optimizations should investigate architectures that process time-frequency matrices directly, or the implementation of the CWT and classification stages on hardware accelerators to ensure the system provides all requirements for continuous RSVP monitoring.

Abstract* — Assessing cervical curvature often relies on the manual identification of anatomical landmarks on radiographs, a time-consuming procedure that depends on the evaluator's experience and is susceptible to intra- and inter-observer variability. This study proposes an automated method for detecting cervical spine anatomical landmarks in lateral radiographs using deep learning. A total of 1,904 images were selected from the public Cervical Spine X-ray Atlas (CSXA) V3.0 dataset, distributed across the lordotic, straight, and kyphotic classes. Following preprocessing, the radiographs were resized to 224 × 224 pixels, and the landmark coordinates were normalized according to image width and height. A ResNet-18 convolutional neural network was adapted to predict the normalized coordinates of 23 anatomical landmarks, resulting in 46 output values. On the test set, the model achieved a mean Euclidean error of 9.44 pixels relative to the manual reference annotations. As a complementary evaluation, the predicted landmarks were used to extract morphometric features and subsequently classify cervical curvature using supervised algorithms. In this stage, Logistic Regression and Support Vector Machine with an RBF kernel achieved accuracies of 91% and 90%, respectively. The results indicate that the detected landmarks preserved relevant information about cervical geometry, enabling their use for automated morphometric feature extraction. The proposed approach shows potential to support the computational assessment of cervical spine radiographs, although validation on external datasets and images from different clinical settings is still required.

Keywords* — cervical curvature, deep learning, digital image processing, anatomical landmarks, lateral radiography.

I. Introduction

Cervical spine alignment is an important parameter for assessing musculoskeletal disorders, degenerative diseases, and postural abnormalities. Alterations in cervical curvature can be associated with pain, functional limitations, and impaired quality of life—conditions characterized by high prevalence and significant socioeconomic impact [1]–[4]. Furthermore, maintaining physiological alignment contributes to the proper distribution of mechanical loads and the preservation of the biomechanical and neurological functions of the cervical spine, underscoring the importance of developing reliable assessment methods [1], [2], [5].

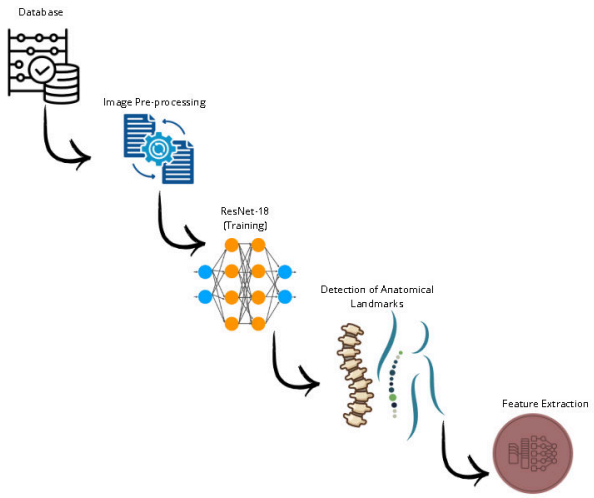
Lateral radiography remains one of the primary examinations used to assess cervical alignment and curvature [3]. However, radiographic analysis still frequently relies on the manual identification of anatomical landmarks and the measurement of morphometric parameters, such as the Cobb angle. This procedure can be time-consuming, dependent on the examiner's experience, and susceptible to intra- and inter-observer variability, factors that may compromise the reproducibility of the measurements obtained [2], [6], [7].

In this context, advances in digital image processing and deep learning have driven the development of automated methods for medical image analysis and the detection of anatomical structures [7], [8]. Models based on convolutional neural networks have demonstrated the ability to automatically localize anatomical landmarks on spinal radiographs, reduce the time required to obtain measurements, and show agreement with assessments performed by specialists [7], [9], [10]. Although these studies have shown promising results, it remains important to investigate approaches that integrate the automatic detection of cervical spine landmarks with the extraction of morphometric features, making it possible to assess whether the predicted landmarks preserve the geometric information required for subsequent analyses.

Thus, this study proposes an automated approach for detecting cervical spine anatomical landmarks in lateral radiographs using deep learning. The methodology integrates digital image processing techniques and a ResNet-18 convolutional neural network adapted to predict the coordinates of 23 anatomical landmarks. As a complementary evaluation, the detected landmarks are used to extract morphometric features and classify cervical curvature, aiming to determine whether the geometric information obtained can support the automated morphometric analysis of this region.

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior — Brasil (CAPES) — Finance Code 001.

II. Materials and Methods



A. Data-base and proposed approach

The study was conducted using the Cervical Spine X-ray Atlas (CSXA) V3.0, a public dataset consisting of 4,963 lateral cervical spine radiographs provided with manual annotations of 23 anatomical landmarks and complementary metadata [3]. The original radiographs have varying resolutions, and the coordinates of the anatomical landmarks are provided in JSON-format files. The reference standard (ground truth) used in this study was derived from annotations independently performed by four orthopedic surgeons specialized in spine surgery, which were subsequently subjected to a three-stage cross-checking procedure. However, the dataset does not provide quantitative measures of intra-observer or inter-observer variability for the annotations used in this study.

For this study, only images classified as lordotic (Class 1), straight (Class 2), or kyphotic (Class 5) were considered. Classes corresponding to sigmoid curvatures were excluded because they require morphometric criteria different from those used for the three selected categories. To reduce class imbalance, up to 700 images from each class were randomly selected using a fixed seed to ensure reproducibility. As the dataset contained only 504 radiographs from the kyphotic class, the final dataset consisted of 1,904 images.

Fig. 1 presents the main stages of the proposed approach, comprising dataset organization, radiograph preprocessing, automatic detection of anatomical landmarks, extraction of morphometric features, and, as a complementary evaluation, classification of cervical curvature.

Fig. 1. Methodological process flowchart.

B. Image preprocessing

Before training the neural network, the radiographs were subjected to a digital image processing pipeline aimed at enhancing bone contours and reducing the influence of noise and contrast variations. Initially, each image was converted to grayscale, focusing the processing on intensity information. Next, Contrast Limited Adaptive Histogram Equalization (CLAHE) was applied with a clip limit of 1.5 and a tile grid size of 8 × 8 to adaptively enhance contrast across different regions of the radiograph [11], [12].

In the next stage, Unsharp Masking was employed to enhance the sharpness of the vertebral contours. A smoothed version of the image was obtained using a Gaussian filter with a 5 × 5 kernel and subsequently combined with the CLAHE-processed image using weights of 1.5 and −0.5, respectively. Sobel operators were also applied in the x and y directions, both with a 5 × 5 kernel, to enhance intensity variations associated with the edges of the bone structures [11].

The gradient map obtained with the Sobel operator in the x direction was inverted and used as an auxiliary mask to attenuate the influence of posterior structures. This mask was combined with the image resulting from Unsharp Masking using weights of 30% and 70%, respectively. Subsequently, the result of this combination was integrated with the gradient map obtained using the Sobel operator in the y direction, with weights of 60% and 40%. The final image resulting from this processing was used as input for the automatic anatomical landmark detection stage. Fig. 2 presents a comparison between the original radiograph and the result of the preprocessing pipeline.

C. Detection of anatomical landmarks

After preprocessing, all radiographs were converted to grayscale—including those originally stored without color information—to ensure the exclusive use of intensity values and avoid the presence of residual color channels. Subsequently, the images were resized to 224×224 pixels and normalized to the 0–1 range. To ensure compatibility with the input of the pre-trained ResNet-18, the intensity channel was replicated three times, resulting in images with dimensions of 224×224×3.

The x and y coordinates of the 23 anatomical landmarks provided by the database were normalized by the image width and height, respectively. This procedure allowed for the standardization of annotations derived from radiographs with varying resolutions [3]. Each sample was associated with an output vector consisting of 46 values, corresponding to the two normalized coordinates of each anatomical landmark.

The set of 1,904 radiographs was split into 80% for training and 20% for testing, using a fixed random seed to ensure the reproducibility of the split. Thus, 1,523 images were allocated for training and 381 for testing. The test set was kept separate during training and subsequently used to evaluate the localization of anatomical landmarks.

Point detection was formulated as a supervised regression problem. For this purpose, a ResNet-18 convolutional neural network, pre-trained on the ImageNet dataset, was used. The fully connected layer originally intended for image classification was replaced by a linear layer with 46 output neurons, enabling the network to simultaneously predict the normalized coordinates of the 23 anatomical points. The ResNet architecture employs residual connections, which facilitate gradient propagation during the training of deep networks [13].

Training was conducted in the Google Colab environment, using a graphics processing unit (GPU) whenever available. Samples were loaded in batches of 16 images and shuffled at each epoch. The Adam optimizer was used with a learning rate of 0.001, and Mean Squared Error (MSE) was used as the loss function.

D. Evaluation of detection and morphometric validation

The localization of the anatomical landmarks was evaluated on the test set, consisting of 381 radiographs not used during training. To quantitatively evaluate the accuracy of anatomical landmark detection, the Euclidean distance between each predicted landmark and its corresponding manual reference annotation (ground truth) was calculated. Since the coordinates used during training were normalized according to the width and height of the images, the predicted coordinates were subsequently converted back to the original dimensions of each radiograph, allowing the localization error to be calculated in pixels in the original image space. The Euclidean distance was calculated according to Eq. (1):

$$E_{px} = \sqrt{\left(x_{pred} - x_{real}\right)^2 + \left(y_{pred} - y_{real}\right)^2} \quad (1)$$

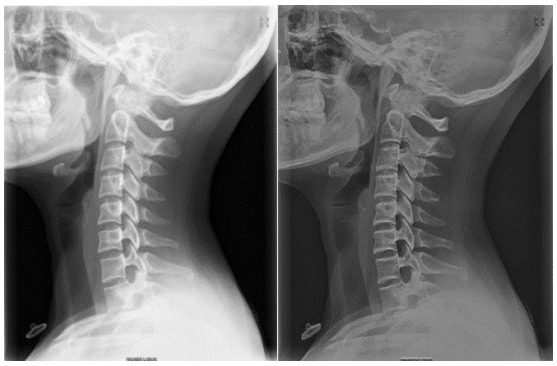
where x_{pred} and y_{pred} correspond to the predicted coordinates converted back to the original radiograph resolution, whereas x_{real} and y_{real} represent the coordinates of the manual reference annotations.

Additionally, using the physical calibration information available in the CSXA metadata, the error in pixels was converted to physical scale using the Pixel equivalent parameter provided individually for each radiograph by the atlas. This conversion allowed the localization error to also be expressed in millimeters, facilitating its interpretation relative to the anatomical scale of the images.

Performance was characterized by the mean, median, standard deviation, and percentiles of the error distribution, both globally and individually for the 23 anatomical landmarks. Detection success rates were also calculated at different distance thresholds, corresponding to the proportion of landmarks whose distance from the reference annotation remained below each established threshold.

Following the detection of anatomical landmarks, morphometric features traditionally used in the assessment of the cervical spine were automatically extracted. Key calculated features included angular measurements, Euclidean distances between anatomical landmarks, vertebral and intervertebral heights, endplate inclinations, geometric descriptors of the vertebrae, and the Cobb angle between C2 and C7. These measurements enabled a quantitative representation of the cervical region's geometry based on the landmarks predicted by the model.

To assess whether the detected anatomical landmarks preserved sufficient morphometric information to distinguish cervical curvature patterns, the extracted features were used as input variables for five families of supervised algorithms: Random Forest, Logistic Regression, Support Vector Machine (SVM), XGBoost, and Multilayer Perceptron (MLP). The SVM was evaluated using both RBF and polynomial kernels, resulting in a total of six classification configurations. At this stage, cervical curvature classification served solely as a complementary validation procedure for the detected anatomical landmarks, rather than as the study's primary objective.



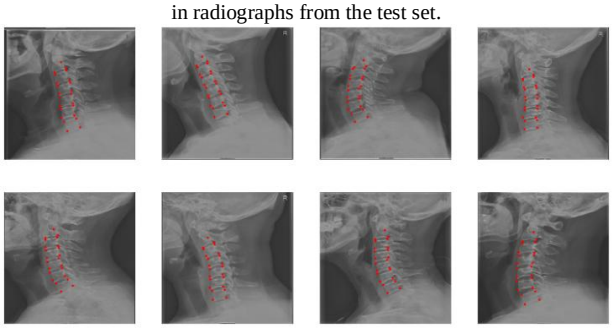
For the classification stage, the morphometric features extracted from the predicted anatomical landmarks were used as input variables for the models. The data were stratified into 75% for training and 25% for testing, using a random seed of 42. The features were standardized to zero mean and unit standard deviation. The performance of the different configurations was evaluated on the test subset using accuracy, precision, sensitivity (recall), and F1-score.

III. RESULTS AND DISCUSSION

A. Preprocessing result

Fig. 2 presents a comparison between an original radiograph and the image obtained after applying the preprocessing pipeline. Visually, the combination of CLAHE, Unsharp Masking, and Sobel operators provided greater differentiation of vertebral contours relative to adjacent tissues and structures. The result preserved the overall anatomical configuration of the cervical spine and enhanced the intensity transitions subsequently used by the neural network to locate anatomical landmarks.

Fig. 2. Comparison between the original radiograph and the image after preprocessing.



Since no specific quantitative metrics were employed to assess preprocessing quality, it is not possible to objectively state that there was an improvement in the visibility, sharpness, or contrast of the radiographs. Therefore, Fig. 2 is presented as a visual comparison between the original image and the result obtained after applying the preprocessing steps.

B. Anatomical landmark detection performance

ResNet-18 was trained for 65 epochs. The number of epochs was empirically determined based on successive training runs, without an automatic stopping criterion, considering the progressive reduction and stabilization of the loss function at values close to 0.001. This behavior indicates convergence of the optimization process. After training, the model was applied to the 381 radiographs in the test set to predict the normalized coordinates of the 23 anatomical landmarks. Fig. 3 presents examples of the predicted landmarks overlaid on the radiographs.

Fig. 3. Examples of the automatic detection of the 23 anatomical landmarks in radiographs from the test set.

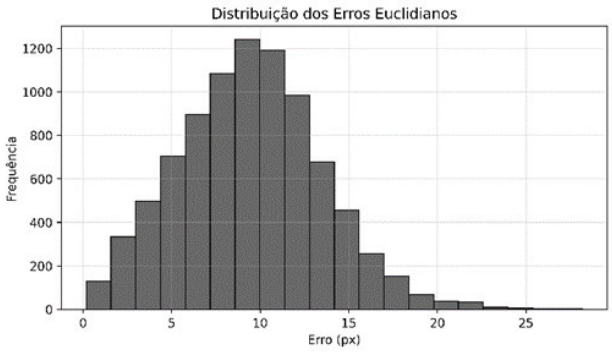
The quantitative evaluation was performed after converting the normalized coordinates back to the original dimensions of each radiograph. Considering the 23 anatomical landmarks across the 381 images, totaling 8,763 evaluated locations, a mean Euclidean error of 9.44 pixels, a median of 9.42 pixels, and a standard deviation of 4.03 pixels were obtained. The 95th percentile was 16.18 pixels, indicating that 95% of the landmark locations had an error less than or equal to this value. After conversion to physical scale using the calibration data provided by the atlas, the corresponding values were a mean error of 3.45 mm, a median of 3.43 mm, a standard deviation of 1.48 mm, and a 95th percentile of 5.96 mm. The cumulative error distribution further showed that 85.94% of the detections were within 5 mm of the reference annotations, whereas 95.32% were within 6 mm and 98.73% were within 7 mm.

TABLE I. GLOBAL STATISTICS OF LANDMARK LOCALIZATION ERRORS

Metric	Pixels	Millimeters
Mean	9.44	3.45
Median	9.42	3.43
Standard deviation	4.03	1.48
P90	14.59	5.34
P95	16.18	5.96
P99	19.83	7.20

The global distribution of errors is presented in Fig. 4. The histogram shows a higher concentration of observations in the intermediate lower-error ranges, with a progressive decrease in frequency as the distance between the prediction and the manual annotation increases. The proximity between the mean and median indicates a relatively balanced distribution in its central region, whereas higher error values represent a smaller proportion of the detections.

Fig. 4. Distribution of Euclidean errors of anatomical landmarks in the test set.



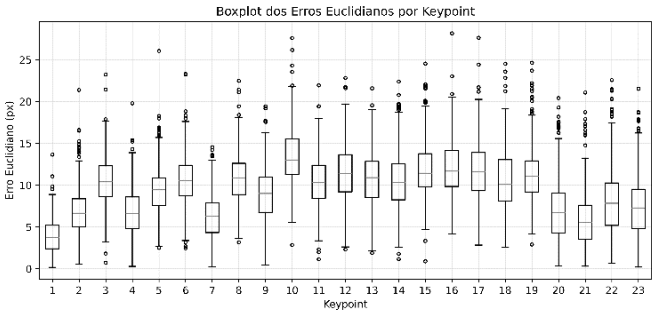


Fig. 5 presents the distribution of Euclidean errors for each of the 23 anatomical landmarks, allowing the behavior of the predictions along the cervical spine to be evaluated individually. Some anatomical landmarks showed lower dispersion and smaller error values, whereas others exhibited greater variability. This behavior indicates that localization difficulty is not uniform across the different landmarks and may be related to the anatomical characteristics of each region and the visualization conditions present in the radiographs.

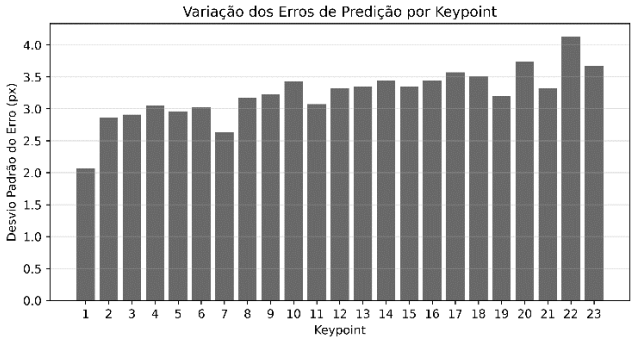

Fig. 5. Distribution of Euclidean errors for each anatomical landmark in the test set.

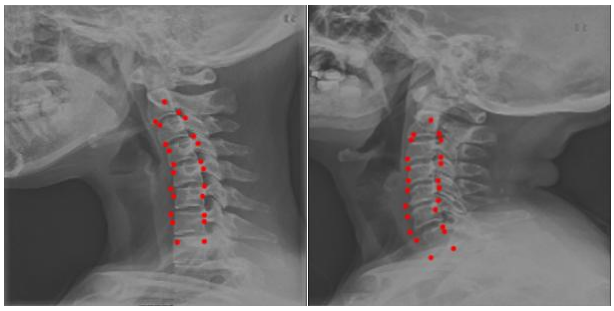
The observed differences may be associated with vertebral position, overlap of bone structures and soft tissues, variations in contrast and positioning during radiographic acquisition, and, in some cases, the presence of external elements, such as clothing, which may hinder the delineation of anatomical contours. These factors may reduce the visibility of specific reference landmarks and contribute to the greater dispersion of errors observed for some landmarks. Therefore, the variation among landmarks reinforces the importance of evaluating model performance individually, since relying exclusively on a global metric may conceal local differences in detection accuracy.

As a complementary analysis of the error distribution by landmark, Fig. 6 presents the standard deviation of the Euclidean error for each anatomical landmark. This measure allows the dispersion of the predictions around the mean behavior of each landmark to be assessed and, consequently, differences in localization consistency among the evaluated landmarks to be identified.

Fig. 6. Distribution of the standard deviation of errors, in pixels, for each anatomical landmark.



The results show that prediction variability was not uniform across the 23 landmarks. While some landmarks exhibited lower error dispersion, indicating more consistent behavior across the evaluated radiographs, others showed higher standard deviations. This analysis complements the differences observed in the boxplot, demonstrating that landmark performance varies not only in terms of error magnitude but also in terms of error dispersion across images. Thus, landmarks with similar mean errors may exhibit different levels of stability, reinforcing the need to consider both the accuracy and variability of the predictions when interpreting the derived morphometric features evaluated in the subsequent stage.

In addition to the quantitative analysis of the error distribution, representative cases in which the predictions showed greater localization difficulty were evaluated. Fig. 7

presents examples in which deviations in the position of some landmarks can be observed, highlighting situations in which the automatic identification of anatomical landmarks showed lower spatial accuracy.

Fig. 7. Examples of radiographs showing deviations in the localization of the predicted anatomical landmarks.

C. *Validation based on morphometric characteristics*

To evaluate whether the detected anatomical landmarks preserved morphometric information useful for differentiating cervical curvature patterns, the extracted features were used as input to five families of supervised algorithms, totaling six configurations. For this stage, the data were stratified into 75% for training and 25% for testing. Tables II–VII present the performance metrics obtained on the test set for each evaluated configuration.

1	0.96	0.94	0.95	175
2	0.82	0.87	0.85	175
5	0.87	0.82	0.84	126

Overall, the metrics showed consistent behavior across the models and complemented the accuracy-based analysis, allowing classifier performance to also be evaluated in terms of their ability to identify the different cervical curvature classes.

Accuracy ranged from 85% to 91%. The best result was obtained by Logistic Regression, with 91%, followed by SVM with an RBF kernel, with 90%. Random Forest and XGBoost achieved 89%, while MLP and SVM with a polynomial kernel showed accuracies of 88% and 85%, respectively.

The performance of Logistic Regression suggests that part of the differences among the lordotic, straight, and kyphotic classes can be represented by approximately linear combinations of the extracted morphometric features. In turn, the performance of SVM with an RBF kernel indicates that nonlinear relationships among these features may also contribute to the separation of curvature patterns. The combined analysis of precision, sensitivity, and F1-score complements these results by considering not only the overall proportion of correct classifications but also the performance of the models in identifying the different curvature patterns. However, since the differences in accuracy among the models were small, it is not possible to claim the definitive superiority of a single configuration without additional analyses, such as cross-validation and confidence intervals.

Considering that the features used by the classifiers were extracted from the anatomical landmarks predicted by ResNet-18, the results indicate that, despite the observed spatial errors, the predicted coordinates remained close to the reference annotations, preserving geometric relationships relevant to the extraction of subsequent morphometric features. The variations resulting from these deviations did not prevent the extracted features from retaining sufficient information to differentiate the evaluated curvature patterns, as demonstrated by the performance of the classifiers. However, this agreement does not imply clinical equivalence of the measurements. For parameters that are more sensitive to small landmark displacements, or for applications requiring greater accuracy, further methodological improvements and additional studies are needed to evaluate the propagation of localization errors to morphometric measurements and their potential impact on clinical decision-making.

Although cervical curvature classification is not the primary objective of this study, the results demonstrate the applicability of the features derived from the predicted landmarks for differentiating the three evaluated curvature patterns. This stage complements the direct evaluation of localization errors and should be interpreted as an internal technical validation of the proposed framework, rather than, in isolation, as a clinical validation of the method.

IV. CONCLUSION

This study presented an automated approach for detecting 23 anatomical landmarks of the cervical spine in lateral

radiographs using a ResNet-18 convolutional neural network. The methodology integrated digital image processing techniques, coordinate normalization, and deep learning, enabling the formulation of landmark localization as a supervised regression task.

Evaluation performed on 381 radiographs not used during training demonstrated a mean Euclidean error of 9.44 pixels, corresponding to 3.45 mm on the considered physical scale. Analysis of the error distribution revealed differences in the magnitude and dispersion of the predictions among the anatomical landmarks, as well as the occurrence of cases with higher deviations. As a complementary analysis, the predicted coordinates were used to extract morphometric features and classify cervical curvature patterns. In this stage, Logistic Regression and SVM with an RBF kernel achieved accuracies of 91% and 90%, respectively, indicating that the detected landmarks preserved geometric information useful for differentiating the lordotic, straight, and kyphotic classes.

As a limitation, the complementary classification stage was conducted as an internal technical evaluation. Future studies should adopt validation strategies that maintain strict separation between the fitting of preprocessing and model selection procedures and the dataset reserved for final evaluation.

The results demonstrate the feasibility of the proposed approach for the automated localization of anatomical landmarks and the extraction of morphometric measurements from the cervical spine. However, the study was conducted using images from a single public dataset and considered only three curvature patterns. Future work should involve evaluating the model on external datasets, including radiographs acquired using different equipment and at different institutions, investigating other deep learning architectures, and directly assessing the propagation of localization errors to morphometric measurements, as well as their clinical relevance through comparisons with assessments performed by specialists.

I. Introduction

The Tilt Test is a test used to assess the cardiovascular response to orthostatic stress and to investigate changes in the autonomic nervous system . The protocol lasts 50 minutes total, with 15 minutes horizontal, 15 minutes inclined and 20 minutes horizontal again. During orthostatic stress, caused by stretcher elevation, an increase in heart rate mediated by sympathetic activation is expected. Changes in this response may indicate autonomic dysfunction.

The Covid-19 pandemic has already affected more than 250 million people globally. Despite advances in understanding COVID-19, there are still many unknowns about its possible repercussions (3,14). Our research group observed a change in heart rate regulation during the Tilt Test in patients with long-term COVID-19.

Notably, there was a significant reduction in spectral density in the high-frequency (HF) heart rate band in this group. Heart rate variability represents a non-invasive biomarker widely used for the assessment of autonomic modulation; post-COVID-19 patients showed a response on the Tilt Test exam that indicates an autonomic dysfunction (2,7,19) . This post-infection autonomic dysfunction is called Long COVID (4,5,10,11,12,16).

In parallel with our research, studies have demonstrated the effectiveness of vaccines in preventing COVID-19-related deaths, highlighting their crucial importance in reducing hospitalizations and deaths (6,13,18). Different vaccine platforms can induce different physiological responses, hence questions arose about the possible dysregulation of the autonomic nervous system also in individuals who did not have COVID-19 (20) but received vaccines, considering that each one was developed by different technologies: vaccine 2 (inactivated virus), vaccine 3 (messenger RNA) and vaccines 1 (viral vector). (21)

Thus, the hypothesis is that different vaccine technologies may be associated with distinct patterns of cardiovascular autonomic regulation, detectable through HRV analysis during the Tilt Test (1,15). And the objective of the study is to investigate possible differences in cardiovascular autonomic regulation associated with different vaccine technologies through the analysis of heart rate variability during the Tilt Test, investigating, in addition to its effectiveness. Using the database of the project "Online non-invasive detection of postural orthostatic tachycardia syndrome in post-COVID-19 patients, Project FAPESP 21/14231-0", we sought to analyze these effects on the body.

This work was supported by the São Paulo Research Foundation (FAPESP), Grant No. 21/14231-0. Ana L. G. Santos was supported by a Scientific Initiation Scholarship from the National Council for Scientific and Technological Development (CNPq).

II. OBJECTIVES

Thus, the hypothesis is that different vaccine technologies may be associated with distinct patterns of cardiovascular autonomic regulation, detectable through HRV analysis during the Tilt Test. And the objective of the study is to investigate possible differences in cardiovascular autonomic regulation associated with different vaccine technologies through the analysis of heart rate variability during the Tilt Test, investigating, in addition to its effectiveness.

III. MATERIALS AND METHODS

For data collection and analysis, a Tilt Test is required, therefore ECG model PC1000 from the Brazilian Electronic Technology TEB, electrodes, a reclining stretcher and automatic digital sphygmomanometer Hem-7320-Br by OMRON. These are the basic materials to be able to take a Tilt Test exam.

The analysis and processing of the collected data are analyzed via computer by programs such as Jamovi and Power Bl. Jamovi assists in the statistical tests of the survey, looking for patterns with the data collected, such as the Mann Whitney (17). Power Bl

unifies all study information, from anamnesis to physiological data during the exam, and makes it easy to visualize it in advanced graphs and filters(8).

The test is collected at the Polyclinic Hospital/University of Mogi das Cruzes (UMC). We look for patients by voluntarism. This study is part of the FAPESP project (Grant 21/14231-0) and was approved by the Institutional Research Ethics Committee (64561022.7.0000.5497).

Before starting data collection, the patient undergoes an anamnesis interview, and then begins the collection of the test. The N of the project is 71 participants, but in this study we will consider only the sample is composed of 19 participants, healthy patients with no history of COVID-19, 7 female and 12 male. As depicted in Image 1.

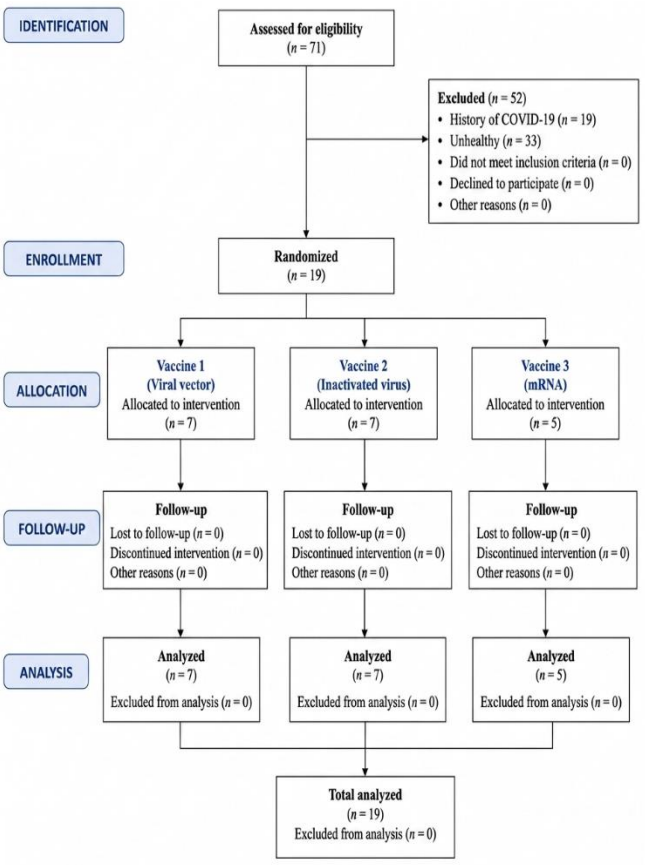

Fig. 1. Consort Flow

Patients who are selected to participate in the study initially go through an inclusion and exclusion criterion, it is necessary to be between 18 and 75 years old, present a negative pregnancy test and PCR, not have any heart problems and not use any medication continuously that alters the autonomic nervous system.

The patient's participation follows the following steps, represented by the following flowchart:

IV. RESULTS

From this part of the study, statistical analysis according to vaccine technology began. As shown in Table 1, a difference in heart rate variation was observed between the vaccine groups studied

As shown in Table 1, the groups also showed differences in heart rate variability indexes, especially in heart rate variation, SDNN, NN50 and pNN50, demonstrating different patterns of cardiovascular response among the vaccine technologies evaluated.

Figure 2 shows the comparison between patients representative

of each vaccine technology, allowing us to visualize the behavior of the heart rate during the Tilt Test.

Regarding Vaccine 2, it was observed that the participants did not show the expected increase in heart rate during the elevation of the stretcher, maintaining similar values throughout the tilt period. Vaccine 3 showed an increase in heart rate during stretcher elevation, followed by stabilization during the examination. Vaccine 1, on the other hand, showed a smaller increase in heart rate during the Tilt Test, remaining with a reduced response during the orthostatic period.

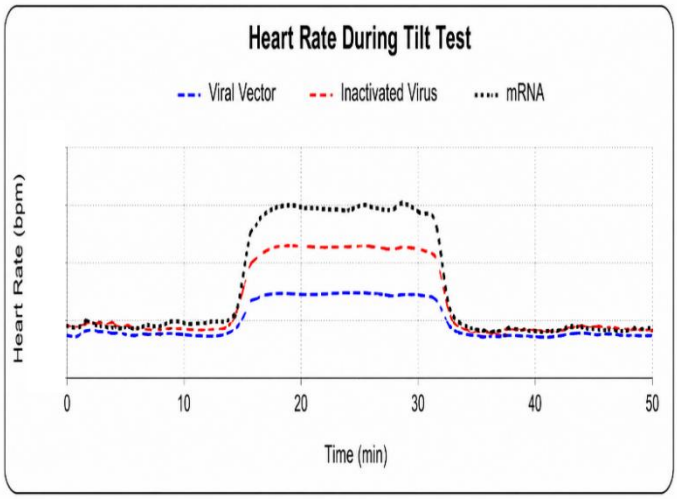

Fig. 2. Group Tilt Test

V. DISCUSSION

The results obtained indicate variations in the physiological responses of the participants, suggesting a possible influence of different vaccine technologies on the autonomic nervous system. The absence of the expected increase in heart rate during stretcher elevation observed mainly in Vaccine 2 may indicate an alteration of cardiovascular autonomic function. On the other hand, Vaccine 3 presented a response closer to the expected physiological behavior during orthostatic stress, characterized by an increase in heart rate followed by stabilization.

The lower heart rate variation observed in Vaccine 1, together with the lower values of the heart rate variability indexes, may suggest a reduction in autonomic modulation when compared to the other groups. These results reinforce the importance of heart rate variability as a non-invasive biomarker for assessing autonomic nervous system function.

It is important to emphasize that the participants evaluated did not have preexisting diseases and did not use continuous medication that could interfere with the autonomic response, reducing possible confounding factors.

However, the study is limited due to the small sample size. Future studies with a larger number of participants and additional analyses of heart rate variability and baroreflex sensitivity will be important to confirm the observed findings and better understand the possible effects of different vaccine technologies on cardiovascular autonomic regulation.

***Abstract*—HER2-positive breast cancer has distinct biological and therapeutic implications, but its assessment remains dependent on pathological testing. This study investigated whether interpretable mammographic descriptors can differentiate HER2-positive breast cancer from other molecular subtypes and healthy controls. Mammograms from the Chinese Mammography Database were analyzed using two feature families: two-dimensional autoregressive descriptors, including coefficients a1-a4 and residual variance s, and fractal descriptors, including box-counting fractal dimension and lacunarity. Pairwise group comparisons were performed using normality-guided Welch t-tests or Mann-Whitney U tests, with effect-size estimation and Benjamini-Hochberg false-discovery-rate correction. The analyzed groups included 124 HER2-positive, 76 luminal A, 36 luminal B, 28 triple-negative, and 126 healthy-control images. Autoregressive features showed consistent FDR-adjusted differences involving HER2-positive cases, with residual variance s significant in all HER2-positive pairwise comparisons. Fractal dimension and lacunarity differentiated HER2-positive cases only from healthy controls. These findings suggest that local gray-level dependency descriptors may capture HER2-associated mammographic patterns more consistently than global fractal morphology descriptors in this dataset.**

***Index Terms*—HER2-positive breast cancer, mammography, radiomics, autoregressive model, fractal analysis, lacunarity.**

I. Introduction

Breast cancer is the most commonly diagnosed malignancy worldwide and remains one of the leading causes of cancer-related mortality among women, underscoring the importance of accurate biological characterization for prognosis estimation, risk stratification, and treatment selection [1]. This disease is recognized as a heterogeneous systemic condition whose clinical management relies on the integration of imaging findings, histopathological assessment, molecular profiling, surgery, radiotherapy, and systemic therapies [2]. Advances in gene-expression profiling demonstrated that breast cancer comprises multiple biologically distinct entities rather than a single disease, revealing molecular patterns associated with differences in tumor biology, clinical behavior, therapeutic response, and patient outcomes [3], [4]. Among these molecular subtypes, tumors characterized by amplification or overexpression of the HER2/neu oncogene represent a clinically important subgroup because of their distinct biological characteristics and prognostic implications [5]. The identification of HER2 status has become a fundamental component of breast cancer management, as it directly influences therapeutic decision-making and determines eligibility for targeted anti-HER2 therapies. Consequently, current ASCO-CAP recommendations emphasize rigorous and standardized HER2 testing to ensure accurate patient classification and appropriate treatment selection [6]. Mammography remains the cornerstone of breast imaging for population-based screening and early cancer detection in average-risk women [7]. Although the balance between screening benefits and potential harms continues to be evaluated, mammography remains one of the primary imaging modalities for the detection and characterization of breast abnormalities and provides a rich source of quantitative information that can be explored through computational image analysis approaches [8]. Radiomics was proposed to extract quantitative information from medical images through high-dimensional feature analysis beyond visual interpretation [9]. Within this framework, medical images are treated as quantitative data sources that may encode tumor phenotype, heterogeneity, and clinically relevant biological variation [10].

The authors are thankful for the received financial support from the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES—Brazil), CNPq—Brazil, and FAPEMIG—Brazil.

To ensure consistency and comparability across studies and institutions, standardized feature definitions and reproducible computational pipelines are required [11]. In mammography, quantitative image features have been investigated for molecular subtype prediction, supporting the hypothesis that subtype-related information can be captured from image-derived patterns [12]. Therefore, the objective of this study was to evaluate whether two interpretable families of mammographic descriptors, two-dimensional autoregressive features and fractal features, can statistically differentiate HER2-positive breast cancer from other molecular subtypes and healthy controls.

II. Materials and Methods

This study was designed as a retrospective computational image-analysis investigation of mammographic features associated with HER2-positive breast cancer. Fig 1 summarizes the methodology employed in this study.

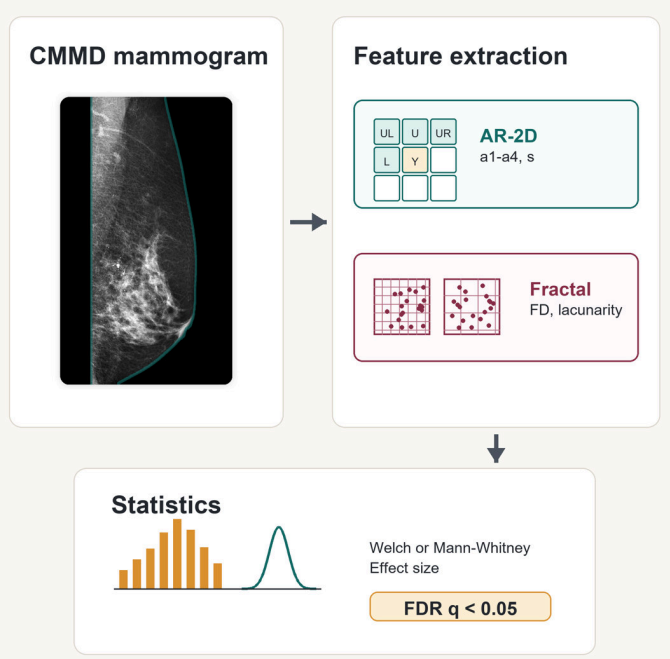

Fig. 1. Flowchat of the proposed methodology.

A. Data Source

Mammographic images were obtained from the Chinese Mammography Database (CMMD), available through The Cancer Imaging Archive (TCIA) [13]. According to the TCIA collection record, CMMD contains mammography data from 1,775 patients from China, including biopsy-confirmed benign or malignant breast disease, with molecular subtype information available for a subset of patients. The collection includes mammographic image data and clinical metadata, including classification, molecular testing, and demographic information [13]. The present analysis focused on image-level groups defined as HER2-positive breast cancer, luminal A breast cancer, luminal B breast cancer and triple-negative breast cancer. The control group was defined as mammograms without any benign or malignant abnormality. The analyzed groups included 124 HER2-positive images, 76 luminal A images, 36 luminal B images, 28 triple-negative images, and 126 control images. The dataset presentes images from both cranio-caudal (CC) and medio-lateral oblique (MLO) views per patient. For the cancer subtypes cases, it was provided images of both breasts and indicates the side affected by malignancy. For the control group, one normal breast per control subjec was used, chosen randomly. The features was extracted from both views and averaged so that each subject contributed a single representative feature set for statistical and classifier-based analyses.

B. Image Preprocessing

The mammographic images were processed from DICOM files using custom MATLAB routines. For each image, a foreground mask was generated by thresholding all pixels greater than the minimum image intensity. Connected components were then computed, and the largest connected component was retained as the breast foreground mask. Pixels outside this mask were removed from the analysis. In the autoregressive-feature pipeline, background pixels were assigned as not-a-number values so that they were excluded from neighborhood-based estimation. In the fractal-feature pipeline, image intensities were normalized to the [0, 1] range before foreground extraction, and the binary foreground mask was used for fractal analysis.

C. Two-Dimensional Autoregressive Feature Extraction

Autoregressive features were extracted using a two-dimensional neighborhood model. For each valid foreground pixel, the current intensity was modeled as a linear combination of four neighboring intensities: left, upper-left, upper, and upper-right. Pixels were included only when the current pixel and all four neighbors were inside the foreground mask. Let Y denote the vector of valid target intensities and X the corresponding matrix of neighboring intensities. The autoregressive coefficients were estimated by least squares as shown in equation (1):

$$\beta = (X^T X)^{-1} X^T Y \tag{1}$$

The four coefficients were retained as features a1, a2, a3, and a4. The variance of the residual error, given by equation (2), was also retained as a regularity-related feature.

$$s = var(Y - X\beta) \tag{2}$$

Therefore, each image was represented by five autoregressive descriptors: a1, a2, a3, a4, and s.

D. Fractal Feature Extraction

Fractal analysis was performed on the binary foreground mask. Fractal dimension was estimated using a box-counting procedure. The mask was evaluated at box sizes defined by powers of two, with zero padding applied when the image dimensions were not exactly divisible by the box size. For each scale, the number of boxes containing at least one foreground

pixel was counted. The fractal dimension was estimated as shown in equation (3)

$$\log N(\varepsilon) = D\ \log(1/\varepsilon) + b \tag{3}$$

where D represents the slope of the fitted line, corresponding to the fractal dimension, and b denotes the intercept of the linear regression. Lacunarity was computed from the distribution of foreground-pixel counts inside boxes across scales. For each box size, the foreground mass was calculated for all boxes, and lacunarity was defined as the variance of box masses divided by the squared mean box mass, with a numerical epsilon added to the denominator. The final lacunarity value was obtained as the mean lacunarity across the evaluated scales. Each image was therefore represented by two fractal descriptors: fractal dimension and lacunarity.

E. Statistical Analysis

Pairwise statistical comparisons were performed between all study groups. For each feature and each pairwise comparison, normality was assessed separately in both groups using the Lilliefors test. When both groups satisfied the normality criterion, the Welch two-sample t-test was used, and the effect size was calculated as Hedges' g. When one group did not satisfy the normality criterion, the Mann-Whitney U test was used, and the effect size was calculated as the rank-biserial correlation. P values were corrected for multiple comparisons within each pairwise feature set using the Benjamini-Hochberg false discovery rate procedure. Statistical significance was defined as an FDR-adjusted p value below 0.05. The analysis was restricted to feature-level group discrimination. No supervised classifier was trained in the current stage of the study. This choice was made to preserve direct interpretability of the extracted mammographic descriptors and to identify which autoregressive and fractal features show statistically supported differences involving the HER2-positive group.

III. Results

The statistical analysis included five image-level groups: HER2-positive breast cancer, luminal A breast cancer, luminal B breast cancer, triple-negative breast cancer, and healthy controls. The sample size used for each group is summarized in Table I.

TABLE I
IMAGE-LEVEL GROUP DISTRIBUTION USED IN THE STATISTICAL ANALYSIS.

Group	**Abbreviation**	n
HER2-positive breast cancer	HER2+	124
Luminal A breast cancer	LA	76
Luminal B breast cancer	LB	36
Triple-negative breast cancer	TNBC	28
Healthy control	Control	126

Autoregressive features showed consistent statistically significant differences involving the HER2-positive group after Benjamini-Hochberg FDR correction. In the comparison between HER2-positive and luminal A images, all five autoregressive descriptors were significant. The same complete separation across the five descriptors was observed for HER2-positive images versus healthy controls. In comparisons with luminal B and triple-negative images, significant findings were more selective, but residual variance s remained significant in both comparisons. Table II presents the summarization of the results for the autoregressive comparisons.

TABLE II
AUTOREGRESSIVE HER2-POSITIVE COMPARISON SUMMARY.

Comparison	**Significant features**	**q(FDR) range**
HER2+ vs LA	all	3.25e-05-6.05e-04
HER2+ vs LB	a4, s	3.66e-04-1.30e-02
HER2+ vs TNBC	a1, a2, a3, s	2.67e-03-6.84e-03
HER2+ vs Control	all	3.62e-16-2.59e-07

At the individual-feature level, the HER2-positive versus luminal A comparison yielded FDR-adjusted significance for a1 (q=3.25e-05), a2 (q=6.00e-05), a3 (q=1.12e-04), a4 (q=6.05e-04), and s (q=3.51e-05). The HER2-positive versus luminal B comparison retained significance for a4 (q=1.30e-02) and s (q=3.66e-04). The HER2-positive versus triple-negative comparison retained significance for a1 (q=6.84e-03), a2 (q=2.67e-03), a3 (q=6.84e-03), and s (q=2.67e-03). The HER2-positive versus control comparison retained significance for all autoregressive descriptors, with q=1.89e-09 for a1, q=5.31e-10 for a2, q=1.20e-10 for a3, q=2.59e-07 for a4, and q=3.62e-16 for s. Fractal descriptors showed a narrower pattern of HER2-positive separation, as shown in Table III. Neither fractal dimension nor lacunarity remained significant after FDR correction in the HER2-positive comparisons against luminal A, luminal B, or triple-negative images. Both fractal descriptors were significant only in the comparison between HER2-positive images and healthy controls.

TABLE III
FRACTAL FEATURES IN HER2-POSITIVE PAIRWISE COMPARISONS.

Comparison	**Fractal dimension**	**Lacunarity**
HER2+ vs LA	0.2429	0.2150
HER2+ vs LB	0.3096	0.1266
HER2+ vs TNBC	0.0967	0.0545
HER2+ vs Control	0.0130	9.33e-04*

In Table III, the asterisk denotes FDR-adjusted statistical significance. The non-significant HER2-positive versus triple-negative lacunarity result approached the adopted threshold but did not pass correction (q=0.0545). Taken together, the feature-level results indicate that autoregressive descriptors provided broader HER2-positive separation across tumor subtypes and controls than fractal descriptors in this dataset. The most consistent autoregressive finding was the residual variance s, which was significant in all HER2-positive pairwise comparisons reported in Table II.

IV. Discussion

This study found that two-dimensional autoregressive descriptors extracted from mammograms provided a broader feature-level separation of HER2-positive breast cancer than fractal descriptors. All five autoregressive variables differed between HER2-positive and luminal A cases and between HER2-positive and healthy controls after FDR correction. In addition, the residual variance s remained significant in every HER2-positive pairwise comparison. By contrast, fractal dimension and lacunarity were significant only when HER2-positive cases were compared with healthy controls. Therefore, within the limits of the current feature-level analysis, local gray-level dependence and residual regularity captured by the autoregressive model appeared more sensitive to HER2-positive differences than global foreground-mask fractal morphology.

These results are consistent with the general radiomics premise that quantitative image descriptors can encode tissue heterogeneity, spatial organization, and phenotype-related information not fully captured by visual interpretation alone [14]. They also agree with recent mammography-based studies showing that HER2 status can be predicted non-invasively from imaging features. Deng et al. developed a multicenter mammographic radiomics model for HER2 status in 1512 patients with improvement after adding clinical characteristics [15]. Although our work did not train a classifier, the consistent FDR-corrected separation of autoregressive features, especially s, supports the same underlying conclusion: mammographic texture contains measurable information associated with HER2-positive disease.

The stronger performance of local texture-related descriptors in our analysis also parallels contrast-enhanced mammography studies. Wang et al. reported that whole-tumor and subregion intratumoral heterogeneity radiomics from CEM differentiated HER2 expression status, with a combined model [16]. Piccolo et al. found that CEM radiomic features, particularly texture features such as gray-level co-occurrence matrix metrics, were associated with HER2 and other prognostic factors [17]. Xu et al. further showed that intra- and peritumoral CEM radiomics could predict equivocal HER2 status [18]. These studies used contrast-enhanced information and tumor/peritumoral segmentation, while the present study used mammographic images and whole-breast foreground processing. Even so, the convergence across studies suggests that spatial heterogeneity and local intensity relationships are relevant imaging correlates of HER2 biology.

Our results are also compatible with studies that address molecular subtype prediction rather than HER2 status alone. Bakker et al. used screening digital mammograms to classify molecular subtypes [19]. Yang et al. integrated mammography and DCE-MRI radiomics and reported better discrimination for luminal A versus HER2 overexpression than for triple-negative versus HER2 overexpression [20]. This pattern is relevant to our data because the autoregressive features separated HER2-positive cases from luminal A and controls more broadly than from luminal B, while the HER2-positive versus triple-negative comparison retained significance for a1, a2, a3, and s but not a4. These subtype-dependent patterns support the interpretation that HER2-related imaging differences are not uniform across all reference groups.

Regarding the fractal descriptors, their limited performance is inherently tied to the type of macro-structural information they encode. Fractal dimension and lacunarity were computed from the foreground breast mask, not from lesion-level gray-level texture. Thus, they primarily summarized global spatial complexity and gap distribution of the segmented breast foreground. Their significance in HER2-positive versus control comparisons may reflect broad disease-versus-healthy structural differences, whereas their lack of significance among tumor subtypes suggests lower sensitivity to molecular subtype variation than autoregressive gray-level descriptors. This interpretation is consistent with radiomics reviews emphasizing that feature class, segmentation strategy, image modality, and preprocessing strongly influence the biological meaning and reproducibility of radiomic features [14], [21].

Recent evidence also indicates that mammography-based AI for receptor or subtype prediction remains promising but not yet clinically definitive. Hosseinzadeh et al., in a systematic review and meta-analysis, highlighted substantial heterogeneity and the need for larger multicenter studies, standardized pipelines, external validation, and uncertainty quantification [22]. Mota reviewed radiomics and deep learning approaches in mammography and tomosynthesis and similarly emphasized that public datasets are used in only a minority of studies, limiting reproducibility [21]. In this context, the present study contributes a transparent feature-level analysis based on a public TCIA dataset rather than an opaque end-to-end prediction model. Several limitations must be acknowledged. First, the analysis was performed at feature level and did not evaluate predictive classification performance, calibration, or external generalization. Therefore, the results cannot be interpreted as diagnostic accuracy estimates. Second, the autoregressive and fractal pipelines used foreground processing rather than manual or automated lesion segmentation; this design improves workflow simplicity but may dilute lesion-specific information. Finally, although FDR correction was applied within pairwise feature sets, the study remains exploratory and should be followed by independent validation and, if appropriate, classifier development using the most stable autoregressive descriptors.

Overall, the findings support the hypothesis that HER2-positive breast cancer may exhibit detectable mammographic texture signatures. The most robust signal in this analysis was not fractal morphology but autoregressive residual regularity, suggesting that local gray-level dependency may be a useful direction for interpretable radiomic modeling of HER2-positive disease.

V. Conclusion

This study evaluated interpretable mammographic descriptors for differentiating HER2-positive breast cancer from other molecular subtypes and healthy controls. The results indicate

that two-dimensional autoregressive features provide broader HER2-positive separation than fractal descriptors, with residual variance s showing FDR-adjusted significance in all HER2-positive pairwise comparisons. In contrast, fractal dimension and lacunarity differentiated HER2-positive cases only from healthy controls, suggesting that these global morphology descriptors were less sensitive to subtype-level differences in the present analysis.

These findings support the use of local gray-level dependency descriptors as a transparent radiomic strategy for exploring HER2-associated mammographic patterns. Future work should validate these descriptors at patient level, evaluate their stability across acquisition settings, and test whether the most robust autoregressive features improve supervised models for non-invasive HER2-positive breast cancer characterization.

***Resumo*—Este estudo analisou retrospectivamente a triagem operacional de retinopatia diabética (DR) referenciável em cenário de restrição de orçamento de revisão e de mudança de distribuição interna–externa. O objetivo principal foi avaliar um protocolo operacional integrado que reúne discriminação, calibração com escalonamento de temperatura, incerteza por Monte Carlo dropout, captura sob orçamento de revisão e mapeamento auditável de prioridades por camada fuzzy. Como instanciação comparativa desse protocolo, a arquitetura EfficientNet-B0 com cabeça inspirada em KAN foi confrontada com uma baseline EfficientNet-B0+MLP, treinadas nos mesmos subconjuntos e com três sementes. Essa abordagem evitou que a avaliação ficasse limitada apenas a métricas puramente agregadas. Os resultados mostraram desempenho discriminativo comparável entre KAN e MLP, com AUC interna de 0.905 ± 0.003 e 0.904 ± 0.003, e externa de 0.959 ± 0.003 e 0.956 ± 0.006, respectivamente; calibração da KAN com Brier scores de 0.075 ± 0.001 (interno) e 0.095 ± 0.008 (externo); captura orçamentária na distribuição externa de 0.239 ± 0.003 dos casos referenciáveis no top-10% e 0.988 ± 0.002 no top-50%; e comportamento da categoria fuzzy de encaminhamento urgente, que absorveu 48.3% da carga de trabalho externa e preservou 0.974 ± 0.009 dos casos referenciáveis externos, o que reitera a necessidade de avaliação integrada em discriminação, calibração, incerteza, captura orçamentária e auditabilidade.**

I. Introdução

A retinopatia diabética (DR) permanece como causa relevante de perda visual evitável em pessoas com diabetes, e a detecção precoce da forma referenciável é central nos programas de rastreamento. Diante do volume de exames que pode sobrecarregar especialistas, o suporte automatizado é mais útil quando tratado como ferramenta de priorização de revisão, não apenas como classificador binário [1]–[5]. Métricas agregadas, como AUC, sensibilidade, especificidade e F1-score, continuam necessárias, mas não descrevem diretamente o desempenho sob orçamento de revisão, os casos referenciáveis não detectados, a redução da carga de trabalho, a segurança das decisões de não encaminhamento ou a precisão entre exames revisados.

A avaliação sob deslocamento de distribuição revela que divergências entre bases, dispositivos, aquisição, prevalência, qualidade de imagem, rotulagem e pré-processamento alteram discriminação, calibração e perfis de erro [6]–[9], de modo que AUC elevada em teste externo pode coexistir com confiabilidade probabilística reduzida e riscos assimétricos. Falsos negativos confiantes constituem o modo de falha de maior relevância operacional: políticas fundamentadas exclusivamente em probabilidade ou incerteza podem postergar casos referenciáveis com baixa probabilidade predita, baixa incerteza estimada e alta confiança.

Este estudo avaliou retrospectivamente uma estrutura de priorização de revisão para DR sob orçamento de revisão e mudança de distribuição interna–externa, sem propor uma arquitetura diagnóstica clinicamente validada. A contribuição principal é um protocolo de avaliação operacional que integra ranqueamento por probabilidade, calibração, incerteza, captura sob orçamento, categorias fuzzy e análise de modos de falha. A comparação entre EfficientNet-B0 com cabeça inspirada em KAN [10], [11] e EfficientNet-B0+MLP, conduzida nos mesmos subconjuntos e sementes, é utilizada como instanciação comparativa desse protocolo, e não como demonstração de superioridade arquitetural. Complementam a avaliação o escalonamento de temperatura, o MC-dropout, os intervalos bootstrap e a camada fuzzy como mapeamento auditável de prioridade, não como substituto do ranqueamento por probabilidade ou de regras clínicas.

II. Trabalhos Relacionados

Modelos convolucionais e transfer learning [1]–[5] têm produzido alta discriminação para DR referenciável em fotografias coloridas de fundo de olho, com métricas como AUC, sensibilidade, especificidade e F1-score. Esses índices, porém, não garantem triagem segura quando a revisão especializada é limitada ou quando há deslocamento dos dados. Diferenças em dispositivos, aquisição, composição dos casos, prevalência, qualidade da imagem e rotulagem podem afetar discriminação, calibração e assimetria dos erros [6]–[9]; por isso, a interpretação de testes externos deve considerar prevalência, confiabilidade probabilística, incerteza e casos referenciáveis residuais. Calibração, quantificação de incerteza, classificação seletiva, predição conformal e

aprendizado com encaminhamento estimam confiabilidade, variabilidade preditiva, cobertura, abstenção e trade-offs de revisão [12]–[21], mas não eliminam necessariamente falsos negativos confiantes, que podem apresentar baixa incerteza e alta confiança. Sistemas fuzzy fornecem funções de pertinência explícitas e regras interpretáveis [22]–[25]; neste estudo, essa abordagem é tratada como camada de auditabilidade, não como regra clínica definitiva. Com esse enquadramento, o manuscrito avalia classificadores com o mesmo backbone e protocolo pareado, calibração, incerteza, ranqueamento por probabilidade, triagem fuzzy, captura sob orçamento de revisão e risco residual, em consonância com diretrizes de relato sobre uso pretendido, validação, calibração, contexto clínico e limitações [26], [27].

III. Metodologia

Esta seção descreve a formulação retrospectiva da triagem, os subconjuntos fixos de avaliação, os modelos, as estimativas de incerteza, a camada fuzzy, as métricas sob orçamento de revisão e os resumos estatísticos. A avaliação foi estruturada como fluxo de priorização de revisão, não como sistema diagnóstico autônomo. Todas as análises usaram apenas subconjuntos fixos, modelos previamente treinados, tabelas de predição e resumos do protocolo experimental predefinido; nenhum treinamento adicional foi realizado para este manuscrito.

A. Desenho do Estudo e Formulação do Problema de Triagem

Este estudo retrospectivo estruturou a triagem de DR referenciável em imagens coloridas de fundo de olho como priorização de revisão sob capacidade limitada. Cada imagem recebeu um rótulo binário de DR referenciável, e o classificador estimou a probabilidade dessa condição. A análise primária foi guiada pelo ranqueamento dos exames para revisão especializada sob orçamentos fixos, embora métricas binárias convencionais também tenham sido reportadas.

Avaliaram-se, nos mesmos casos, três estratégias de priorização para DR referenciável: ranqueamento por probabilidade, priorização por incerteza como baseline de ablação e triagem fuzzy guiada por probabilidade como mapeamento operacional inspecionável, não como diagnóstico autônomo. O objetivo foi caracterizar a captura de casos referenciáveis no subconjunto revisado e a ocorrência de patologias não detectadas sob priorização operacional. Situações inseguras de não encaminhamento corresponderam a exames referenciáveis incorretamente direcionados ou mantidos abaixo do limiar de revisão; falsos negativos confiantes corresponderam a exames referenciáveis com baixa probabilidade predita, baixa incerteza e alta confiança. Os subconjuntos interno e externo foram analisados separadamente quanto à discriminação, calibração, incerteza, distribuição da triagem e desempenho sob orçamento em cenário de mudança de distribuição interna–externa.

B. Descrição do Dataset e Subconjuntos Experimentais

A triagem retrospectiva binária de DR referenciável usou imagens de fundo de olho de `carlos-brasil/dr-triage-kan-fuzzy-dataset`; graus 0–1 foram mapeados como não referenciáveis, e graus 2–4 como referenciáveis. Foram contempladas nos subconjuntos fixos as 29,857 imagens de treinamento, as 5,269 de validação (com uma estratificação de 15% configurada por `referable_dr` sob a semente 42), as 53,576 de teste interno e as 3,662 de teste externo, as quais foram divididas entre o EyePACS 2015, representando o domínio interno, e o APTOS 2019, voltado ao teste externo. Treinamento e validação foram usados para ajuste dos modelos e suporte à calibração; os testes interno e externo avaliaram, respectivamente, o domínio-fonte e o cenário deslocado.

As verificações de integridade foram guiadas pelos identificadores disponíveis. Não houve evidência de sobreposição em nível de imagem, e a sobreposição em nível de paciente apareceu apenas entre treinamento e validação, o que exige cautela analítica. As imagens foram processadas em RGB, redimensionadas para 224×224 pixels e, no treinamento, receberam aumento de dados por espelhamento aleatório (probabilidade 0.5) e rotação de até 10 graus. Na avaliação, aplicaram-se apenas normalização ImageNet e conversão para tensor. O subconjunto externo permaneceu fora do treinamento e da seleção de limiares; seus resultados foram interpretados como evidência sob deslocamento em relação ao EyePACS. A Tabela I resume os testes e o desempenho médio da KAN.

Tabela I
Resumo dos conjuntos de teste interno e externo, com prevalência das bases e desempenho da KAN relatado como média ± desvio-padrão em três sementes

Subconjunto de avaliação	Casos	Referenciáveis n (%)	AUC	Brier
Teste interno	53,576	10,281 (19.2%)	0.905 ± 0.003	0.075 ± 0.001
Teste externo	3,662	1,487 (40.6%)	0.959 ± 0.003	0.095 ± 0.008

C. Modelo de Classificação

O classificador de DR referenciável usou um backbone EfficientNet-B0 e uma cabeça de duas classes. Para a imagem x_i, definiram-se a representação visual, os logits e a probabilidade da classe referenciável.

$$\begin{aligned} z_i &= g_\phi(x_i), \\ l_i &= h_\psi(z_i) \in \mathbb{R}^2, \\ P_{r,i} &= \frac{\exp(l_{i,1})}{\exp(l_{i,0}) + \exp(l_{i,1})}, \end{aligned} \tag{1}$$

em que $g_\phi(\cdot)$ denota o backbone e $h_\psi(\cdot)$ a cabeça de classificação. A EfficientNet-B0 da `torchvision` foi inicializada com pesos pré-treinados padrão. O classificador original foi substituído por uma cabeça inspirada em KAN, composta por duas camadas totalmente conectadas com 256 unidades, cada uma seguida por ativação spline treinável baseada em tanh e dropout de 0.2, além de uma camada linear final de duas classes.

Os modelos foram treinados com perda de entropia cruzada,

$$L_{CE} = -\frac{1}{N} \sum_{i=1}^{N} \sum_{k=0}^{1} \mathbb{I}(y_i = k) \log \left(\mathrm{softmax}(l_i)_k \right), \tag{2}$$

em que $y_i \in \{0, 1\}$, foram mobilizados na execução do treinamento o otimizador AdamW, uma taxa de aprendizado

estipulada em 1×10^{-4}, o decaimento de pesos em 1×10^{-4}, o tamanho de lote fixado em 32, a extensão de 5 épocas e o mapeamento pelas sementes 42, 123 e 2026. Sob essa mesma lógica de reprodutibilidade, processou-se diretamente nas frentes do Python, NumPy, PyTorch e CUDA o estrito controle da aleatoriedade, diretriz que também norteou a ativação do cuDNN em modo determinístico e a desabilitação completa do benchmarking.

A avaliação utilizou a probabilidade softmax da classe referenciável e um limiar fixo de 0,5 para o cálculo das métricas binárias. A apresentação dos resultados concentrou-se em AUC, Brier score, calibração binária, falsos positivos e falsos negativos, captura sob orçamento de revisão e precisão entre os casos revisados, com médias entre sementes quando disponíveis, sem extrapolação além dos resumos relatados.

O comparador consistiu no backbone EfficientNet-B0 acoplado a uma cabeça MLP convencional, camada totalmente conectada de 256 unidades, ReLU, dropout de 0,2 e camada linear de duas classes, segundo os mesmos subconjuntos, pré-processamento, sementes, otimizador, limiar, métricas de calibração e análises sob orçamento de revisão. Desse modo, a comparação configura um pareamento por backbone e protocolo, e não uma ablação de capacidade idêntica, uma vez que as cabeças diferem em profundidade e parametrização interna.

D. Quantificação de Incerteza

Este procedimento operacional utilizou estimativas de incerteza na condição de descritores auxiliares voltados à priorização de revisão e à análise de modos de falha, sem caracterizá-las como indicadores definitivos de correção ou segurança clínica. A inferência por MC-dropout foi conduzida com o mesmo backbone EfficientNet-B0 e com a cabeça inspirada em KAN adotados no pipeline principal, sendo aplicada aos subconjuntos de validação, teste interno e teste externo nas sementes 42, 123 e 2026.

Na etapa de inferência, o modelo foi mantido em modo de avaliação, preservando-se ativas apenas as camadas de dropout para estimativa estocástica da incerteza. Cada imagem foi processada por meio de $T = 10$ passagens forward, das quais foram obtidas as probabilidades de classe referenciável $q_i^{(t)}{}_{t=1}^{T}$.

$$\begin{aligned} \bar{q}_i &= \frac{1}{T}\sum_{t=1}^{T} q_i^{(t)}, \\ H_i &= -\bar{q}_i \log(\bar{q}_i) - (1-\bar{q}_i)\log(1-\bar{q}_i), \\ U_{e,i} &= \frac{H_i}{\log(2)}, \\ \sigma_{\mathrm{MC},i} &= \sqrt{\frac{1}{T-1}\sum_{t=1}^{T}\left(q_i^{(t)} - \bar{q}_i\right)^2}, \\ C_i &= \max(P_{r,i}, 1 - P_{r,i}). \end{aligned} \tag{3}$$

Aqui, $\bar{q}_i$ é a probabilidade média por MC-dropout, H_i a entropia preditiva, $U_{e,i}$ a entropia normalizada, $\sigma_{\mathrm{MC},i}$ o desvio-padrão por MC-dropout e C_i a confiança determinística calculada a partir de $P_{r,i}$. No controle negativo baseado apenas em incerteza, a variabilidade MC foi normalizada dentro de cada subconjunto,

$$\begin{aligned} U_{a,i} &= \frac{\sigma_{\mathrm{MC},i} - \min_j \sigma_{\mathrm{MC},j}}{\max_j \sigma_{\mathrm{MC},j} - \min_j \sigma_{\mathrm{MC},j} + \epsilon}, \\ r_i^{\mathrm{unc}} &= \frac{U_{e,i} + U_{a,i} + (1 - C_i)}{3}. \end{aligned} \tag{4}$$

Esse escore não incorporou a direção da probabilidade de doença e foi usado apenas como baseline negativo de priorização.

Esses descritores apoiaram a avaliação da calibração e a análise de modos de falha. Sua interpretação foi estritamente empírica, pois casos referenciáveis ainda podem receber baixa probabilidade predita, baixa incerteza estimada e alta confiança do modelo.

E. Comparadores Baseline e Protocolos de Calibração/Seleção

Esta análise comparativa foi conduzida sob desenho pareado por backbone e protocolo, confrontando EfficientNet-B0 com cabeça inspirada em KAN à baseline EfficientNet-B0+MLP, com os mesmos subconjuntos, sementes, pré-processamento, limiar e avaliação downstream. O objetivo foi verificar se, sob esse protocolo, a cabeça inspirada em KAN alterou o comportamento retrospectivo da triagem em relação a uma cabeça neural convencional.

Todas as análises determinísticas utilizaram a probabilidade de DR referenciável p_i para a imagem x_i, com rótulo binário $y_i \in \{0, 1\}$. As predições binárias usaram limiar fixo de 0.5,

$$\hat{y}_i = \mathbb{I}(p_i \geq 0.5). \tag{5}$$

As métricas de classificação incluíram AUC, acurácia, acurácia balanceada, F1-score, sensibilidade, especificidade e Brier score,

$$\mathrm{Brier} = \frac{1}{N}\sum_{i=1}^{N}(p_i - y_i)^2. \tag{6}$$

Na análise sob orçamento de revisão, os casos foram ranqueados pela probabilidade predita de DR referenciável. Para um orçamento $b \in (0, 1]$, os casos do topo

$$K_b = \lceil bN \rceil \tag{7}$$

foram selecionados para revisão simulada por especialista. Seja $\mathcal{S}_b$ esse subconjunto. A captura de casos referenciáveis foi

$$\mathrm{Capture}(b) = \frac{\sum_{i \in \mathcal{S}_b} y_i}{\sum_{i=1}^{N} y_i}. \tag{8}$$

A precisão dentro do subconjunto revisado foi

$$\mathrm{Precision}_{\mathrm{review}}(b) = \frac{\sum_{i \in \mathcal{S}_b} y_i}{|\mathcal{S}_b|}. \tag{9}$$

O escalonamento de temperatura *post-hoc* foi avaliado nas saídas probabilísticas determinísticas da KAN e da MLP. A temperatura escalar T_{cal} foi ajustada na validação para cada modelo e semente e aplicada, sem reajuste subsequente, às predições de validação, teste interno e teste externo. No cenário binário, o escalonamento foi aplicado às log-odds implicadas por p_i,

$$\tilde{p}_i(T_{\mathrm{cal}}) = \sigma\left(\frac{\log\left(\frac{p_i}{1-p_i}\right)}{T_{\mathrm{cal}}}\right), \tag{10}$$

em que $\sigma(\cdot)$ é a sigmoide logística. Como a transformação é monotônica, ela foi interpretada como ajuste de calibração, não como alteração da discriminação ou do ranqueamento por probabilidade. A calibração antes e depois do escalonamento foi avaliada por erro esperado de calibração, *negative log-likelihood*, Brier score e diagramas de confiabilidade.

A incerteza estatística foi estimada por bootstrap em nível de caso, com 1,000 reamostragens. Para a métrica m, as amostras bootstrap produziram $\{m^{(r)}\}_{r=1}^{1000}$, e o intervalo de confiança de 95% foi definido pelos percentis empíricos 2.5 e 97.5,

$$\mathrm{CI}_{95\%}(m) = \left[Q_{0.025}\left(\{m^{(r)}\}_{r=1}^{1000}\right), Q_{0.975}\left(\{m^{(r)}\}_{r=1}^{1000}\right) \right]. \tag{11}$$

Os intervalos por bootstrap foram calculados para métricas de classificação e orçamento de revisão. Na comparação KAN-versus-MLP em nível de manuscrito, os intervalos de confiança incorporaram as saídas probabilísticas médias entre sementes e foram interpretados de forma estritamente descritiva, não como testes formais de superioridade.

F. Camada de Triagem por Inferência Fuzzy

Uma camada de triagem por inferência fuzzy mapeou cada probabilidade determinística de DR referenciável para uma categoria inspecionável de prioridade de revisão. Para cada imagem x_i, essa estrutura atribuiu uma categoria e expôs o grau de pertinência da probabilidade predita p_i em conjuntos fuzzy adjacentes. O componente foi avaliado como mecanismo de auditabilidade operacional, não como substituto do ranqueamento por probabilidade nem como regra diagnóstica independente.

Sobre p_i definiram-se quatro funções de pertinência: baixa, moderada, alta e muito alta. As categorias moderada e alta usaram uma função triangular genérica,

$$\mu_{\mathrm{tri}}(p; a, b, c) = \begin{cases} 0, & p \le a \text{ ou } p \ge c, \\ \dfrac{p-a}{b-a}, & a < p < b, \\ 1, & p = b, \\ \dfrac{c-p}{c-b}, & b < p < c, \end{cases} \tag{12}$$

com $\mu_{\mathrm{moderate}}(p_i) = \mu_{\mathrm{tri}}(p_i; 0.10, 0.35, 0.60)$ e $\mu_{\mathrm{high}}(p_i) = \mu_{\mathrm{tri}}(p_i; 0.40, 0.65, 0.90)$. Como os conjuntos baixo e muito alto correspondem aos ombros esquerdo e direito de trapézios degenerados, suas fronteiras foram escritas explicitamente para evitar divisão por zero na forma trapezoidal genérica:

$$\mu_{\mathrm{low}}(p) = \begin{cases} 1, & 0 \le p \le 0.10, \\ \dfrac{0.30-p}{0.20}, & 0.10 < p < 0.30, \\ 0, & p \ge 0.30, \end{cases} \tag{13}$$

$$\mu_{\text{very high}}(p) = \begin{cases} 0, & p \le 0.70, \\ \dfrac{p-0.70}{0.20}, & 0.70 < p < 0.90, \\ 1, & 0.90 \le p \le 1.00. \end{cases} \tag{14}$$

A pertinência dominante foi definida pelo maior grau, e eventuais empates foram resolvidos em favor da categoria de maior prioridade. Para fins operacionais, as categorias fuzzy foram mapeadas como segue: baixa correspondeu a não encaminhamento, moderada a revisão de rotina, alta a revisão prioritária e muito alta a prioridade urgente de revisão. Esses rótulos foram usados apenas como categorias auditáveis de carga de trabalho e prioridade, não como decisão clínica autônoma.

A proximidade da fronteira foi quantificada pela margem fuzzy entre o maior e o segundo maior grau de pertinência,

$$m_i = \mu_{(1)}(p_i) - \mu_{(2)}(p_i), \tag{15}$$

em que $\mu_{(1)}(p_i)$ e $\mu_{(2)}(p_i)$ são o maior e o segundo maior valores de pertinência para x_i. Valores pequenos de m_i indicaram proximidade entre conjuntos fuzzy adjacentes.

Este estudo avaliou retrospectivamente a camada fuzzy por meio da fração de casos por categoria, da fração de referenciáveis, da captura de casos referenciáveis, da taxa residual de referenciáveis entre os casos não encaminhados e da fração de casos de fronteira. O objetivo foi investigar se esse componente fornecia um resumo operacional interpretável dos escores, sem implicar melhora discriminativa em relação ao ranqueamento por probabilidade nem validação clínica como regra independente de encaminhamento.

G. Análise Estatística

As análises estatísticas foram conduzidas a partir das tabelas fixas de predição obtidas na validação e nos testes interno e externo. A classificação sob limiar fixo de 0,5 foi caracterizada por AUC, sensibilidade, especificidade, F1-score e matriz de confusão, enquanto a calibração foi avaliada por Brier score, erro esperado de calibração e negative log-likelihood. Sensibilidade e especificidade foram definidas como:

$$\mathrm{Sensitivity} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FN}} \tag{16}$$

e

$$\mathrm{Specificity} = \frac{\mathrm{TN}}{\mathrm{TN} + \mathrm{FP}}, \tag{17}$$

em que TP, TN, FP e FN denotam verdadeiros positivos, verdadeiros negativos, falsos positivos e falsos negativos. O Brier score foi:

$$\mathrm{Brier} = \frac{1}{N} \sum_{i=1}^{N} (p_i - y_i)^2. \tag{18}$$

O erro esperado de calibração foi calculado para a probabilidade binária de DR referenciável. Com $B_m = \{i : p_i \in I_m\}$, $n_m = |B_m|$ e M bins, comparou-se, em cada bin, a fração observada de referenciáveis com a probabilidade média predita:

$$\mathrm{ECE}_{\mathrm{bin}} = \sum_{m=1}^{M} \frac{n_m}{N} \left| \frac{1}{n_m} \sum_{i \in B_m} y_i - \frac{1}{n_m} \sum_{i \in B_m} p_i \right|. \tag{19}$$

A análise final usou $M = 10$ bins de largura igual.

A incerteza das estimativas pontuais foi quantificada por bootstrap não paramétrico em nível de caso, aplicado separadamente por subconjunto e estratégia de priorização às tabelas fixas de predição [28]. Para cada métrica m, 1,000 reamostragens geraram os valores $\{m^{(r)}\}_{r=1}^{1000}$, e o intervalo de confiança de 95% foi definido por:

$$\mathrm{CI}_{95\%}(m) = \left[Q_{0.025}\left(\{m^{(r)}\}_{r=1}^{1000}\right), Q_{0.975}\left(\{m^{(r)}\}_{r=1}^{1000}\right) \right]. \tag{20}$$

Às métricas de classificação, calibração e captura sob orçamento aplicou-se o método de bootstrap, enquanto na média das saídas probabilísticas entre sementes fundamentou-se a comparação KAN versus MLP. Atentou-se também para a avaliação de métricas operacionais nos subconjuntos interno e externo, o que envolveu taxas de detecção, casos referenciáveis não detectados, precisão entre casos revisados, redução da carga de trabalho, atribuições inseguras de não encaminhamento e falsos negativos confiantes. Como não se buscou na aplicação de testes formais de superioridade a evidência primária deste estudo, ganharam o sentido de resultados descritivos e específicos de cada subconjunto os intervalos de confiança, o ranqueamento por probabilidade, a priorização por incerteza, a triagem fuzzy e os exemplos Grad-CAM, sem que isso signifique uma robustez pronta para implantação.

IV. Resultados

A. Mudança de Distribuição dos Dados e Resultados de Classificação sob Protocolo Pareado

No teste interno EyePACS, a prevalência de retinopatia diabética referenciável foi 19.19% em 53,576 imagens. No teste externo APTOS, essa taxa subiu para 40.61% em 3,662 imagens, aproximadamente 2.12 vezes maior. Por isso, os resultados externos foram interpretados como comportamento em cenário deslocado, não como prova de robustez pronta para implantação.

A comparação pareada caracterizou discriminação semelhante entre as cabeças KAN e MLP — KAN com AUC de 0.905 ± 0.003 no teste interno e 0.959 ± 0.003 no externo; MLP com 0.904 ± 0.003 e 0.956 ± 0.006, respectivamente, em três sementes, com variabilidade sobreposta sustentando interpretação estritamente descritiva, sem alegar superioridade da cabeça KAN nem equivalência de capacidade.

A redução do limiar operacional de 0.50 para 0.20 diminuiu os falsos negativos na KAN em 1028.7 casos internos e 9.3 externos, com acréscimo de 2131.0 e 122.0 falsos positivos; na MLP, reduziu-os em 1330.7 e 25.7, com acréscimo de 2740.0 e 158.7 falsos positivos, respectivamente. O ajuste alterou o ponto operacional sem evidenciar robustez aprimorada.

As métricas de calibração também exigem cautela. O Brier score da KAN aumentou de 0.075 ± 0.001 no teste interno para 0.095 ± 0.008 no externo; na MLP, passou de 0.075 ± 0.001 para 0.096 ± 0.010. Como prevalência e incerteza basal do desfecho afetam diretamente o Brier bruto, esse aumento isolado não prova piora definitiva da calibração externa. A interpretação exigiu avaliação conjunta com diagramas de confiabilidade, ECE binário e NLL.

B. Resultados de Calibração e Ranqueamento sob Orçamento de Revisão

O escalonamento de temperatura foi ajustado por modelo e semente na validação e aplicado, sem reajuste, à validação, ao teste interno e ao teste externo. Na média entre sementes, a KAN obteve Brier scores de 0.073 ± 0.001 na validação, 0.075 ± 0.001 internamente e 0.095 ± 0.008 externamente; os valores da MLP foram 0.073 ± 0.000, 0.075 ± 0.001 e 0.096 ± 0.010. Como as prevalências internas e externas diferiram, o Brier foi interpretado como dependente da prevalência, e a calibração externa foi avaliada junto aos diagramas de confiabilidade, ECE binário e NLL. A Fig. 1 mostra os diagramas de confiabilidade.

Tabela II
Leitura operacional do orçamento externo para o ranqueamento por probabilidade da KAN. O teto máximo considera a prevalência externa e o número de exames que cabem no orçamento.

Orçamento	Revisados	Teto cap.	Cap. KAN	Ref. não capt.	Prec. rev.
Top-10%	367	0.247	0.239	1132	96.7%
Top-20%	733	0.493	0.465	796	94.3%
Top-30%	1099	0.739	0.671	489	90.8%
Top-40%	1465	0.985	0.851	222	86.3%
Top-50%	1831	1.000	0.988	18	80.2%

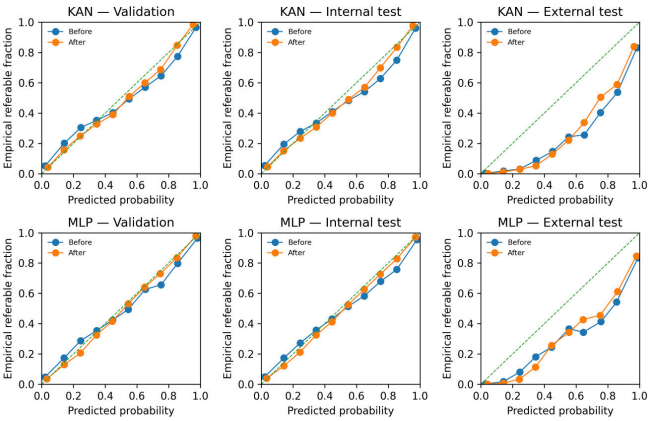

Fig. 1. Diagramas de confiabilidade antes e depois do escalonamento de temperatura ajustado na validação. A calibração melhorou nas predições de validação e de teste interno, mas foi transferida de forma imperfeita para o subconjunto externo deslocado.

A análise sob orçamento avaliou o ranqueamento por probabilidade quando a revisão especializada é restrita. No teste externo, na média entre sementes, a KAN capturou 0.239 ± 0.003, 0.465 ± 0.005, 0.671 ± 0.010, 0.851 ± 0.005 e 0.988 ± 0.002 dos casos referenciáveis nos orçamentos top-10%, 20%, 30%, 40% e 50%, respectivamente. Como o teste externo tinha 1,487 casos referenciáveis entre 3,662 imagens, o orçamento top-10% permitia revisar apenas 367 exames e impunha teto teórico de captura de 0.247; a captura da KAN, 0.239, ficou próxima desse limite. O composto baseado apenas em incerteza, usado como controle negativo, capturou apenas 0.051 ± 0.002, 0.161 ± 0.003 e 0.357 ± 0.007 nos orçamentos top-10%, top-30% e top-50%, respectivamente. Esse resultado indica que a incerteza isolada não deve assumir o papel de critério primário de triagem.

C. Resultados de Auditabilidade da Triagem Fuzzy

A análise da camada de triagem fuzzy sintetizou as saídas fixas do modelo em categorias auditáveis e inspecionáveis. A categoria urgente não deve ser interpretada como equivalente ao orçamento top-10%, pois correspondeu a 48.3% dos casos externos na KAN e 47.2% na MLP; portanto, sua captura caracteriza carga de trabalho auditável, não ranqueamento pareado sob orçamento. Na KAN, os casos de fronteira permaneceram pouco frequentes, com 1.3% no conjunto interno e 0.9% no externo. As frações residuais de casos

Tabela III
RESUMO INTEGRATIVO MÉDIO ENTRE SEMENTES. A CATEGORIA FUZZY DE PRIORIDADE URGENTE DE REVISÃO É APRESENTADA COM SUA CARGA DE TRABALHO, CAPTURA E PUREZA, EVITANDO COMPARAÇÃO DIRETA COM O ORÇAMENTO TOP-10%.

Modelo	Subconj.	AUC	Brier	Top-10 cap.	Carga urg.	Cap. urg.	Pureza urg.
KAN	Interno	0.905 ± 0.003	0.075 ± 0.001	–	11.1%	0.536	92.7%
KAN	Externo	0.959 ± 0.003	0.095 ± 0.008	0.239 ± 0.003	48.3%	0.974 ± 0.009	82.0%
MLP	Interno	0.904 ± 0.003	0.075 ± 0.001	–	10.9%	0.529	93.0%
MLP	Externo	0.956 ± 0.006	0.096 ± 0.010	0.236 ± 0.006	47.2%	0.958 ± 0.020	82.4%

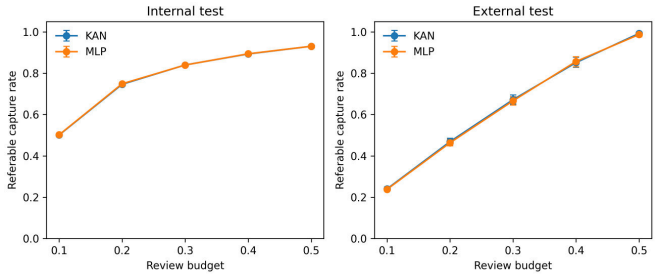

Fig. 2. Incerteza por bootstrap em torno das estimativas de captura sob orçamento de revisão. Os classificadores com cabeça inspirada em KAN e com cabeça MLP apresentaram comportamento de captura semelhante ao longo das cargas de trabalho de revisão.

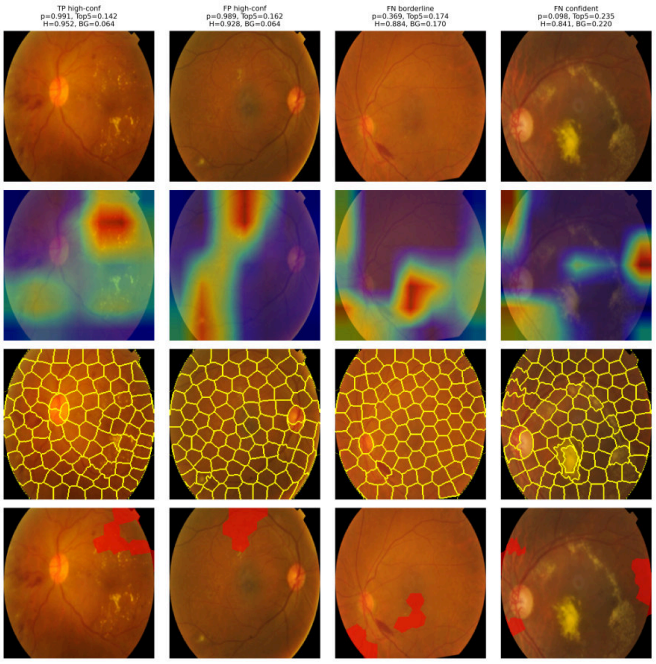

Fig. 3. Inspeção por Masked Grad-CAM/SLIC de casos externos representativos: verdadeiro positivo de alta confiança, falso positivo de alta confiança, falso negativo borderline e falso negativo confiante.

referenciáveis classificados como não encaminhamento foram de 27.2% e 0.4%, respectivamente.

A Tabela III separa o desempenho do classificador do comportamento operacional da camada fuzzy. Essa distinção reforça que a captura da categoria de prioridade urgente representa uma categoria auditável de carga de trabalho, não um método de ranqueamento sob o mesmo orçamento nem evidência de prontidão clínica autônoma.

D. Orçamento de Revisão e Métricas Operacionais Clínicas

A análise sob orçamento mensurou a captura de casos referenciáveis quando a revisão especializada é restrita. O ranqueamento por probabilidade foi a principal baseline operacional, enquanto a priorização apenas por incerteza atuou como controle negativo. A triagem fuzzy foi avaliada como mapeamento categórico inspecionável, não como regra diagnóstica.

KAN e MLP apresentaram captura de 0.239 ± 0.003 e 0.236 ± 0.006 dos referenciáveis sob orçamento de 10%, elevando-se para 0.988 ± 0.002 e 0.985 ± 0.004 a 50%, caracterizando o trade-off carga de trabalho–captura: mais exames revisados, menos casos referenciáveis não detectados. A Tabela II detalha os resultados operacionais da KAN (teto teórico, referenciáveis não capturados, precisão entre revisados); a Fig. 2 exibe a incerteza bootstrap dessas estimativas.

A triagem fuzzy complementou a auditoria ao resumir carga de trabalho, captura urgente, pureza das categorias, casos de fronteira e casos referenciáveis residuais em baixa prioridade. Como baseline operacional mais forte, manteve-se o ranqueamento por probabilidade; à triagem fuzzy, por sua vez, coube o papel de resumo inspecionável de prioridade, sem constituir evidência de prontidão clínica autônoma.

E. Modos de Falha e Inspeção por Masked Grad-CAM/SLIC

A auditoria de modos de falha usou casos selecionados do teste externo, avaliados pelo modelo inspirado em KAN com semente 42 e limiar fixo de DR referenciável de $p = 0.5$.

Tabela IV
ANÁLISE EXPLORATÓRIA POR MASKED GRAD-CAM/SLIC PARA VERDADEIROS POSITIVOS DE ALTA CONFIANÇA VERSUS FALSOS NEGATIVOS CONFIANTES. VALORES EM MEDIANA [IQR]; $\Delta_{\mathrm{FN-TP}}$ É A DIFERENÇA MÉDIA FN CONFIANTE MENOS TP ALTA CONFIANÇA. OS VALORES DE p SÃO EXPLORATÓRIOS E CONDICIONADOS À AMOSTRA DE AUDITORIA SELECIONADA, NÃO CONSTITUINDO INFERÊNCIA EM NÍVEL POPULACIONAL.

Métrica	TP alta conf.	FN confiante	$\Delta_{\mathrm{FN-TP}}$	IC 95%	p BH (expl.)
Energia top-5	0.143 [0.126, 0.151]	0.238 [0.194, 0.276]	0.094	[0.067, 0.122]	9.07e-05
Entropia	0.949 [0.932, 0.957]	0.823 [0.811, 0.846]	-0.118	[-0.135, -0.100]	2.88e-04
Gini	0.375 [0.341, 0.433]	0.656 [0.622, 0.679]	0.263	[0.225, 0.301]	1.44e-04
Superpixels efetivos	76.387 [72.563, 78.040]	42.974 [40.403, 47.973]	-31.192	[-35.083, -27.258]	9.59e-05
Energia de fundo	0.072 [0.059, 0.093]	0.201 [0.158, 0.223]	0.094	[0.037, 0.142]	1.63e-02

A análise incluiu quatro grupos, totalizando 60 imagens: 20 verdadeiros positivos de alta confiança ($y = 1$, $\hat{y} = 1$, $p \geq 0.9$), 20 falsos positivos de alta confiança ($y = 0$, $\hat{y} = 1$, $p \geq 0.9$), 10 falsos negativos borderline logo abaixo do limiar e 10 falsos negativos confiantes com as menores probabilidades preditas. Os mapas Grad-CAM [29] da classe de DR referenciável foram projetados e agregados sobre superpixels SLIC retinianos definidos por $n_{\mathrm{segments}} = 100$ e compactness $= 10$. As métricas avaliadas foram energia Grad-CAM top-5, entropia de saliência normalizada, concentração de Gini, número efetivo de superpixels ativados e fração de energia de fundo/borda. O contraste tabulado usa $\Delta_{\mathrm{FN-TP}} = n_{\mathrm{FN}}^{-1} \sum_{i \in \mathrm{FN_{conf}}} s_i - n_{\mathrm{TP}}^{-1} \sum_{i \in \mathrm{TP_{high}}} s_i$, em que s_i é a métrica Grad-CAM/SLIC; os valores de p são descritores exploratórios condicionados ao conjunto de auditoria selecionado, não inferência clínica populacional.

Esta análise avaliou falsos negativos confiantes contra verdadeiros positivos de alta confiança (Fig. 3, Tabela IV), caracterizando falhas por saliência concentrada periférica/não retiniana, com maior energia top-5, menor entropia, maior Gini, menos superpixels efetivos e maior energia de fundo/borda, e não por mera ausência de ativação. Avaliou-se a direção das métricas primárias nas nove configurações de

segmentação SLIC $n_{\text{segments}} \in \{50, 100, 150\}$ e compactness $\in \{5, 10, 20\}$, constatando-se sua preservação em todas as condições examinadas. O Masked Grad-CAM/SLIC constitui, portanto, uma auditoria exploratória de falhas, cujos valores de p permanecem condicionados à amostra selecionada, sem estabelecer correção clínica em nível de lesão.

V. Discussão

Este estudo demonstra que a avaliação da triagem operacional de DR referenciável deve ir muito além das métricas agregadas de discriminação. Desempenhos semelhantes em discriminação, calibração e comportamento sob orçamento de revisão foram apresentados pelas cabeças inspiradas em KAN e MLP, tanto no teste interno quanto no externo, de modo que na variabilidade sobreposta entre sementes não encontra sustentação uma superioridade robusta da cabeça KAN sob o protocolo pareado. Como principal achado consolida-se a necessidade de avaliar conjuntamente o ranqueamento por probabilidade, a calibração, a captura sob orçamento, os casos referenciáveis não detectados, as categorias fuzzy e os modos de falha. Esse ponto acabou reforçado pelo teste externo deslocado no APTOS, cenário no qual, devido à maior prevalência de DR referenciável, viram-se comprometidas a transferência de limiares e a operação sob orçamento, a despeito de ter sido registrada AUC externa elevada. Sob o orçamento top-10%, conseguiu-se capturar apenas cerca de um quarto dos casos referenciáveis externos, ao passo que da totalidade aproximou-se a recuperação no top-50%. Mais informativos do que a suposição de uma transferibilidade direta entre diferentes cenários revelam-se, portanto, os relatos específicos por orçamento.

Calibração, incerteza e camada fuzzy não eliminaram riscos residuais: o escalonamento de temperatura melhorou a calibração na validação e no teste interno, mas apresentou transferência imperfeita ao teste externo e não alterou o ranqueamento; a incerteza via MC-dropout evidenciou predições ambíguas, embora o ranqueamento exclusivo por incerteza tenha capturado menos casos externos referenciáveis do que o ranqueamento por probabilidade, mantendo os falsos negativos confiantes como limitação operacional persistente; e a camada fuzzy constituiu mecanismo de auditabilidade operacional, capaz de resumir carga de trabalho, prioridade urgente, pureza das categorias, casos de fronteira e referenciáveis residuais de baixa prioridade, e não evidência de robustez clínica autônoma. A sobreposição em nível de paciente, restrita ao treinamento e à validação, pode tornar ligeiramente otimistas as análises de calibração nesse estágio, sem afetar as estimativas dos testes interno e externo.

VI. Limitações

Com bases públicas de DR e rótulos em nível de imagem, este estudo retrospectivo foi conduzido sem adjudicação clínica prospectiva, estudo com leitores ou ground truth em nível de lesão. Dessa forma, descreve-se o comportamento do modelo em subconjuntos predefinidos, sem comprovação de efetividade clínica ou de prontidão para implantação. Também permaneceu limitado a uma única base deslocada o teste externo; embora APTOS e EyePACS apresentassem diferenças de prevalência e de distribuição de escores, não foi abrangida uma variação ampla de dispositivos, populações, espectro da doença, qualidade de imagem, rotulagem e fluxos de trabalho. Não foi realizada análise estratificada por qualidade de imagem; portanto, permanece desconhecido se discriminação, calibração, captura sob orçamento e atribuições de prioridade se mantêm consistentes entre diferentes níveis de qualidade. Como subgrupos demográficos e fairness não foram avaliados, seguem desconhecidas possíveis disparidades de desempenho, calibração, casos referenciáveis não detectados ou atribuições de baixa prioridade.

A baseline EfficientNet-B0+MLP foi utilizada como comparador pareado por backbone e protocolo, não constituindo benchmark exaustivo do estado da arte nem ablação de igual capacidade. Assim, as conclusões sobre a cabeça KAN restringem-se aos mesmos subconjuntos, sementes, protocolo de calibração e análises sob orçamento. A camada fuzzy deve ser interpretada como mapeamento auditável de prioridade, dependente de funções de pertinência predefinidas e das distribuições dos escores, e não como substituto de regras clínicas. A incerteza por MC-dropout constitui descritor auxiliar aproximado; o escalonamento de temperatura caracterizou a transferência de calibração sem reajuste externo; e os intervalos bootstrap permanecem descritivos, sem testes formais de superioridade. O Masked Grad-CAM/SLIC teve papel estritamente exploratório, pois a ausência de máscaras de lesão, bounding boxes, anotações pontuais ou estudo com leitores impede estabelecer correção clínica em nível de lesão.

VII. Conclusão

Este estudo avaliou retrospectivamente a triagem de retinopatia diabética sob restrição de capacidade, deslocamento de distribuição, calibração, incerteza e falhas residuais. Sua contribuição principal é o protocolo de avaliação operacional integrado, que amplia a análise além de métricas agregadas de discriminação ao incorporar captura sob orçamento, categorização fuzzy, intervalos de bootstrap e inspeção de falhas. A comparação pareada entre as cabeças KAN e MLP funciona, nesse contexto, como aplicação comparativa do protocolo, e não como reivindicação de superioridade arquitetural.

Desempenho comparável em discriminação, calibração e comportamento sob orçamento foi apresentado pela EfficientNet-B0 com cabeça inspirada em KAN e pela baseline EfficientNet-B0+MLP, sem que se evidenciasse superioridade sólida da cabeça KAN no protocolo pareado. À camada fuzzy coube fornecer um mapeamento inspecionável para a prioridade de revisão, devendo sua interpretação ser limitada à auditabilidade, e não estendida a regras clínicas ou modelos diagnósticos autônomos. Em conjunto, os achados reforçam que sistemas de rastreamento de DR precisam ser rigorosamente avaliados quanto à calibração, ao orçamento de revisão, ao risco residual, ao comportamento sob mudança de distribuição e aos modos de falha antes de qualquer alegação de implantação clínica.

Abstract—Surface electromyography (sEMG) is an important tool for neuromuscular analysis during functional tasks; however, the high cost of commercial systems may limit its use in clinical, educational, and applied research settings. Low-cost electromyographic systems represent promising alternatives, provided they are supported by appropriate acquisition, processing, and preliminary comparison procedures against reference equipment. This study aimed to perform a preliminary evaluation of the effect of the Berouti spectral subtraction method on electromyographic signals acquired using a low-cost system during overground walking, with a commercial system serving as the reference. Signals were acquired simultaneously using the Aquamove and Miotec systems, with electrodes positioned over adjacent regions of the tibialis anterior muscle. The experimental protocol consisted of eleven consecutive gait cycles, with gait cycles two through ten selected for analysis to minimize transient effects associated with gait initiation and termination. After preprocessing, the Berouti spectral subtraction technique was applied exclusively to the Aquamove signals. Root mean square (RMS), median frequency, and mean frequency were extracted and compared between systems using agreement and error metrics. The technique did not consistently improve RMS agreement but was associated with reduced error and bias in the spectral metrics, particularly median frequency (MDF) and mean frequency (MNF). These preliminary findings suggest that the adapted Berouti spectral subtraction approach may contribute to reducing spectral discrepancies in electromyographic signals acquired from low-cost systems, especially regarding spectral feature estimation, representing a relevant step toward the development of more accessible EMG solutions.

Keywords—Electromyography; Signal Processing; Spectral Subtraction; Noise Reduction; Gait Analysis.

I. Introduction

Surface electromyography (sEMG) is a non-invasive technique widely used to assess muscle activation in biomechanical, functional, and clinical contexts. By recording the electrical potentials generated during muscle contraction, sEMG enables the analysis of the temporal and spectral characteristics of neuromuscular activity, contributing to the evaluation of human movement, rehabilitation, motor control, and the development of health-related technologies [1]–[3].

Despite its relevance, the use of sEMG may still be limited by the high cost of commercial acquisition systems, particularly in clinical, educational, and applied research settings with limited resources. Commercial systems typically incorporate signal-conditioning circuits, filters, analog-to-digital converters, and proprietary software, which can reduce the occurrence of artifacts but also increase acquisition and maintenance costs. In this context, the development and evaluation of low-cost EMG systems represent promising alternatives for expanding access to neuromuscular assessment, provided they are supported by appropriate comparison procedures and progressive technical evaluation against reference systems [4]–[6].

However, reducing the cost of biomedical systems should not be understood merely as replacing electronic components with more affordable alternatives. For electromyographic signals acquired using low-cost systems to be used reliably, robust strategies for signal detection, conditioning, filtering, and digital processing are required to preserve physiologically relevant signal characteristics while minimizing unwanted components. Beyond cost reduction, these algorithms can be embedded into microcontroller firmware, enabling part of the signal processing to be performed locally on the device itself. In wearable biomedical systems integrated with the Internet of Things (IoT), this approach, combined with edge computing, can reduce both latency and the volume of transmitted data while decreasing dependence on continuous communication with remote servers [7], [8]. This aspect is particularly important in dynamic applications such as gait analysis, where body movement, the electrode–skin interface, and biomechanical variations increase the complexity of signal acquisition and interpretation [1], [9], [10].

Electromyographic signals are inherently susceptible to several sources of contamination, including instrumental noise, power-line interference, motion artifacts, instability at the skin–electrode interface, and crosstalk from adjacent muscles. These contaminating factors may compromise the estimation of temporal and spectral features, such as the root mean square (RMS), median frequency, and mean frequency, which are commonly used to characterize the

intensity and frequency content of muscle activity. Therefore, noise reduction techniques play a fundamental role in improving signal quality and enabling the extraction of more reliable parameters for comparative analyses between acquisition systems [9], [11].

Among the available noise reduction strategies, the spectral subtraction method proposed by Berouti stands out for its computational simplicity and its operation in the frequency domain based on estimating the noise spectrum present in the analyzed signal. Although originally developed for enhancing speech signals contaminated by acoustic noise, this approach can be adapted to other signal types when the objective is to attenuate unwanted components while preserving, as much as possible, the spectral structure of the signal of interest [12]. In this context, applying an adapted version of the Berouti method to electromyographic signals may represent a useful strategy for improving the quality of signals acquired using low-cost EMG systems.

Accordingly, the present study aimed to perform a preliminary evaluation of the effect of an adapted Berouti spectral subtraction technique on electromyographic signals acquired using a low-cost system during overground walking, using a commercial EMG system as the reference and considering both amplitude- and frequency-based signal metrics. This work is situated within the field of biomedical signal processing and seeks to contribute to the development of more accessible EMG solutions, with potential future applications in clinical, educational, and applied research settings.

II. Materials and Methods

A. Database and Signal Acquisition

Electromyographic signals were acquired from one participant during two experimental sessions using the low-cost Aquamove system, developed by the Human–Machine Interaction Laboratory at the Federal University of Pernambuco (LIHOM/UFPE), and the commercial Miotec system, which served as the reference device. Both systems simultaneously recorded the same overground walking trials. The participant walked at a self-selected comfortable speed. The two experimental sessions were treated as independent acquisition sets, each containing simultaneously recorded Aquamove and Miotec signals. Each session contributed nine analyzed gait cycles, resulting in 18 paired muscle contractions in the concatenated analysis. The experimental protocol was approved by the Research Ethics Committee of the Federal University of Pernambuco (UFPE), Brazil (approval no. 8.136.554; CAAE 92738325.0.0000.5208). Written informed consent was obtained from the participant before data collection. The Aquamove and Miotec signals were originally sampled at 1000 and 2000 Hz, respectively. The Miotec signals were subsequently resampled to 1000 Hz before comparison.

Surface electromyographic signals from the tibialis anterior muscle were acquired following the recommendations of the Surface ElectroMyoGraphy for the Non-Invasive Assessment of Muscles (SENIAM) project [13], [14]. First, an imaginary line was identified between the tip of the fibula and the tip of the medial malleolus. The recording electrodes were placed over the tibialis anterior muscle at one-third of this line measured from the fibular tip, with their orientation parallel to the muscle fibers. The reference electrode was positioned over the lateral malleolus in accordance with the SENIAM guidelines [14].

Before electrode placement, the skin was cleaned with 70% isopropyl alcohol, and hair was removed when necessary to reduce the impedance at the skin–electrode interface and minimize acquisition artifacts. Electrode placement and orientation were standardized across all recording sessions.

Because the signals from both systems were acquired simultaneously, it was not possible to place the Aquamove and Miotec electrodes in the exact same location. Therefore, the electrodes of both systems were positioned over adjacent regions of the tibialis anterior muscle while maintaining, as closely as possible, an orientation parallel to the muscle fibers and proximity to the anatomical location recommended by the SENIAM guidelines.

The Berouti spectral subtraction technique was applied exclusively to the signals acquired with the Aquamove system. Consequently, two conditions of the low-cost system were evaluated: one using only conventional preprocessing and another using conventional preprocessing followed by spectral subtraction. Both conditions were compared with the reference Miotec system.

B. Signal Preprocessing

Initially, the DC component was removed by subtracting the signal mean. Subsequently, a fourth-order Butterworth band-pass filter with cutoff frequencies of 20–400 Hz was applied to attenuate frequency components outside the muscle activity bandwidth, followed by a 60 Hz notch filter to suppress power-line interference.

C. Adaptation of the Berouti Spectral Subtraction Technique for Electromyographic Signals

In this study, an adapted version of the Berouti spectral subtraction technique, originally developed for speech processing, was implemented for application to electromyographic signals. The implementation operates on the spectral magnitude, uses an average noise profile estimated during a resting period, and incorporates signal mirroring at the boundaries and spectral interpolation to accommodate the characteristics of EMG signals.

The spectral noise profile was estimated from approximately 8 s of resting data recorded at the end of each acquisition. These recordings were subjected to the same preprocessing steps applied to the electromyographic signals. The time–frequency representation was obtained using the Short-Time Fourier Transform (STFT) with a 256-sample Hann window, 128-sample overlap, and a 256-point FFT. At the sampling frequency adopted in this study, these values correspond to a 256 milliseconds (ms) window and 128 ms overlap.

The average noise magnitude was estimated as:

$$D(k) = (1/M)\ \Sigma\square_{=1}^{M}\ |S(m,k)|, \qquad (1)$$

where (D(k)) represents the average spectral magnitude profile of the noise, (M) is the number of time frames used to estimate the spectral profile, and (S(m,k)) corresponds to the Short-Time Fourier Transform (STFT) of the noise segment. The resulting spectral profile was subsequently interpolated to match the spectral grid of the STFT computed from the electromyographic signal.

The spectral magnitude of the processed signal was computed as:

$$|\hat{X}(m,k)| = \max[|Y(m,k)| - \alpha D(k),\ \beta D(k)], \qquad (2)$$

where ($Y(m,k)$) denotes the STFT of the electromyographic signal, $|Y(m,k)|$ is its spectral magnitude, and ($\hat{X}(m,k)$) is the estimated spectral magnitude after processing, (α) represents the noise overestimation factor, (β) defines the spectral floor, and (D(k)) corresponds to the average spectral noise magnitude profile defined in Equation (1). The values of α and β were empirically selected during preliminary processing trials to provide a practical compromise between background-noise attenuation and preservation of the original electromyographic signal. The selected parameters reduced the background spectral components without excessively attenuating the muscle activation bursts or substantially altering their temporal structure. This was particularly important because subsequent muscle activation detection was based on the RMS envelope; overly aggressive spectral subtraction could attenuate or distort activation peaks and consequently affect their automatic detection and segmentation. Therefore, $\alpha = 1.3$ and $\beta = 0.08$ were retained as conservative parameters for this preliminary evaluation rather than as globally optimized values.

The original phase was preserved throughout the entire processing procedure, and the signal was reconstructed in the time domain using the Inverse Short-Time Fourier Transform (ISTFT). Finally, the samples added during the signal mirroring step were removed.

D. Signal Feature Extraction

Following preprocessing and, when applicable, application of the Berouti spectral subtraction technique, three classical electromyographic signal features were extracted: root mean square (RMS), median frequency (MDF), and mean frequency (MNF). These metrics are widely used to characterize signal amplitude and spectral content in biomechanics, gait analysis, and neuromuscular assessment applications [15]–[17].

For the window-by-window analysis, RMS was computed directly from the nonrectified time-domain signal using 150-sample windows with 75-sample overlap. At the sampling frequency of 1000 Hz, these values correspond to a 150 ms window and 75 ms overlap. The resulting temporal RMS sequence was used for signal synchronization and automatic muscle activation detection.

Muscle activation peaks were identified using an adaptive threshold. The baseline was estimated as the median of the RMS sequence, and the minimum peak height was defined as the baseline plus 25% of the difference between the maximum RMS value and the baseline. A minimum temporal distance of 0.25 s was imposed between consecutive peaks. To determine the onset and offset of each activation, the RMS sequence was smoothed using a three-point moving average. For each detected peak, the contraction threshold was defined as the baseline plus 50% of the peak-to-baseline amplitude. The onset and offset were identified by searching backward and forward from the peak until the smoothed RMS sequence crossed this threshold. Overlapping activations, as well as activations separated by no more than 50 ms, were merged into a single event. When multiple peaks were merged, the peak with the highest amplitude was retained.

After segmentation, RMS, MDF, and MNF were recalculated for each complete muscle contraction. RMS was computed directly from the nonrectified time-domain signal, whereas MDF and MNF were obtained from the power spectral density estimated using Welch's method with a 256-sample periodic Hamming window, 128-sample overlap, and a 1024-point FFT [18]. For contractions shorter than 256 samples, the Welch window length and overlap were reduced to fit the available signal segment. Spectral features were calculated within the 20–400 Hz frequency band. The overground walking protocol was performed with simultaneous acquisition of electromyographic signals using the Aquamove and Miotec systems. To achieve this, the electrodes of both devices were placed over the same tibialis anterior muscle in adjacent regions, allowing concurrent recording of electromyographic activity throughout the walking task. This configuration enabled simultaneous recording during the same walking task and over the same time interval. However, because the electrodes could not occupy identical anatomical locations, the measurements should not be considered spatially equivalent. Differences in local muscle sampling may therefore contribute to discrepancies between systems, particularly for amplitude-dependent metrics.

During the overground walking protocol, 11 consecutive gait cycles were recorded. To minimize transient effects associated with gait initiation and termination, only gait cycles 2 through 10 were included in the analysis. Consequently, each experimental session contributed nine valid gait cycles for signal processing. After segmenting the signal into the selected gait cycles, the amplitude- and frequency-based metrics, including RMS, MDF, and MNF, were recalculated for each complete muscle contraction and subsequently used for comparison between the Aquamove and Miotec systems.

Before comparing the two systems, the signals were temporally synchronized using cross-correlation applied to the window-by-window RMS sequences. The estimated time delay was then used to align the muscle contractions identified by the Aquamove system with those recorded by the Miotec system.

Following synchronization, muscle contractions were matched according to their order of occurrence, allowing a maximum difference of 1 s between their temporal centers.

Contractions containing invalid values were excluded from the analysis. RMS values were normalized individually within each dataset relative to the maximum observed value, whereas MDF and MNF remained expressed in hertz (Hz).

Comparisons between the two systems were performed individually for each dataset and subsequently using the concatenated set of all valid contractions. For each metric, the intraclass correlation coefficient for absolute agreement (ICC(A,1)) was calculated according to the recommendations of Koo and Li [19], with 95% confidence intervals estimated using bootstrap resampling (5,000 iterations). In addition, the root mean square error (RMSE), relative RMSE, mean bias (Bias), and Bland–Altman limits of agreement (LoA) [20], [21] were computed.

Figure 1 provides an overview of the methodology adopted in this study. Initially, the signals acquired by the Aquamove and Miotec systems underwent the same preprocessing steps. Subsequently, the adapted Berouti spectral subtraction technique was applied exclusively to the Aquamove signals. Next, the RMS, MDF, and MNF metrics were extracted, muscle activations were detected and segmented, the valid gait cycles from the walking protocol were selected, and temporal alignment and contraction matching were performed between the two systems. Finally, statistical agreement metrics were computed to evaluate the performance of the proposed method. Table I summarizes the main parameters used for signal processing and muscle activation detection.

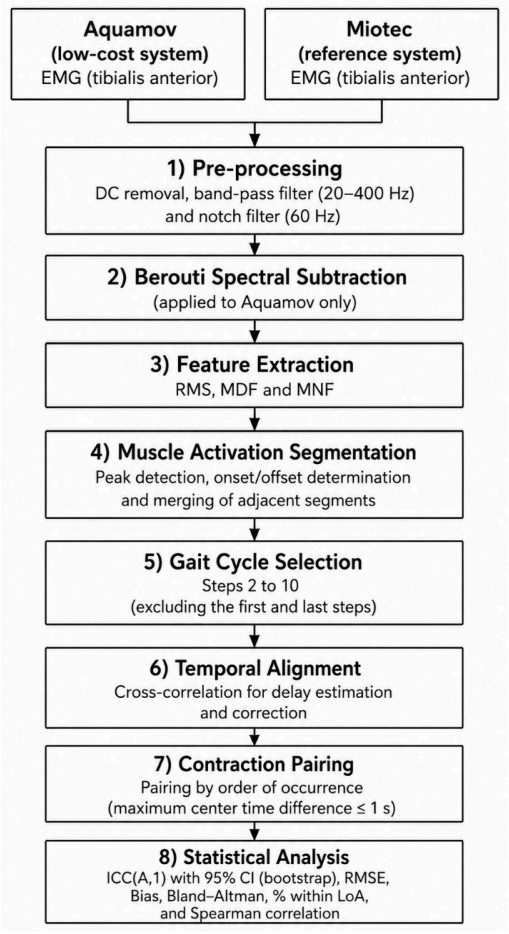

Fig. 1. Signal processing and statistical analysis pipeline adopted for the comparison between the Aquamove and Miotec systems.

TABLE I. SIGNAL PROCESSING AND ACTIVATION DETECTION PARAMETERS

Parameter	**Value**
Analysis sampling frequency	1000 Hz
Band-pass filter	20–400 Hz
Notch filter	60 Hz
Temporal analysis window	150 samples (150 ms)
Temporal window overlap	75 samples (75 ms)
STFT parameters	256-sample Hann window; 128-sample overlap; 256-point FFT
Noise segment duration	8 s
Berouti parameters	α= 1.3; β= 0.08
Welch parameters	256-sample Hamming window; 128-sample overlap; 1024-point FFT
Peak detection parameters	25% threshold; 0.25 s minimum distance
Activation segmentation	50% boundary threshold; 50 ms merging tolerance
Gait cycles analyzed	Cycles 2–10

III. RESULTS AND DISCUSSION

A. *Effect of Spectral Subtraction*

As shown in Figure 2, the application of spectral subtraction reduced the background noise present in the Aquamove signal while preserving the main bursts of muscle activation. For comparison, Figure 3 presents the signal acquired by the Miotec system, showing a qualitative similarity between the signals processed by the two systems. A quantitative comparison is provided in the following subsection using statistical metrics.

Figure 4 illustrates the RMS envelope and the automatically detected muscle activations. The detected activations are numbered from 1 to 11, while only gait cycles 2 through 10 were retained for feature extraction and statistical analysis.

B. *Quantitative Evaluation of the Proposed Method*

Following temporal synchronization of the muscle contractions by cross-correlation and their subsequent matching, agreement metrics were calculated to compare the Aquamove system with the Miotec reference device.

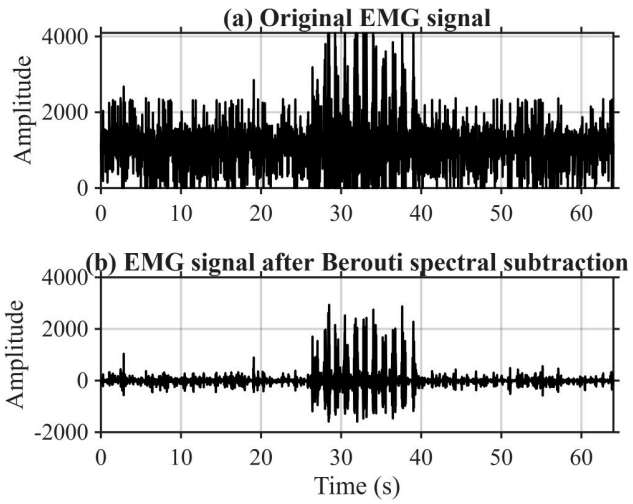

Fig. 2. EMG signal acquired by the Aquamove system during the walking protocol: (a) original signal; (b) after preprocessing and the proposed adaptation of the Berouti spectral subtraction method.

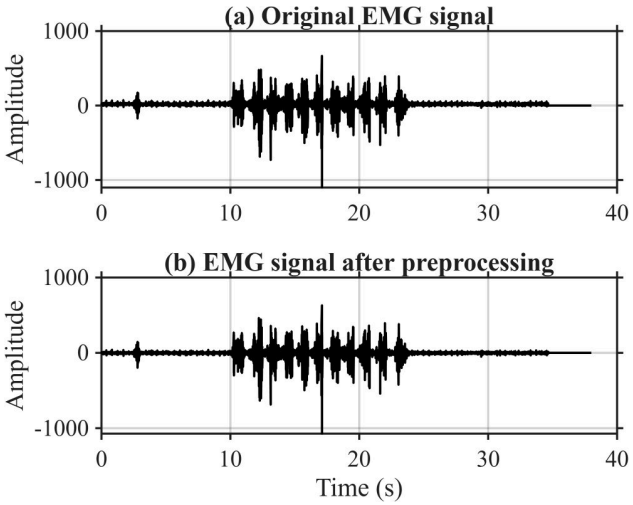

Fig. 3. EMG signal acquired by the Miotec system during the walking protocol: (a) original signal; (b) signal after preprocessing.

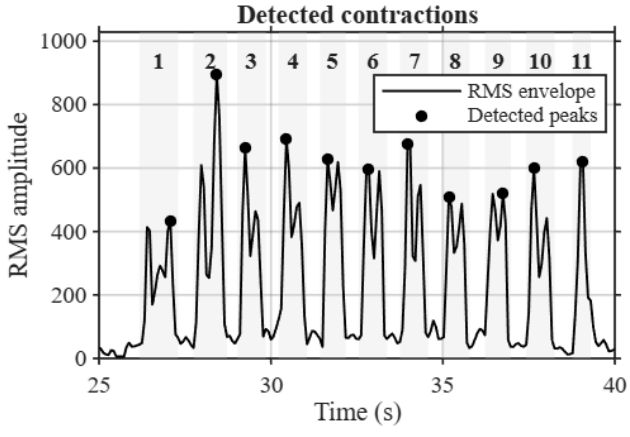

Fig. 4. Detection of muscle activation peaks and delineation of the activation windows.

For RMS, spectral subtraction did not produce a consistent improvement in agreement. The RMSE increased slightly from 8.43% to 9.03%, whereas the mean bias decreased from 1.70% to 1.45%, and the intraclass correlation coefficient (ICC) remained essentially unchanged (0.485 to 0.491). These results indicate that the proposed method had only a limited effect on amplitude-based measurements, in contrast to the clearer reductions in error and bias observed for MDF and MNF.

These results suggest that the noise reduction achieved by spectral subtraction primarily improves the spectral representation of the signal, thereby enhancing the estimation of characteristic EMG frequencies. Nevertheless, the ICC values should be interpreted with caution, as the analysis was based on only 18 paired contractions obtained from one participant across two experimental sessions. Furthermore, the experimental protocol consisted of a single walking condition, resulting in low variability among the spectral characteristics of the contractions. Because the ICC depends on the ratio between variability across samples and measurement error, this limited variability may contribute to low ICC values even when absolute error metrics, such as RMSE and bias, are reduced for the spectral metrics.

The RMS results yielded an ICC(A,1) of 0.491, with a wide 95% confidence interval ranging from 0.002 to 0.782, indicating substantial uncertainty in the agreement estimate. Although this value is lower than those typically reported in the literature for systems with identically positioned electrodes, it should be noted that, in the present study, the Aquamove and Miotec electrodes were placed on adjacent regions of the tibialis anterior muscle to enable simultaneous signal acquisition. Small differences in electrode placement can substantially affect the amplitude of the electromyographic signal and, consequently, influence metrics that depend on muscle activation intensity. Therefore, part of the disagreement observed between systems may reflect spatial sampling differences rather than acquisition-system performance alone.

Figure 5 presents the Bland–Altman plot for the MDF metric. Nearly all observations fell within the limits of agreement (LoA). However, the clinical and technical acceptability of these limits must be interpreted considering their width and the intended application. Furthermore, no evident trend of increasing error with measurement magnitude was observed, suggesting approximately uniform agreement across the analyzed range. Similar behavior was observed for the RMS and MNF metrics, whose quantitative results are summarized in Tables II–IV.

Importantly, the increases in ICC observed for MDF and MNF did not result in values indicative of strong agreement, as both coefficients remained close to 0.10 after spectral subtraction. Moreover, the corresponding 95% confidence intervals were wide and included zero (−0.106 to 0.382 for MDF and −0.077 to 0.312 for MNF), further indicating substantial uncertainty and limited agreement. Therefore, the practical benefit observed in this preliminary dataset should be interpreted primarily in terms of reduced absolute error and systematic bias rather than improved agreement. Specifically, MDF RMSE and bias decreased by 18.0% and 22.0%, respectively, whereas MNF RMSE and bias decreased by 29.4% and 38.1%. Despite the remaining positive bias, these reductions suggest that spectral subtraction may reduce systematic spectral discrepancies between the Aquamove and Miotec systems, even though agreement, as assessed by ICC, remains limited.

Overall, the proposed adaptation of the spectral subtraction method was associated with reductions in error and bias for the spectral metrics obtained with the Aquamove system compared with conventional preprocessing alone. Although studies involving a larger number of participants are still required to confirm and expand these preliminary findings, the proposed technique shows considerable potential for improving the quality of signals acquired by low-cost electromyographic systems, thereby contributing to the development of more accessible solutions without requiring modifications to the acquisition hardware.

Tables II and III summarize the agreement metrics obtained from the comparison between the Aquamove and Miotec systems. Table II reports the results for Aquamove signals processed using only the conventional preprocessing pipeline, whereas Table III presents the results after applying the proposed adaptation of the Berouti spectral subtraction method. ICC(A,1) denotes the intraclass correlation coefficient for absolute agreement and is reported with its bootstrap 95% confidence interval (95% CI); RMSE denotes the root mean square error; Relative RMSE (%) denotes the relative root mean square error; and Bias represents the mean difference between measurements obtained from the two systems and is reported together with the 95% Bland–Altman limits of agreement (LoA). RMS values are expressed as a percentage of the maximum activation, whereas MDF and MNF are reported in hertz (Hz).

TABLE II. Aquamove vs. Miotec Comparison (without subtraction)

Metric	**ICC(A,1) (95% CI)**	**RMSE**	**Relative RMSE (%)**	**Bias (95% LoA)**
RMS (%)	0.485 (0.019 to 0.757)	8.43	9.90	1.70 (−14.95 to 18.36)
MDF (Hz)	0.032 (−0.093 to 0.229)	20.90	18.09	18.09 (−3.03 to 39.20)
MNF (Hz)	0.040 (−0.041 to 0.151)	18.22	13.63	16.34 (0.10 to 32.58)

TABLE III. Aquamove vs. Miotec Comparison (with subtraction)

Metric	**ICC(A,1) (95% CI)**	**RMSE**	**Relative RMSE (%)**	**Bias (95% LoA)**
RMS (%)	0.491 (0.002 to 0.782)	9.03	10.59	1.45 (−16.53 to 19.42)
MDF (Hz)	0.103 (−0.106 to 0.382)	17.14	14.83	14.12 (−5.48 to 33.71)
MNF (Hz)	0.102 (−0.077 to 0.312)	12.87	9.63	10.11 (−5.96 to 26.18)

TABLE IV. Performance comparison before and after Berouti spectral subtraction

Metric	**Conventional**	**Berouti**	**Change**
RMS ICC	0.485	**0.491**	+0.006
MDF ICC	0.032	**0.103**	+0.071
MNF ICC	0.040	**0.102**	+0.062
RMS RMSE (%)	8.43	9.03	↑7.1%
MDF RMSE (Hz)	20.90	**17.14**	↓18.0%
MNF RMSE (Hz)	18.22	**12.87**	↓29.4%
RMS Bias (%)	1.70	**1.45**	↓14.7%
MDF Bias (Hz)	18.09	**14.12**	↓22.0%
MNF Bias (Hz)	16.34	**10.11**	↓38.1%

For ICC, change is reported as the absolute difference; for RMSE and bias, change is reported as the percentage variation relative to conventional preprocessing.

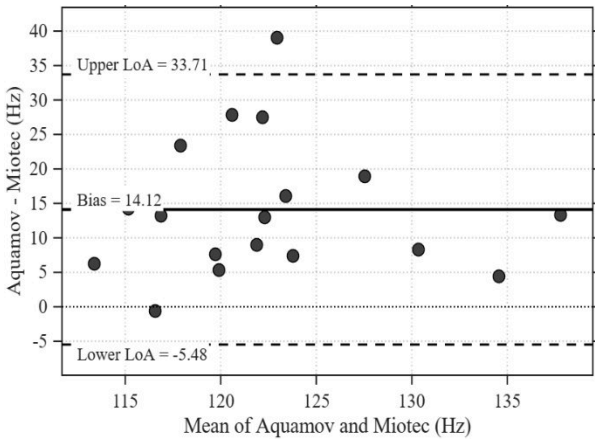

Fig. 5. Bland–Altman plot comparing median frequency (MDF) measurements obtained with the Aquamove and Miotec systems. The solid line indicates the mean bias, and the dashed lines indicate the 95% limits of agreement (LoA).

IV. Conclusion and Future Work

The results suggest that the proposed adaptation of the Berouti spectral subtraction technique was associated with reduced error and bias in spectral metrics obtained from electromyographic signals acquired by the Aquamove system during overground walking. However, these effects were metric-dependent, since RMS error did not decrease after spectral subtraction and the ICC values for MDF and MNF remained low. Therefore, the findings should be interpreted as preliminary evidence that the method may reduce spectral discrepancies between a low-cost EMG system and a commercial reference device, rather than as definitive validation of the system or the algorithm.

In addition to the observed reductions in spectral error and bias, the proposed spectral subtraction method remains attractive from an engineering perspective because it relies on relatively simple mathematical operations performed in the frequency domain. This characteristic may favor future implementation in embedded systems and edge computing devices, enabling local signal processing while reducing the need for continuous transmission of large volumes of data.

In this context, combining the proposed technique with the Aquamove system highlights its potential for the future development of portable, miniaturized, and low-cost electromyographic monitoring solutions. Such integration may expand applicability to Internet of Things (IoT) platforms, rehabilitation, remote monitoring, and wearable systems. Furthermore, the system's portability, ease of use, and compact dimensions may support future investigations in aquatic environments, contributing to research on gait analysis and electromyographic monitoring during water-based exercise.

Future work will focus on further evaluating the proposed method using a larger cohort of participants, standardized electrode configurations, additional walking protocols, and systematic sensitivity analyses of the spectral subtraction parameters. Data-driven optimization strategies, including machine-learning approaches, may also be investigated to adapt α and β according to signal characteristics, aiming to improve noise attenuation while preserving physiologically relevant EMG information. In addition, the algorithm will be implemented directly on the Aquamove hardware to investigate real-time processing on embedded devices and integration with IoT and edge computing architectures.

Acknowledgments

The authors acknowledge the collaboration between the Departments of Electronics and Systems Engineering and Physical Therapy, whose interdisciplinary partnership was fundamental to this study. The integration of expertise in biomedical signal acquisition and processing, human movement analysis, and rehabilitation was essential for the design, execution, and interpretation of the experimental protocol. The authors also gratefully acknowledge the institutional and technical support provided throughout the course of this research.

Abstract*—Electrocardiographic (ECG) signals have emerged as a promising biometric modality due to their physiological uniqueness and resistance to spoofing. This study investigates the feasibility of using ECG-derived features to predict biometric and demographic attributes through supervised and unsupervised machine learning techniques. ECG signals were collected from 26 participants under resting and post-activity conditions using an AD8232-based acquisition system. After preprocessing and heartbeat segmentation, temporal, spectral, statistical, and morphological features were extracted from each cardiac cycle. Supervised models, including k-Nearest Neighbors, Naive Bayes, Random Forest, and Multilayer Perceptron (MLP), were evaluated for classification and regression tasks involving sex, age, weight, height, blood type, and subject identification. Participant-independent validation was adopted for demographic prediction tasks, whereas conventional stratified cross-validation was maintained for closed-set subject identification. In parallel, unsupervised approaches such as k-means, DBSCAN, and hierarchical clustering were applied to investigate the existence of natural groupings in the data. The results showed strong performance for closed-set subject identification, with Random Forest achieving an F1-score of 0.941. However, performance decreased substantially for demographic attributes under participant-independent validation, with the best F1-scores reaching 0.755 for sex and 0.734 for age-group classification. Regression models also showed limited generalization, producing negative coefficients of determination for age, height, and weight prediction. Unsupervised methods did not reveal consistent natural groupings associated with the investigated biometric and demographic characteristics. These findings indicate that ECG-derived features contain strong subject-specific information, while their ability to generalize demographic characteristics to unseen individuals remains limited under the investigated conditions. Larger and more balanced datasets are necessary to improve robustness and evaluate generalization across broader populations.

I. Introduction

The use of physiological characteristics for identifying individuals, known as biometrics, has gained increasing relevance in various areas such as security, identity authentication, and medical applications [1], [2]. Among existing biometric approaches, biopotentials—such as electromyographic (EMG), electrocardiographic (ECG), and electroencephalographic (EEG) signals—stand out for reflecting intrinsic characteristics of the human body, potentially unique to each individual [1], [2].

An ECG is the recording of the electrical activity generated by the depolarization of the cardiac muscle during its rhythmic and organized contractions [3]. This electrical activity results directly from the excitation of cardiac cells, whose pattern is influenced by the anatomy of the heart

and individual physiological conditions. Changes in these characteristics can be captured as morphological variations in the ECG waveform [4]–[6]. Thus, differences in cardiac structure and body composition among individuals produce subtly distinct electrocardiographic patterns, which underpins the use of ECG not only for medical diagnosis but also as a possible unique biometric signature for each person [4]–[6].

In parallel, advances in machine learning techniques have provided new tools for analysing and extracting patterns from large volumes of data [4]–[6]. Applications that combine physiological signals with intelligent algorithms have been developed with the aim of exploring complex biometric characteristics that are still not fully understood or leveraged in practical solutions [4]–[6].

In this context, investigating whether demographic attributes can be inferred from ECG-derived features is relevant not only for biometric identification but also for understanding potential sources of demographic bias. If ECG biometric models implicitly exploit information related to sex, age, or body characteristics, their performance may depend on the demographic composition of the training data. Therefore, identifying the demographic information encoded in ECG signals represents an initial step toward the development of more representative datasets and subgroup-aware evaluation protocols. This study does not aim to solve demographic generalization directly, but rather to investigate one of the factors that may influence it.

This work has as its main objective to investigate the potential of surface electrocardiography (ECG) signals in the identification of biometric and demographic patterns using supervised and unsupervised machine learning techniques.

To achieve this goal, the following specific objectives were defined:

- Develop a protocol for acquiring ECG signals under different physiological conditions (rest and light activity), ensuring quality and variability in the recordings;
- Perform the extraction of relevant features from ECG signals, covering temporal, spectral, and morphological information, in order to compose a robust set of attributes for analysis;
- Analyse the ability of unsupervised learning techniques (k-means, DBSCAN, and hierarchical clustering) to identify natural groupings related to biometric and demographic attributes;
- Apply supervised learning algorithms (kNN, Naive Bayes, Random Forest, and MLP) to predict biometric and demographic attributes from ECG signals; and
- Compare the performance between supervised and unsupervised techniques in pattern identification, using appropriate metrics such as F1-Score, R^2, AUC, and silhouette coefficient.

II. Background

Scientific literature indicates that physiological and biomechanical biosignals are highly suitable for biometric identification and authentication [7] [8]. In general, these signals offer three intrinsic advantages over traditional biometric traits: liveness detection, because they reflect active physiological function; resistance to spoofing, because they are dynamic and largely involuntary; and hidden nature, because they cannot be remotely observed as easily as facial images or fingerprints [9]. These properties make biosignals particularly attractive for secure authentication systems.

Among the main modalities, electrocardiography (ECG) is one of the most established. ECG achieves an average recognition rate of 94.3% across five public datasets and is especially valuable because, in addition to being distinctive across individuals, it provides proof of liveness that traditional biometrics cannot guarantee [10] [11]. Electroencephalography (EEG) also shows strong biometric potential, with reported identification accuracy ranging from 80% to 99%, while offering high resistance to replication [12]. Surface electromyography (sEMG) presents competitive performance, reaching an Equal Error Rate (EER) of 3.5% in verification with only 0.8 seconds of gesture data and 90.3% identification accuracy for static wrist and hand gestures. Unlike ECG and EEG, sEMG also enables customizable gestures that can function as "biometric passwords", adding a knowledge-based layer to the authentication process [13]. Photoplethysmography (PPG) likewise shows promising results, with 96% cross-validation accuracy under physical activity, and can reach 99.8% accuracy with an error rate of 0.16% when fused with ECG in a multimodal framework [10].

Multimodal biometric systems further strengthen the case for biosignal-based authentication. The fusion of multiple biosignals, such as ECG, PPG, and respiratory signals, has achieved experimentally validated high accuracy across diverse populations. In addition to improving recognition performance, multimodal systems are harder to spoof and more robust than unimodal approaches, even when sample sizes are limited [9]. However, the benefits of fusion are not always consistent: in some cases, combining ECG and PPG yields only marginal gains over ECG alone, which suggests that the effectiveness of feature-level and decision-level fusion strategies remains insufficiently understood [10] [14].

Despite these advances, several technical barriers still limit practical deployment. Biosignals typically have low amplitude and are highly susceptible to environmental noise and motion artifacts. Conventional electrodes, such as Ag/AgCl, degrade over time and often require skin preparation and conductive gel, which reduces usability in real-world settings. In non-shielded environments, motion artifacts may be up to ten times stronger than the target signal. In addition, signal contamination across modalities remains a major challenge: ECG can interfere with EMG because of overlapping spectral components, and EMG artifacts are particularly difficult to remove from EEG using conventional filtering methods. As a result, signal quality may vary substantially across sessions, locations, and devices, compromising biometric reliability [15] [16] [17].

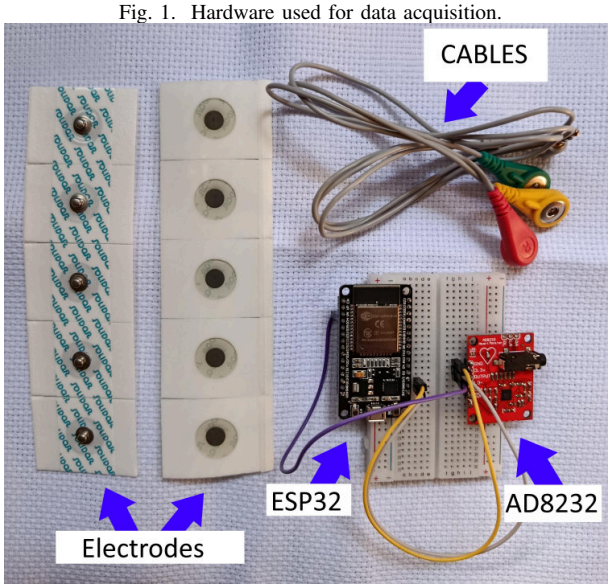
Methodological fragmentation is another important limitation. Although ECG biometrics have been widely studied, there is still no consensus on standard methodolo-

gies [7] [18] [18]. More broadly, biosignal research still lacks standardized practices for data curation, pretraining objectives, model architectures, and evaluation protocols, unlike fields such as natural language processing and computer vision [19].

These methodological issues are compounded by demographic imbalance and limited dataset documentation. In the PhysioNet repository, fewer than 7% of datasets report the four key demographic variables of race, ethnicity, sex/gender, and age. Among datasets that report sex, most are predominantly male, and most studies have been conducted in North America, especially in the United States. This raises serious concerns about bias in machine learning models trained on such data. Evidence from biometric systems such as facial recognition shows higher false rejection rates for women, children, and racial or ethnic minority groups, as well as higher false-positive rates for these populations. Therefore, the high performance often reported for biosignal biometrics, typically between 80% and 99%, may not generalize consistently across demographic groups [20] [21].

Security and temporal stability also remain open concerns. PPG acquired through non-invasive sensors is vulnerable to spoofing, and many legacy systems still lack integrated safeguards against signals from unverified sources. Signal quality is also affected by factors such as sensor characteristics, emotional state, energy consumption, and the interaction between light and melanin, which may vary across ethnic groups. Although countermeasures such as waveform analysis and liveness detection based on the Hilbert transform have been proposed, standardized defences are still lacking [15]. In addition, some biosignals and biomechanical patterns, such as gait, vary over time, emotional state, and pathological condition. Even within the same individual, physiological biosignals may change from day to day, which complicates robust biometric modelling [15] [8].

Finally, several research directions remain insufficiently explored. Modelling temporal dependencies in PPG is still an unresolved challenge, and although more complex architectures such as bidirectional LSTM networks can better capture temporal structure, they are also more prone to overfitting, sometimes reaching 100% training accuracy with only marginal gains in practical generalization [15]. The integration of physiological biosignals with behavioural signals, such as gait and gestures, is also still at an early stage [14]. At the data level, collection protocols vary widely in terms of activity, duration, environment, and participant instructions, and there are still no clear guidelines for gathering data across broad age ranges, such as 18 to 65 years, or across different physiological conditions [19]. This lack of standardization is aggravated both by data scarcity in some scenarios, which favours overfitting in deep learning models, and by the absence of consistent standards for data organization and storage, even when large datasets are available. As a result, inconsistencies may arise even within the same laboratory, generating rework and reducing reproducibility [21].



III. Methodology

This section describes the complete experimental workflow adopted in this study, including ECG acquisition, signal preprocessing, feature extraction, and the machine learning methodologies employed for both supervised and unsupervised analyses. The proposed pipeline was designed to evaluate whether ECG-derived features contain sufficient information to identify biometric and demographic characteristics while also investigating the existence of natural latent structures within the data.

A. Data Acquisition Hardware

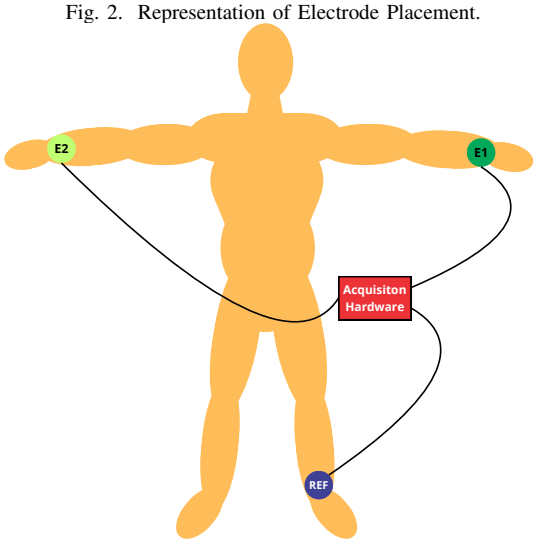
The system used for surface electrocardiography signal acquisition consists of an AD8232-based biopotential acquisition module, an ESP32 microcontroller, and disposable silver/silver chloride (Ag/AgCl) electrodes with conductive gel, as shown in Figure 1. The AD8232 is an integrated biopotential amplifier specifically designed for high-quality, low-noise electrocardiographic signal acquisition, and it is widely employed in portable and wearable applications [22].

Fig. 1. Hardware used for data acquisition.

The signal amplified by the AD8232 was transmitted to the ESP32 microcontroller, which was responsible for analog-to-digital conversion and for sending the data via a serial interface for storage and subsequent analysis. The ESP32 was chosen due to its versatility, low power consumption, and wireless communication capabilities, although in this experiment it was primarily used in wired mode.

The electrodes used were of the Ag/AgCl type, which are standard in electrophysiological signal acquisition due to their low contact impedance and good chemical stability. The use of conductive gel aimed to reduce the resistance between the skin and the electrode, thereby improving the quality of the recorded signal.

B. Data Collection Protocol



The data collection protocol was designed with the objective of evaluating the possibility of identifying individuals or groups of individuals from surface electrocardiography (ECG) signals. Participant selection followed predefined eligibility criteria intended to reduce major physiological and acquisition-related confounding factors, ensure adequate electrode–skin contact, and protect participants during the post-activity protocol. These criteria were adopted because the present investigation was designed as an initial feasibility study under controlled conditions rather than as a validation for commercial deployment. Individuals aged between 18 and 65 years, of both sexes, and capable of understanding and following the provided instructions were included. These criteria aimed to avoid anatomical interferences in surface signals and to ensure participant cooperation during the procedures.

Individuals with reduced motor mobility, those using medications that affect the nervous or cardiovascular systems, those with wounds, allergies, or dermatitis at the electrode placement sites, those who had consumed alcohol within the previous 24 hours, or those who were pregnant were excluded from the study. These conditions could compromise signal quality or pose ethical and physiological risks. Although these criteria improved experimental control, they reduced the clinical and physiological diversity of the sample and consequently limited the external validity of the results.

Before the start of data collection, all participants were properly instructed regarding the procedures to be performed. The electrode contact areas were cleaned with 70% ethyl alcohol, and participants were instructed to remove metallic objects such as earrings, bracelets, and rings, as well as to avoid carrying electronic devices during recording, such as mobile phones or smartwatches.

The electrodes were positioned on both wrists of the participants, while a reference electrode was placed on the left ankle, as shown in Figure 2.

Fig. 2. Representation of Electrode Placement.

The data collection procedure consisted of two distinct stages for each participant. In the first stage, the signal was recorded under resting conditions, with the individual in a basal state and heart rate within expected average values. In the second stage, data collection was performed immediately after light physical activity, such as jumping jacks or rapidly ascending and descending stairs, in order to increase heart rate. This strategy aimed to obtain signals under different physiological conditions, enabling comparative analyses between resting and active states. The acquired data were properly stored in digital files for subsequent processing and analysis.

C. Feature Extraction

ECG preprocessing and feature extraction were performed using a reproducible computational pipeline. First, baseline wander was reduced using median filtering. A fourth-order Butterworth band-pass filter with cutoff frequencies of 0.5 and 50 Hz was then applied to attenuate low- and high-frequency interference while preserving the frequency range relevant to ECG analysis. The complete source code, processing parameters, software dependencies, and execution instructions are available at https://github.com/CristianVeggian/ecg-analise-biometrica. Initially, the raw signals underwent a preprocessing stage, which consisted of applying median filters to remove baseline wander and low-frequency components associated with the QRS complex and the T wave.

Subsequently, the filtered signals were segmented into individual heartbeats. For this purpose, the `ecg.ecg()` function from the *biosppy* library was used for automatic R-peak detection. The signal was segmented at each heartbeat by extracting a temporal window of 0.2 seconds before and 0.4 seconds after the corresponding R-peak, allowing the isolation of complete cardiac events for analysis.

Feature extraction was carried out in two stages. First, time-domain, spectral, and statistical features were automatically extracted from each window using the *TSFEL* (*Time Series Feature Extraction Library*), covering a diverse set of numerical descriptors. In addition, specific features related to the morphology of the QRS complex were manually computed, such as the amplitude of the R peak, the amplitude of the S valley, the ratio between these amplitudes ($R/|S|$), the duration of the QRS complex (in seconds), the slope between the R and S points, and the area under the QRS complex, obtained through numerical integration. Table I summarizes the main feature categories considered in this study. Due to the large number of extracted features, the complete feature list, including the corresponding computational definitions, is provided in the project repository.

A total of 162 ECG-derived features were considered, including six QRS-based morphological features and 156 statistical, temporal, spectral, time–frequency, and cepstral descriptors. All extracted features were organized into a CSV file, which also included the corresponding subject identifier and the condition under which the signal was recorded, categorized into two distinct states: rest or activity.

TABLE I
SUMMARY OF ECG-DERIVED FEATURE CATEGORIES USED IN THIS STUDY.

Category	Examples of extracted features	Description
Morphological	R amplitude, S amplitude, R/|S| ratio, QRS duration, R–S slope, QRS area	Features specifically derived from the morphology of the QRS complex, describing amplitudes, duration, shape, and area of individual heartbeats.
Statistical	Mean, median, variance, standard deviation, root mean square, skewness, kurtosis, interquartile range, mean absolute deviation, median absolute deviation	Statistical descriptors characterizing the distribution, dispersion, central tendency, and shape of ECG amplitude values within each heartbeat segment.
Temporal	Absolute energy, area under the curve, autocorrelation, zero-crossing rate, peak-to-peak distance, positive and negative turning points, neighbourhood peaks, signal distance	Time-domain descriptors characterizing signal variation, energy, temporal dynamics, transitions, and waveform behavior within each segmented heartbeat.
Spectral	Fundamental frequency, median frequency, maximum frequency, spectral centroid, spectral entropy, spectral spread, spectral slope, spectral skewness, spectral kurtosis, spectral roll-on, spectral roll-off, power bandwidth	Frequency-domain descriptors characterizing the distribution, shape, complexity, and concentration of the ECG signal energy across frequencies.
Time–frequency	Wavelet energy, wavelet entropy, wavelet absolute mean, wavelet standard deviation, wavelet variance, spectrogram mean coefficients	Time–frequency descriptors representing variations in ECG frequency content over time at different frequency scales.
Cepstral	MFCC coefficients, LPCC coefficients	Cepstral-domain descriptors representing compact transformations of the signal spectrum and its spectral envelope.

D. Unsupervised Learning

Clustering analyses were performed using the Orange Data Mining platform. The process began with the import of files containing the features extracted from each heartbeat along with the metadata file, which included demographic characteristics of the individuals (ID, sex, state, weight, height, blood type). After merging the files and performing initial preprocessing—such as discretizing continuous variables into categories and selecting relevant columns — an outlier filtering step was applied to reduce potential interference in the clustering process.

Three main clustering approaches were used: *k-means*, DBSCAN, and hierarchical clustering. The *k-means* algorithm was configured with the number of clusters adjusted according to the objective of the analysis. In one approach, the goal was to form a number of clusters corresponding to the number of individuals in the dataset, in order to evaluate whether the extracted features would be sufficient to differentiate heartbeats from different individuals, functioning as a biometric signature. In other approaches, the clusters were adjusted to reflect specific characteristics of individuals, such as age group (young, adult, elderly), sex (male or female), weight (three categories), and height (three categories), as well as attempts to cluster by blood type.

In addition to *k-means*, the DBSCAN algorithm was employed to identify clusters with non-spherical shapes and to automatically detect outliers. Hierarchical clustering was applied using the distance matrix between samples, allowing visual analysis of group formation through dendrograms. To evaluate clustering quality, visualizations such as scatter plots and t-SNE projections were used, along with the silhouette metric to assess cluster cohesion and separation.

This approach enabled the evaluation of the ability of features extracted from heartbeats to discriminate individuals or subgroups based on biometric and demographic attributes.

E. Supervised Learning

The supervised learning stage was also conducted using the Orange platform, based on datasets containing features extracted from heartbeats. After importing and organizing the CSV files, preprocessing steps were performed, including file merging, variable discretization, and selection of relevant columns.

The main objective was to evaluate the predictive capability of the extracted features with respect to biometric and demographic attributes of individuals, such as age, sex, weight, height, and blood type. For categorical attributes, including subject ID, sex, recording state, and blood type, supervised classification algorithms were applied. In addition, age, weight, and height were discretized into predefined intervals and evaluated as classification tasks. In this context, four main classifiers were tested: k-Nearest Neighbors (kNN), Naive Bayes, Random Forest, and Multilayer Perceptron. Each algorithm was executed with its default settings, allowing an initial comparison between probabilistic approaches, instance-based methods, and ensemble learning techniques.

For numerical variables (age, weight, and height), two distinct strategies were evaluated. In the first approach, these variables were discretized into predefined intervals to transform the problem into a classification task. However, due to class imbalance observed in some variables—especially age—experiments were also conducted using supervised regression to predict continuous values. For regression tasks, the algorithms used included k-Nearest Neighbors, Linear Regression, Random Forest, and Multilayer Perceptron.

Model validation was performed using the Test and Score widget. For demographic classification and regression tasks, participant-independent validation was adopted using cross-validation grouped by subject identifier (ID). Therefore, all heartbeat segments belonging to the same participant were assigned to the same fold, preventing samples from a given individual from appearing simultaneously in the training and test

sets. For closed-set subject identification, conventional stratified 10-fold cross-validation was maintained, since subject-wise splitting would remove from the training set the identity class to be predicted. Classification performance was evaluated using accuracy, precision, recall, F1-score, AUC, and Matthews correlation coefficient (MCC), whereas regression performance was assessed using MSE, RMSE, MAE, MAPE, and R^2.

IV. Results

This section presents the experimental results obtained from both the unsupervised and supervised learning analyses. Initially, the characteristics of the generated dataset are described, followed by the evaluation of clustering algorithms and predictive models. The results are analyzed using quantitative performance metrics and visual inspection in order to assess the feasibility of identifying biometric and demographic information from ECG-derived features.

A. Generated Dataset

A total of 52 recordings were performed across 26 distinct participants. In total, 1,858 electrocardiographic segments were obtained, distributed between resting and activity conditions.

The generated dataset can be found in the following GitHub repository: https://github.com/CristianVeggian/ecg-analise-biometrica.

Figure 3 shows the distribution of the dataset metadata, which were used as target variables in classification and regression tasks. A significant imbalance can be observed in some variables, such as sex and age. The number of segments from male participants is substantially higher compared to female participants, which may impact the performance of supervised classifiers. Similarly, there is a predominance of participants classified in the "young" age group, with lower representation in the "adult" and "elderly" categories.

The distributions of weight and height show a more balanced division among the established categories, which is favorable for model training. In the case of blood type, there is a concentration of records in the "Not Specified" (N/S) category, in addition to a non-uniform distribution among the different types, representing an additional challenge for predictive algorithms.

These observations highlight the need to carefully evaluate the impact of imbalance during the supervised learning stage, especially in multiclass classification tasks. For discretized numerical variables, the imbalance motivated additional experiments using supervised regression in order to explore alternative approaches and mitigate the limitations imposed by the data distribution.

B. Unsupervised Learning

Three main unsupervised learning algorithms were tested: k-means, DBSCAN, and hierarchical clustering. The quantitative evaluation of clustering quality was performed using the silhouette coefficient.

The elbow method was applied to determine the optimal number of clusters in the k-means algorithm, testing values of k between 2 (minimum expected number of clusters) and 26 (maximum expected, based on the number of individuals). Despite this approach, it was not possible to identify a clear inflection point in the curve, reinforcing the absence of well-defined clustering structures in the dataset, as shown in Figure 4.

Furthermore, even with manual adjustments of k, the silhouette coefficient values remained low, indicating that the separation between clusters did not represent cohesive or consistent groupings. These results suggest that, within the context of this study and given the extracted features, ECG signals did not exhibit sufficient natural separations for meaningful clustering through unsupervised learning.

Despite attempts to optimize the DBSCAN algorithm through systematic tuning of the *eps* and *min_samples* parameters, the resulting partition was highly unbalanced. DBSCAN identified two clusters, containing 1,650 and 20 samples, respectively, while only two samples (0.1%) were classified as noise. The silhouette coefficient, calculated excluding noise samples, was 0.520. Although this value indicates moderate separation between the identified clusters, the strong imbalance in cluster sizes indicates that the data were predominantly represented by a single large cluster rather than by two comparably sized natural groups.

Additionally, the t-SNE projection did not reveal a clear correspondence between the DBSCAN partition and the investigated metadata. When the same projection was visualized according to recording state, sex, and subject ID, substantial overlap remained between the corresponding groups. Therefore, although DBSCAN produced a moderately separated partition according to the silhouette coefficient, the identified clusters could not be clearly associated with the investigated biometric or demographic characteristics.

Figure 5 presents the t-SNE projection of the DBSCAN results together with the corresponding metadata. Cluster 0 represents the dominant group containing 1,650 samples, Cluster 1 contains 20 samples, and only two samples were classified as noise. The comparison between the clustering result and the available metadata illustrates the absence of a clear demographic or biometric interpretation for the partition obtained by DBSCAN.

Hierarchical clustering was also applied using Euclidean distance and the *Ward* linkage method. The number of clusters was not defined a priori, since this analysis was exploratory and aimed at investigating the intrinsic organization of the ECG-derived feature space. The *Ward* criterion was selected because it minimizes within-cluster variance and is appropriate for continuous numerical data analyzed with Euclidean distances.

Inspection of the dendrogram revealed two major branches separated at a relatively high linkage distance, motivating the evaluation of a two-cluster partition. The resulting partition contained 1,038 samples in Cluster 1 and 634 samples in Cluster 2. Although the dendrogram revealed a clear high-

Fig. 3. Distribution of participants according to (a) state, (b) sex, (c) age group, (d) weight group, (e) height group, and (f) blood type.

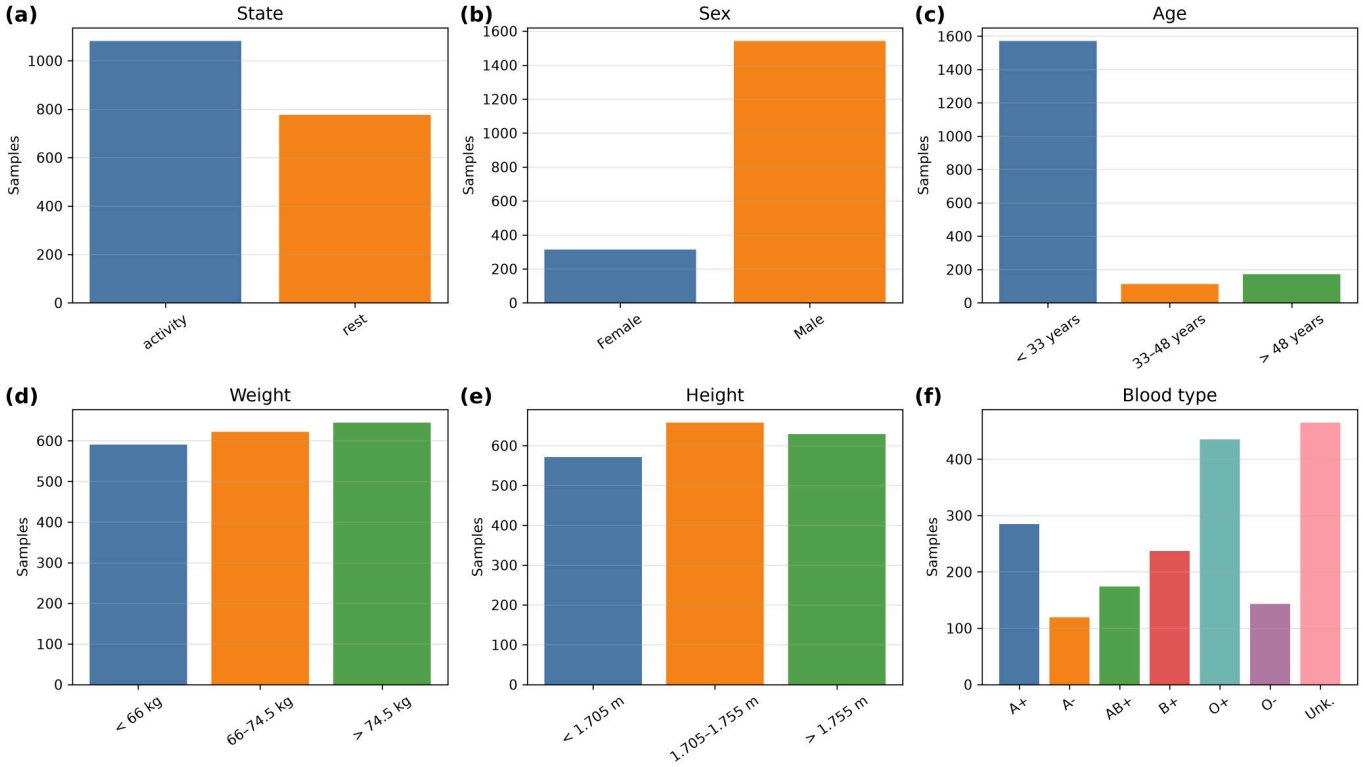


Fig. 4. Elbow method applied to k-means.

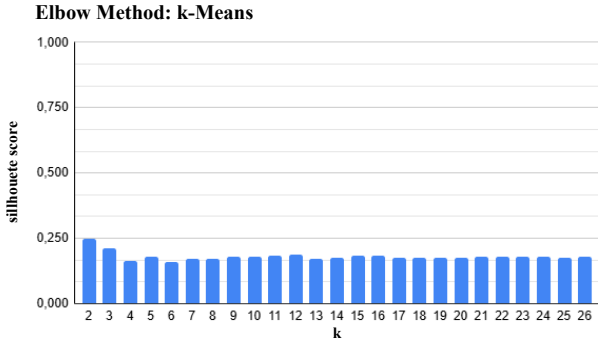

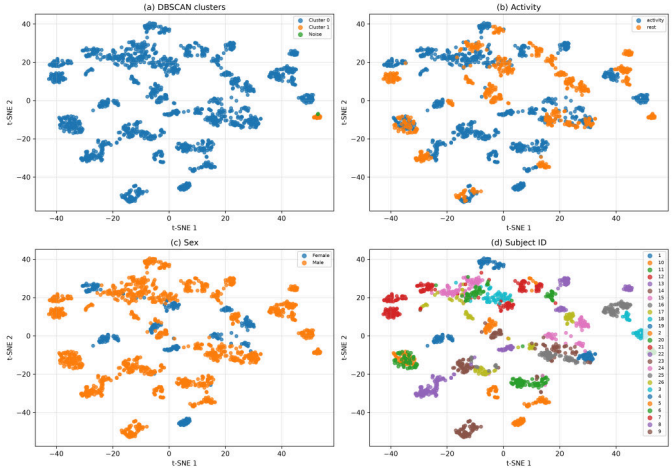

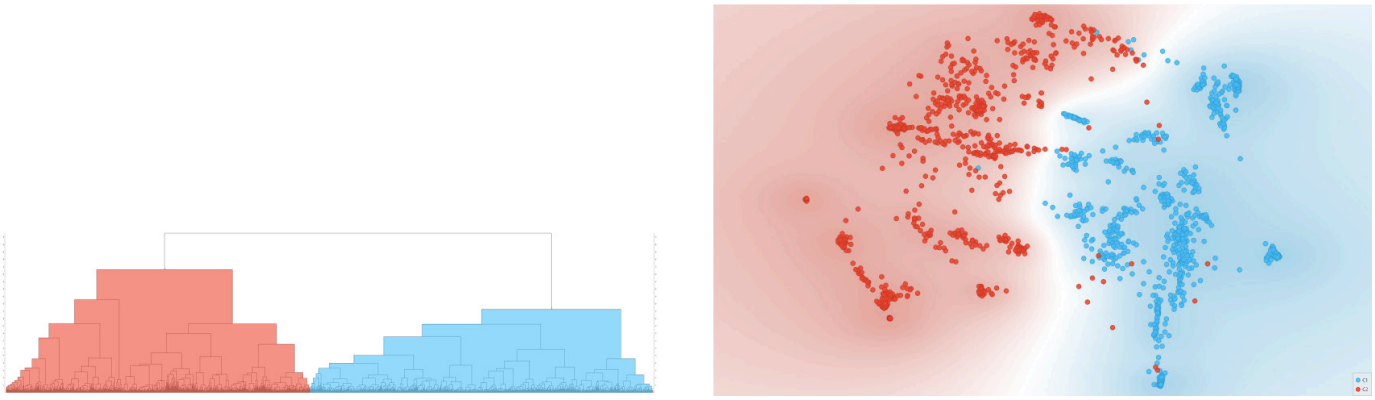

Fig. 5. t-SNE visualization of the DBSCAN clustering results and selected metadata. Cluster 0 and Cluster 1 represent the groups identified by DBSCAN, whereas Noise represents samples that were not assigned to any cluster. The remaining panels show the same t-SNE projection colored according to recording state, sex, and subject ID.

level bifurcation, the silhouette analysis showed substantial variability in cluster cohesion, including negative silhouette values for several samples. This indicates that a considerable number of observations were not clearly separated between the two clusters.

Figure 6 presents the dendrogram together with the corresponding t-SNE projection. The t-SNE visualization showed considerable overlap between the two groups and did not reveal a clear correspondence with the investigated demographic or biometric attributes. Therefore, the two-cluster solution was interpreted as an exploratory representation of the hierarchical structure of the feature space rather than as evidence of two predefined or well-separated demographic or biometric groups.

These findings indicate that, similarly to *k-means* and DBSCAN, hierarchical clustering did not identify natural groups that could be consistently associated with the investigated demographic or biometric attributes. The presence of two major branches in the dendrogram reflects a high-level hierarchical

(a) Hierarchical clustering dendrogram.

(b) t-SNE projection of the two-cluster partition.

Fig. 6. Hierarchical clustering analysis using Ward linkage and Euclidean distance. (a) Dendrogram showing the hierarchical organization of the ECG-derived samples; the two-cluster partition corresponds to the two major branches observed before the final high-level merge. (b) t-SNE projection of the resulting two-cluster partition, showing regions of overlap between the clusters. The partition contained 1,038 samples in Cluster 1 and 634 samples in Cluster 2.

division of the feature space, but the silhouette distribution and the overlapping t-SNE projection indicate that this division should not be interpreted as two clearly separable biological or demographic populations.

C. Supervised Learning

Table II presents the F1-scores obtained for the supervised classification tasks. A clear distinction can be observed between closed-set subject identification and participant-independent demographic classification.

TABLE II
F1-SCORE BY ATTRIBUTE AND ALGORITHM.

Class	kNN	Naive Bayes	Random Forest	MLP
ID (26 classes)	0.343	0.834	**0.941**	0.922
Sex (2 classes)	**0.755**	0.661	0.696	0.730
Age (3 classes)	**0.734**	0.615	0.721	0.713
State (rest/activity)	0.482	**0.617**	0.551	0.568
Height (3 classes)	**0.291**	0.175	0.157	0.145
Weight (3 classes)	0.192	0.203	0.195	**0.280**
Blood type (7)	0.167	0.204	0.173	**0.229**

For closed-set subject identification, Random Forest achieved the highest F1-score (0.941), followed by MLP (0.922) and Naive Bayes (0.834), whereas kNN obtained a considerably lower F1-score of 0.343. These results indicate that the extracted ECG features contain strong subject-specific information when the identities evaluated during testing are represented in the training data.

In contrast, performance decreased when participant-independent validation was applied to demographic attributes. Sex classification achieved its highest F1-score with kNN (0.755), followed by MLP (0.730), Random Forest (0.696), and Naive Bayes (0.661). For age-group classification, kNN also obtained the highest F1-score (0.734), while Random Forest and MLP achieved 0.721 and 0.713, respectively. State classification presented lower performance, with Naive Bayes achieving the highest F1-score of 0.617.

The remaining demographic attributes presented considerably lower predictive performance. For height classification, the highest F1-score was 0.291 with kNN. Weight classification reached a maximum F1-score of 0.280 with MLP, whereas blood-type classification reached a maximum F1-score of 0.229, also with MLP. These results indicate that, under participant-independent validation, the extracted ECG features provided limited discriminative information for these attributes.

Overall, the reduction in demographic classification performance compared with closed-set subject identification suggests that ECG-derived features contain substantial subject-specific information, whereas demographic patterns are considerably more difficult to generalize to participants not represented during model training.

Within the supervised learning analysis, regression experiments were also conducted to evaluate the ability of the models to predict continuous demographic variables, namely height, age, and weight, under participant-independent validation.

Table III presents the performance of the regression models for height prediction. All evaluated models produced negative coefficients of determination, indicating limited generalization to unseen participants. Among the evaluated methods, kNN achieved the highest R^2 value ($R^2 = -0.416$), with an RMSE of 0.082 and an MAE of 0.063. Random Forest obtained $R^2 = -0.619$, while Linear Regression and MLP presented substantially lower values of $R^2 = -2.268$ and $R^2 = -7.854$, respectively. These results indicate that none of the evaluated models reliably explained height variability for participants not represented during training.

TABLE III
PERFORMANCE OF REGRESSION MODELS FOR HEIGHT PREDICTION.

Model	MSE	RMSE	MAE	MAPE (%)	R^2
kNN	0.007	0.082	0.063	3.582	**-0.416**
Linear Regression	0.015	0.124	0.081	4.609	-2.268
Neural Network (MLP)	0.042	0.204	0.147	8.429	-7.854
Random Forest	0.008	0.087	0.067	3.812	-0.619

Table IV presents the regression results for age prediction. Similar to the height prediction task, all models produced

negative R^2 values. Random Forest achieved the highest coefficient of determination ($R^2 = -0.497$), with an RMSE of 13.369 and an MAE of 9.064 years. kNN obtained a similar performance, with $R^2 = -0.594$, whereas MLP and Linear Regression presented R^2 values of -0.848 and -3.520, respectively. Therefore, none of the evaluated models outperformed a baseline based on the mean target value when predicting the age of unseen participants.

TABLE IV
PERFORMANCE OF REGRESSION MODELS FOR AGE PREDICTION.

Model	MSE	RMSE	MAE	MAPE (%)	R^2
kNN	190.320	13.796	9.632	33.391	-0.594
Linear Regression	539.767	23.233	12.574	47.098	-3.520
Neural Network (MLP)	220.725	14.857	10.263	36.180	-0.848
Random Forest	178.719	13.369	9.064	30.520	**-0.497**

Table V presents the results obtained for weight prediction. Random Forest achieved the best performance among the evaluated models, with an RMSE of 15.991 kg, an MAE of 11.680 kg, and $R^2 = -0.369$. However, the negative coefficient of determination indicates that its predictions did not generalize adequately to unseen participants. kNN obtained $R^2 = -0.456$, while MLP and Linear Regression achieved $R^2 = -0.807$ and $R^2 = -1.162$, respectively.

TABLE V
PERFORMANCE OF REGRESSION MODELS FOR WEIGHT PREDICTION.

Model	MSE	RMSE	MAE	MAPE (%)	R^2
kNN	272.097	16.495	12.339	16.500	-0.456
Linear Regression	403.913	20.098	14.904	20.138	-1.162
Neural Network (MLP)	337.636	18.375	14.362	19.132	-0.807
Random Forest	255.714	15.991	11.680	15.337	**-0.369**

Taken together, the regression results demonstrate that the evaluated models were unable to reliably generalize continuous demographic attributes across participants. This contrasts with the strong closed-set subject identification performance and further indicates that subject-specific ECG characteristics are more readily captured by the extracted features than demographic patterns that generalize across individuals.

V. DISCUSSION

The results obtained in this study reveal an important distinction between closed-set biometric identification and demographic prediction from ECG-derived features. While subject identification remained highly effective, participant-independent validation substantially reduced the performance of models applied to demographic attributes. This finding indicates that ECG-derived features contain strong subject-specific information, but their ability to generalize demographic characteristics to previously unseen individuals is considerably more limited.

For closed-set subject identification, Random Forest achieved the highest performance, with an F1-score of 0.941, followed by the Multilayer Perceptron with an F1-score of 0.922. In this task, conventional stratified cross-validation was maintained because all identity classes must be represented in the training set. These results reinforce the hypothesis that morphological, temporal, statistical, and spectral characteristics extracted from ECG signals contain discriminative information capable of differentiating individuals.

In contrast, when participant-independent validation was adopted for demographic classification, performance decreased substantially. The best F1-scores were 0.755 for sex classification and 0.734 for age-group classification, both obtained with kNN. State classification reached a maximum F1-score of 0.617 with Naive Bayes, whereas height, weight, and blood-type classification presented considerably lower results. These findings suggest that part of the high performance observed under heartbeat-level cross-validation was likely associated with subject-specific patterns shared between training and test samples rather than with demographic characteristics that generalize across individuals.

The regression experiments provide further evidence of this limitation. Under participant-independent validation, all evaluated models produced negative R^2 values for age, height, and weight prediction. The best results were R^2 = -0.416 for height using kNN, R^2 = -0.497 for age using Random Forest, and R^2 = -0.369 for weight using Random Forest. Negative coefficients of determination indicate that, under the investigated conditions, the models did not generalize these continuous demographic attributes to unseen participants and performed worse than a baseline prediction based on the target mean.

These results highlight the methodological importance of subject-wise validation when multiple heartbeat segments are extracted from the same participant. Because several segments originate from a single individual, conventional sample-level cross-validation may allow subject-specific physiological information to appear in both training and test sets, resulting in optimistic estimates of model performance. The participant-independent evaluation therefore provides a more conservative and realistic assessment of the demographic information that can be generalized from ECG-derived features.

The unsupervised learning results are consistent with this interpretation. k-means, DBSCAN, and hierarchical clustering did not reveal natural groupings that could be clearly associated with the investigated demographic and biometric characteristics. In particular, DBSCAN identified two highly unbalanced clusters, containing 1,650 and 20 samples, respectively, with only two samples (0.1%) classified as noise. Although the silhouette coefficient of 0.520 indicated moderate separation between the DBSCAN clusters, their substantial size imbalance and the absence of a clear correspondence with the available metadata suggest that this partition does not represent a meaningful demographic or biometric grouping. Similarly, the other clustering approaches showed considerable overlap between groups and no consistent association with the investigated attributes. Nevertheless, the strong closed-set identification results demonstrate that the absence of clear unsupervised groupings does not imply an absence of subject-specific information in the ECG signals.

Several factors may have contributed to the limited de-

mographic generalization observed in this study. The dataset contains only 26 participants and presents demographic imbalance, particularly regarding sex, age, and blood type. In addition, the relatively small number of subjects restricts the diversity represented in participant-independent validation folds. High feature dimensionality and physiological variability between recording conditions may also contribute to the difficulty of learning patterns that generalize across participants.

Therefore, the results should be interpreted as evidence that ECG-derived features are highly informative for distinguishing individuals already represented in the biometric system, while their ability to predict demographic attributes for unseen individuals remains limited under the investigated conditions. Larger and more representative datasets, together with participant-independent evaluation protocols, will be necessary to determine whether demographic information can be reliably generalized from ECG signals.

VI. Conclusion

This work investigated the feasibility of extracting biometric and demographic information from ECG signals using supervised and unsupervised machine learning techniques. A dataset containing ECG recordings from 26 participants under resting and post-activity conditions was collected, and more than 160 temporal, spectral, statistical, and morphological features were extracted from each heartbeat.

The participant-independent evaluation revealed a clear distinction between biometric identification and demographic prediction. ECG-derived features demonstrated strong discriminative capability for closed-set subject identification, with Random Forest achieving an F1-score of 0.941. However, when heartbeat segments from the same participant were prevented from appearing simultaneously in the training and test sets, classification performance decreased substantially for demographic attributes.

Regression results further demonstrated limited generalization to unseen participants. All evaluated models produced negative R^2 values for age, height, and weight prediction, indicating that the extracted features were insufficient to reliably estimate these continuous demographic variables under participant-independent validation.

Similarly, unsupervised approaches, including k-means, DBSCAN, and hierarchical clustering, were unable to identify consistent latent structures associated with the investigated biometric and demographic attributes. Overall, these findings indicate that ECG-derived features contain strong subject-specific information, supporting their potential for closed-set biometric identification, while demographic characteristics were not reliably generalized from the extracted feature space in the present dataset.

The results also emphasize the importance of participant-independent validation in studies involving multiple physiological segments from the same individuals, since sample-level cross-validation may lead to optimistic performance estimates due to subject-specific information shared between training and test sets.

Future work will focus on expanding the dataset with a larger and more demographically diverse cohort, improving the balance among demographic groups, investigating feature selection and dimensionality reduction techniques, and evaluating additional machine learning and deep learning approaches under participant-independent validation protocols.

***Abstract*—**
BioStatusIA is a multi-agent architecture for clinical decision support that combines biomedical data processing, classifier selection, and local report generation. CrewAI coordinates the agents, and a local Large Language Model (LLM) runs through Ollama. Eight completed executions covered five tabular datasets and three labeled medical image collections, processed independently. Each run compared six classifiers using an internal cross-validation score and reported performance on a separate test set. The selected models achieved mean AUROC 0.866 ± 0.109 and Matthews Correlation Coefficient (MCC) 0.580 ± 0.295; these values summarize variation across datasets. Four runs failed the minimum cross-validation sensitivity of 0.80, and four selected models had calibration error above 0.10. End-to-end processing took 80.073–809.475 s, LLM generation took 41.593–789.218 s, and selected-classifier inference took 0.0005–0.4427 ms per sample. Times were measured once per dataset. The results document operation on tabular and image data but do not establish patient-independent generalization, report accuracy, or clinical validity.

I. Introduction

Routine clinical practice generates physiological signals, medical images, volumetric examinations, laboratory records, and electronic health records. These sources provide complementary information for clinical decisions, but differences in representation, preprocessing, and analysis complicate their integration into a common workflow [1].

Clinical Decision Support Systems (CDSS) have evolved from rule-based expert systems [2] into data-driven platforms for diagnostic support and clinical workflow assistance [3]. Large Language Models (LLMs) support natural language interaction, report generation, and contextual reasoning [4], [5]. Multi-agent architectures, implemented with frameworks such as CrewAI [6], divide clinical workflows into tasks handled by collaborating agents [7].

Existing studies often focus on individual tasks, such as medical image interpretation or physiological signal analysis [8]. Combining these tasks can require separate pipelines, adding implementation work and limiting interoperability. Fewer studies examine multi-agent orchestration for multimodal biomedical decision support with a locally deployed LLM [9].

This paper presents BioStatusIA, a local multi-agent architecture for multimodal clinical decision support. It combines agents orchestrated through CrewAI with an LLM executed using Ollama [10]. All processing stages, including inference, run within the institution's infrastructure. A normalization layer supports one-dimensional physiological signals, two-dimensional medical images, three-dimensional volumetric examinations, and structured clinical datasets within a common pipeline.

The contributions are:

- A multi-agent architecture that processes physiological signals, medical images, volumes, and structured clinical data within a single workflow.
- A normalization layer that handles differences in biomedical file formats, dimensions, and metadata.
- An orchestration framework combining analytical agents with a local LLM for structured clinical report generation.
- An evaluation of eight completed runs on tabular and image datasets, with six candidate classifiers per dataset, separate cross-validation and test sensitivities, MCC and calibration metrics, and measurements of end-to-end time, LLM generation, training, and inference.

The remainder of this paper reviews related work (Section II), presents the proposed architecture (Section III) and its experimental evaluation (Section IV), discusses the results (Section V), and closes with limitations and conclusions (Sections VI and VII).

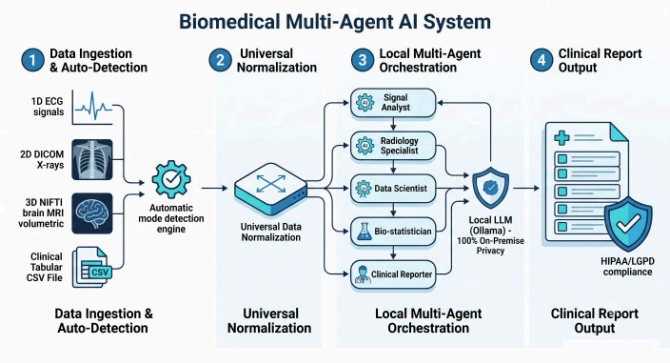

Fig. 1. Overall workflow of the BioStatusIA architecture. An automatic mode-detection step routes each normalized input to the matching specialized agent (Signal Analyst, Radiology Specialist, Data Scientist, or Bio-statistician), whose output is consolidated by the Clinical Reporter using the local LLM; agent roles match Table II.

II. Related Work

Clinical Decision Support Systems (CDSS) range from rule-based systems such as MYCIN [2] to data-driven tools for diagnosis, treatment planning, and documentation [3], [11]. Task-specific pipelines can handle individual clinical problems but require additional integration to process heterogeneous biomedical data within one workflow.

Foundation models support biomedical question answering and text generation, as illustrated by generalist biomedical models [4], LLaMA [5], and Med-Flamingo [8]. Their use in healthcare also requires attention to privacy, computational resources, and response time [9]. Predictive performance alone does not describe the cost of running a complete reporting workflow.

Multi-agent systems divide workflows among specialized components [7]. Frameworks such as CrewAI [6] coordinate these components, allowing modality-specific analysis, model selection, statistical assessment, and report generation to remain separate tasks.

BioStatusIA combines this task separation with local LLM inference and a common interface for biomedical inputs. Its evaluation measures classifier performance and execution time across independent datasets, rather than patient-level multimodal fusion. Table I summarizes the architectural comparison.

III. Proposed Architecture

BioStatusIA combines a data normalization layer, agents orchestrated with CrewAI [6], and a local Large Language Model (LLM) executed through Ollama [10].

Figure 1 illustrates the overall workflow: biomedical data from different modalities are standardized through a normalization layer, dispatched to specialized agents, and consolidated into a structured clinical report.

A. System Overview

BioStatusIA has five layers: Biomedical Data Acquisition, Data Normalization, Multi-Agent Orchestration, Local LLM Reasoning, and Clinical Report Generation. Input data pass through normalization and modality detection before being routed to the appropriate agent. CrewAI coordinates the agents, and the local LLM uses their outputs to produce a structured report. The layers separate modality-specific processing from orchestration and report generation.

B. Multi-modality Data Processing

BioStatusIA handles four data categories, each with a feature-extraction routine. One-dimensional signals (ECG, PPG, EEG) yield time-domain and spectral biomarkers, including RMSSD, SDNN, pNN50, and Welch-FFT band power via `mne`. Two-dimensional image processing supports DICOM-native inputs (Hounsfield-unit windowing and tissue-density estimation) and common formats (CLAHE/Non-Local Means denoising, GLCM texture, and morphology measures such as entropy, contrast, solidity, and circularity). Three-dimensional volumes (CT, MRI) yield tri-planar radiomics, including lesion volume in mm^3, 3D sphericity, and GLCM features. Structured datasets use SHAP-ranked adaptive imputation and feature selection. The normalization layer handles differences in file formats, dimensions, and metadata before agent analysis.

C. Multi-Agent Orchestration

Each agent has a specific task. The *Signal Analyst* processes one-dimensional physiological signals (ECG, PPG, EEG); the *Radiology Specialist* analyzes two-dimensional images (DICOM and common formats) and three-dimensional CT/MRI volumes; the *Data Scientist* runs the AutoML model-selection pipeline (Section IV-A) on structured clinical data; and the *Bio-statistician* performs the EDA statistical audit (Section IV-A) and calibration analysis. The *Clinical Reporter* combines the outputs and forwards them to the local LLM. Table II summarizes these responsibilities.

D. Local LLM Reasoning

BioStatusIA performs LLM inference locally through Ollama [10], without a cloud API. The implementation described here uses Qwen2.5:3B-Instruct. The execution reports used in Section IV do not record the model identifier, quantization, context limit, or hardware, so those runtime settings cannot be confirmed for the reported measurements. The LLM receives structured agent outputs rather than raw biomedical data and uses them to generate clinical summaries. The intended report-generation workflow is represented as

$$R = f(A_1, A_2, \ldots, A_5, M), \tag{1}$$

where A_i denotes each specialized agent (Signal Analyst, Radiology Specialist, Data Scientist, Bio-statistician, Clinical Reporter), M corresponds to the locally deployed LLM, and R is the final structured clinical report.

IV. Experimental Evaluation

A. Experimental Setup

BioStatusIA uses Python, CrewAI [6], and a local LLM served through Ollama [10]. The eight reports dated September

TABLE II
RESPONSIBILITIES OF THE BIOSTATUSIA AGENTS.

Agent	Primary Responsibility
Signal Analyst	Physiological signal analysis (1D)
Radiology Specialist	Medical imaging analysis (2D/3D)
Data Scientist	AutoML model selection
Bio-statistician	Statistical audit & calibration
Clinical Reporter	Evidence consolidation & report generation

14, 2026 record preprocessing, classifier results, confusion matrices, and execution times. Candidate classifiers were Logistic Regression (LR), Random Forest (RF), Support Vector Machine (SVM), K-Nearest Neighbors (KNN), Gradient Boosting (GB), and Multi-Layer Perceptron (MLP).

The preprocessing records indicate robust scaling for all five tabular datasets and median imputation for Heart Disease Cleveland; no imputation was recorded for the other tabular datasets. The three image datasets used Gaussian smoothing, min–max normalization, and resizing to 256×256, without contrast equalization.

B. Datasets

Table III lists the datasets included in the completed runs. Breast Cancer Wisconsin[1] [12], Stroke Prediction Clinical[2], PIMA Diabetes[3] [13], Heart Disease Cleveland[4], and Parkinson's Vocal Biomarkers[5] [14] were processed as tabular data. BUSI[6] [15], Brain Tumor MRI[7], and Brain MRI Oncology[8] were processed as labeled image collections. Parkinson's inputs were acoustic measurements rather than raw audio. These runs therefore cover tabular data and two-dimensional images, not raw physiological signals or three-dimensional volumes. The datasets were analyzed independently, without patient-level multimodal fusion.

The Brain Tumor MRI run contains 7,200 images across four encoded classes. Heart Disease Cleveland retains five classes and is not a binary disease-detection task. BUSI is reported with two encoded classes, but the export does not document how the original diagnostic categories were mapped to these labels.

TABLE III
DATASETS IN THE EXECUTION REPORTS. N IS THE REPORTED SAMPLE COUNT, N_{test} IS THE CONFUSION-MATRIX TOTAL, AND C IS THE NUMBER OF ENCODED CLASSES.

Dataset	N	N_{test}	C
Breast Cancer Wisconsin	569	114	2
BUSI Ultrasound	780	156	2
Stroke Clinical	5,110	1,022	2
PIMA Diabetes	768	154	2
Brain Tumor MRI	7,200	1,440	4
Brain MRI Oncology	253	51	2
Heart Cleveland	303	61	5
Parkinson's Voice	195	39	2

C. Model Selection and Evaluation Protocol

Models were ranked by an internal cross-validation clinical score, not test performance, with a sensitivity floor of $S_{\min} = 0.80$. No candidate met this floor for BUSI, Stroke, PIMA, or Heart Disease Cleveland. The returned models had cross-validation sensitivities of 0.619, 0.761, 0.724, and 0.345, respectively, and carried explicit warnings. They remain in the descriptive comparison despite failing the selection constraint.

The confusion-matrix totals are consistent with approximately 20% of each dataset being reserved for testing. The reports distinguish internal cross-validation sensitivity from test sensitivity, but do not identify the random seeds, fold count, subject-group assignments, or fold-specific preprocessing fits. Patient-level separation and training-only preprocessing cannot be verified from these exports. In particular, the Parkinson's results cannot be described as performance on held-out subjects without the corresponding partition records.

Table IV reproduces the selected models' reported metrics. Percentage values were converted to proportions. AUROC denotes the area under the ROC curve, MCC the Matthews Correlation Coefficient, and ECE the Expected Calibration Error. Multiclass aggregation settings and ECE binning are not specified in the reports. Cross-dataset summaries use an unweighted mean and sample standard deviation over the eight reported values; they describe variation across tasks, not uncertainty from repeated runs. ROC curves are not reconstructed because prediction scores are unavailable.

D. Predictive Performance

Across the eight datasets, mean AUROC was 0.866 ± 0.109 and mean MCC was 0.580 ± 0.295. Breast Cancer Wisconsin

TABLE IV
SELECTED-MODEL PERFORMANCE. ONLY SENS. CV IS FROM INTERNAL CROSS-VALIDATION; ALL OTHER METRICS ARE FROM THE HELD-OUT TEST SET.

Dataset	Model	Acc.	AUROC	Sens. CV	Sens. test	Spec.	MCC	ECE
Breast Cancer Wisconsin	MLP	.991	.995	.971	.976	1.000	.981	.010
BUSI Ultrasound	SVM†	.744	.733	.619	.667	.772	.409	.146
Stroke Clinical	LR†	.750	.841	.761	.780	.748	.254	.259
PIMA Diabetes	SVM†	.734	.794	.724	.778	.710	.467	.125
Brain Tumor MRI (4-class)	RF	.901	.983	.880	.901	.967	.868	.082
Brain MRI Oncology	RF	.804	.849	.856	.871	.700	.583	.092
Heart Cleveland (5-class)	RF†	.508	.746	.345	.222	.862	.211	.156
Parkinson's Voice	MLP	.949	.986	.926	.965	.900	.866	.059
Mean	–	.798	.866	.760	.770	.832	.580	.116
Sample SD	–	.153	.109	.203	.245	.116	.295	.075

† No candidate reached the internal cross-validation sensitivity floor of 0.80. The returned model carries a warning in the execution report.

had the highest MCC (0.981), followed by Brain Tumor MRI (0.868) and Parkinson's Voice (0.866). BUSI, Stroke, PIMA, and Heart Disease Cleveland had MCC values between 0.211 and 0.467 and did not meet the internal sensitivity floor. Four selected models had $ECE > 0.10$: BUSI, Stroke, PIMA, and Heart Disease Cleveland.

Selection did not necessarily maximize test performance: on Brain MRI Oncology, RF had MCC 0.583 versus MLP's 0.715; on BUSI, the selected SVM had AUROC 0.733 versus RF's 0.824. Neither comparison justifies selecting a different model after observing test results.

E. Execution Time

End-to-end time ranged from 80.073 to 809.475 s, while LLM generation took 41.593–789.218 s (Table V). Selected-model training took 0.035–1.959 s, and classifier inference took 0.0005–0.4427 ms per sample. The inference measurement does not include feature extraction, model search, orchestration, or report generation. LLM throughput ranged from 3.51 to 26.89 tokens/s.

For Stroke, LLM and AutoML completion occurred at 52.285 and 507.249 s, respectively; selected-model training took 0.035 s and does not represent total search time. For Brain Tumor MRI, LLM generation occupied 789.218 of 809.475 s. Without a complete timing breakdown or repeated measurements, stage-specific overhead and timing variance cannot be inferred.

V. DISCUSSION

The eight runs document a common workflow for tabular clinical data and labeled medical images. They do not test the joint analysis of multiple modalities from the same patient. The architectural support for signals and volumes should therefore be distinguished from the modalities covered by this evaluation.

Predictive performance varied substantially across tasks. Breast Cancer Wisconsin, Brain Tumor MRI, and Parkinson's Voice had MCC values above 0.86, while Stroke and Heart Disease Cleveland remained below 0.26. For Stroke, the selected LR model detected 39 of 50 positive test cases but produced 245 false positives. Its AUROC of 0.841 must therefore be considered alongside MCC 0.254 and ECE 0.259. In Cleveland's five-class task, RF correctly classified 29 of 33 class-0 cases but only two of the remaining 28 cases. The overall specificity of 0.862 does not offset this poor recognition of the other classes.

Four runs failed the internal sensitivity requirement. Returning a model with a warning preserves the analytical output, but does not make that model suitable for clinical use. The same four selected models also had $ECE > 0.10$. Changes to class weighting, decision thresholds, and probability calibration require assessment within the training procedure, followed by evaluation on independent data.

The execution times separate fast classifier inference from the much longer interval needed to complete the workflow. LLM generation accounted for most of the elapsed time in the image runs, while Stroke had a long interval between LLM and AutoML completion. Optimizing classifier inference alone would not address these costs. Since the LLM-completion milestone precedes AutoML completion in all eight reports, these records also do not establish that the generated narrative incorporated the final selected classifier's results.

Local report generation is an architectural feature, not evidence of report accuracy. The exported Parkinson's narrative describes a distribution of 48 controls and 147 disease-labeled recordings as balanced and asserts feature significance without presenting a corresponding inferential test. These statements should not be carried into the interpretation of the quantitative results. Clinical review must assess whether generated text accurately reflects the data and avoids unsupported conclusions.

VI. LIMITATIONS

The evaluation is based on one exported run per dataset. The reports do not include partition indices, random seeds, cross-validation fold definitions, or preprocessing-fit records. They therefore do not establish patient-level independence or exclude preprocessing leakage. This is particularly relevant to repeated acoustic recordings in Parkinson's and to image collections that may contain multiple samples from one patient. The reported Parkinson's performance should not be interpreted as subject-independent generalization.

TABLE V
RECORDED EXECUTION TIMES AND LLM THROUGHPUT. EACH ROW REPRESENTS ONE RUN. TRAINING AND INFERENCE MEASUREMENTS REFER ONLY TO THE SELECTED CLASSIFIER.

Dataset	End-to-end (s)	LLM generation (s)	Training (s)	Inference (ms/sample)	LLM (tokens/s)
Breast Cancer Wisconsin	80.073	41.593	1.387	0.0040	21.95
BUSI Ultrasound	314.781	304.126	0.189	0.0713	8.15
Stroke Clinical	507.249	52.280	0.035	0.0005	24.06
PIMA Diabetes	170.711	43.783	0.122	0.0550	24.48
Brain Tumor MRI	809.475	789.218	1.959	0.0268	3.51
Brain MRI Oncology	143.343	142.190	0.242	0.4427	12.17
Heart Cleveland	172.130	99.161	0.341	0.3419	26.89
Parkinson's Voice	90.358	49.431	0.921	0.0155	14.30

End-to-end time is the reported upload-to-ready interval. LLM generation time is a duration, not the report-completion timestamp. Stage durations are not assumed to be additive.

Dataset construction also requires further documentation. The BUSI export uses two labels without specifying the mapping from diagnostic categories. The Brain Tumor MRI export reports 7,200 images without identifying their provenance or any duplicate or augmentation checks. The Wisconsin descriptive statistics include an identifier column, but the report does not establish whether it was excluded from classifier inputs. Multiclass metric aggregation and ECE binning are also unspecified.

The means across datasets combine binary and multiclass tasks with different sample sizes and class distributions. They are descriptive summaries, not pooled clinical performance estimates. No repeated-split uncertainty estimates, independent baseline comparisons, or matched hypothesis tests are available in these exports. Four runs failed the sensitivity floor, and four selected models had elevated calibration error.

Timing values come from single executions and do not include a complete breakdown of preprocessing, feature extraction, search, and orchestration. The exports do not identify the hardware, model quantization, context configuration, or concurrency settings used in each run. These measurements cannot establish real-time performance or portability across devices.

The datasets were processed independently, without hospital deployment, Electronic Health Record integration, or prospective validation. Raw-signal processing and volumetric analysis were not evaluated in these runs. Report quality was not assessed by clinical raters; factual accuracy and agreement between reviewers remain to be measured.

VII. CONCLUSION

BioStatusIA combines data normalization, task-specific agents, classifier selection, and local LLM report generation. The eight completed runs cover five tabular datasets and three labeled image collections. Selected classifiers achieved mean AUROC 0.866 ± 0.109 and MCC 0.580 ± 0.295, with substantial differences between datasets. Four runs did not meet the internal cross-validation sensitivity floor of 0.80.

End-to-end processing took 80.073–809.475 s, and LLM generation took 41.593–789.218 s. Classifier inference was below 0.443 ms per sample, but this measurement excludes the other workflow stages. These results document execution on the tested datasets, not clinical validity or real-time operation.

Further evaluation requires reproducible patient-level partitions, documented label mappings and preprocessing, repeated timing measurements, and independent assessment of calibration and report accuracy. Prospective clinical testing should follow these checks.

***Abstract*—Post-stroke spasticity is associated with pathological interhemispheric asymmetry in cortical excitability. Cathodal transcranial direct current stimulation (c-tDCS) over the vertex may help restore interhemispheric balance by reducing hyperexcitability in cortical regions. This is an exploratory study which aimed to assess the effects of c-tDCS combined with extended reality rehabilitation on the revised Brain Symmetry Index (r-BSI), an EEG-derived measure of interhemispheric power asymmetry, in spastic stroke survivors. Thirteen (post data curation) patients underwent ten rehabilitation sessions over two weeks in a crossover design, with EEG recorded before and after stimulation on the first and last session days. The r-BSI was computed across delta, theta, alpha, beta, and broadband (1–30 Hz) frequency ranges. Within-session comparisons revealed a significant reduction in delta-band r-BSI following real tDCS, indicating an acute increase in interhemispheric symmetry; the broadband showed a nominally significant effect that did not survive correction for multiple comparisons, likely reflecting limited statistical power given the sample size. No significant differences were observed in the sham group for any frequency band. Between the first and last sessions, no cumulative effect on r-BSI was detected. These findings suggest that c-tDCS produces an acute, stimulus-locked modulation of interhemispheric asymmetry, but that this effect does not accumulate across a ten-session protocol. Larger samples and longer follow-up are needed to clarify the neurophysiological trajectory of tDCS-based rehabilitation.**

***Index Terms*—stroke, rehabilitation, transcranial direct current stimulation (tDCS), revised brain symmetry index (r-BSI), electroencephalography (EEG), interhemispheric asymmetry, spasticity**

I. Introduction

Stroke is one of the leading conditions causing motor impairments in people worldwide and in Brazil [1]. Chronic stroke survivors frequently present with sensorimotor impairments, including hemiparesis and spasticity. Post-stroke spasticity is characterized by a velocity-dependent increase in tonic stretch reflexes resulting from disrupted supraspinal control over spinal motor circuits [2]. Beyond its impact on motor function and quality of life, spasticity contributes significantly to pain, contractures, and caregiver burden, making its effective management a central goal of neurological rehabilitation [3].

Reduced access to exercise and technology-based rehabilitation programs can further compromise quality of life and functional independence in these individuals [4], [5]. Although conventional exercise rehabilitation programs have been shown to yield modest improvements in sensorimotor function, long-term exercise combined with neuromodulation, such as transcranial direct current stimulation (tDCS), may be more effective in addressing these impairments [6]–[8]. TDCS

is a non-invasive neuromodulatory technique that applies weak direct electrical currents to the scalp to modulate cortical excitability in a polarity-dependent manner. Anodal tDCS generally increases neuronal firing thresholds, while cathodal tDCS suppresses cortical excitability in the targeted region. The somatosensory cortex is the brain region responsible for processing afferent input from mechanoreceptors (i.e; information from sensory fibres) that are located in muscles, tendons, joints, and skin [9]. Cathodal tDCS (c-tDCS) may reduce hyperexcitability of peri-lesional tissue, thereby attenuating the excessive cortical activity thought to contribute to spasticity [10]–[12]. By reducing this asymmetric cortical excitability between hemispheres, c-tDCS over the somatosensory cortex may help restore interhemispheric balance in spastic stroke survivors [13], [14].

Indeed, a key neurophysiological mechanism underlying post-stroke motor impairment, including spasticity, is the disruption of interhemispheric balance. Following a unilateral lesion, the contralesional (unaffected) hemisphere tends to exert excessive inhibition over the ipsilesional (affected) hemisphere through transcallosal pathways, a phenomenon known as interhemispheric competition. This pathological asymmetry in cortical excitability is thought to further suppress motor output from the lesioned side, compounding functional deficits [15]. Therefore, assessing this balance may give a measure of patient recovery. This can be done using the brain symmetry index (BSI) - an electroencephalography (EEG)-derived measure of interhemispheric power asymmetry [16]. BSI has been shown to be significantly elevated in post-stroke patients compared to healthy controls, and early BSI values correlate with motor function scores measured one to two months later, supporting its value as both a prognostic and an outcome measure [15]. Further evidence indicates that BSI is independently associated with functional disability at six months post-stroke, reinforcing its relevance beyond the acute phase [17].

Despite this, BSI has been rarely employed as an outcome measure in tDCS intervention trials. Among the few intervention studies that have incorporated BSI, Williamson et al. examined the effects of high-definition tDCS on quantitative EEG metrics in stroke survivors and reported that both anodal and cathodal stimulation significantly decreased BSI across multiple frequency bands, a finding associated with reduced motor impairments and improved corticomotor conduction, suggesting that BSI may serve as a sensitive indicator of neurophysiological change induced by tDCS [18]. In a study combining tDCS with extended reality (XR) rehabilitation in chronic stroke, significant reductions in both BSI and the directional BSI were observed in the active tDCS group across alpha, beta, and gamma frequency bands, suggesting an increase in interhemispheric symmetry following intervention; notably, symmetry indices at higher frequencies correlated significantly with clinical improvements, showing a stronger relationship with lower extremity function and an increasing symmetry trend across the rehabilitation program [19]. In a pilot study combining motor imagery brain-computer interface with tDCS, BSI change emerged as the signature neurophysiological biomarker for the tDCS condition, in contrast to relative theta power which characterized the BCI-only group, suggesting that these two approaches engage distinct mechanisms of neural repair [20]. These findings support BSI as a meaningful and sensitive neurophysiological outcome measure in tDCS-based rehabilitation, yet its application remains limited to a small number of studies, none of which have specifically examined cathodal tDCS in the context of post-stroke spasticity.

Therefore, the aim of this study was to apply c-tDCS over the somatosensory cortex (Cz, EEG 10–20 system) across ten rehabilitation sessions focusing on the lower limb, and to assess brain symmetry indices in spastic stroke survivors.

II. MATERIALS AND METHODS

A. Subjects

The cohort for this study consisted of fifteen individuals (age 54.5 ± 14.6 years, nine women) who had suffered a stroke with a minimum of six months previously (57.6 ± 46.5 months post-stroke). All exhibited some degree of hemiparesis, as assessed by the Fugl-Meyer scale. The experimental protocol was approved by the local ethics committee (CAAE 75571323.3.0000.5404), and all participants signed a written informed consent form before entering the study. Of the fifteen initial patients, one did not complete the protocol and some EEG data from another were lost, so that a final total of 13 patients (age 53.9 ± 12.8, eight women) were considered for this study. Table I shows the ages, sex and affected hemisphere of the participants. The data from patients "LA" and "BV" were not included in this study, the first due to the loss of some EEG data and the second because the patient did not complete the two week rehabilitation protocol.

B. Experimental protocol

Patients underwent ten days of rehabilitation over two weeks. In the first and last days, EEG evaluations were also performed, following the same schedule. At the beginning, a one-minute resting-state EEG was recorded with eyes closed, in a dimly lit room. After the EEG, physiotherapists carried out a functional assessment of the patient, followed by a rehabilitation session combining extended reality exergames with tDCS. Patients were randomly allocated to the experimental or control group, and a double-blind design was maintained throughout the study, such that neither the patient nor the evaluator administering the tDCS were aware of group allocation (sham vs. real tDCS). If the patient belonged to the sham group, sham tDCS was applied instead. At the end of the rehabilitation session, the patient underwent another EEG evaluation under the same conditions as at the beginning. This protocol was also repeated on the last day of rehabilitation, resulting in a total of four EEG acquisitions, which throughout this article will be referred to as:

- S1-pre: first EEG acquisition of the first rehabilitation day, before tDCS (real or sham) application;
- S1-post: last EEG acquisition of the first rehabilitation day, after tDCS (real or sham) application;
- S10-pre: first EEG acquisition of the last rehabilitation day, before tDCS (real or sham) application;
- S10-post: last EEG acquisition of the last rehabilitation day, after tDCS (real or sham) application.

In sessions 2 through 9, patients underwent a rehabilitation session similar to those on days 1 and 10, including tDCS, but without EEG recordings or other assessments.

After completing the first rehabilitation round, patients were invited to participate in a second identical round, with the only difference being a reversal of group membership: patients who had received sham tDCS in the first round received active tDCS in the second, and vice versa. Of the thirteen patients included in the analysis, eight completed the second round of sessions. In the end, we have:

- Real tDCS group: 7 patients in the first round, 4 in the second round $\rightarrow$ 11 acquisitions.
- Sham tDCS group: 6 patients in the first round, 4 in the second round $\rightarrow$ 10 acquisitions.

C. Rehabilitation protocol

The rehabilitation protocol consisted of ten sessions over two weeks conducted on weekdays. In each session, participants performed upper limb exercises followed by lower limb exercises using the BRAINN XR tools [21], [22]. Lower limb exercises focused on ankle mobility. The session began with a warm-up consisting of three components: three minutes of walking, followed by two sets of ten repetitions of dynamic stretching using a ramp, and two sets of ten repetitions of dynamic stretching with a resistance band. A five-minute rest was observed between the warm-up and the main exercises. The main circuit included seven exercises: 1) Sit-to-stand from a chair: the participant rose from and returned to a seated position five times per set, with an object moving towards their head to challenge postural control; 2) Sit-to-stand with the ramp: the same movement performed with the feet on the inclined ramp and an object moving towards their head; 3) Squat with feet on the ramp: a squatting movement with both feet on the ramp and an objects moving towards their head; 4) Stationary marching with obstacle clearance Google Maps-based environment: the participant marched in place lifting the feet to step over ground-level obstacles, for three minutes; 5) Step-ups and step-downs with the ramp: the participant stepped up and down using the ramp while clearing obstacles, for three minutes; 6) Seated dynamic stretching with the resistance band: dynamic ankle stretches performed seated using the band; 7) Sit-to-stand holding the resistance band with the opposite (non-paretic hand) hand: the sit-to-stand movement performed while holding the band contralateral to the affected limb. Each exercise began with one set of five repetitions and was progressively increased based on heart rate response and perceived exertion. The session closed with a 10-minute cool-down of static stretching, three sets of 30 seconds per stretch.

Cathodal tDCS was applied to the real tDCS group during the main exercise circuit, for 15 minutes, using a 1 mA current, with a ramp-up and ramp-down time of 30 seconds. The electrodes (35 cm^2) were fitted with surface sponges soaked in saline solution and mounted with care to avoid leakage onto the hair, while ensuring the sponges maintained consistent moisture throughout the entire stimulation session. The cathode was positioned on the scalp over the legs' motor cortex region (equivalent to Cz in the 10-20 system) and the anode was positioned on the middle of the forehead, above the eyebrow. For the sham tDCS group, the only difference was that immediately after the 30 seconds ramp-up a 30 s ramp-down to 0 mA current was applied, and it remained at 0 mA during the whole 15 minutes.

D. EEG equipment

EEG recordings were performed using a g.USBAmp amplifier and 16 dry electrodes (g.SAHARA, g.tec, Austria). Electrodes were positioned in the 10-20 system in the following locations: AFz, F1, F2, F5, F6, Cz, C1, C2, C3, C4, C5, C6, P1, P2, P5, P6.

E. Preprocessing

The first second of each recording was discarded to remove the transient interval during which the signal tends to be noisier. To facilitate the analysis, the right hemisphere was designated as the affected hemisphere for all patients; for those whose lesion was located in the left hemisphere, the electrode labels were mirrored from left to right. For each acquisition, the power spectrum of the signal was computed to identify interference or peaks not consistent with typical EEG activity.

The data were then processed using the HAPPE pipeline [24]. Within the pipeline, the data were filtered with a notch filter at 60 Hz and a bandpass filter from 1 Hz to 100 Hz, together

with CleanLine filtering (EEGLAB) at frequencies where atypical peaks were observed. The pipeline was configured to perform bad channel detection, so that electrodes whose quality were deemed sub-optimal by the pipeline were eliminated. The software then performs artifact detection through independent component decomposition combined with a wavelet transform. Finally, the pipeline applies EEGLAB ICA to detect muscular artifacts in the data.

The preprocessed data were filtered into frequency bands: delta (1–4 Hz), theta (4–8 Hz), alpha (8–13 Hz), and beta (13–30 Hz). The gamma band was excluded because, in resting-state EEG, activity in this frequency range is rarely attributable to genuine brain activity.

F. Data analysis

The Revised Brain Symmetry Index (r-BSI) [23] is defined as

$$\text{r-BSI} = \frac{1}{K}\sum_{n=1}^{K}\frac{|R_n^*(t) - L_n^*(t)|}{R_n^*(t) + L_n^*(t)}$$

where the summation runs over frequencies $n = 1, \ldots, K$ and

$$R_n^*(t) = \frac{1}{M}\sum_{ch=1}^{M} a_n^2(ch, t).$$

The coefficients $a_n(ch, t)$ are the Fourier coefficients at frequency n for channel ch at time t. The channels considered for R_n^* are those located in the right hemisphere, and analogously for L_n^* with the channels of the left hemisphere. The summation in R_n^* (L_n^*) runs over indices $i = 1, \ldots, M$, corresponding to the M channels located in the right (left) hemisphere, thus computing the mean power of each hemisphere at each frequency bin. The r-BSI compares these powers at each frequency and averages across all of them. Note that, as aforementioned, here the right hemisphere represents the lesioned one.

Asymmetry indices (note that r-BSI, despite its name, measures asymmetry, i.e., it is larger the more asymmetric the hemispheres are) were computed for each EEG acquisition, and then averaged per session and across patient groups (real and sham tDCS), in order to compare the evolution of this metric across sessions.

It is worth mentioning that changes in other biomarkers were explored, specifically functional connectivity and network topology, but no significant variations were registered with these methods.

G. Statistical analysis

The r-BSI distributions for the pre and post-tDCS EEG acquisitions were assessed for normality using the Shapiro-Wilk test. Given that some were not normal, a Wilcoxon signed-rank test was used to compare the distributions between pre and post-tDCS EEG acquisitions, for each group (real and sham tDCS). The results were then corrected using the Benjamini–Hochberg (BH) procedure to control for False Discovery Rate (FDR), considering five frequency bands.

III. Results

Figure 1 shows the mean values of r-BSI for each frequency band (delta, theta, alpha and beta, as well as for the broadband - 1-30 Hz), averaged across each patient group.

It can be observed that the variation of the symmetry index shows, across all frequency bands, a consistent pattern in the real tDCS group: higher index values in acquisitions performed before tDCS application, and a reduction in those performed after. For patients in the sham tDCS group, mostly no consistent trend can be identified across frequency bands or recording conditions, apart from in the theta band, where a trend similar to that of the real tDCS group is observed, though less pronounced. For this group, in the alpha and beta bands, as well as in the broadband (1-30 Hz), the index remains approximately constant across sessions. In the delta band, the index shows a slight decrease in the intermediate sessions followed by a slight increase in the last session.

The results indicate that tDCS produces an immediate reduction in interhemispheric asymmetry; however, this effect does not appear to persist over time, as values return toward baseline by S10-pre. With this in mind, the joint distribution of the r-BSI values for both sessions (S1 and S10) pre-tDCS and post-tDCS were examined and compared, which can be seen in Figure 2. Only the mean values of r-BSI for the delta band of the real tDCS group were significantly greater for the pre-tDCS acquisition (larger symmetry) than for the pre-tDCS acquisition. The broad band also showed a tendency (before FDR correction) toward a lower value in the post-tDCS session. On the other hand, for the sham tDCS group, there were no statistically significant differences among pre and post-tDCS acquisition for any frequency band.

IV. Discussion

The aim of this study was to assess a possible recovery of interhemispheric symmetry in stroke survivors who underwent a rehabilitation protocol using cathodal tDCS over the motor cortex related to the lower limbs (Cz). The aim behind using cathodal, rather than the more common, anodal tDCS, was to reduce spasticity in the affected lower limb. Our hypothesis was that this would facilitate motor rehabilitation of the affected limb and consequently, increase interhemispheric symmetry. Our results showed a significant decrease in the delta frequency band r-BSI (increase in symmetry) and a tendency of decrease for the beta and broad band (1-30 Hz) r-BSI within a single session, i.e., just after the tDCS application, but not between the first and last rehabilitation sessions. This decrease was not observed for the sham tDCS group, which seems to indicate that rehabilitation alone, without tDCS, does not significantly influence the symmetry index.

The within-session decrease in delta band r-BSI observed in the real tDCS group — but not in the sham group — is consistent with findings from other tDCS-EEG studies, both in terms of the acute modulation of interhemispheric asymmetry and the apparent dissociation between immediate neurophysiological effects and longer-term cumulative changes. Regarding the acute effect on EEG power, a randomized crossover study

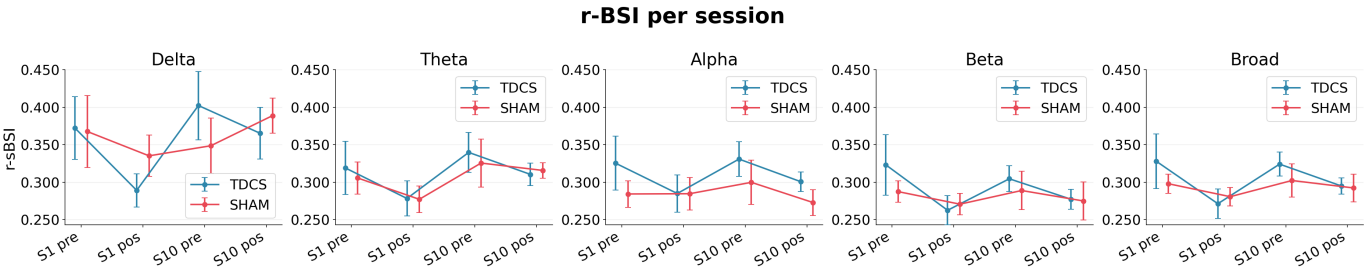

Fig. 1. Variation of the mean r-BSI between the real and sham tDCS groups by frequency band and session for the resting-state EEG.

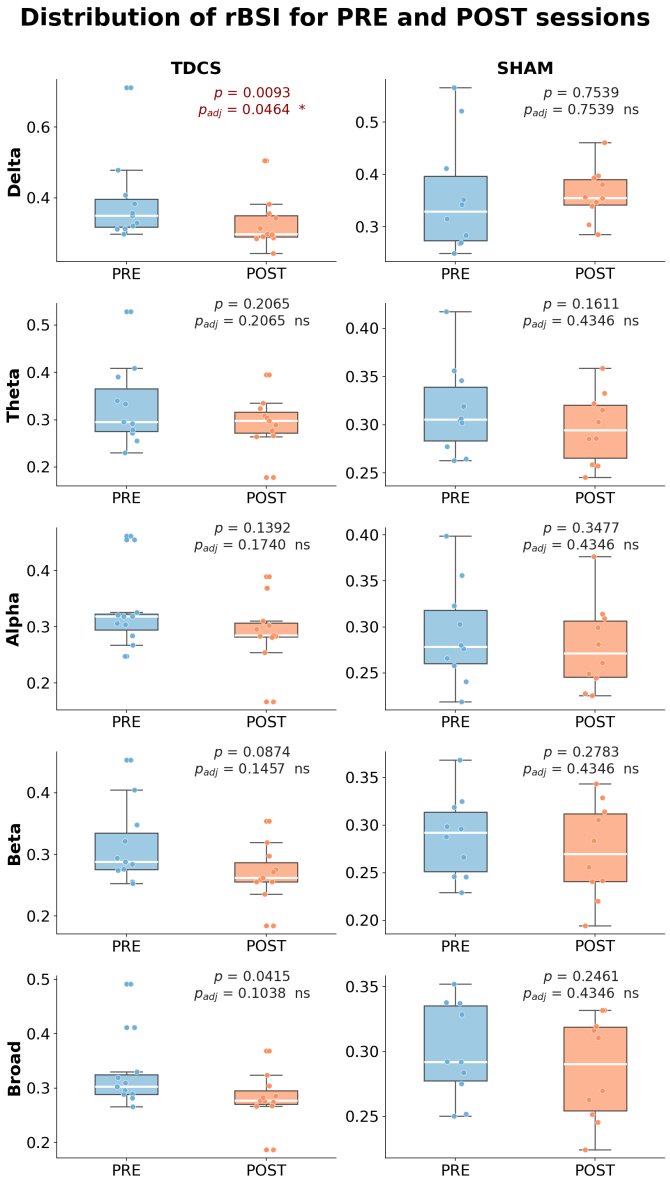

Fig. 2. Variation of the mean interhemispheric symmetry index (r-BSI) between the real and sham tDCS groups by frequency band and session for resting-state EEG. The p-values before and after FDR correction (the latter corresponding to p_{adj}) are shown. The alternative hypothesis was that r-BSI values were greater in the pre-stimulation distribution than in the post-stimulation distribution.

in ischemic stroke patients found that real tDCS, compared to sham, produced a significant decrease in delta power alongside a significant increase in alpha power in resting-state EEG recorded immediately after stimulation, with no such changes observed in the sham condition — a pattern that closely mirrors our within-session r-BSI results [25]. In terms of BSI specifically, Williamson et al. reported that both anodal and cathodal high density (HD)-tDCS of the contralesional hemisphere significantly decreased BSI across multiple frequency bands in stroke survivors, with this reduction associated with decreased motor impairments, further supporting the sensitivity of BSI to the acute neurophysiological effects of tDCS [26].

Regarding the absence of a cumulative BSI effect across sessions, a randomized controlled trial of five consecutive sessions of anodal tDCS combined with physical therapy in acute stroke found that tDCS did not result in superior EEG changes over sham across sessions, despite improvements in lower extremity function in participants with low motor impairment, suggesting that neurophysiological and clinical trajectories do not always align over a multi-session course [27]. Similarly, Di Lazzaro et al. found that bilateral tDCS combined with constraint-induced movement therapy significantly reduced interhemispheric imbalance at neurophysiological level, yet none of the clinical outcome measures showed differential modulation between real and sham groups [28], a dissociation also noted in a study of bihemispheric tDCS in chronic stroke where neurophysiological adaptations including lasting reductions in interhemispheric inhibition did not correlate with any clinical improvement, which the authors attributed to a possible ceiling effect for motor recovery [29]. These findings suggest that the acute, within-session modulation of interhemispheric symmetry by cathodal tDCS may reflect a transient and stimulus-locked neurophysiological effect that does not necessarily accumulate linearly across a rehabilitation program — a pattern that warrants further investigation with longer follow-up and larger samples.

The pattern of results is consistent with the proposed mechanism: cathodal tDCS consistently reduces r-BSI across all frequency bands, with the most pronounced and statistically robust effect in the delta band. The complete absence of significant results in the sham group — even without correction — strengthens the interpretation that the observed changes in the tDCS condition are specific to the stimulation and

not attributable to rehabilitation practice effects, procedural learning, or regression to the mean.

A possible physiological explanation for this effect lies in the mechanism of action of cathodal tDCS. Unlike anodal stimulation, which increases cortical excitability in the stimulated hemisphere, cathodal current hyperpolarizes cortical neurons, reducing their resting membrane potential and decreasing their spontaneous firing rate [30]. In the context of stroke, the contralesional hemisphere frequently exhibits secondary hyperexcitability, resulting from the loss of interhemispheric inhibition exerted by the affected hemisphere — a well-documented phenomenon in the reciprocal interhemispheric inhibition model [31]. The placement of the cathodal electrode over Cz, a vertex position overlying the medial aspects of both motor cortices, results in a broadly distributed current that may exert a net inhibitory influence over hyperexcitable cortical regions in both hemispheres, with the contralesional hemisphere potentially being more susceptible given its elevated excitability at baseline [32]–[34]. This reduction in spectral power asymmetry between hemispheres would bring both hemispheres closer together in terms of electrophysiological activity and, since the r-BSI quantifies the relative power asymmetry between them, would result in a decrease in the index, consistent with the observed pattern. It should be acknowledged, however, that the vertex montage introduces greater uncertainty regarding the spatial specificity of the neuromodulatory effect compared to montages targeting the contralesional motor cortex directly, and future studies using individualized current modeling would help clarify the cortical regions most affected by this electrode configuration.

This study has some limitations, the main one being sample size ($n = 11$): the BH correction with families of five comparisons is relatively costly in terms of statistical power, and several comparisons with medium effect sizes fall in the marginal zone (p_{adj} between 0.07 and 0.11). This does not imply absence of effect, but rather insufficient statistical power to confirm it with certainty. Nevertheless, it is important to clarify that intervention studies with disabled patients are inherently difficult in terms of having a large sample. As described in the methodology section, the rehabilitation protocol lasted for two weeks. Because participants have mobility issues, most of them depend on other people (usually someone from the family) to bring them to the sessions; which means in many cases this person has to miss work for this. Also, due to physical space and staff constraints, we could only rehabilitate a maximum of two patients per two-week period. Finally, it was hard to find patients that attended to the inclusion and exclusion criteria. Due to all these issues, data collection from these 15 participants took almost two years to complete, which explains the small sample size. No confidence intervals were calculated between comparisons; we acknowledge this as a limitation of the current statistical approach and consider it a priority for a follow-up study with a larger sample, where effect sizes and their corresponding confidence intervals could be estimated more reliably. Another limitation is the fact that not all participants performed the two stages of the rehabilitation protocol, which may hinder the obtained results. Therefore, studies with larger samples should be carried out to confirm these results.

***Abstract*—Brain tumors represent neoplasms associated with high global mortality rates. In this context, manual analysis of Magnetic Resonance Imaging (MRI) scans for brain tumor diagnosis is complex and error-prone due to high tumor heterogeneity. To overcome these limitations, we propose a Computer-Aided Diagnosis (CAD) system that integrates automatic lesion segmentation and multiclass classification, comparing deep learning models with radiomics-based classifiers. In segmentation, the EfficientNetB7 FPN architecture achieved an F1-Score of 85.68%. In classification, the Swin Transformer-B model achieved the best overall performance, with an F1-Score of 93.52%, while LightGBM stood out among the radiomics-based approaches with an F1-Score of 87.99%. In summary, the system demonstrated efficacy and robustness, establishing itself as an important clinical decision-support tool.**

***Index Terms*—brain tumor, magnetic resonance imaging, segmentation, classification, radiomic features.**

I. Introduction

Brain tumors arise from abnormal cell proliferation within brain tissue [1]. These neoplasms represent some of the most aggressive malignancies in the central nervous system and contribute substantially to cancer-related mortality [2]. The World Health Organization (WHO) reports that this cancer type is among the most lethal and can affect individuals globally [3].

Magnetic Resonance Imaging (MRI) is regarded as a primary imaging modality for the detection and monitoring of brain tumors, due to its non-invasive nature and ability to produce high-resolution images [3]–[5]. These features facilitate the identification of brain abnormalities, enhance the accuracy of early diagnosis, and improve patient survival rates [6].

The heterogeneous nature of tumors renders manual analysis of MRI scans a complex task that depends significantly on the expertise of specialist radiologists [6]–[8]. As a result, lesion analysis is particularly challenging when large volumes of examinations and substantial variability in tumor characteristics are present [3]. In this context, deep learning-based techniques demonstrate considerable effectiveness in medical image classification and segmentation [6].

The authors would like to thank the Brazilian National Council for Scientific and Technological Development (CNPq) under Grant No. 315447/2023-0 and Coordination of Superior Level Staff Improvement (CAPES)-Finance Code 001 for the support to this research.

In this work, we aim to develop a Computer-Aided Diagnosis (CAD) system for segmentation, radiomic feature extraction, and multiclass classification of brain tumors, including meningioma, glioma, and pituitary tumors. The proposed tool does not aim to replace the specialist, but rather to act as clinical decision support, aiding in improved clinical outcomes, i.e., faster and more accurate diagnoses.

The experiments were conducted in two stages: (i) tumor region segmentation and (ii) tumor classification. Quantitative biomarkers were extracted via radiomics from the segmented regions and used to train traditional machine learning (ML) classifiers. A comparative analysis was then performed with deep learning models, including convolutional neural networks, Vision Transformers, and Foundation Models.

The main contributions of this work are:

- (i) the development of a CAD system for brain tumor segmentation and classification;
- (ii) a comparative analysis of approaches based on MRI scans and radiomic features;
- (iii) the application of non-parametric tests to statistically compare the performance of the architectures;
- (iv) validation of experiments on external datasets to ensure model reproducibility.

The structure of this paper is as follows: Section II reviews the principal related works in the literature. Section III outlines the methodological steps employed. Section IV discusses the experimental results. Section V provides the concluding remarks.

II. Related Works

This section synthesizes recent advances in artificial intelligence for brain tumor segmentation and classification in MRI, identifying current methodologies and gaps in the literature. To consolidate the review, related studies are compared with the proposed approach in Table I, detailing criteria such as datasets, preprocessing, architectures, external validation, statistical tests, and results.

In the field of deep learning, Ullah et al. (2026) [9] introduced a framework that combines the Bayesian DeepLabV3+ architecture for segmentation with a hybrid deep network for classification. Similarly, Kumar and Singh (2026) [10]

TABLE I: Summary of related works.

developed an explainable architecture that integrates MDU-Net and SwinCT, while Hussain et al. (2025) [11] implemented a U-Net variant with residual attention to address both tasks concurrently. Although these methods demonstrate effectiveness in hierarchical learning, they primarily rely on local convolution operations and do not facilitate the joint extraction of quantitative radiomic features.

In the context of radiomic strategies, Bhattacharjee et al. (2022) [12] integrated statistical descriptors with the Random Forest algorithm for classification, resulting in an accuracy of 84.0%. Similarly, Souza et al. (2021) [13] combined texture and first-order features with classifiers such as XGBoost and dense networks, achieving an average accuracy of 88.51%. However, these approaches encounter significant operational limitations because they depend on manual annotations by radiologists or inflexible thresholding techniques.

To address these challenges, we propose a CAD system that fully automates the diagnostic workflow. The segmentation stage utilizes the EfficientNetB7 FPN semantic network. For multiclass classification, we employ Vision Transformers (Swin Transformer-B) and Foundation Models (CLIP and DINOv2), resulting in an accuracy of 93.55%. We conducted a direct comparison between deep learning and radiomic approaches (using LightGBM), with robustness and reproducibility ensured through validation on external datasets and statistical confirmation using the Wilcoxon test.

III. Methodology

In this section, we outline the methodology employed in this work. We provide details on the datasets, preprocessing, and data augmentation procedures. Additionally, we describe the segmentation processes, biomarker extraction, classification methods, model evaluation, and the statistical tests applied.

A. Experimental Approaches

We propose the development of a CAD system designed to segment and classify brain tumors as meningioma, glioma, or pituitary. The workflow stages are illustrated in Figure 1.

Segmentation models were trained using MRI scans from the Figshare dataset [14], which contains brain tumor examinations and corresponding tumor masks. The trained model was subsequently applied to images from the Brain Tumor Classification dataset [15] to automatically segment tumor regions. The resulting regions of interest (ROIs) obtained through segmentation served as inputs for the subsequent classification stages.

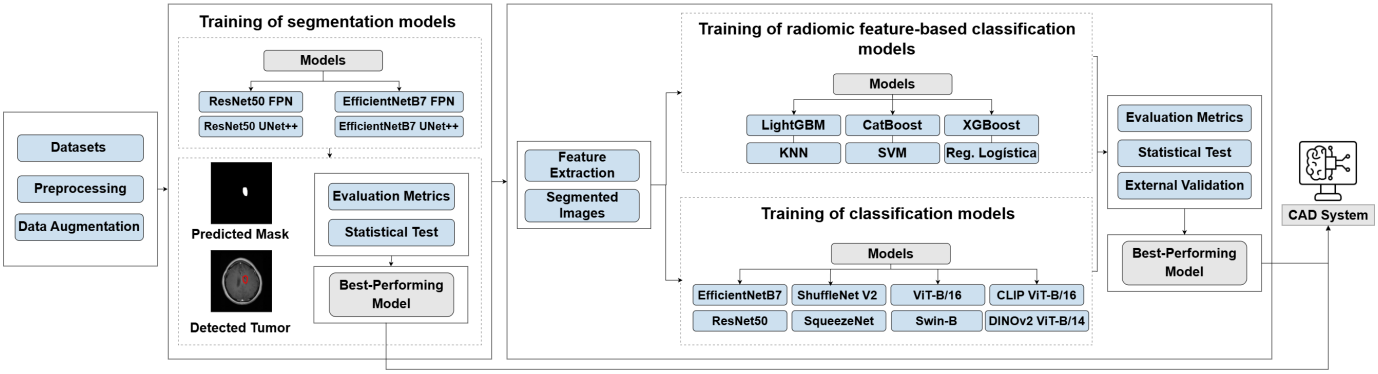
Radiomic features, including intensity, texture, shape, and spatial distribution, were extracted from the segmented regions to train traditional classifiers. The performance of this approach was compared with that of deep learning models applied directly to the images to evaluate the effectiveness of both strategies.

B. Datasets

For the tumor segmentation task, the Figshare dataset [14] was utilized, comprising 3,064 images. Figure 2 presents sample MRI scans and their corresponding tumor region segmentation masks. The images are distributed across three classes: meningioma (708 images), glioma (1,426 images), and pituitary tumor (930 images).

We applied the trained segmentation model to the public Brain Tumor Classification (MRI) dataset [15] to automatically segment tumoral regions. Of the 3,264 MRI images, we selected the 2,764 with confirmed tumors (meningioma: 937, glioma: 926, pituitary: 901), excluding the 500 no-tumor cases. This selection supports our goal of histological differentiation among tumor types, which requires feature extraction from a defined ROI. Figure 3 shows representative samples for each class.

For external validation of the classification module, we utilized the public Figshare dataset. While this dataset was previously employed during the training stage of the segmentation models, its use in classification was strictly limited to an unseen test set. Independence between stages was maintained at both the patient and examination levels, ensuring that Figshare images were used exclusively for feature extraction and class prediction by the pre-trained classifier. This approach



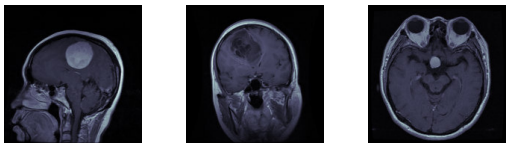


Fig. 1: Overview of the primary phases implemented in this study.

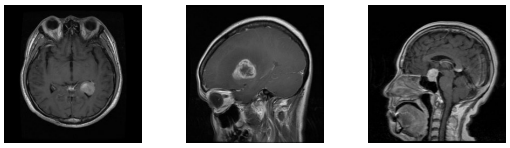

(a) Meningioma. (b) Glioma. (c) Pituitary.

(d) Meningioma. (e) Glioma. (f) Pituitary.

Fig. 2: Samples from the Figshare dataset.

(a) Meningioma. (b) Glioma. (c) Pituitary.

Fig. 3: Samples from the Brain Tumor Classification dataset.

prevented data leakage and avoided artificial inflation of performance metrics.

C. Preprocessing

We performed preprocessing to improve the visual quality of the scans and minimize unwanted artifacts, which facilitated more efficient feature extraction by computational models. Initially, we converted the images from the datasets to grayscale, resized them to 224 x 224 pixels, and stored them in PNG format.

Next, we applied a bilateral filter to smooth the images, reduce noise, and preserve the sharpness of anatomical edges. Additionally, we employed Contrast Limited Adaptive Histogram Equalization (CLAHE) for local adaptive contrast enhancement, which improved the visibility of structures of interest within the images. Finally, we applied simple thresholding to the tumor segmentation masks to ensure accurate binarization of the segmented regions.

D. Data Augmentation

To increase dataset diversity, reduce overfitting, and improve model generalization, data augmentation techniques based on spatial and radiometric transformations were implemented. These transformations were applied exclusively to the training set, thereby maintaining the integrity of the validation and test subsets and ensuring unbiased evaluation.

Affine transformations were applied with a probability of $p = 0.5$, including brightness and contrast adjustments (limits of 0.3), horizontal flipping, and scale, translation, and rotation shifts (parameters: 0.1 for scale, 0.05 for translation, and $15°$ for rotation).

E. Segmentation

We performed brain tumor segmentation in MRI scans using architectures grounded in the encoder-decoder paradigm. The encoder transforms the input image into hierarchical feature representations at multiple resolution levels. The decoder then projects these features back into the pixel space, facilitating dense classification to delineate tumor structures.

In this work, we evaluated combinations of different models. For the encoder, we used pre-trained DenseNet201, EfficientNetB7, and ResNet50 networks. For the decoder, we implemented both FPN and UNet++ architectures. During training, each model received an MRI scan and its corresponding ground-truth mask as input, producing a predicted mask indicating the tumor location as output.

We trained the models for 50 epochs and applied early stopping with a patience of 5 epochs to mitigate overfitting. The experimental hyperparameters included a batch size of 4, a Lovász-Softmax-based loss function, the Adam optimizer, and a learning rate of 0.0005.

Finally, we used the segmentation model as an automated module to identify and delineate tumor regions in MRI scans. Each scan was processed by the segmentation algorithm to extract tumor regions, and the resulting regions of interest (ROIs) were forwarded to subsequent classification stages.

F. Radiomic Feature-Based Classification

Radiomic features were extracted from the segmented region. This approach involves the automatic acquisition of

a large set of high-throughput features from medical images, which describe lesion morphology, gray-level intensity distribution, and complex texture patterns to mathematically represent tissue heterogeneity. The open-source *PyRadiomics* package[1] was used to extract these features from the MRI scans, thereby structuring the feature vector for model training.

To address the curse of dimensionality, we performed feature selection exclusively on the training set to prevent data leakage. After excluding operational metadata, we applied a low-variance filter to remove features with minimal variability, followed by a Spearman high-correlation filter to eliminate redundant, collinear attributes prior to model fitting.

Following the filtering process, an optimized vector comprising nine fundamental radiomic features was selected for classification. These descriptors summarize brain tumor heterogeneity across three categories: first-order intensity statistics (skewness, kurtosis, energy, and minimum intensity), lesion morphology (geometric dimensions), and texture (gray-level patterns via higher-order matrices). Collectively, these features provide a quantitative representation of the morphological and textural heterogeneity of brain tumors.

The selected features were used as input variables to train and benchmark six traditional machine learning algorithms, LightGBM, Support Vector Machines (SVM), XGBoost, K-Nearest Neighbors (KNN), CatBoost, and Logistic Regression. The models were trained exclusively with the optimized feature vector, enabling evaluation of the predictive potential and performance of each architecture in the brain tumor classification task.

G. Grid Search

We optimized deep learning models for brain tumor classification using grid search. Hyperparameter tuning was conducted only on the training partitions of each fold, keeping test data fully isolated. The search covered all combinations of learning rates (0.0001, 0.0003, 0.001), optimizers (Adam, RMSprop, SGD), batch sizes (16, 32, 64), and weight decay values (0.0001, 0.00001).

H. Multiclass Classification

To recognize different types of brain tumors, the images segmented in the previous stage, containing only the regions of interest delineated by the tumor segmentation models, were utilized. These segmented images served as input for training classification models, enabling a comparative analysis of various deep learning paradigms.

We evaluated eight pre-trained architectures, including traditional convolutional neural networks (ResNet50 and EfficientNetB7), lightweight convolutional architectures (ShuffleNet V2 and SqueezeNet), Vision Transformer-based models (ViT-B/16 and Swin Transformer-B), and foundation models (CLIP ViT-B/16 and DINOv2 ViT-B/14). The selection of these architectures facilitated the investigation of performance and generalization capability across diverse approaches.

[1]https://pyradiomics.readthedocs.io/

The models were trained for 50 epochs, corresponding to the number of iterations over the training set. Cross-entropy loss, which is commonly employed in multiclass classification problems, was used as the loss function. An early stopping strategy with a patience parameter of 5 was implemented, halting training when no performance improvement was observed for five consecutive epochs.

The training hyperparameters were determined using a grid search strategy, which enabled the selection of the most suitable configuration for each evaluated model. Table II presents the value configurations considered for each hyperparameter.

TABLE II: Defined hyperparameters for the classification models.

Architecture	LR	Optimizer	Batch Size	WD
ResNet50	0.0001	Adam	32	0.0001
EfficientNetB7	0.0003	Adam	32	0.0001
ShuffleNet V2	0.0001	RMSprop	32	0.00001
SqueezeNet	0.0003	Adam	32	0.00001
ViT-B/16	0.0001	Adam	32	0.0001
Swin Transformer-B	0.0001	Adam	32	0.00001
CLIP ViT-B/16	0.0001	Adam	32	0.00001
DINOv2 ViT-B/14	0.0001	Adam	32	0.00001

I. Cross-Validation

We structured the training and evaluation process using a k-fold cross-validation protocol ($k = 10$) with three repetitions. In each fold, 80% of the data was allocated for training and 20% for testing. From the training portion of each fold, 10% of the samples were reserved for validation during the iterative learning process. Model performance was determined by calculating the arithmetic mean of the metrics obtained across the 30 repetitions.

J. Evaluation Metrics

Quantitative assessment of model performance necessitates the selection of metrics that align with the specific objectives of the project. In medical image semantic segmentation, True Positives (TP) and True Negatives (TN) denote correctly classified tumor and background pixels, respectively. In contrast, False Positives (FP) arise when background pixels are misclassified as tumor, whereas False Negatives (FN) correspond to tumor pixels that the model fails to identify.

The performance of the segmentation architectures was formally evaluated using metrics based on geometric similarity and area overlap. We quantified the behavior of the models using the following equations:

$$\text{Acc} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}}, \tag{1}$$

$$\text{F}_1\text{-score} = \frac{2 \times \text{Prec} \times \text{Recall}}{\text{Prec} + \text{Recall}}, \tag{2}$$

$$\text{IoU} = \frac{\text{TP}}{\text{TP} + \text{FP} + \text{FN}}, \tag{3}$$

$$\text{Hausdorff} = \max(h(A, B), h(B, A)). \tag{4}$$

Accuracy (1) quantifies the overall proportion of correct predictions relative to the total number of analyzed pixels. The F1-score (2) serves as the primary validation index by balancing precision and recall. Intersection over Union (IoU) (3) measures the overlap between the predicted region and the ground truth. The Hausdorff Distance (4) is a boundary-based metric that quantifies the maximum distance between points on the ground-truth and estimated contours.

In image classification, the confusion matrix is used to evaluate model predictions for each class. TP denotes correctly identified samples of a given category, while FP indicates cases from other classes that are incorrectly assigned to the target class. Similarly, TN corresponds to samples correctly identified as not belonging to the target class, and FN refers to images of the target category that are incorrectly classified.

Classifier performance in the brain tumor scenario was evaluated using accuracy, precision, recall, F1-score, and specificity, defined as follows:

$$\text{Prec} = \frac{\text{TP}}{\text{TP} + \text{FP}}, \tag{5}$$

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}}, \tag{6}$$

$$\text{Spec} = \frac{\text{TN}}{\text{TN} + \text{FP}}. \tag{7}$$

Accuracy (1) indicates the overall correct classification rate of the model. Precision (5) measures the reliability of positive predictions by reducing false alarms. Recall (6) reflects the classifier's ability to identify all true positive cases. The F1-score (2) represents the harmonic mean between precision and recall, offering a robust indicator for class-imbalanced scenarios. Specificity (7) assesses the model's ability to correctly identify negative samples.

K. Statistical Tests

To assess the statistical significance of performance differences among the proposed models, an inferential analysis was performed using the non-parametric Wilcoxon test. This method was selected because it does not require normality assumptions, making it appropriate for comparing models in experimental scenarios with unknown or non-Gaussian distributions.

Statistical analyses were conducted individually for each metric obtained via cross-validation, resulting in 30 paired observations per architecture for hypothesis evaluation. For all tests, a two-tailed significance level of $\alpha = 0.05$ was used. The null hypothesis (H_0) posits no significant differences between the compared models, while the alternative hypothesis (H_1) indicates the presence of statistically significant differences.

L. External Validation

To assess the robustness and generalization capability of the proposed classifiers, an external validation stage was implemented using the *Figshare* dataset. The images were strictly isolated throughout all feature selection, model training, and internal testing stages to mitigate any risk of data leakage or optimization bias. This methodological approach is essential for evaluating the effectiveness of the algorithms when exposed to the clinical variability inherent in real-world application scenarios.

M. Development of the CAD System

The final step involved implementing a CAD system within a web application developed using *Streamlit*, which integrates the most effective segmentation and classification pipelines. The interface enables users to upload brain MRI scans, after which the system automatically processes the data and displays both the segmented tumor region and the multiclass histological diagnosis. This solution serves as a clinical decision-support tool to assist healthcare professionals in diagnosis and patient monitoring.

IV. Results

In this section, we present and discuss the results obtained using the brain tumor segmentation and classification methodology, with particular emphasis on the model performance and the effectiveness of the proposed approach.

A. Performance of Deep Learning Models in Segmentation

Quantitative evaluation is essential for assessing the effectiveness and reliability of brain tumor segmentation models. In this work, multiple metrics were used to evaluate the performance of the examined architectures, enabling a comprehensive analysis of segmentation quality.

Table III summarizes the results for the evaluated architectures. Alongside mean values, 95% confidence intervals (95% CI) are reported to estimate the range in which the true model performance is likely to fall. Narrower confidence intervals reflect greater stability and lower variability across runs, while wider intervals indicate increased sensitivity to data partitioning.

The EfficientNetB7 FPN architecture demonstrated the highest overall performance among the evaluated models, achieving a mean accuracy of 99.53%, an F1-score of 85.68%, an IoU of 74.97%, and a Hausdorff Distance of 7.68. The consistently narrow confidence intervals across all metrics indicate robust results throughout the validation folds.

Comparable results were obtained for the EfficientNetB7 UNet++ architecture, which achieved an accuracy of 99.50%, an F1-score of 84.73%, an IoU of 73.52%, and a Hausdorff Distance of 7.93. The DenseNet201 UNet++ architecture also demonstrated competitive performance, with an F1-score of 82.57%, an IoU of 71.01%, and a Hausdorff Distance of 8.31. Although the mean values for these architectures are similar to those of EfficientNetB7 FPN, the slightly wider confidence intervals indicate increased variability across runs.

In contrast, the DenseNet201-FPN and ResNet50-FPN models achieved accuracies of approximately 97.4%; however, this metric is inflated by class imbalance, as background pixels constitute the majority of each image. Their F1-scores were 39.33% and 34.72%, respectively, with IoU values below 25% and Hausdorff Distances of 49.69 and 55.17. These findings

TABLE III: Mean results of the segmentation models.

Metric	DenseNet201 FPN	DenseNet201 UNet++	EfficientNetB7 FPN	EfficientNetB7 UNet++	ResNet50 FPN	ResNet50 UNet++
Accuracy (%)	97.37 ± 0.85	99.45 ± 0.16	$\mathbf{99.53 \pm 0.04}$	99.50 ± 0.04	97.39 ± 0.53	99.35 ± 0.27
F1-Score (%)	39.33 ± 4.44	82.57 ± 8.94	$\mathbf{85.68 \pm 1.09}$	84.73 ± 1.25	34.72 ± 4.04	77.12 ± 18.19
IoU (%)	24.57 ± 3.47	71.01 ± 9.47	$\mathbf{74.97 \pm 1.67}$	73.52 ± 1.88	21.08 ± 2.99	65.18 ± 17.09
Hausdorff Distance	49.69 ± 8.49	8.31 ± 0.75	$\mathbf{7.68 \pm 0.61}$	7.93 ± 0.72	55.17 ± 6.66	14.40 ± 17.68

indicate that, despite high accuracy, these models have limited capability to delineate tumors.

B. Statistical Analysis of Segmentation Performance Using the Wilcoxon Test

The statistical significance of the segmentation models was assessed using the Wilcoxon test. For the accuracy metric, only the comparison between DenseNet201 FPN and ResNet50 FPN did not demonstrate a statistically significant difference ($p = 0.73$), while all other comparisons were significant. Additionally, for the F1-score, IoU, and Hausdorff Distance metrics, all comparisons yielded $p < 0.05$, indicating distinct performances among the architectures in terms of tumor segmentation capability.

The EfficientNetB7 FPN architecture achieved the highest results for F1-score, IoU, and Hausdorff Distance. The Wilcoxon test confirms that these improvements are statistically significant compared to the other architectures. In contrast, the DenseNet201 FPN and ResNet50 FPN models demonstrated significantly lower segmentation performance, supporting the findings from the previous descriptive analysis.

C. Qualitative Analysis of Segmentation Results

Beyond quantitative metrics, visual analysis is crucial for assessing the models' capacity to delineate tumor regions. Figure 4 displays segmentation results generated by the EfficientNetB7 FPN architecture, which demonstrated the highest overall performance in this work. The first column shows the original image, while the second and third columns present the ground-truth mask and the model-predicted mask, respectively. The fourth and fifth columns depict the original MRI scans with their corresponding segmentations overlaid.

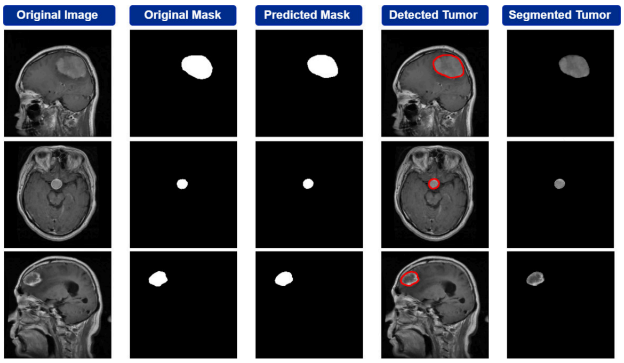

Fig. 4: Segmentation results on MRI scans produced by the EfficientNetB7 FPN architecture are shown.

The visual agreement between the predicted and ground-truth masks supports the quantitative findings. The close alignment of contours demonstrates the model's capacity to accurately identify and delineate tumor boundaries, even in cases with significant heterogeneity in shape, size, and contrast. Furthermore, the network exhibited robustness in detecting small-scale lesions, which is essential for clinical practice due to its influence on early diagnosis.

D. Performance of traditional ML algorithms in radiomic feature classification

In this stage, classification algorithms were trained using texture, shape, and intensity features extracted with the *Pyradiomics* library. The comparative analysis assessed accuracy, F1-score, precision, recall, specificity, and the mean area under the receiver operating characteristic (ROC) curve (AUC) across the validation folds. Table IV provides a summary of the results for each classifier and reports the corresponding 95% confidence intervals (95% CI).

The analysis indicates the relative performance of the evaluated architectures in differentiating brain tumors. Among the tested models, LightGBM achieved the highest mean F1-score (87.99%), as well as high precision (88.06%), recall (88.03%), and accuracy (88.00%). LightGBM also demonstrated the greatest overall discriminatory capability, with a mean AUC of 97.14% and a specificity of 94.00%.

The XGBoost and SVM models demonstrated intermediate and comparable performance, with mean F1-scores of 86.44% and 86.41%, respectively. The KNN classifier showed lower performance, achieving a mean F1-score of 85.22% and an AUC of 94.82%. CatBoost and Logistic Regression exhibited the lowest overall performance. CatBoost achieved a mean F1-score of 84.29% and an AUC of 95.68%, while Logistic Regression recorded the F1-score (83.56%) and AUC (94.70%).

Although the pipeline based on radiomic features and traditional classifiers produced promising results, further investigation of deep learning approaches is necessary. The following section evaluates the performance of deep learning architectures applied directly to the segmented images.

E. Performance of Deep Learning Models in Classification

Table V presents the quantitative performance of deep learning models trained exclusively on segmented images for multiclass classification, along with the corresponding 95% confidence intervals. Swin Transformer-B demonstrated the highest overall performance, achieving an accuracy of 93.55%, an F1-score of 93.52%, a specificity of 96.79%, and a mean

TABLE IV: Mean results of the classifiers based on radiomic features.

Metric	LightGBM	SVM	XGBoost	KNN	CatBoost	Logistic Regression
Accuracy (%)	$\mathbf{88.00 \pm 1.55}$	86.47 ± 1.71	86.46 ± 1.74	85.26 ± 1.80	84.32 ± 1.87	83.60 ± 1.66
Precision (%)	$\mathbf{88.06 \pm 1.50}$	86.54 ± 1.72	86.53 ± 1.73	85.48 ± 1.82	84.41 ± 1.89	83.70 ± 1.69
Recall (%)	$\mathbf{88.03 \pm 1.54}$	86.50 ± 1.72	86.49 ± 1.74	85.32 ± 1.80	84.35 ± 1.87	83.63 ± 1.66
F1-Score (%)	$\mathbf{87.99 \pm 1.55}$	86.41 ± 1.74	86.44 ± 1.74	85.22 ± 1.82	84.29 ± 1.87	83.56 ± 1.69
Specificity (%)	$\mathbf{94.00 \pm 0.77}$	93.24 ± 0.86	93.23 ± 0.87	92.65 ± 0.90	92.17 ± 0.93	91.80 ± 0.83
Mean AUC (%)	$\mathbf{97.14 \pm 0.79}$	95.96 ± 1.14	96.54 ± 0.93	94.82 ± 1.27	95.68 ± 0.95	94.70 ± 1.23

AUC of 98.49%. ResNet50 and ViT-B/16 also exhibited strong results, with ResNet50 reaching an accuracy of 92.04% and a mean AUC of 98.31%, and ViT-B/16 attaining an accuracy of 89.64% and a mean AUC of 97.60%.

EfficientNetB7 and SqueezeNet also demonstrated competitive performance, each recording mean AUCs above 97%, although their accuracy values were lower than those of the top-performing models. In contrast, ShuffleNet V2 and DINOv2 ViT-B/14 achieved the lowest accuracies, at 79.97% and 83.96%, respectively, indicating greater difficulty in discriminating among the dataset classes.

A comparison with classifiers based on radiomic features (Table IV) reveals a consistent advantage for the leading deep learning architectures. The best radiomic model, LightGBM, achieved an accuracy of 88.00% and a mean AUC of 97.14%, whereas Swin Transformer-B surpassed these results by approximately 5.6 percentage points in accuracy and 1.35 percentage points in mean AUC.

However, deep learning did not demonstrate absolute superiority in all scenarios. Architectures such as ShuffleNet V2 (79.47%), DINOv2 ViT-B/14 (83.56%), and CLIP ViT-B/16 (85.76%) produced lower F1-scores than LightGBM (87.99%) and XGBoost (86.44%), and were outperformed by classifiers trained exclusively on radiomic features. These findings underscore the importance of model selection and tuning to achieve optimal performance with deep learning compared to traditional machine learning models.

F. Statistical Analysis of Classification via the Wilcoxon Test

To assess the statistical significance of differences among the 14 classifiers (8 deep learning and 6 traditional models), the paired-sample Wilcoxon test ($\alpha = 0.05$) was applied. Among the 91 pairwise comparisons for the F1-score metric, 79 (86.8%) demonstrated statistically significant differences ($p < 0.05$), confirming the decisive impact of model selection on diagnostic accuracy.

The results confirmed the superiority of Swin Transformer-B, which achieved an F1-score significantly higher than all other approaches ($p < 0.001$). When compared to ResNet50, the second-best deep learning model, the difference was statistically significant ($p = 0.000256$). Additionally, in comparison with LightGBM, the best radiomic model, the superiority of Swin Transformer-B was confirmed ($p = 1.86 \times 10^{-9}$).

Conversely, statistical equivalence ($p \geq 0.05$) was observed among models with numerically similar performances. The most evident case occurred between SVM and XGBoost ($p = 0.9354$), a pattern also observed between SqueezeNet and LightGBM ($p = 0.0523$) and between CatBoost and Logistic Regression ($p = 0.0606$).

In summary, the analysis indicated that deep learning is not universally superior. LightGBM (F1-score of 87.99%) exhibited significant differences compared to the deep architectures CLIP ViT-B/16 ($p = 1.22 \times 10^{-2}$), DINOv2 ViT-B/14 ($p = 2.54 \times 10^{-3}$), and ShuffleNet V2 ($p = 1.86 \times 10^{-9}$). These findings demonstrate that, although deep networks generally achieve higher classification performance, lightweight deep models can be outperformed by optimized tree ensembles.

G. External Validation

The generalization capability of the Swin Transformer-B model was evaluated through external validation using the *Figshare* dataset. The pipeline demonstrated robust performance on previously unseen data, achieving an F1-score of 88.62%, a specificity of 94.59%, and a mean AUC of 98.65%. Table VI presents the results for each class.

Glioma demonstrated the highest precision (97.70%), which reduced the occurrence of false positives in this aggressive tumor type. Pituitary tumors achieved the highest sensitivity (96.13%), indicating effectiveness as a screening mechanism by minimizing missed lesions. Meningioma exhibited the most balanced performance, with an F1-score of 89.06%. The strong performance on unseen data further demonstrates the generalization capability of Swin Transformer-B and supports its feasibility for real-world clinical applications.

H. Computer-Aided Diagnosis System

A functional CAD system was developed, as shown in Figure 5. When an MRI scan is uploaded, the platform automatically processes the image and generates a segmentation that highlights the precise location of the tumor lesion, along with its corresponding classification. This unified interface integrates the segmentation (EfficientNetB7 FPN) and classification (Swin Transformer-B) stages into a streamlined workflow, offering practical and visual decision support.

V. Conclusion

This work describes an integrated CAD research prototype for MRI brain tumor segmentation and multiclass classification. While promising for preliminary decision support, clinical implementation requires prospective validation, multicenter studies with diverse imaging protocols, and formal evaluation by radiologists.

During the segmentation stage, the EfficientNetB7 FPN architecture achieved an F1-score of 85.68%, indicating high precision and stability despite lesion heterogeneity. In the

TABLE VI: External validation results for the Swin Transformer-B model.

Class	Support	Precision (%)	Recall (%)	F1 (%)
Meningioma	708	88.44	89.69	89.06
Glioma	1,426	97.70	83.38	89.97
Pituitary	930	79.19	96.13	86.84
Mean	**3,064**	**88.44**	**89.73**	**88.62**

classification stage, deep learning architectures applied directly to images outperformed traditional methods based on radiomic features. The Swin Transformer-B model demonstrated the highest overall performance with an F1-score of 93.52%, while the LightGBM classifier achieved the best results among radiomic approaches with an F1-score of 87.99%.

The project's practical viability was demonstrated through an interactive web application that automates the diagnostic workflow with the top-performing models. However, the current prototype only classifies previously detected tumors. Future work should investigate multimodal approaches, such as combining MRI with PET scans, to enhance biomarker extraction. Controlled prospective trials will be needed to validate clinical adoption in routine radiological practice.

***Abstract*—Accurate preservation of Electrocardiogram (ECG) morphology, particularly the QRS complex, is essential for reliable arrhythmia detection and clinical decision support. State-space models combined with nonlinear Bayesian filters, such as the Extended Kalman Filter (EKF) and Unscented Kalman Filter (UKF), are widely used for ECG reconstruction under noisy conditions. However, most existing approaches primarily focus on improving filtering strategies, while the influence of the underlying state-space representation is often overlooked. In this work, we investigate the impact of Cartesian and Cylindrical models of a nonlinear ECG dynamical model on signal reconstruction and morphological preservation. By explicitly modeling phase as an independent state variable, the Cylindrical Model decouples phase and amplitude dynamics, improving temporal stability of the QRS complex. Experiments conducted on the MIT-BIH Arrhythmia Database demonstrate that the proposed Cylindrical representation consistently outperforms the Cartesian Model under both EKF and UKF frameworks, achieving superior morphological fidelity and improved discrimination of Premature Ventricular Contractions (PVC). Results further indicate that state-space representation plays a more critical role than the choice of nonlinear estimator in preserving ECG structure under stochastic noise.**

***Index Terms*—Electrocardiogram, State-space Modeling, Cylindrical Modeling, Nonlinear Bayesian Filtering.**

I. Introduction

Electrocardiogram (ECG) analysis plays a central role in cardiovascular diagnosis and monitoring, supporting applications such as Heart Rate Variability (HRV) analysis, arrhythmia detection, and real-time cardiac surveillance [1], [2]. In these applications, both the timing and morphology of the QRS complex are clinically relevant, since abnormalities in waveform width, amplitude, or temporal alignment may indicate conduction disturbances and ventricular arrhythmias [3]. However, ECG recordings are frequently contaminated by noise sources including muscle artifacts, electrode motion, and baseline wander, which degrade signal quality and complicate reliable morphological analysis [4].

To address these challenges, state-space representation of dynamical models, combined with nonlinear Bayesian filters, have been widely adopted for ECG reconstruction and denoising. The limit-cycle formulation introduced in [5] represents the cardiac cycle as a nonlinear trajectory driven by Gaussian functions associated with the P, QRS, and T waves. When embedded within Extended Kalman Filter (EKF) or Unscented Kalman Filter (UKF) frameworks [6], this model enables recursive estimation of latent cardiac states under uncertainty.

Despite their success, most existing approaches have focused primarily on improving nonlinear Bayesian filtering algorithms while adopting essentially the same underlying ECG dynamical model [6], [7]. In the original Cartesian formulation proposed by McSharry et al. [5], the cardiac phase is implicitly encoded in the planar state variables, whereas the formulation adopted by Sameni et al. [6] represents phase explicitly as a state variable. Consequently, perturbations affecting the planar states may propagate to phase estimation and ultimately to waveform reconstruction. This effect is particularly relevant in noisy recordings, where preserving QRS morphology is challenging [6], [8].

In this work, we investigate how the choice of state-space representation affects ECG morphology preservation under nonlinear Bayesian filtering. Rather than proposing a new filtering algorithm, the study focuses on the dynamical model used by the estimator. Specifically, Cartesian and Cylindrical ECG models are evaluated under both EKF and UKF frameworks. The Cylindrical formulation explicitly represents cardiac phase as a state variable, separating phase evolution from waveform amplitude dynamics and thereby providing a different geometric description of the cardiac cycle.

The results indicate that, within the evaluated configura-

tions, the choice of state-space representation has a larger effect on morphology preservation and PVC discrimination than the choice between EKF and UKF. The Cylindrical Model provides more stable phase tracking and more consistent reconstruction of QRS morphology, leading to improved R-peak timing accuracy and reliable detection of Premature Ventricular Contractions (PVC). This comparison therefore highlights the role of dynamical model structure as an important design choice in state-space-based ECG reconstruction.

The main contributions of this work are: (i) a systematic comparison between Cartesian and Cylindrical ECG state-space formulations under EKF and UKF frameworks; (ii) an analysis of how state-space geometry affects QRS morphology preservation and phase stability under noisy conditions; (iii) an experimental validation on the MIT-BIH Arrhythmia Database demonstrating that, within the evaluated scenarios, the Cylindrical Model provides more consistent reconstruction and classification performance across both estimators.

The remainder of this paper is organized as follows. Section II presents the Cartesian and Cylindrical ECG models. Section III describes the EKF and UKF frameworks. Section IV presents the experimental setup, including the dataset and evaluation protocol. Section V presents and discusses the results, comparing state-space representations and filtering strategies. Finally, Section VI concludes the paper.

II. ECG Mathematical Modeling

In order to a stochastic filter track a cardiac signal, it is imperative to establish a robust mathematical foundation describing the expected continuous dynamics of a normal ECG (sinus rhythm). There are two state-space-based formulations considered in this work: the Cartesian Model [5] and the Cylindrical Model [6].

A. Cartesian Model

The Cartesian Model proposed by [5] generates a synthetic ECG signal as a trajectory in a three-dimensional space with coordinates $x(t) \in \mathbb{R}$, $y(t) \in \mathbb{R}$, and $z(t) \in \mathbb{R}$. The quasi-periodic nature of the ECG signal, i.e., the temporal repetition of heartbeats, is simulated by a limit-cycle trajectory with unit radius in the $x(t)$-$y(t)$ plane. Each complete turn corresponds to an RR interval, i.e., the duration of a heartbeat.

The PQRST morphology, characteristic of a normal ECG cycle, is reproduced using trajectory movement in the z-axis direction. Characteristic ECG points, such as the P, Q, R, S, and T waves, are described as events. These events correspond to negative and positive attractors or repellers in the z-axis direction. They are placed at fixed angles along the unit circle, specified as Θ_P, Θ_Q, Θ_R, Θ_S, and Θ_T for the P, Q, R, S, and T events, respectively. When the trajectory approaches one of these events, that is, when its current angle is close to the event angle, it is shifted upwards or downwards, moving away from the boundary cycle in the z-axis direction. In Figure 1 it is possible to visualize the boundary cycle by the dashed circle; the events are represented by the red spheres.

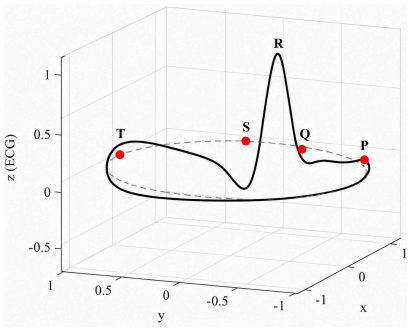

Fig. 1: Typical trajectory generated by the dynamical model; the dashed line indicates the limit cycle, the red spheres represent the events, while the motion along the z-axis modulates the shape of the P, Q, R, S, and T waves [5].

This model uses a set of three first-order Ordinary Differential Equations (ODE), as follows:

$$\dot{x}(t) = \alpha(t)x(t) - \omega y(t), \tag{1}$$

$$\dot{y}(t) = \alpha(t)y(t) + \omega x(t), \tag{2}$$

$$\dot{z}(t) = -\sum_{i\in\mathbb{E}} a_i \Delta\theta_i(t) \exp\left(-\frac{\Delta\theta_i^2(t)}{2b_i^2}\right) + (z_0(t) - z(t)), \tag{3}$$

where $\alpha(t) = 1 - \sqrt{x(t)^2 + y(t)^2}$, $\Delta\theta_i(t) = (\theta(t) - \theta_i) \mod 2\pi$, $\theta(t) = \tan^{-1}(y(t)/x(t))$, with $-\pi \leq \theta(t) \leq \pi$, and $\omega \in \mathbb{R}$ is the angular velocity of the trajectory as it moves around the limit cycle. The parameters a_i, b_i, and θ_i are constants that, for each waveform in the set $\mathbb{E} \in \{\text{P,Q,R,S,T}\}$, are related to its amplitude, width, and position, respectively. Their values are presented in Table I. Furthermore, the effect of respiration on the cardiac cycle is modeled by the function $z_0(t) = A\sin(2\pi f_r t)$, where $A = 0.15$ mV and f_r is the respiratory rate. Also, the term $z_0(t) - z(t)$ refers to the baseline fluctuation [9].

TABLE I: Parameters of the mathematical model of the ECG given by Equations (1)–(3).

Index (i)	P	Q	R	S	T
Time [s]	-0.2	-0.05	0	0.05	0.3
θ_i [rad]	$-\pi/3$	$-\pi/12$	0	$\pi/12$	$\pi/2$
a_i	1.2	-5.0	30.0	-7.5	0.75
b_i	0.25	0.1	0.1	0.1	0.4

Using the parameters in Table I, the system in Equations (1)–(3) was solved without respiratory influence. The generated signal (Figure 2) is similar to a real ECG signal.

B. Cylindrical Model

A potential problem with the Cartesian Model, presented in Section II-A, is that it possesses intrinsic limitations when subjected to recursive stochastic filtering processes, as it couples angular dynamics (e.g. the phase of the heartbeat) with its geometric amplitude. In order to avoid chronic tracking errors, a dynamic model based on a Cylindrical representation was presented in [6].

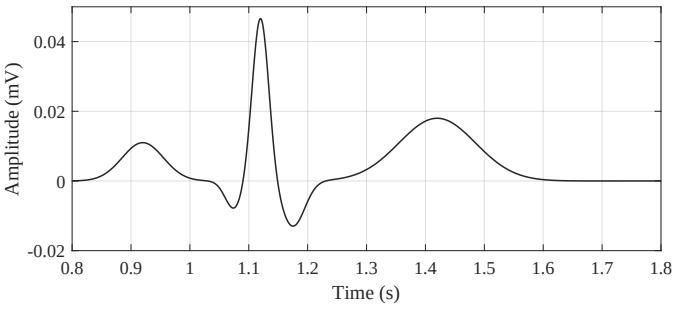

Fig. 2: Morphology of a synthetic ECG.

The transformation to Cylindrical coordinates $r(t) \in \mathbb{R}^+$, $\theta(t) \in [0; 2\pi]$, and $z(t) \in \mathbb{R}$ allows a more compact representation of system dynamics, focusing strictly on angle $\theta(t)$ and amplitude $z(t)$ states, providing a representation in which phase and amplitude dynamics are explicitly separated. In [6], the authors also state that the dynamic equation related to the $r(t)$ variable could be removed because it is redundant for the stochastic filter estimation. Therefore, the dynamics can be represented by the ODE in Equations (4) and (5).

$$\dot{\theta}(t) = \omega, \tag{4}$$

$$\dot{z}(t) = -\sum_{i\in\mathbb{E}} \alpha_i\, \omega\, \Delta\theta_i(t)\, \exp\left(-\frac{\Delta\theta_i^2(t)}{2b_i^2}\right) + (z_0(t) - z(t)), \tag{5}$$

where $\omega \in \mathbb{R}$ is the angular velocity related to the instantaneous heart rate, $b_i \in \mathbb{R}^+$ denotes the width of each wave, $\Delta\theta_i(t) \in [0; 2\pi]$ is the angular deviation of the trajectory relative to the centers of the Gaussian waves, $\alpha_i \in \mathbb{R}^+$ is the peak amplitude coefficients of the Gaussian functions that models the P, Q, R, S, and T components of the ECG.

C. Discretizations of the ECG Models

For the application of stochastic filters later on, it is necessary that the state-space model be written in discrete time. Therefore, Equations (1)–(3), and (4)–(5), must be discretized. In this work, we used the Euler method to perform the discretization [10]. The Euler method applied to the Cartesian Model results in the following set of Difference Equations, now including the measurement equation:

$$\mathbf{x}_{\text{cart}}(k+1) = \begin{bmatrix} x(k) + T\left[\alpha(k)x(k) - \omega y(k)\right] \\ y(k) + T\left[\alpha(k)y(k) + \omega x(k)\right] \\ z(k+1) \end{bmatrix} + \mathbf{w}(k), \tag{6}$$

$$z(k+1) = \\ z(k) + T\left[-\sum_{i\in\mathbb{E}} a_i \Delta\theta_i \exp\left(-\frac{\Delta\theta_i^2}{2b_i^2}\right) + (z_0(t) - z(k))\right] \tag{7}$$

$$z_{\text{cart}}(k) = z(k) + v_{\text{cart}}(k). \tag{8}$$

where $\mathbf{x}_{\text{cart}}(k) = \begin{bmatrix} x(k) & y(k) & z(k) \end{bmatrix}^\intercal \in \mathbb{R}^3$ is Cartesian Model state vector, $z_{\text{cart}}(k) \in \mathbb{R}$ is the Cartesian Model measurement vector, T is the sampling time, $\mathbf{w}_{\text{cart}}(k) \in \mathbb{R}^3$ is the Cartesian Model Gaussian process noise vector with zero mean and covariance matrix $Q_{\text{cart}}(k) \in \mathbb{R}^{3\times3}$, which represents the imperfection of the dynamic model, and $v_{\text{cart}}(k) \in \mathbb{R}$ is the Cartesian Model Gaussian measurement noise vector with zero mean and covariance matrix $R_{\text{cart}}(k) \in \mathbb{R}$, which represents the inaccuracies in the measurements.

Now, applying the Euler method to the Cylindrical Model and considering the inclusion of additive stochastic noises to each equation, the equivalent discrete-time mathematical model is obtained as follows:

$$\mathbf{x}_{\text{cyl}}(k+1) = \begin{bmatrix} \{\theta(k) + \omega T\} \mod (2\pi) \\ z(k+1) \end{bmatrix} + \mathbf{w}_{\text{cyl}}(k), \tag{9}$$

$$z(k+1) = z(k) - \sum_{i\in\mathbb{E}} T\, \frac{\alpha_i\, \omega}{b_i^2}\, \Delta\theta_i(k)\, \exp\left(-\frac{\Delta\theta_i^2(k)}{2b_i^2}\right) \tag{10}$$

$$\mathbf{z}_{\text{cyl}}(k) = \begin{bmatrix} \phi(k) & s(k) \end{bmatrix}^\intercal + \mathbf{v}_{\text{cyl}}(k), \tag{11}$$

where $\mathbf{x}_{\text{cyl}}(k) = \begin{bmatrix} \theta(k) & z(k) \end{bmatrix}^\intercal \in \mathbb{R}^2$ is the Cylindrical Model state vector, $\mathbf{w}_{\text{cyl}}(k) \in \mathbb{R}^2$ is the Cylindrical Model Gaussian process noise vector with zero mean and covariance matrix $Q_{\text{cyl}}(k) \in \mathbb{R}^{2\times2}$, $\mathbf{z}_{\text{cyl}}(k) = \begin{bmatrix} \phi(k) & s(k) \end{bmatrix}^\intercal \in \mathbb{R}^2$ is the measurement vector, $\phi(k) \in [-\pi; \pi)$ is the phase measurement, $s(k) \in \mathbb{R}$ is the ECG amplitude measurement, $\mathbf{v}_{\text{cyl}}(k) \in \mathbb{R}^2$ is the Cylindrical Model Gaussian measurement noise vector with zero mean and covariance matrix $R_{\text{cyl}}(k) \in \mathbb{R}^{2\times2}$.

III. Stochastic Filtering Framework

As presented in Section II, both Cartesian and Cylindrical Models are nonlinear. Therefore, the stochastic filters based on these models should be chosen in such a way to handle nonlinear models appropriately. The Kalman Filter (KF) [11] is one of the most used stochastic filters in the literature but it is formulated based on a linearity hypothesis, preventing the use of nonlinear models to obtain state estimates.

Thus, we choose two nonlinear stochastic filters which are KF variations, in order to obtain state estimations based on those nonlinear models: the EKF [12], [13] and the UKF [14].

A. Extended Kalman Filter

The EKF is a stochastic filter that is based on the linearization of the nonlinear mathematical models in discrete-time state-space representation. This stochastic filter allows the application of its equations to nonlinear systems through local linearization of the nonlinear model.

This linearization is performed using the First-Order Taylor Series (FOTS) expansion of the nonlinear functions around the predicted and estimated states operating point of the system, depending on which step the filter is localized. Considering the following nonlinear state-space representation:

$$\mathbf{x}(k+1) = \mathbf{f}[k, \mathbf{x}(k)] + \mathbf{w}(k), \tag{12}$$

$$\mathbf{z}(k) = \mathbf{h}[k, \mathbf{x}(k)] + \mathbf{v}(k), \tag{13}$$

where $\mathbf{x}(k) \in \mathbb{R}^n$ is the state vector of the system, $\mathbf{z}(k) \in \mathbb{R}^m$ is the measurement vector, $\mathbf{f} : \mathbb{R}^n \to \mathbb{R}^n$ and $\mathbf{h} : \mathbb{R}^n \to \mathbb{R}^m$ are nonlinear functions and the process noise $\mathbf{w}(k) \in \mathbb{R}^n$

and measurement noise $\mathbf{v}(k) \in \mathbb{R}^m$ are Gaussian, additive and uncorrelated, such that $\mathbf{v}(k) \sim \mathcal{N}(0, Q(k))$ and $\mathbf{w}(k) \sim \mathcal{N}(0, R(k))$, where $Q(k) \in \mathbb{R}^{n\times n}$ and $R(k) \in \mathbb{R}^{m\times m}$ are the process and measurement noises covariance matrices, respectively.

The EKF is based on a equation set, divided into two main steps: the prediction step and the update step.

1) EKF Prediction Step: the equations for the EKF Prediction Step are given by:

$$\hat{\mathbf{x}}(k+1|k) = \mathbf{f}[k, \hat{\mathbf{x}}(k|k)], \tag{14}$$

$$P(k+1|k) = \mathscr{F}_x(k)P(k|k)\mathscr{F}_x^\intercal(k) + Q(k), \tag{15}$$

$$\hat{\mathbf{z}}(k+1|k) = \mathbf{h}(k+1, \hat{\mathbf{x}}(k+1|k)), \tag{16}$$

$$S(k+1) = \mathscr{H}_{\mathbf{x}}(k+1)P(k+1|k)\mathscr{H}_{\mathbf{x}}^\intercal(k+1) + R(k+1), \tag{17}$$

$$K(k+1) = P(k+1|k)\mathscr{H}_{\mathbf{x}}^\intercal(k+1)S^{-1}(k+1), \tag{18}$$

where $\hat{\mathbf{x}}(k|k) \in \mathbb{R}^n$ is the estimated state vector at k, $\hat{\mathbf{x}}(k+1|k) \in \mathbb{R}^n$ is the predicted state vector at $k+1$, $P(k|k) \in \mathbb{R}^{n\times n}$ is the estimation error covariance matrix at k, $P(k+1|k) \in \mathbb{R}^{n\times n}$ is the prediction error covariance matrix at $k+1$, $S(k+1) \in \mathbb{R}^{m\times m}$ is the innovation covariance matrix, and $K(k+1) \in \mathbb{R}^{n\times m}$ is the filter gain. The Jacobian matrices $\mathscr{F}_x(k)$ and $\mathscr{H}_{\mathbf{x}}(k+1)$ are given by:

$$\mathscr{F}_{\mathbf{x}}(k) = \left[\frac{\partial \mathbf{f}}{\partial \mathbf{x}}\right]_{\mathbf{x}=\hat{\mathbf{x}}(k|k)}, \tag{19}$$

$$\mathscr{H}_{\mathbf{x}}(k+1) = \left[\frac{\partial \mathbf{h}}{\partial \mathbf{x}}\right]_{\mathbf{x}=\hat{\mathbf{x}}(k+1|k)}. \tag{20}$$

2) EKF Update Step: the equations for the EKF Prediction Step are given by:

$$\hat{\mathbf{x}}(k+1|k+1) = \hat{\mathbf{x}}(k+1|k) + K(k+1)[\mathbf{z}(k+1) - \hat{\mathbf{z}}(k+1|k)], \tag{21}$$

$$P(k+1|k+1) = [I - K(k+1)\mathscr{H}_{\mathbf{x}}(k+1)]P(k+1|k), \tag{22}$$

where $\hat{\mathbf{x}}(k+1|k+1) \in \mathbb{R}^n$ is the estimated vector at $k+1$, $P(k+1|k+1) \in \mathbb{R}^{n\times n}$ is the estimation error covariance matrix at $k+1$.

B. Unscented Kalman Filter

The UKF has a different approach when compared to the EKF: it summarily avoids the use of FOTS expansions and Jacobian matrices by applying the Unscented Transform (UT) [14], [15]. The UT deterministically selects a minimal set of statistical points, called sigma-points, which captures the true mean and true covariance of the current state, instead of approximated values of mean and covariance.

1) UKF Prediction Step: Consider a state vector $\mathbf{x}(k) \in \mathbb{R}^n$, its estimation in time instant k, $\hat{\mathbf{x}}(k|k) \in \mathbb{R}^n$, based on a set of measurement vectors $Z^k = \{\mathbf{z}(0), \mathbf{z}(1), \ldots, \mathbf{z}(k)\}$, and a nonlinear function $\mathbf{f} : \mathbb{R}^n \to \mathbb{R}^n$, where $\mathbf{x}(k+1) = \mathbf{f}(\mathbf{x}(k))$.

In the UKF Prediction Step, a set of $2n+1$ sigma-points $\widehat{\mathscr{X}}(k|k)$ is created, given the updated state vector and covariance matrix, both evaluated at time instant k, for $i = 1, \ldots, n$.

$$\widehat{\mathscr{X}}(k|k)^{(i)} = \hat{\mathbf{x}}(k|k) + \left(\sqrt{(n+\lambda)P(k|k)}\right)_i^\intercal, \tag{23}$$

$$\widehat{\mathscr{X}}(k|k)^{(n+i)} = \hat{\mathbf{x}}(k|k) - \left(\sqrt{(n+\lambda)P(k|k)}\right)_i^\intercal, \tag{24}$$

where $P(k|k) \in \mathbb{R}^{n\times n}$ is the estimation error covariance matrix, $\lambda > 0$ is a parameter that reduces the approximation errors due to high order terms, and $(\cdot)_i^\intercal$ indicates the i-th column of the matrix.

Next, $\mathbf{f}$ is applied to each sigma-point, resulting in a new set of predicted sigma-points, given by:

$$\widehat{\mathscr{X}}(k+1|k)^{(i)} = \mathbf{f}(\widehat{\mathscr{X}}(k)^{(i)}). \tag{25}$$

After that, the predicted state is obtained as follows:

$$\hat{\mathbf{x}}(k+1|k) = \sum_{i=1}^{2n} W_m^{(i)}\, \widehat{\mathscr{X}}(k+1|k)^{(i)}, \tag{26}$$

where $W_m^{(i)} \in (0,1)$ is the weight related to the i-th sigma-point; these weights are given by, for $i = 1, \ldots, 2n$:

$$W_m^{(0)} = \lambda/(n+\lambda) \text{ and } W_m^{(i)} = 1/(2(n+\lambda)). \tag{27}$$

These weights in Equation (27) depend on a set of scaling parameters, as seen in [14]: λ is obtained as $\lambda = \alpha^2(n+p) - n$, where α defines the spread of the sigma-points around the estimation and it has a suggested value of 1×10^{-3}, p is a secondary scalar parameter, usually equal to zero.

The last part of the UKF Prediction Step is obtaining the prediction error covariance matrix, given by:

$$P(k+1|k) = Q(k) + \sum_{i=1}^{2n}\{W_c^{(i)}[\widehat{\mathscr{X}}(k+1|k)^{(i)} - \hat{\mathbf{x}}(k+1|k)][*]^\intercal\}, \tag{28}$$

where $W_c^{(i)} \in (0,1)$ is the weight related to the i-th sigma-point, related to the covariance matrix and the '*' symbol represents the same expression in the brackets on the left; these weights are given by, for $i = 1, \ldots, 2n$:

$$W_c^{(0)} = (1 - \alpha^2 + \beta) + \lambda/(n+\lambda), \tag{29}$$

$$W_c^{(i)} = 1/(2(n+\lambda)), \tag{30}$$

where $\beta > 0$ is the prior knowledge of the distribution; for Gaussian distributions, β is commonly set as 2.

2) UKF Update Step: In the UKF Update Step, new sigma-points are calculated, as follows, based on the prediction state $\hat{\mathbf{x}}(k+1|k)$ and the prediction error covariance matrix $P(k+1|k)$, as in Equations (26) and (28), respectively, for $i = 1, \ldots, n$:

$$\widehat{\mathscr{X}}(k+1|k)^{(i)} = \hat{\mathbf{x}}(k+1|k) + \left(\sqrt{nP(k+1|k)}\right)_i^\intercal, \tag{31}$$

$$\widehat{\mathscr{X}}(k+1|k)^{(n+i)} = \hat{\mathbf{x}}(k+1|k) - \left(\sqrt{nP(k+1|k)}\right)_i^\intercal. \tag{32}$$

Next, the new sigma-points in Equations (31) and (32) are transformed from the function $\mathbf{h}$ to the predicted measurement sigma-points $\widehat{\mathscr{Z}}(k+1|k)^{(i)}$. These points are combined in order to obtain the predicted measurement $\hat{\mathbf{z}}(k+1|k)$:

$$\widehat{\mathscr{Z}}(k+1|k)^{(i)} = \mathbf{h}(\widehat{\mathscr{X}}(k+1|k)^{(i)}), \tag{33}$$

$$\hat{\mathbf{z}}(k+1|k) = \sum_{i=1}^{2n} W_m^{(i)} \widehat{\mathscr{Z}}(k+1|k)^{(i)}. \tag{34}$$

The predicted measurement error covariance and cross-covariance matrices are given by, respectively:

$$P_z(k+1) = R(k+1) + \sum_{i=1}^{2n} W_c^{(i)} [\widehat{\mathscr{Z}}(k+1|k)^{(i)} - \hat{\mathbf{z}}(k+1|k)][*]^\intercal \tag{35}$$

$$P_{xz}(k+1) = \sum_{i=1}^{2n} W_c^{(i)} [\widehat{\mathscr{X}}(k+1|k)^{(i)} - \hat{\mathbf{x}}(k+1|k)][*]^\intercal. \tag{36}$$

The matrices in Equations (35) and (36) are fundamental for obtaining the UKF gain, as follows:

$$K(k+1) = P_{xz}(k+1) P_z^{-1}(k+1). \tag{37}$$

Finally, the updated state vector and the estimation error covariance matrix can be obtained, as follows:

$$\hat{\mathbf{x}}(k+1|k+1) = \hat{\mathbf{x}}(k+1|k) + K(k+1)[\mathbf{z}(k+1) - \hat{\mathbf{z}}(k+1|k)], \tag{38}$$

$$P(k+1|k+1) = P(k+1|k) - K(k+1) P_z(k+1) K(k+1)^\intercal. \tag{39}$$

IV. Experimental Setup

This section describes the experimental setup used to evaluate the proposed ECG-based arrhythmia detection framework. Here, we consider four scenarios based on the combination between the Cartesian and Cylindrical models and the EKF and the UKF: (i) Scenario 1: Cartesian + EKF; (ii) Scenario 2: Cartesian + UKF; (iii) Scenario 3: Cylindrical + EKF; and (iv) Scenario 4: Cylindrical + UKF.

A. Dataset

The proposed methodology was validated using the MIT-BIH Arrhythmia Database [16], [17], which provides gold-standard annotated ECG recordings. This database contains comprehensive, long-term ambulatory records of patients exhibiting several cardiac arrhythmias, providing a robust foundation for the detection algorithm. The validation signals, sampled at 360 Hz, were initially band-pass filtered using the same preprocessing procedure for all evaluated scenarios.

The study focused on PVC, using 79 signal segments of 20 seconds each, extracted from Lead II across 9 distinct patients. This selection totaled 1,299 normal beats and 649 PVC.

B. Filter Parameterization

The computational implementation of the stochastic filters was parameterized to function strictly as a normal sinus rhythm tracker, ensuring that any significant morphological deviation would be reflected in the innovation. As summarized in Table II, the parameters of each ECG dynamical formulation and its corresponding stochastic filter were defined according to their respective state-space representation.

The ECG model parameters — peak amplitudes (a_i, α_i), angular positions (θ_i), and wave widths (b_i) — were fixed a priori to define the standard morphology of the P, Q, R, S, and T waves. The sampling frequency f_s was set to 360 Hz to maintain consistency with the Database specifications.

To allow the stochastic filters to adapt their tracking windows to the patient's current physiological state, the state vectors and error covariance matrices were initialized based on heart rate estimates derived from the local average RR interval. Furthermore, the process and measurement noise covariance matrices were were defined for each state-space representation to provide stable tracking of healthy sinus rhythms. In the Cartesian model, an additive noise formulation uses a static 3×3 diagonal matrix for $Q(k)$. In the Cylindrical model, the measurement variance for the phase channel explicitly incorporates the angular velocity to account for time quantization.

While the UKF relies on purely additive process covariances, the Cylindrical EKF employs a non-additive structure where $Q(k) = \mathscr{W}(k) Q_{\text{init}} \mathscr{W}(k)^\intercal$. This formulation dynamically scales a 17×17 base matrix Q_{init}, which holds the physiological parameter uncertainties, through the process noise Jacobian matrix $\mathscr{W}(k)$. Finally, regarding the UKF tuning, the scaling constants (α, β, κ) were selected to maintain an optimal sigma-point spread for Gaussian distributions.

The two formulations are not intended to constitute matched-complexity models. Their state dimensions and covariance structures follow from the respective state-space representations and are therefore inherently different. The purpose of the comparison is not to equalize model complexity, but to evaluate how the choice of dynamical representation affects recursive ECG estimation when each formulation is implemented according to its corresponding state-space representation.

C. Beat Segmentation and Error Analysis

Individual cardiac cycles were identified using the estimated phase variable $\phi(k)$, mapped onto the interval $[-\pi, \pi)$ such that $\phi(k) = 0$ rad corresponds to the R-peak location. Each heartbeat was therefore defined as one complete phase transition within this interval, i.e., $-\pi \leq \phi(k) < \pi$. Segments corresponding to incomplete cardiac cycles at the boundaries of the 20-second windows were discarded.

The proposed detection strategy relies on the innovation generated by the stochastic filters. For every segmented heartbeat, the discrepancy between the measured ECG waveform

TABLE II: Dynamic model parameters and stochastic filter configurations for all evaluated scenarios.

Framework Component	Parameter / Configuration	Cartesian Model	Cylindrical Model
ECG Dynamical Model	Sampling Frequency (f_s)	360 Hz	360 Hz
	Peak Amplitudes (a_i, α_i)	$\{1.2, -5.0, 30.0, -7.5, 0.75\}$ mV	$\{0.25, -0.15, 1.8, -0.2, 0.5\}$ mV
	Angular Positions (θ_i)	$\{-\pi/3, -\pi/12, 0, \pi/12, \pi/2\}$ rad	$\{-\pi/3, -\pi/12, 0, \pi/12, \pi/2\}$ rad
	Wave Widths (b_i)	$\{0.25, 0.1, 0.1, 0.1, 0.5\}$ rad	$\{0.25, 0.1, 0.1, 0.1, 0.5\}$ rad
EKF Scenarios	State Dimension (n)	3	2
	Process Noise Covariance (Q)	$10^{-3} \times \text{diag}(1, 1, 0.1)$	$Q_{\text{init}} = \text{diag}(\sigma^2_{\alpha_i}, \sigma^2_{b_j}, \sigma^2_{\theta_i}, \sigma^2_{\omega}, \sigma^2_{\eta})_{17\times 17}$
	Measurement Noise Covariance (R)	10^{-2}	$\text{diag}\left((\omega T)^2/12, 10^{-2}\right)$
UKF Scenarios	State Dimension (n)	3	2
	Process Noise Covariance (Q)	$10^{-3} \times \text{diag}(1, 1, 0.1)$	$10^{-3} \times \text{diag}(1, 0.1)$
	Measurement Noise Covariance (R)	10^{-2}	$\text{diag}\left((\omega T)^2/12, 10^{-2}\right)$
	Spread of Sigma Points (α)	10^{-3}	10^{-3}
	Prior Distribution Parameter (β)	2	2
	Secondary Scaling Parameter (κ)	0	0

and the corresponding filter prediction was quantified through the Normalized Mean Squared Error (NMSE), defined as:

$$\text{NMSE} = \frac{\sum_{i=1}^{N} (y_i - \hat{y}_i)^2}{\sum_{i=1}^{N} (y_i - \bar{y})^2}, \tag{40}$$

where $y_i \in \mathbb{R}$ denotes the observed ECG sample, $\hat{y}_i \in \mathbb{R}$ represents the estimated sample provided by either the EKF or UKF frameworks, and $\bar{y} \in \mathbb{R}$ is the mean value of the observed beat. The variable $N \in \mathbb{N}^*$ indicates the total number of samples within the analyzed cardiac cycle.

By normalizing the squared reconstruction error with respect to the signal variance, the NMSE provides a compact measure of reconstruction error for beat-level discrimination.

D. Classification and Cross-Validation

Arrhythmia detection was formulated as a beat-level binary classification problem, distinguishing normal beats from PVC events. A decision threshold T was optimized based on training data to maximize the Macro F1-score.

A 10-fold cross-validation scheme was adopted to assess performance variability across segment-level train/test partitions. In each fold, 90% of the data was used for threshold optimization and 10% for testing. Given the class imbalance in the dataset, Macro F1-score was selected as the primary evaluation metric, complemented by sensitivity to emphasize the importance of minimizing false negatives.

V. Results and Discussion

This section presents the qualitative and quantitative evaluation of the proposed ECG estimation-based arrhythmia detection framework. The analysis compares Scenarios 1–4 applied to the MIT-BIH Arrhythmia Database, focusing on their ability to reconstruct the ECG signal and to discriminate PVC through the NMSE.

A. Qualitative analysis: Scenarios 1 & 2

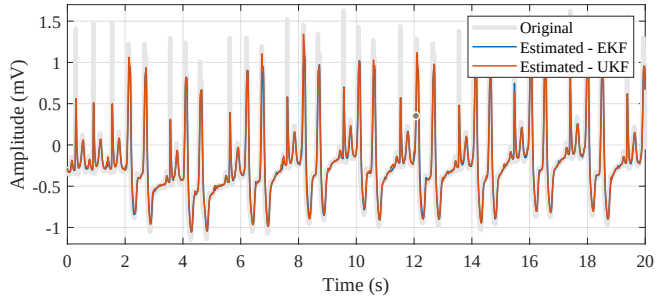
The first set of experiments evaluates the Cartesian Model using both the EKF (Scenario 1) and the UKF (Scenario 2). In both cases, the stochastic filters are able to approximate low-frequency components of the ECG signal, such as P and T waves, but fail to accurately reconstruct the R-peak amplitude, as showed in Figure 3a.

A more critical limitation is observed in phase estimation, where a significant mismatch between measured and estimated phase introduces temporal misalignment in the reconstructed signal (Figure 3b). As a consequence, the instantaneous estimation error does not reliably reflect the presence of arrhythmias.

This behavior is reflected in the per-beat NMSE distribution, which does not show a clear separation between normal and PVC beats (Figure 3c). Several abnormal beats exhibit NMSE values comparable to or even lower than normal beats, indicating that error-based thresholding is not reliable under the Cartesian Model.

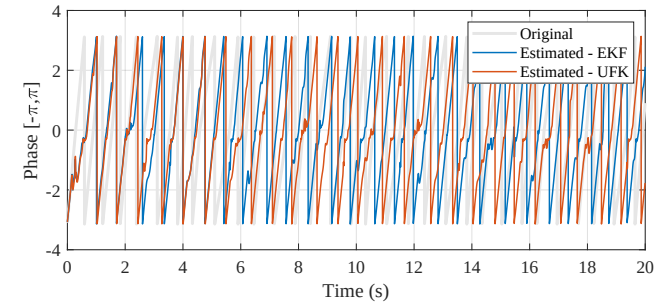
In general, both Cartesian Model-based approaches show limited discriminative capability, mainly due to phase instability and R-peak underestimation.

B. Qualitative analysis: Scenarios 3 & 4



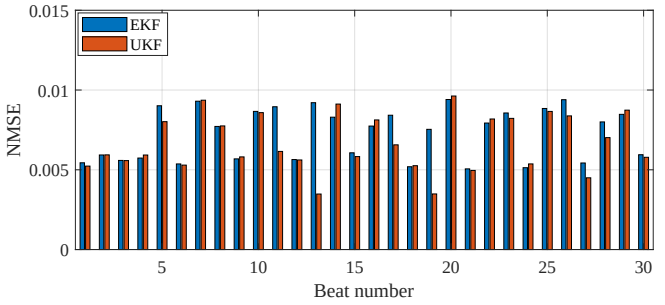
The second set of experiments evaluates the Cylindrical Model using both the EKF (Scenario 3) and the UKF (Scenario 4). These configurations significantly improve signal reconstruction quality. In both cases, phase tracking becomes stable and closely aligned with the measured signal (Figure 4). More importantly, the reconstructed ECG closely follows the morphology of normal beats, while showing clear deviations during PVC events (Figure 4b). These deviations manifest as sharp peaks in the instantaneous estimation error, which align consistently with abnormal beats. Unlike the Scenarios 1 and 2, the NMSE distribution exhibits here a clear separation between normal and PVC classes (Figure 4c).

The improvement is consistent across Scenarios 3 and 4 within the Cylindrical Model, supporting the interpretation that the state-space representation has a dominant influence on performance relative to the stochastic filter.



C. Quantitative evaluation

The quantitative evaluation was performed using 10-fold cross-validation over 79 annotated ECG segments. Performance was assessed at the beat level using Macro F1-score and sensitivity, prioritizing sensitivity due to the clinical importance of minimizing false negatives, as shown in Table III.



Cartesian-based configurations show low sensitivity, failing to detect a large portion of PVC events. In contrast, both Cylindrical Model-based configurations achieve substantially

TABLE III: Performance comparison of the proposed scenarios based on Sensitivity and Macro F1-score.

Scenario	Sensitivity (%)	Macro F1-score
1	47.63 ± 6.40	0.6905 ± 0.0347
2	31.59 ± 3.44	0.6963 ± 0.0193
3	89.99 ± 3.49	0.8843 ± 0.0171
4	85.83 ± 3.44	0.8924 ± 0.0160

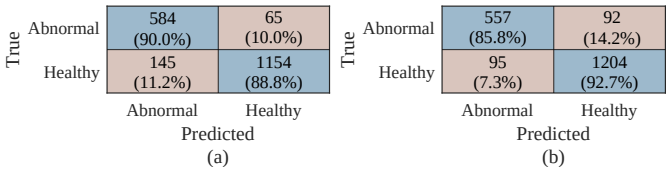

Fig. 5: Confusion matrices obtained for (a) Scenario 3 – EKF and (b) Scenario 4 – UKF.

higher sensitivity and overall classification performance. The Scenario 3 configuration attains the highest sensitivity, while the Scenario 4 configuration achieves the best balance between sensitivity and precision, leading to the highest Macro F1-score. The corresponding confusion matrices for the two Cylindrical Model scenarios summarize these results and are presented in Figure 5.

D. Discussion

The results indicate that, within the evaluated scenarios, the Cartesian Model was more limiting to ECG reconstruction than the choice of stochastic filtering technique. These findings suggest that state-space representation directly influences the stability of ECG morphological features during recursive estimation.

In particular, two issues dominate performance degradation: phase instability, which introduces temporal misalignment between measured and estimated signals, and R-peak underes-

timation, which reduces the discriminative power of the error signal. These limitations prevent NMSE from serving as a reliable proxy for morphological abnormalities.

The Cylindrical Model resolves both issues by explicitly modeling phase evolution and improving amplitude representation. As a result, estimation errors become strongly correlated with physiological abnormalities, particularly PVC.

Interestingly, the difference between EKF and UKF becomes marginal under the Cylindrical Model. While Scenario 3 (using EKF) achieves the highest sensitivity (89.99%), Scenario 4 (using UKF) yields a slightly higher Macro F1-score (0.8924), indicating a trade-off between sensitivity and precision. This behavior is also reflected in the confusion matrix, where Scenario 4 produces the lowest number of false positives (95) and achieves the highest accuracy for the healthy class (92.7%). Therefore, although its sensitivity is slightly lower ($85.83\% \pm 3.44\%$), the improved precision results in a more balanced classifier. These findings suggest that once the state-space representation is appropriate, the choice of the stochastic filter has a secondary impact on performance. From a practical perspective, the proposed recursive framework is compatible with real-time ECG processing, since both EKF and UKF operate sequentially without requiring future samples. However, the computational cost differs between the two estimators, particularly because the EKF requires Jacobian evaluation and matrix inversions, whereas the UKF propagates multiple sigma points at each step. This trade-off is relevant for wearable and embedded cardiac monitoring systems, where computational resources are limited.

VI. Conclusion

This work investigated the impact of state-space representation on ECG morphology preservation under nonlinear Kalman filtering. A systematic comparison between Cartesian and Cylindrical ECG dynamical models was performed using both EKF and UKF frameworks.

In the evaluated dataset and validation protocol, the Cylindrical Model provided substantially better phase stability, QRS morphology preservation, and PVC discrimination than the Cartesian Model. By explicitly decoupling phase and amplitude dynamics, the Cylindrical Model significantly reduces temporal misalignment effects and improves the correlation between estimation error and physiological abnormalities.

Quantitative evaluation on the MIT-BIH Arrhythmia Database showed substantial improvements in sensitivity and Macro F1-score for both Cylindrical Model-based configurations, regardless of the nonlinear stochastic filter employed. These findings suggest that, within the evaluated configurations, the state-space representation has a greater influence on ECG reconstruction quality than the choice between the EKF and UKF. Although the UKF achieved slightly higher overall classification performance, the difference between EKF and UKF became marginal once an appropriate state representation was adopted. This suggests that improving model geometry may provide greater benefits than increasing the stochastic filter complexity.

These findings should be interpreted within the limitations of the evaluated patient population, database, and segment-level validation protocol. Future work includes patient-independent validation on additional databases and ECG conditions, adaptive parameter estimation, other nonlinear stochastic filters such as Adaptive EKF/UKF and Particle Filter (PF), and real-time implementation, including computational and numerical stability assessment, for cardiac monitoring systems.

Response to Reviewers

Dear Reviewers,

First, we thank you for your suggestions and time dedicated to reviewing the manuscript "Characterisation of Motor Profiles in Bilateral Extension and Flexion Movements in Individuals with Parkinson's Disease" (Paper ID: 286), as well as for the opportunity to submit a revised version of this manuscript to the "Brazilian Congress on Biomedical Engineering".

We have carefully considered all suggestions and revised the manuscript accordingly. Below, we provide a point-by-point response to each comment. For clarity, the reviewers' comments are presented in bold, followed by our responses. Changes made to the manuscript are indicated in red in the annotated version of the article.

Responses to the comments from Reviewer 1

Comment: Unsupervised profiling of bilateral wrist extension-flexion can reveal heterogeneity, but clusters from a small medicated Parkinson cohort are exploratory and highly sensitive to feature scaling and sample dependence.

Response: Thank you for this comment. We agree that these factors may affect the results and, as further explained in our responses to the subsequent comments, we have addressed this concern by including a sensitivity analysis in the revised version of the manuscript.

Comment: State the number and characteristics of participants, medication timing, clinical ratings, sensor setup, trial count and all extracted variables.

Response: We thank the reviewer for this suggestion. We would like to clarify that most of these points had already been addressed in the original version of the manuscript. To provide further detail on the description already provided, we added information regarding the time elapsed between medication administration and assessment, as well as the anatomical region in which the sensors were positioned and the device used to acquire signals, with its settings. Although MDS-UPDRS scores are not reported, scores on the Hoehn and Yahr scale are provided, which reflect the patient's overall clinical status; this scale is not as sensitive to motor fluctuations as the MDS-UPDRS, but it is statistically correlated with it (M. Skorvanek, P. Martinez-Martin, N. Kovacs et al., "Differences in MDS-UPDRS scores based on Hoehn and Yahr stage and disease duration," Movement

Disorders Clinical Practice, vol. 4, no. 4, pp. 536-544, 2017). The modifications made to the text are highlighted in red.

<u>Comment:</u> Repeated movements and two limbs from one person must remain linked statistically.

Response: For statistical comparisons, the measurements extracted from the cycles (i.e., the peak-to-peak values) were obtained from the same participant for each limb, and these values were averaged within each limb for each participant prior to statistical analysis; this was not necessary for the others features, given that these measurements are already an aggregate of the cycles. The aggregated values for the two limbs were then compared using a paired-samples t-test or Wilcoxon signed-rank test, with each participant serving as the pairing unit. To help readers better understand this in the text, we explain this point in more detail in the "Statistical Analysis" subsection. All modifications made to the text are highlighted in red.

<u>Comment:</u> Justify retained PCA components and cluster number, show stability under resampling and alternative distances, and report participant membership rather than treating cycles as independent cases.

Response: We thank the reviewer for these important points. First, we would like to clarify that the clustering analysis was conducted at the participant level, with one observation per participant. The features used in the analysis were participant-level aggregated measures, and individual cycles were therefore not treated as independent observations. Second, the component-selection procedure is now best described in the Methods section. The number of principal components retained for the HCPC analysis was determined using generalized cross-validation, which indicated that three components were necessary to adequately represent the data. Third, we would like to clarify that, as described in the previous version of the manuscript, the number of groupings was not specified manually. The optimal partition was determined automatically based on the changes in within-cluster inertia associated with successive cuts of the hierarchical tree. This procedure resulted in a four-cluster solution. Finally, to assess the robustness of the clustering solution, we performed additional sensitivity analyses. These analyses and their results have been incorporated into the revised manuscript.

<u>Comment:</u> Clusters require external clinical interpretation and should not be described as levels of impairment without validated anchors.

Response: Thank you for this suggestion. We agree that the clusters should not be interpreted as levels of impairment in the absence of validated clinical references. We have revised the manuscript to make it clear that the clusters are descriptive

categorizations that require external clinical interpretation, and are not direct indicators of the severity of impairment.

Coment: The manuscript's fluent path from four clusters to personalized treatment may reflect automated language support, although style cannot establish authorship. Human revision should replace treatment-response claims with observed kinematic patterns, discuss fatigue and task-order effects and compare with healthy controls or OFF-medication data. The contribution is an exploratory motor-profile workflow. Verify terminology, sample counts, equations, cluster figures, references and all statements about precision medicine.

Response: Thank you for all suggestions. We acknowledge that assessing these conditions would be beneficial in allowing a comparison of different profiles, and in this regard, we recognize this as one of the limitations of the present study. However, we also acknowledge that, even if these comparisons were included, the findings could not be interpreted as evidence of a response to treatment or as a disease-specific impairment. This is because the effect of medication on each individual's voluntary motor response will also depend on whether the voluntary activity was learned under the influence of the medication or not. Therefore, we hypothesize that medication may contribute to both voluntary and involuntary responses in some cases but not in others, given that even when a person is under the influence of the medication. Thus, we revised the manuscript to ensure that these points were better addressed and discussed in the text. In addition, the suggested points are compared with the relevant literature. All changes have been incorporated into the revised manuscript and are highlighted in red.

Responses to the comments from Reviewer 2

Comment: The analysis focuses on wrist flexion-extension performed under controlled laboratory conditions, without investigating other clinically relevant motor tasks, OFF-medication assessments, longitudinal follow-up, or correlations with established clinical scales such as the MDS-UPDRS. While the clustering analysis identifies distinct motor phenotypes, no external validation or predictive assessment is provided to demonstrate their clinical utility in diagnosis, disease progression, or treatment monitoring.

Response: Thank you for your comment. We agree that all aspects you mentioned are among the limitations of this study. In particular, we acknowledge that assessing these conditions would be beneficial in allowing a comparison of different profiles, and in this regard, we recognize this as one of the limitations of the present study. However, we also acknowledge that, even if these comparisons were included, the findings could not be interpreted as evidence of a response to treatment or as a disease-specific impairment.

This is because the effect of medication on each individual's voluntary motor response will also depend on whether the voluntary activity was learned under the influence of the medication or not. Therefore, we hypothesize that medication may contribute to both voluntary and involuntary responses in some cases but not in others, given that even when a person is under the influence of the medication. In response to this comment, we have discussed these aspects in greater detail and have explicitly acknowledged them as limitations of the present study.

<u>Comment:</u> I also recommend a careful review to ensure full compliance with the CBEB formatting guidelines.

Response: We thank the reviewer for this suggestion. The manuscript has been carefully reviewed and reformatted to ensure compliance with the event template.

Characterization of Thermal Profiles in Pressure Injuries Using the Thermal Laplacian

***Abstract*—Pressure injuries represent a relevant problem in clinical practice, given the associated morbidity and the need for quantitative methods that contribute to the objective analysis of cutaneous perfusion. In this context, infrared thermography is a promising alternative for obtaining thermal information from the body surface; however, its interpretation remains predominantly qualitative or relies on global metrics, which limits the analysis of pressure injuries. Accordingly, there remains a gap in the application of mathematical methods capable of quantitatively describing this perfusion. The objective of this study was to evaluate the performance of the thermal Laplacian as an indicator of perfusion patterns in thermographic images of patients at risk of pressure injury by comparing representative level curves from distinct thermal profiles. A descriptive study with a quantitative approach was conducted using thermographic images from a previously established database of patients admitted to a reference hospital. Each image was organized as a two-dimensional temperature matrix, from which level curves with distinct spatial behaviors were extracted. For each curve, a thermal surface was fitted using a generalized linear model; subsequently, the thermal gradient and Laplacian were computed together with the associated descriptive statistics. The results identified three distinct thermal profiles: one with predominantly positive curvature, associated with local thermal concentration; one with approximately neutral curvature, indicating no significant mean curvature; and one with predominantly negative curvature, associated with greater spatial heterogeneity. These findings indicate that the thermal Laplacian discriminates patterns not adequately captured by global measures alone, such as mean temperature or thermal amplitude, highlighting the potential of mathematical modeling as a complementary quantitative tool for characterizing thermographic images of pressure injuries.**

***Index Terms*—pressure injuries, infrared thermography, thermal Laplacian, tissue perfusion, mathematical modeling.**

I. Introduction

Pressure injuries (PIs) are lesions resulting from deformation of the skin and underlying soft tissues, caused by sustained pressure alone or by pressure combined with shear forces exerted by body weight or medical devices [1], [2]. These factors lead to restricted blood flow, tissue hypoxia, and inflammation, ranging from intact skin to open wounds and frequently accompanied by pain [1], [3]–[5]. From a physical standpoint, these alterations modify the local heat balance in the tissue, since reduced perfusion interferes with thermal exchange between the blood, skin, and external environment, producing spatial temperature variations that can be represented mathematically as thermal fields [6], [7].

PIs develop preferentially over bony prominences [1], [2] and are particularly prevalent in individuals with reduced mobility or those admitted to intensive care units (ICUs) [1], [8], [9]. Under these conditions, continuous pressure on the skin may produce regions with different thermal regimes related to heat conduction, dissipation, and redistribution within the tissues.

In clinical practice, risk assessment is performed using scales such as the Braden, Norton, and Waterlow scales, which are based on clinical variables including mobility, nutrition, moisture, and pressure and/or shear forces [10]–[13]. Although widely used, these tools rely on the assessor's clinical judgment, which may introduce inter- and intra-observer variability and hinder the early detection of perfusion alterations [14]. Recent international guidelines emphasize that risk assessment should be structured, periodic, and complemented by additional clinical factors, especially in critically ill individuals with perfusion alterations, shock, mechanical ventilation, vasopressor use, or medical devices [2]. Moreover, these scales do not directly describe the spatial distribution of temperature or the local geometry of the thermal field, both of which may be relevant to characterizing alterations associated with cutaneous perfusion.

In this context, infrared thermography (IT) is a complementary method that enables objective measurement of the thermal distribution of the skin surface [15], [16]. Local thermal variations may reflect microcirculatory changes associated with inflammatory or ischemic processes, thereby enabling the early identification of regions susceptible to injury [4], [17], [18].

Recent studies also indicate that skin temperature differences may serve as indicators of imminent tissue damage in pressure injuries, especially when combined with computational image-analysis methods [19]. However, when used in isolation, its interpretation remains predominantly qualitative or relies on global metrics, such as mean temperature, maximum temperature, or thermal amplitude, which limits the analysis of the spatial organization of the thermal field [15], [16], [20].

In this regard, there remains a gap in the application of quantitative methods capable of describing the spatial structure of temperature to support clinical assessment, both in the context of traditional scales and in infrared thermography analysis [14]–[16], [21], [25]. Global measures may summarize overall thermal intensity but do not necessarily capture local information, such as concentration, dispersion, asymmetry, and spatial heterogeneity. Therefore, mathematical approaches based on local and global descriptors have been proposed to improve the quantification of information contained in thermal images [20].

From a mathematical standpoint, the temperature distribution in biological tissues can be described as a continuous scalar field $T(x, y)$ associated with thermal conduction, blood perfusion, and metabolic heat generation. Models based on partial differential equations, such as the Pennes bioheat equation, establish this relationship by connecting thermal gradients to physiological terms [22]–[24]. Recent bioheat simulation studies reinforce that skin-surface temperature can be analyzed using differential models that incorporate tissue thermal properties, blood perfusion, metabolic heat generation, and boundary conditions [6], [7]. In this context, the Laplacian operator, associated with the second spatial derivative of temperature, describes the curvature of the thermal surface and is related to heat diffusion and redistribution processes, allowing the identification of spatial patterns that are not captured by global thermal measures [21], [25].

In light of this scenario, this study aims to evaluate the performance of the thermal Laplacian as an indicator of perfusion patterns in thermographic images of patients at risk of PI. Specifically, it seeks to model the thermal surface from representative level curves, estimate the thermal Laplacian as a measure of spatial heat redistribution, and compare distinct thermal profiles with respect to their spatial organization.

II. Material and Methods

A descriptive study with a quantitative approach and non-probability sampling was conducted using thermographic images from a previously established database comprising 30 individuals admitted to the intensive care unit (ICU), internal medicine ward, or trauma unit of a reference hospital in Curitiba, Brazil. The study was approved by the Research Ethics Committee (CAAE: 57943822.9.3001.5225; approval no. 5.651.212).

The inclusion criteria comprised bedridden individuals or those with reduced mobility, classified as having or not having a pressure injury. Clinical interpretation and injury staging were performed in accordance with the National Pressure Injury Advisory Panel (NPIAP) guidelines [2].

Three distinct thermal patterns were identified in the analyzed regions. To exemplify these patterns in the proposed mathematical analysis, three representative thermal curves were selected from the complete image database. Each selected thermal curve was defined as a region of interest, enabling comparative evaluation of the spatial temperature distribution and the observed thermal curvature.

A. Thermographic image acquisition

Thermographic images of the gluteal and sacrococcygeal regions were acquired using an infrared camera (Ti32, 320×240 infrared sensor; Fluke Thermography, Everett, WA, USA). The standardized protocol included exposing the region of interest for five minutes of thermal acclimatization in an environment maintained at 22 ± 1 °C and monitored using a digital thermo-hygrometer with an external probe (SH 112; J-Prolab, Brazil).

During acquisition, participants were placed in the lateral decubitus position, with an approximate distance of 50 cm between the skin surface and the camera.

An example of the optical image and the corresponding thermographic image is shown in Fig. 1.

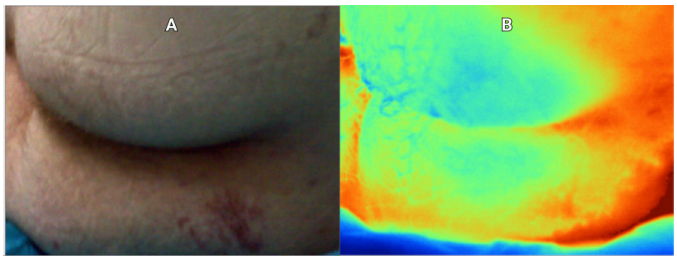

Fig. 1. Example of acquisition: (a) optical image of the analyzed region; (b) thermographic image.

B. Image processing and extraction of thermal curves

All statistical and mathematical processing was performed using R (version 4.3.0; R Foundation for Statistical Computing, Vienna, Austria). The thermographic image was organized as a two-dimensional temperature matrix, allowing the spatial thermal distribution to be represented by the scalar function $T(x, y)$.

From this matrix, thermal level curves were obtained, defined as sets of points that share the same temperature value. To exemplify the three identified patterns, the selected thermal curves were denoted P1, P2, and P3.

Each selected thermal curve was defined as a region of interest and spatially delimited to extract the local thermal data used for surface modeling.

C. Thermal surface modeling

For each region of interest, the spatial temperature distribution was modeled using a generalized linear model (GLM), assuming a normal distribution and an identity link function.

The thermal surface was represented by a polynomial function of two variables, allowing the spatial variation of temperature in each analyzed region to be described. The final model structure was defined through automatic term selection, retaining only those terms that were statistically relevant to representing the local thermal geometry. From this fit, the fitted thermal surface $T(x, y)$ was obtained and used as the basis for the differential analysis.

D. Computation of the thermal gradient and Laplacian

From the fitted thermal surface, the thermal gradient was computed to describe the direction and magnitude of the greatest local temperature variation, as shown in (1).

$$\nabla T(x, y) = \left(\frac{\partial T}{\partial x}(x, y),\ \frac{\partial T}{\partial y}(x, y) \right) \tag{1}$$

Next, the thermal Laplacian was computed and adopted as the central parameter of the analysis because it represents the local curvature of the thermal surface. Previous studies by our research group evaluated the use of the Pennes equation to estimate blood perfusion in pressure injuries and to model thermal gradients in thermographic images of these lesions [26], [27]. The formulation is based on the Pennes bioheat equation, which represents heat transfer in perfused tissue and explicitly includes the blood-perfusion term, as shown in (2) [22].

$$\nabla \cdot (k \nabla T) - \rho_b c_b \omega_b (T - T_a) + q_m = 0 \tag{2}$$

where k is the thermal conductivity of the tissue, ρ_b is blood density, c_b is the specific heat of blood, ω_b is the blood perfusion rate, T is tissue temperature, T_a is arterial temperature, and q_m represents metabolic heat generation.

Under the assumption of local homogeneity of the thermal parameters and neglecting spatial variations in k, the equation can be reduced to a form proportional to the Laplacian operator, as shown in (3).

$$\nabla^2 T(x, y) = \frac{\partial^2 T}{\partial x^2}(x, y) + \frac{\partial^2 T}{\partial y^2}(x, y) \tag{3}$$

In terms of curvature, $\nabla^2 T > 0$ indicates predominantly positive curvature; $\nabla^2 T \approx 0$ indicates approximately null mean curvature; and $\nabla^2 T < 0$ indicates predominantly negative curvature. Thus, the Laplacian was used to mathematically summarize differences among the thermal profiles represented by the three selected curves. These values are presented as mathematical descriptors of the spatial organization of temperature rather than as diagnostic indicators.

E. Statistical analysis

For each region of interest, descriptive statistics of the thermal Laplacian values were computed, including the number of points, mean, standard deviation, and 95% confidence interval. Next, a one-sample Student's t-test was performed to evaluate the null hypothesis of a mean Laplacian equal to zero, as shown in (4).

TABLE I
DESCRIPTIVE CHARACTERISTICS OF THE SAMPLE ($n = 30$)

Variable	Median	SD	P25–P75	Min.–Max.	n (%)
Continuous characteristics					
Age (years)	62	23	45–81	22–91	–
Weight (kg)	64	13	58–71	35–97	–
Height (m)	1.6	0.11	1.6–1.7	1.4–1.8	–
Sex and ethnicity					
Female sex	–	–	–	–	11 (35%)
Male sex	–	–	–	–	19 (65%)
White ethnicity	–	–	–	–	23 (77%)
Mixed-race ethnicity	–	–	–	–	7 (23%)

Note: SD = standard deviation; P25 = 25th percentile; P75 = 75th percentile.

$$H_0 : \mu_{\nabla^2 T} = 0 \tag{4}$$

Failure to reject this hypothesis was interpreted as indicative of approximately null mean curvature, whereas its rejection was considered evidence of significant thermal curvature. All analyses adopted a significance level of 5%.

III. RESULTS AND DISCUSSION

Table I summarizes the continuous descriptive characteristics and the distribution of categorical variables in the sample ($n = 30$). The median age was 62 years, with a predominance of male participants (65%) and individuals identified as White (77%). Regarding anthropometric measurements, the median weight and height were 64 kg and 1.60 m, respectively.

Regarding comorbidities, the most frequent were arterial hypertension (43%), diabetes mellitus (13%), chronic lung disease (10%), and heart disease (7%). For approximately one-fifth of the participants, the electronic medical record contained insufficient information to confirm the presence or absence of comorbidities.

The clinical characterization of pressure injuries, including staging, anatomical location, and risk stratification using the Braden scale, was performed by the hospital team, with clinical interpretation based on the NPIAP guidelines [2]. Table II presents these clinical characteristics separately. With respect to injury stage, participants without a pressure injury were the most frequent group (48%), followed by Stage 2 (29%) and Stage 1 (13%). Unstageable cases accounted for 6% of the sample, whereas Stage 3 had the lowest frequency (3%).

Based on the thermographic analysis of the regions of interest and the three images selected to exemplify the thermal patterns, 43 valid level curves were considered. The distribution by temperature range showed a predominance of curves with temperatures equal to or greater than 32 °C. Twenty-one curves (48.8%) had temperatures equal to or greater than 35 °C, 20 curves (46.5%) ranged from 32 to 34.9 °C, and two curves (4.7%) ranged from 28 to 32 °C. No cases below 28 °C were detected, as shown in Table III.

The analysis identified three distinct thermal profiles according to the curvature of the fitted thermal surface, corresponding to positive (P1), approximately neutral (P2), and

TABLE II
CLINICAL CHARACTERISTICS OF PRESSURE INJURIES: STAGES, ANATOMICAL LOCATION, AND RISK STRATIFICATION

Variable	Frequency	%
Pressure injury stages		
Stage 1	4	13%
Stage 2	9	29%
Stage 3	1	3%
Unstageable	2	6%
No pressure injury	15	48%
Anatomical location		
Gluteal region	7	23%
Sacral region	10	33%
Risk stratification (Braden)		
High risk	9	30%
Low risk	4	13%
Moderate risk	9	30%
Very high risk	8	27%

TABLE III
DISTRIBUTION OF LEVEL CURVES BY TEMPERATURE RANGE

Temperature range	Count	% of total ($n = 43$)
$\geq 35\,^{\circ}$C	21	48.8%
32–34.9 °C	20	46.5%
28–32 °C	2	4.7%
$< 28\,^{\circ}$C	ND	ND

Note: ND = not detected (no cases recorded in this category).

negative (P3) Laplacian values. Fig. 2 combines representative examples of these three profiles into a single composition. In each row, the unsmoothed thermal level curves, the thermal surface fitted by the GLM, and the thermal-gradient vector field are presented for the same profile. The level curves represent contours of equal temperature and allow thermally homogeneous zones and transition regions to be visualized. In the three-dimensional surfaces, the spatial axes represent the region of interest and the vertical axis represents the fitted temperature, while the gradient vectors indicate the direction and magnitude of the greatest local temperature variation.

A. Profile 1: predominantly positive curvature

In the first row of Fig. 2, corresponding to Profile 1, the unsmoothed thermal level curves, the thermal surface fitted by the GLM, and the thermal-gradient vector field are shown. A well-defined central elevation and continuous spatial variation are evident.

The thermal Laplacian had a mean of $\overline{\nabla^2 T} = 0.1385$, a standard deviation of 0.1298, a 95% confidence interval from 0.1030 to 0.1739, and $p = 2.03 \times 10^{-10}$ in the t-test for $H_0 : \mu_{\nabla^2 T} = 0$ ($n = 54$). Because the confidence interval lies entirely above zero and the null hypothesis was rejected, $\nabla^2 T > 0$ characterizes predominantly positive curvature associated with local spatial concentration of the thermal surface.

B. Profile 2: approximately neutral curvature

In the second row of Fig. 2, corresponding to Profile 2, the unsmoothed thermal level curves, the thermal surface fitted by the GLM, and the thermal-gradient vector field are shown. A more distributed spatial variation is evident.

The thermal Laplacian had a mean of $\overline{\nabla^2 T} = -0.0108$, a standard deviation of 0.0647, a 95% confidence interval from -0.0330 to 0.0114, and $p = 0.331$ in the t-test for $H_0 : \mu_{\nabla^2 T} = 0$ ($n = 35$). Because the confidence interval includes zero and the null hypothesis was not rejected, $\nabla^2 T \approx 0$ characterizes the absence of significant mean curvature, although local positive and negative variations remain present.

C. Profile 3: predominantly negative curvature

In the third row of Fig. 2, corresponding to Profile 3, the unsmoothed thermal level curves, the thermal surface fitted by the GLM, and the thermal-gradient vector field are shown. A concave configuration with a central depression is observed.

The thermal Laplacian had a mean of $\overline{\nabla^2 T} = -0.0729$, a standard deviation of 0.0253, a 95% confidence interval from -0.0778 to -0.0680, and $p = 6.77 \times 10^{-52}$ in the t-test for $H_0 : \mu_{\nabla^2 T} = 0$ ($n = 104$). Because the confidence interval lies entirely below zero and the null hypothesis was rejected, $\nabla^2 T < 0$ characterizes predominantly negative curvature associated with greater spatial heterogeneity of the thermal surface.

D. Comparison of the profiles

Comparison of the three profiles reveals three curvature regimes of the fitted thermal surface: predominantly positive in P1, approximately null in P2, and predominantly negative in P3. The sign and magnitude of the Laplacian provide information about the local geometry that is not supplied by global measures such as mean temperature or thermal amplitude [21], [25].

The gradient describes the direction of thermal variation, whereas the Laplacian summarizes the curvature of the surface. Polynomial modeling enabled these differential descriptors to be computed and provided a quantitative representation of the spatial organization of temperature [15], [16], [21], [25]. Integrating these metrics with machine-learning methods remains a direction for future research [14], [19].

IV. CONCLUSION

This study evaluated the thermal Laplacian as a descriptor of the spatial organization of temperature in thermographic images of patients at risk of pressure injury. The thermal surfaces were modeled using a GLM, allowing comparison of three curvature regimes: predominantly positive ($\nabla^2 T > 0$, P1), approximately neutral ($\nabla^2 T \approx 0$, P2), and predominantly negative ($\nabla^2 T < 0$, P3).

The results show that the Laplacian provides local information not supplied by global metrics alone. As a methodological contribution, these descriptors may support future quantitative approaches and automated classifiers, including neural-network-based models.

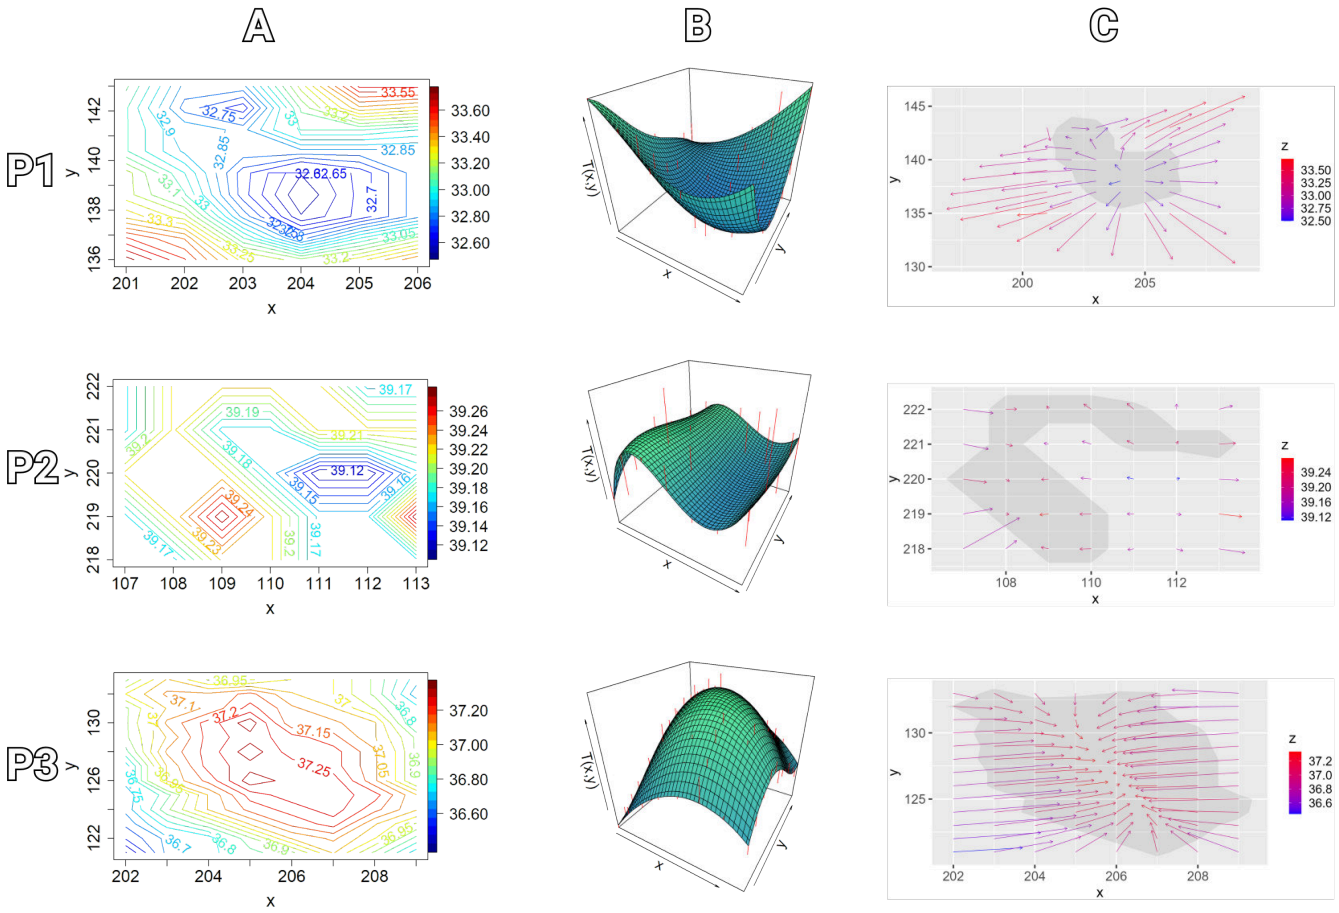

Fig. 2. Single composition of the three representative thermal profiles. The rows correspond to profiles P1, P2, and P3. The columns correspond to: (A) unsmoothed thermal level curves of the region of interest; (B) thermal surface fitted by the generalized linear model (GLM); and (C) thermal-gradient vector field.

***Abstract*—Alzheimer's disease is a progressive neurodegenerative condition, and the analysis of magnetic resonance imaging (MRI) has been explored as a support for automatic image classification studies. This work evaluates pre-trained convolutional neural network architectures for classifying MRI images into four classes: Mild Demented, Moderate Demented, Non Demented, and Very Mild Demented. The dataset was obtained from Kaggle and was already made available with balanced and augmented images. Architectures from the ResNet, DenseNet, EfficientNet, EfficientNetV2, Inception, and Xception families were tested, with transfer learning, fine-tuning, data augmentation, regularization, Test-Time Augmentation (TTA), and ensemble by soft voting. The best individual model was the optimized EfficientNetV2-B2, with a macro F1-score of 0.9919. The final ensemble, composed of five models, achieved a macro F1-score of 0.9959 and an accuracy of 0.9958. The results indicate that combining complementary architectures and fine-tuning strategies can increase the robustness of multiclass classification on this dataset. However patient-level evaluation on original volumetric MRI remains necessary before any clinical use.**

***Index Terms*—Alzheimer; Magnetic Resonance Imaging; Convolutional Neural Networks; Transfer Learning; Ensemble.**

I. Introduction

Alzheimer's disease is a neurodegenerative disorder associated with the progressive deterioration of memory, cognition, and functional autonomy. Clinical diagnosis depends on specialized medical evaluation and can be supported by imaging exams, including magnetic resonance imaging (MRI), which is capable of revealing structural changes related to the neurodegenerative process. In this context, computational methods can assist in analyzing large amounts of images and support automatic classification studies [1].

Convolutional neural networks (CNNs) have shown impressive performance in computer vision and medical image analysis, as they learn hierarchical representations directly from pixels [2], [10]. In biomedical problems, however, the number of labeled images is usually smaller than in general computer vision datasets, which increases the risk of overfitting and makes transfer learning particularly relevant [4].

In transfer learning, an architecture previously trained on a large dataset, such as ImageNet, is adapted to a new domain by replacing the classifier layer and performing partial or full weight adjustment. This strategy is useful in medical imaging because it reduces training time and allows reuse of visual filters already learned, such as edges, textures, and intensity patterns [4], [10].

Studies on Alzheimer's disease classification using CNNs report that comparison across studies can be hampered by differences in preprocessing, data splitting, patient selection, and experimental validation [3]. Therefore, in addition to comparing architectures, it is important to record the tested variations, including those that did not lead to improvements, as they help understand model behavior when dealing with visually similar classes.

Given this context, this work aims to evaluate different pre-trained CNN architectures for the classification of Alzheimer's MRI images into four classes, comparing baselines, training variations, fine-tuning, TTA, and ensemble. The main focus is

to identify which strategies improved performance and which techniques did not contribute to better results. We emphasize that the study is restricted to a public, pre-balanced and pre-augmented image dataset and that part of the evaluation relies on image-level splitting. Accordingly, the results characterize internal performance on this processed dataset and are not intended as clinical evidence.

II. Methodology

A. Dataset

The public dataset *Alzheimer's Disease Multiclass Images Dataset*, available on Kaggle, specifically the `combined_images` folder, was used [5]. The dataset consists of MRI images organized into four classes: Mild Demented, Moderate Demented, Non Demented, and Very Mild Demented. The subset used in the main experiments (Table I) contains 12,000 images, with 3,000 images per class. For the main training runs, 2,400 images per class were used for training and 600 images per class for validation/testing, totaling 9,600 training images and 2,400 validation/test images.

Table I
Distribution of the main dataset used in the experiments.

Class	Total	Train	Val.
Mild	3000	2400	600
Moderate	3000	2400	600
Non	3000	2400	600
Very Mild	3000	2400	600
Total	12000	9600	2400

The dataset had already undergone a prior balancing and data augmentation process before being made available in the repository. Thus, the experiments in this work were conducted on a previously augmented dataset, and additional data augmentation techniques were applied only to the training set when specified in each experimental variation. The four classes represent different conditions or levels of cognitive impairment. The Moderate Demented class was the easiest to classify, while Non Demented and Very Mild Demented were the most frequently misclassified classes.

B. Preprocessing

Images were resized according to the architecture being evaluated: 224×224 for most models, 260×260 for EfficientNetV2-B2, and 299×299 for Inception-V3. ImageNet-based normalization was applied, along with grayscale conversion in some experiments, auto-contrast, black border removal, and mild histogram equalization during training.

Data augmentation transformations such as RandomResizedCrop, light rotation, horizontal flip, RandomAffine, and RandomErasing were evaluated. Transformations were applied only to the training set. The validation and test sets were kept without artificial augmentation, except in TTA experiments, in which inference combines the original image and transformed versions.

C. Architectures and variations

Pre-trained architectures from the ResNet [6], DenseNet [7], EfficientNet, EfficientNetV2 [9], Inception [8], and Xception families were evaluated. For all architectures, the final layer was replaced by a classifier head compatible with the four classes of the problem. Initially, baselines with a frozen backbone were trained to establish a reference for comparison.

After the baselines, models with the greatest potential were subjected to experimental variations (II). Among them, the following stand out: fine-tuning techniques such as partial and full backbone unfreezing, classifier head modification, class weights, Focal Loss, moderate MRI augmentation, learning rate schedulers, optimizers such as Adam and AdamW, weight decay, label smoothing, and TTA.

Table II
Experimental configurations evaluated.

Exper.	Architecture	Strategy
Baseline	ResNet / DenseNet / EfficientNet	Frozen backbone
Variations	DenseNet-169 / 201	Weights, Focal, Aug. and TTA
Optimized	EfficientNetV2-B2	TL + partial FT + TTA
Ensemble	Top-5	Soft voting

D. Training and evaluation

Models were implemented in Python and, in some experiments, using the timm library. The Adam and AdamW optimizers were tested, along with different learning rates, early stopping, and schedulers such as ReduceLROnPlateau and CosineAnnealingLR. The main metric for selecting the best models was the macro F1-score.

The macro F1-score was chosen because accuracy alone can mask difficulties in specific classes. Since the problem has four classes and some of them are visually similar, the analysis of confusion matrix, precision, recall, and per-class F1 was essential for interpreting model behavior.

After individual evaluation, five models were selected for the final ensemble: DenseNet-169, DenseNet-201, EfficientNetV2-B2, Inception-V3, and EfficientNetV2-B0. Two soft voting strategies were evaluated: simple averaging of probabilities and weighted averaging based on the individual macro F1-score.

III. Results and Discussion

A. Baselines

The baselines allowed comparing the initial behavior of the architectures with a frozen backbone. EfficientNetV2-B2 was the best baseline, with a macro F1-score of 0.8082, indicating better initial adaptation to the image set. In contrast, ResNet-50 and Inception-V3 showed lower performance, with macro F1-scores of 0.6467 and 0.6124, respectively, as shown in Table III.

Table III
EVALUATED BASELINES.

Model	Acc.	F1
EffNetV2-B2	0.8114	0.8082
EffNet-B0	0.7427	0.7337
EffNet-B2	0.7408	0.7346
DenseNet-169	0.7342	0.7387
DenseNet-201	0.7225	0.7318
DenseNet-121	0.7192	0.7245
ResNet-34	0.6717	0.6761
Xception	0.6650	0.6672
ResNet-18	0.6642	0.6636
ResNet-101	0.6583	0.6595
ResNet-50	0.6492	0.6467
Inception-V3	0.6125	0.6124

B. Variations and best models

The variations demonstrated that fine-tuning and regularization were more effective than simply increasing the complexity of the classifier head or applying balancing techniques in isolation (Table IV). DenseNet-201 with full fine-tuning and differentiated learning rate achieved a macro F1-score of 0.9861, while the optimized EfficientNetV2-B2 obtained the best individual result, with a macro F1-score of 0.9919.

Table IV
MAIN EXPERIMENTAL VARIATIONS.

Model/Variation	Strategy	Acc.	F1
EffNetV2-B2 optim.	TL + FT + TTA	0.9919	0.9919
DenseNet-201 V1	Full FT + diff. LR	0.9858	0.9861
DenseNet-169 V1	Partial FT + Cosine	0.9325	0.9338
Inception-V3 V4	AdamW + TTA	0.8821	0.8819
DenseNet-169 V4	TTA 5x	0.7642	0.7680
DenseNet-201 V4	TTA 5x	0.7592	0.7669
DenseNet-201 V3	Robust head	0.6775	0.6837
DenseNet-169 V3	Focal Loss	0.6800	0.6833
DenseNet-169 V3	Moderate aug.	0.6767	0.6795
DenseNet-201 V2	Class weights	0.6633	0.6764

On the other hand, some techniques reduced performance. In DenseNet-201, class weights resulted in a macro F1-score of 0.6764 and the robust head achieved 0.6837, both below the baseline. In DenseNet-169, Focal Loss and moderate augmentation also reduced performance. These results suggest that balancing strategies need to be carefully calibrated.

C. Best individual model

The optimized EfficientNetV2-B2 combined transfer learning, partial fine-tuning, dropout, weight decay, label smoothing, class weights, ReduceLROnPlateau, gradient clipping, and TTA. The training curves are presented in Figs. 1–3, and indicate consistent loss reduction, progressive accuracy increase, and stabilization of the macro F1-score at a high level. The confusion matrix in Fig. 4 shows high performance across all classes, with residual errors concentrated mainly between Non Demented and Very Mild Demented.

In Fig. 1, a continuous decrease in training and validation loss is observed, indicating progressive convergence. The most pronounced reduction occurs after the onset of fine-tuning,

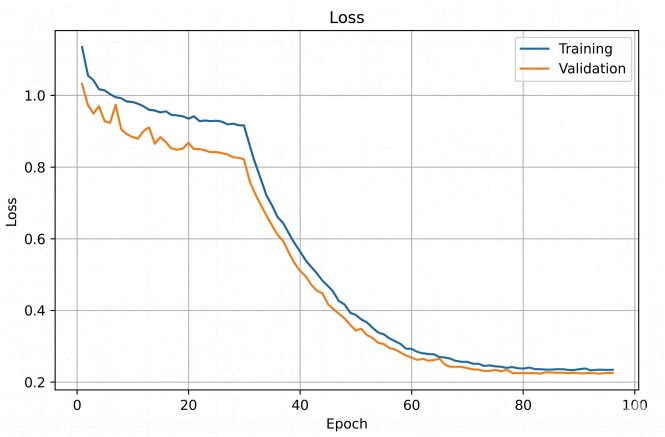

Figure 1. Loss curve of the optimized EfficientNetV2-B2.

when the model begins to better adapt its final blocks to the MRI image domain.

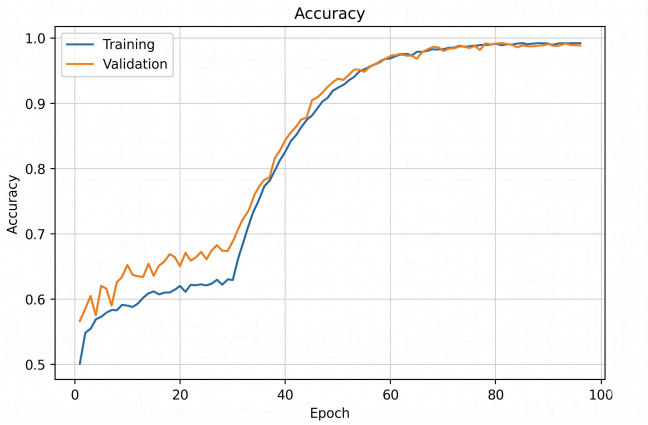

Figure 2. Accuracy curve of the optimized EfficientNetV2-B2.

In Fig. 2, accuracy increases gradually over epochs, with stronger growth after the fine-tuning stage. The proximity between training and validation curves indicates stable training and low evidence of severe overfitting.

In Fig. 3, the macro F1-score grows consistently and stabilizes near the end of training, showing balanced improvement across all four classes and justifying the choice of the optimized model as the best individual classifier.

In Fig. 4, the main diagonal presents values close to 1.00 for all classes, indicating high per-class recall. The few remaining errors appear mainly between Non Demented and Very Mild Demented, which is consistent with the visual similarity between these patterns.

D. Final ensemble

The final ensemble was the best overall strategy (Table 5). The combination of the five selected models resulted in a macro F1-score of 0.9959 and an accuracy of 0.9958, surpassing the best individual model used in the ensemble, which was DenseNet-201 with a macro F1-score of 0.9852.

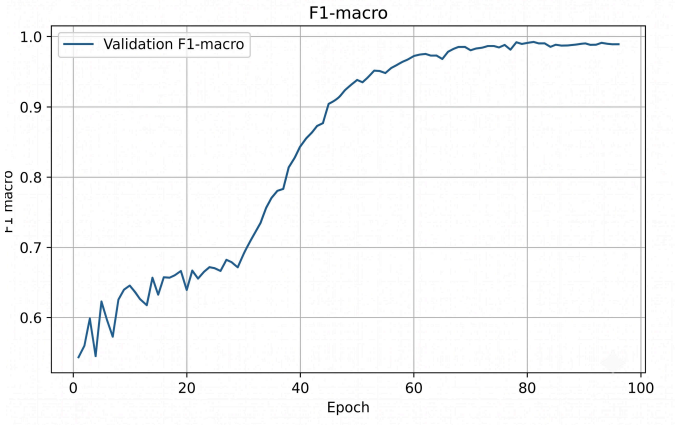

Figure 3. Validation macro F1-score evolution of the optimized EfficientNetV2-B2.

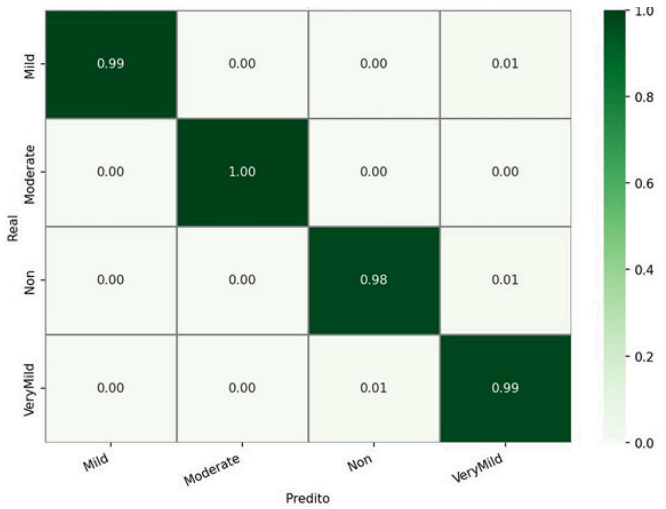

Figure 4. Normalized confusion matrix of the optimized EfficientNetV2-B2 with TTA.

The improvement indicates that the models captured complementary patterns.

Table V
MODELS USED IN THE FINAL ENSEMBLE.

Model	Strategy	F1
DenseNet-169	Partial FT	0.9322
DenseNet-201	Full FT	0.9852
EffNetV2-B2	TTA 2x	0.9820
Inception-V3	TTA 2x	0.9795
EffNetV2-B0	TTA 2x	0.9762
Simple ensemble	Soft voting	0.9959
Weighted ensemble	Soft voting	0.9959

In Fig. 5, it is observed that individual models achieve high performance, with macro F1-scores above 0.93. However, the simple and weighted soft voting ensemble strategies reach 0.9959, surpassing all individual classifiers. This result indicates that the combination of complementary architectures reduced individual errors and increased classification robustness.

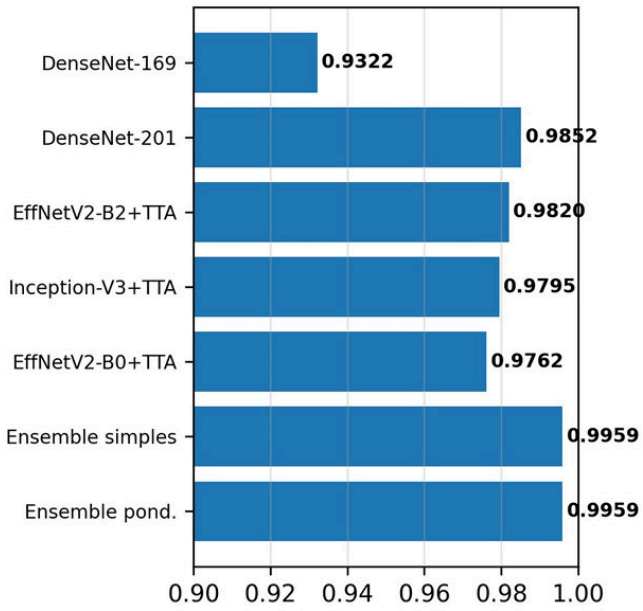

Figure 5. Macro F1-score comparison between individual models and ensemble.

In Fig. 6, DenseNet-169 shows good concentration of correct predictions on the diagonal, but still maintains confusion between Non Demented and Very Mild Demented, indicating difficulty with the visually closest classes.

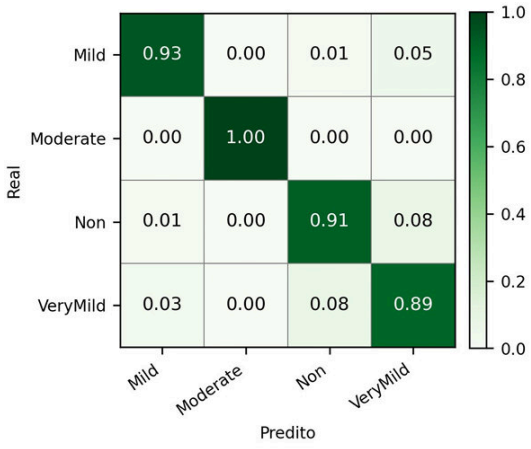

Figure 6. Normalized confusion matrix - DenseNet-169.

In Fig. 7, DenseNet-201 reduces errors compared to DenseNet-169 and presents a stronger diagonal, especially for the Mild Demented and Moderate Demented classes.

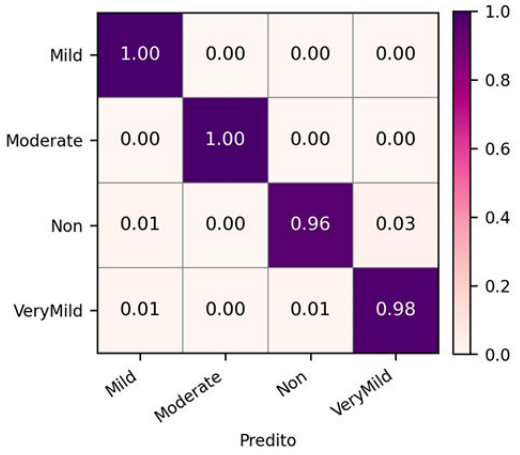

Figure 7. Normalized confusion matrix - DenseNet-201.

In Fig. 8, EfficientNetV2-B2 with TTA maintains high performance across all classes, with minor confusion between Non Demented and Very Mild Demented.

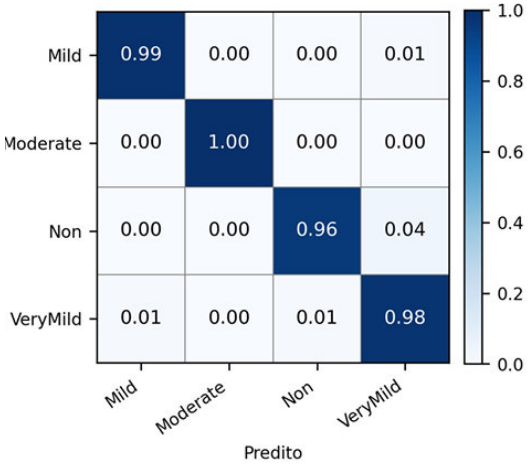

Figure 8. Normalized confusion matrix - EfficientNetV2-B2.

In Fig. 9, Inception-V3 also presents a matrix with high diagonal concentration, demonstrating good generalization capacity across the four classes.

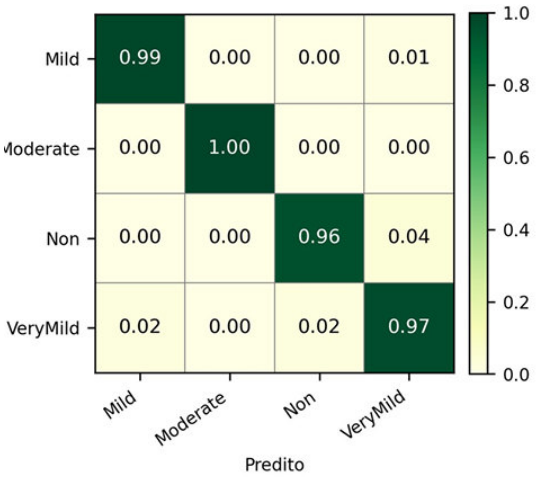

Figure 9. Normalized confusion matrix - Inception-V3.

In Fig. 10, EfficientNetV2-B0 presents near-total correct predictions for Mild and Moderate, but still registers errors between Non Demented and Very Mild Demented.

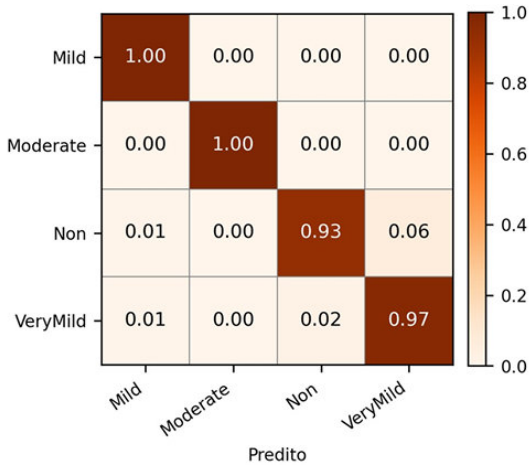

Figure 10. Normalized confusion matrix - EfficientNetV2-B0.

In Fig. 11, the simple soft voting ensemble reduces the errors observed in individual models, strengthening the main diagonal of the confusion matrix.

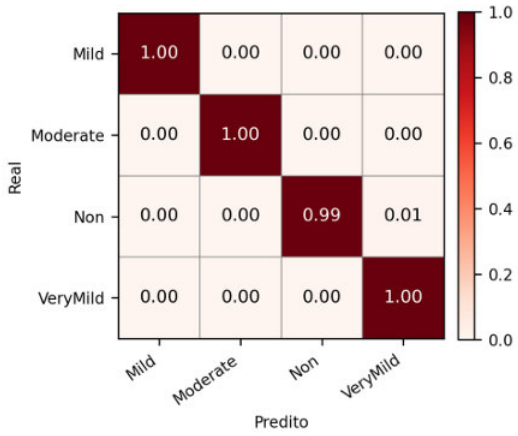

Figure 11. Normalized confusion matrix - Simple ensemble.

In Fig. 12, the weighted ensemble maintains equivalent performance to the simple ensemble, with near-total correct predictions and only minor residual confusion between adjacent classes.

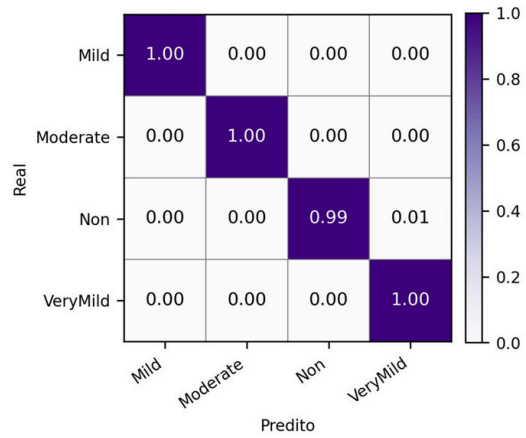

Figure 12. Normalized confusion matrix - Weighted ensemble.

E. External validation

External validation was used as a complementary step to verify model robustness on datasets different from those used in the main training runs. DenseNet-201 achieved a macro F1-score of 0.9856 on 32,000 external images, a performance close to that obtained internally. EfficientNetV2-B2 also maintained high performance, with a macro F1-score of 0.9852 on 8,000 external images.

These results (Table VI) reinforce that the more robust models not only fitted the main dataset but also maintained good generalization capacity on external datasets. Nevertheless, since external datasets may have different distributions, the comparison should be interpreted separately from the internal ranking.

Table VI
EXTERNAL VALIDATION RESULTS.

Model	Imgs.	Acc.	F1
DenseNet-201	32000	0.9843	0.9856
EffNetV2-B2	8000	0.9852	0.9852
EffNetV2-B0	8000	0.9774	0.9773
DenseNet-169	32000	0.9255	0.9289
Inception-V3	28000	0.9169	0.9166

In Fig. 13, the external validation of DenseNet-201 maintains high values on the main diagonal, indicating good generalization to images not used in the main training runs. Residual errors remain concentrated between Non Demented and Very Mild Demented.

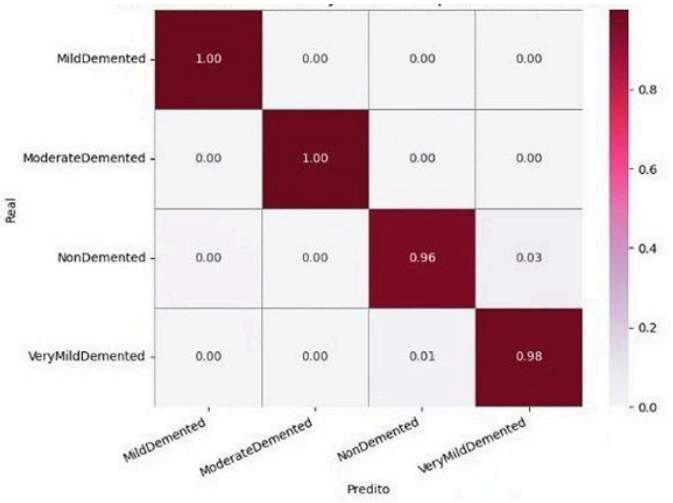

Figure 13. External validation of DenseNet-201.

In Fig. 14, EfficientNetV2-B2 also presents high external performance, with near-total correct predictions for Mild and Moderate classes. The remaining confusions occur mainly between Non and Very Mild, reinforcing that these classes are the most difficult in the problem.

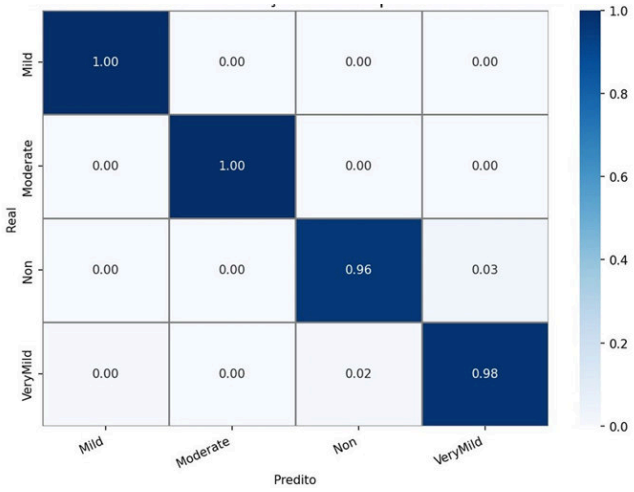

Figure 14. External validation of EfficientNetV2-B2.

F. Error analysis, robustness, and computational cost

Analysis of the confusion matrices revealed a recurring pattern: the Moderate Demented class was recognized with greater stability, while Non Demented and Very Mild Demented concentrated most errors. This difficulty suggests that the visual patterns between the absence of dementia and very mild signs may be close in the images used, requiring more sensitive models and careful validation.

Balancing techniques were not necessarily beneficial. Class weights and Focal Loss aimed to increase model attention to difficult classes, but in some variations there was a drop in macro F1-score. This indicates that artificial class penalization can shift learning and harm classes that were previously classified with greater confidence.

The best improvements occurred when fine-tuning was performed in a controlled manner. Partial fine-tuning allowed adapting the final blocks to the characteristics of MRI images without excessively altering the general representations learned from ImageNet. Full fine-tuning was effective in DenseNet-201 when combined with differentiated learning rates.

The ensemble showed the best overall performance (Table VII), but its use increases computational cost, as it requires loading and running multiple architectures. In real-world applications, this strategy may be indicated when the priority is to maximize performance. For scenarios with time or hardware constraints, the optimized EfficientNetV2-B2 represents a simpler individual alternative with very high performance.

Table VII
SUMMARY OF THE IMPACT OF EVALUATED STRATEGIES.

Technique	**Effect**	**Interpretation**
Controlled fine-tuning	Improved	Adapted to MRI domain
AdamW + regularization	Improved	Reduced overfitting
TTA	Stabilized	Reduced variance
Class weights	Worsened	Excessive penalization
Focal Loss	Worsened	Did not compensate
Ensemble	Best	Combined models

IV. CONCLUSION

This work evaluated multiple pre-trained CNN architectures for classifying four Alzheimer's classes in MRI images. The results demonstrated that simple baselines show limited performance, while transfer learning, fine-tuning, regularization, and TTA strategies significantly increase performance. The best individual model was the optimized EfficientNetV2-B2, with a macro F1-score of 0.9919, and the best overall result was obtained by the ensemble of five models, with a macro F1-score of 0.9959.

As a limitation, it should be noted that part of the experiments used image-level splitting rather than patient-level splitting, which may influence the generalization estimate. Additionally, the ensemble increases inference computational cost. As future work, it is recommended to standardize patient-level validation, broaden the diversity of external datasets, apply explainability techniques, and evaluate the deployment of models in controlled clinical scenarios.

***Abstract*—O câncer renal é uma das neoplasias urológicas de maior mortalidade, com diagnóstico frequentemente tardio. Este trabalho investiga o impacto de duas técnicas de pré-processamento de contraste — CLAHE e correção gama (com fator gama igual a 0,7) — em comparação com a condição base sobre cinco arquiteturas de Redes Neurais Convolucionais com aprendizado por transferência: ResNet-18, ResNet-34, ResNet-50, AlexNet e VGG-16. O conjunto de dados empregado é o CT Kidney Dataset, com 4.566 imagens balanceadas entre as classes Normal e Tumor, divididas nas proporções 60/20/20 para treino, validação e teste. Os resultados demonstram que a correção gama melhora ou mantém estável o desempenho em todas as arquiteturas avaliadas, ao passo que o CLAHE apresenta comportamento inconsistente, reduzindo a acurácia das redes mais rasas. O melhor resultado global foi obtido pela VGG-16 com correção gama, que alcançou 99,12% de acurácia e revocação de 100% para a classe Tumor.**

I. Introdução

O diagnóstico precoce configura-se como elemento determinante para o êxito terapêutico em oncologia, repercutindo de forma direta sobre a sobrevida e o bem-estar dos pacientes [1]. Dentre as neoplasias de maior relevância clínica, o câncer renal destaca-se como a neoplasia urológica de maior letalidade [2], manifestando-se predominantemente em indivíduos na faixa etária de 50 a 70 anos. No Brasil, foram registrados aproximadamente 13.000 novos casos e mais de 4.000 óbitos no ano de 2020 [3]. Não obstante, a inespecificidade sintomatológica nos estágios iniciais, associada à reduzida eficácia das estratégias de rastreamento populacional, compromete a identificação precoce da enfermidade [4]. Em razão disso, parcela considerável dos casos é diagnosticada em fases avançadas, o que restringe de maneira substancial as possibilidades de intervenção terapêutica eficaz.

As consequências desse diagnóstico tardio tornam-se mais graves em virtude do papel essencial exercido pelos rins no organismo, responsáveis por funções como a filtração de metabólitos, a regulação da pressão arterial e a produção de hormônios fundamentais, a exemplo da eritropoietina [5]. À medida que o câncer renal avança, essas funções podem ser severamente comprometidas, tornando necessários tratamentos invasivos como hemodiálise e nefrectomia, podendo a doença evoluir, nos casos mais graves, para o óbito [3]. Como o surgimento de sintomas físicos não pode ser utilizado como parâmetro confiável, uma vez que costumam aparecer apenas quando o órgão já se encontra gravemente comprometido, é fundamental que a investigação médica adote uma postura proativa. Nesse contexto, o desenvolvimento de ferramentas diagnósticas mais precisas, sobretudo aquelas fundamentadas em exames de imagem, configura-se como uma estratégia indispensável [6].

Na prática clínica, a tomografia computadorizada é o principal exame para a detecção e a caracterização de massas renais, frequentemente identificadas de forma incidental. Sua acurácia, contudo, é limitada: uma revisão sistemática de 40 estudos, abrangendo 4.354 pacientes, reportou especificidade mediana de 75% para a TC no diagnóstico do carcinoma de células renais, com intervalo interquartil de 51% a 90% [7]. A dificuldade decorre da sobreposição de características radiológicas: lesões benignas como o angiomiolipoma pobre em gordura e o oncocitoma podem exibir padrões tomográficos semelhantes aos do carcinoma, levando a nefrectomias desnecessárias [8]. Exames amplamente disponíveis, porém de interpretação ambígua, evidenciam a lacuna que métodos computacionais de apoio à decisão podem preencher.

Diante dessa necessidade de métodos diagnósticos mais precisos e objetivos, o aprendizado profundo (*deep learning*) tem se consolidado como uma abordagem promissora para a análise automatizada de imagens médicas [9]. Dentre essas técnicas, as Redes Neurais Convolucionais (CNNs) destacam-se pela capacidade de extrair automaticamente características discriminativas a partir de dados visuais, identificando padrões sutis frequentemente imperceptíveis ao olho humano [10]. No contexto específico do câncer renal, modelos baseados em CNNs vêm sendo empregados em tarefas como a segmentação de rins e lesões tumorais [11] e a classificação de massas renais em exames de tomografia computadorizada [8], [12], contribuindo para diagnósticos mais rápidos e menos dependentes

da experiência subjetiva do especialista.

Apesar dos recentes avanços, a eficácia das CNNs na classificação de imagens médicas permanece fortemente condicionada à qualidade dos dados de entrada. Em exames de tomografia computadorizada, fatores como baixo contraste entre tecidos e a presença de ruído podem comprometer a extração de características relevantes pelos modelos, impactando negativamente o desempenho diagnóstico. Diante disso, técnicas de pré-processamento de imagem surgem como uma estratégia promissora para mitigar essas limitações, sendo capazes de realçar estruturas anatômicas e regiões de interesse antes da etapa de classificação. Contudo, ainda são escassos os estudos que avaliam de forma sistemática o impacto desse tipo de pré-processamento sobre diferentes arquiteturas de CNNs aplicadas à classificação de massas renais, especialmente quando se compara o desempenho de modelos consolidados, como as variantes da família ResNet [13].

Dentre as técnicas de pré-processamento disponíveis, destacam-se o CLAHE (*Contrast Limited Adaptive Histogram Equalization*) [14] e a correção gama [15], amplamente empregadas para aprimorar a qualidade visual de imagens médicas. Enquanto o CLAHE promove o realce local do contraste, preservando detalhes anatômicos e limitando a amplificação de ruídos, a correção gama atua sobre a distribuição de intensidades dos pixels, possibilitando evidenciar regiões de interesse por meio do ajuste não linear do brilho. Essas características tornam ambas as técnicas particularmente adequadas para exames de tomografia computadorizada, nos quais a distinção entre tecidos renais saudáveis e regiões tumorais depende de sutis variações de contraste. Nesse contexto, o presente trabalho propõe uma análise comparativa do desempenho de cinco arquiteturas de CNNs — ResNet-18, ResNet-34, ResNet-50, AlexNet e VGG-16 — em três cenários de pré-processamento: sem realce de contraste, com aplicação de CLAHE e com aplicação de correção gama, visando quantificar o impacto dessas técnicas sobre a capacidade de classificação dos modelos e contribuir para o desenvolvimento de uma ferramenta clínica de apoio ao diagnóstico precoce do câncer renal.

O restante deste artigo está organizado da seguinte forma: a Seção II apresenta trabalhos relacionados; a Seção III descreve os materiais e métodos; a Seção IV apresenta e discute os resultados; a Seção V conclui o trabalho.

II. Trabalhos Relacionados

A utilização de redes neurais convolucionais para classificação de imagens médicas renais tem recebido crescente atenção na literatura, com diferentes grupos propondo abordagens baseadas em aprendizado profundo e aprendizado por transferência. Os trabalhos a seguir representam contribuições diretamente relacionadas ao problema investigado neste artigo.

Santos et al. [2] propuseram um sistema de classificação de câncer renal em imagens de tomografia computadorizada baseado em CNNs com aprendizado por transferência. O sistema utiliza o CT Kidney Dataset, composto por imagens das classes Normal e Tumor, com divisão estratificada em conjuntos de treino, validação e teste. O pré-processamento limitou-se à conversão das imagens para escala de cinza em 8 bits, sem aplicação de técnicas adicionais de realce de contraste.

Rajkumar et al. [16] propuseram a detecção de câncer renal utilizando modelos de aprendizado profundo a partir de imagens da mesma base Kaggle. O modelo CNN desenvolvido atingiu acurácia de treinamento de 96,4% e acurácia de validação de 99,6%.

Alzu'bi et al. [17] avaliaram arquiteturas como VGG-16, ResNet-50, CNN-6 e CNN-4 para detecção e classificação de tumores renais em tomografias. O melhor resultado foi obtido pelo modelo CNN-4, com 97,70% de acurácia. O trabalho enfatiza a importância da qualidade do pré-processamento para o desempenho dos classificadores.

Hadjiyski [18] empregou a rede Inception V3 para estadiamento de câncer renal utilizando imagens de TC em 3D, das quais fatias 2D foram extraídas. Após 4.000 épocas de treinamento, a acurácia atingiu 97% no treino e 90% no teste.

Diferentemente dos trabalhos citados, o presente estudo conduz um experimento fatorial controlado entre técnicas de pré-processamento e arquiteturas CNN, com protocolo de divisão de dados replicável e semente fixada.

III. Materiais e Métodos

A Fig. 1 apresenta uma visão geral da metodologia adotada, composta por cinco etapas: (*i*) organização do *dataset* em treino, validação e teste; (*ii*) aplicação das condições de pré-processamento (Base, CLAHE e Gama); (*iii*) extração de características pelas arquiteturas CNN avaliadas; (*iv*) classificação binária entre Normal e Tumor; e (*v*) avaliação por métricas de desempenho. Cada etapa é detalhada nas subseções a seguir.[1]

A. Conjunto de Dados

O conjunto de dados utilizado é o *CT Kidney Dataset: Normal-Cyst-Tumor and Stone* [19], disponível na plataforma Kaggle. O dataset contém 12.446 imagens únicas de tomografia computadorizada distribuídas em quatro classes: cistos (3.709), rins normais (5.077), pedras (1.377) e tumor (2.283). Para este trabalho, foram utilizadas apenas as classes *Normal* e *Tumor*.

B. Arquiteturas de CNNs

Foram avaliadas cinco arquiteturas de CNNs pré-treinadas na base ImageNet, todas consolidadas na literatura de visão computacional. Em todos os modelos adotou-se a estratégia de aprendizado por transferência: as camadas convolucionais, responsáveis pela extração de características, foram mantidas congeladas com os pesos pré-treinados, e apenas a camada de classificação final foi substituída por uma nova camada totalmente conectada com duas saídas, correspondentes às classes Normal e Tumor, sendo a única treinada para a tarefa em questão.

[1]O código-fonte completo dos experimentos — incluindo os *scripts* de organização do conjunto de dados, pré-processamento, treinamento e avaliação — está disponível publicamente em https://github.com/thiagocordeirum/kidney-ct-cnn-classification.

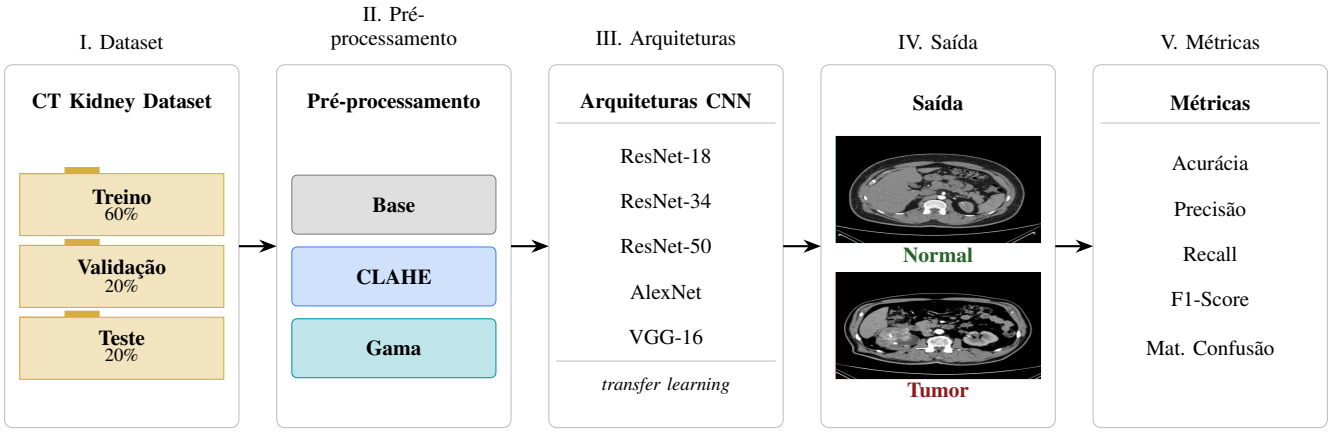

Fig. 1. Diagrama geral da metodologia proposta.

As redes da família *ResNet* (*Residual Neural Network*) foram introduzidas por He et al. [13] em 2016 e caracterizam-se pelo empilhamento de blocos residuais com conexões de atalho, que somam a entrada de um bloco diretamente à sua saída. Esse mecanismo viabiliza o treinamento de redes muito profundas sem a degradação provocada pelo desaparecimento do gradiente. Neste trabalho foram avaliadas três profundidades: a ResNet-18 e a ResNet-34, com 18 e 34 camadas organizadas em blocos residuais simples, e a ResNet-50, com 50 camadas estruturadas em blocos do tipo gargalo, que ampliam a capacidade de representação com menor custo computacional.

A *AlexNet* [20], vencedora do desafio ImageNet de 2012 por ampla margem, é composta por cinco camadas convolucionais seguidas de três camadas totalmente conectadas. Foi a primeira arquitetura a demonstrar a viabilidade da extração automática de características em larga escala, rompendo o paradigma dos descritores projetados manualmente, e introduziu o uso da função de ativação ReLU e o treinamento acelerado por unidades de processamento gráfico.

A *VGG-16* [21], desenvolvida por Simonyan e Zisserman na Universidade de Oxford, deve seu nome ao grupo *Visual Geometry Group*. Sua principal característica é a profundidade obtida pelo empilhamento sucessivo de pequenos filtros convolucionais de tamanho 3×3, totalizando 16 camadas com pesos — 13 convolucionais e três totalmente conectadas. Originalmente projetada para classificar imagens em até mil categorias, recebe imagens na resolução de 224×224 pixels.

C. Critérios de Inclusão e Exclusão

Foram incluídas as classes *Normal* e *Tumor*, excluindo-se *Cisto* e *Pedra* por não serem relevantes ao objetivo de discriminação entre tecido renal saudável e tumoral. Para garantir equilíbrio entre as classes, foram selecionadas aleatoriamente 2.283 imagens da classe Normal (correspondendo ao total disponível da classe Tumor), totalizando 4.566 imagens. O conjunto balanceado foi dividido de forma estratificada nas proporções de 60% treino (2.738 imagens), 20% validação (914 imagens) e 20% teste (914 imagens), com semente aleatória s=42 para reprodutibilidade. A Fig. 1 ilustra o fluxo completo desde a seleção dos dados até a avaliação.

D. Pré-processamento

Foram avaliadas três condições de pré-processamento, mantendo um grupo base sem realce de contraste para fins de comparação.

Base (sem realce). As imagens são convertidas para escala de cinza em 8 bits e replicadas nos três canais RGB para compatibilidade com os pesos pré-treinados no ImageNet.

CLAHE (*Contrast Limited Adaptive Histogram Equalization*). Técnica que divide a imagem em $M_x\times M_y$ *tiles* locais e equaliza o histograma de cada *tile* com limitação do contraste máximo. Seja $I:\Omega\to\{0,\dots,L{-}1\}$ uma imagem com N pixels e $L=256$ níveis, o histograma normalizado é:

$$p(r)=\frac{h(r)}{N},\quad r\in\{0,\dots,L-1\}. \tag{1}$$

A equalização global obtém a CDF $F(r)=\sum_{s=0}^{r}p(s)$ e aplica $T(r)=\lfloor(L{-}1)\cdot F(r)\rfloor$. Na CLAHE, o histograma local de cada *tile* $\mathcal{T}_{ij}$ é recortado no limite $C=\beta\,N_t/L$, em que $N_t=w\,h$ é o número de pixels do *tile* e β o fator de recorte de contraste:

$$h_c(r)=\min\big(h_{ij}(r),\,C\big), \tag{2}$$

sendo o excesso redistribuído uniformemente antes da equalização local, com interpolação bilinear nas bordas dos *tiles*. Neste trabalho adotou-se fator de recorte β=2,0 e divisão da imagem em uma grade de 8×8 *tiles* [14].

Correção Gama. Aplica um mapeamento não-linear pixel a pixel:

$$I_{\text{out}}(x,y)=\left(\frac{I_{\text{in}}(x,y)}{255}\right)^{\gamma}\times\,255, \tag{3}$$

com γ=0,7. Para $\gamma<1$, a curva clareia seletivamente regiões escuras sem saturar as já contrastadas, evidenciando padrões texturais de baixo contraste característicos de massas tumorais em TC [15].

Após a técnica selecionada, todas as imagens seguem o mesmo fluxo final: conversão para RGB, redimensionamento para 224×224 px e normalização canal a canal com os parâmetros ImageNet:

$$\tilde{x}_c = \frac{x_c - \mu_c}{\sigma_c}, \quad c \in \{R, G, B\}, \tag{4}$$

com $\boldsymbol{\mu}$=[0,485, 0,456, 0,406] e $\boldsymbol{\sigma}$=[0,229, 0,224, 0,225].

E. Parâmetros de Treinamento e Avaliação

O treinamento foi conduzido por 100 épocas, com otimizador Adam, taxa de aprendizado de $1{,}0 \times 10^{-4}$, lote de 32 amostras e semente aleatória s=42. Como função de perda adotou-se a entropia cruzada (*Cross-Entropy*) com duas saídas, sendo a predição final dada pela classe de maior probabilidade. Os pesos correspondentes à época de maior acurácia de validação foram retidos e empregados na avaliação sobre o conjunto de teste.

F. Avaliação dos Modelos

Os modelos foram avaliados no conjunto de teste (914 amostras), com classe positiva definida como Tumor (TP: verdadeiros positivos; TN: verdadeiros negativos; FP: falsos positivos; FN: falsos negativos):

$$\text{Acurácia} = \frac{TP + TN}{TP + TN + FP + FN}, \tag{5}$$

$$\text{Precisão} = \frac{TP}{TP + FP}, \tag{6}$$

$$\text{Recall} = \frac{TP}{TP + FN}, \tag{7}$$

$$F_1 = 2 \cdot \frac{\text{Precisão} \times \text{Recall}}{\text{Precisão} + \text{Recall}}, \tag{8}$$

$$\mathcal{L}(y, \hat{p}) = -\sum_{c \in \{0,1\}} y_c \log \hat{p}_c. \tag{9}$$

Adicionalmente, foram analisadas matrizes de confusão e curvas de acurácia e perda por época para as condições CLAHE e Gama.

G. Recursos Computacionais

Os experimentos foram executados em um servidor equipado com o NVIDIA GB10 Grace Blackwell Superchip, que integra processador ARM Cortex-X925 (10 núcleos) e Cortex-A725 (10 núcleos) com 128 GB de memória unificada compartilhada entre CPU e GPU, eliminando transferências explícitas entre os dois componentes. O ambiente de software utilizou Python 3.10.20, PyTorch 2.12.0, TorchVision 0.27.0 (ambos com suporte a CUDA 13.0), OpenCV, NumPy, Pandas, Scikit-Learn e Matplotlib.

TABLE I
MÉTRICAS NO CONJUNTO DE TESTE (914 AMOSTRAS)

Modelo	Cond.	Acc. (%)	Prec. (%)	Rec. (%)	F1 (%)
ResNet-18	Base	96,94	**97,35**	96,50	96,92
	CLAHE	95,19	95,38	94,97	95,18
	Gama	**97,48**	97,17	**97,81**	**97,49**
ResNet-34	Base	95,19	95,58	94,75	95,16
	CLAHE	95,40	95,21	**95,62**	95,41
	Gama	**96,06**	**97,30**	94,75	**96,01**
ResNet-50	Base	95,73	95,43	96,06	95,75
	CLAHE	96,06	**96,67**	95,40	96,04
	Gama	**96,50**	96,50	**96,50**	**96,50**

	CLAHE	98,36	**99,11**	97,59	98,35
	Gama	**99,12**	98,28	**100,00**	**99,13**

IV. RESULTADOS E DISCUSSÃO

A. Resultados no Conjunto de Teste

A Tabela I apresenta as métricas de teste dos 15 experimentos. Resultados em negrito indicam o melhor valor por modelo.

B. Impacto do Pré-processamento

Arquiteturas ResNet. A correção gama (γ=0,7) beneficiou consistentemente todas as arquiteturas ResNet, com ganhos de $+0{,}54$ p.p. (ResNet-18), $+0{,}87$ p.p. (ResNet-34) e $+0{,}77$ p.p. (ResNet-50) sobre a condição base. O mapeamento não linear da (3) clareia regiões escuras correspondentes a tecido tumoral de baixo contraste espontâneo, evidenciando padrões que os blocos residuais exploram com maior eficiência. O CLAHE produziu queda de $-1{,}75$ p.p. na ResNet-18 e ganhos discretos nas demais ($+0{,}21$ p.p. na ResNet-34 e $+0{,}33$ p.p. na ResNet-50), sugerindo que os artefatos de borda entre *tiles* perturbam sobretudo as ativações das primeiras camadas convolucionais das redes mais rasas.

AlexNet e VGG-16. AlexNet e VGG-16 atingiram $98{,}91\%$ na condição base, superando as ResNets (entre 95% e 97%). O CLAHE causou queda de $-1{,}75$ p.p. na AlexNet ($97{,}16\%$) e queda menor de $-0{,}55$ p.p. na VGG-16 ($98{,}36\%$). A correção gama, por ser uma transformação monotônica suave, elevou o desempenho de ambas: a AlexNet atingiu $99{,}02\%$ e a VGG-16 alcançou **99,12%**, melhor resultado global do experimento, com revocação de 100% na classe Tumor. O comportamento é atribuído ao classificador denso de três camadas totalmente conectadas presente em ambas as redes: o CLAHE altera a distribuição de ativações de forma incompatível com os padrões aprendidos na base ImageNet, enquanto a correção gama preserva a ordem relativa das intensidades.

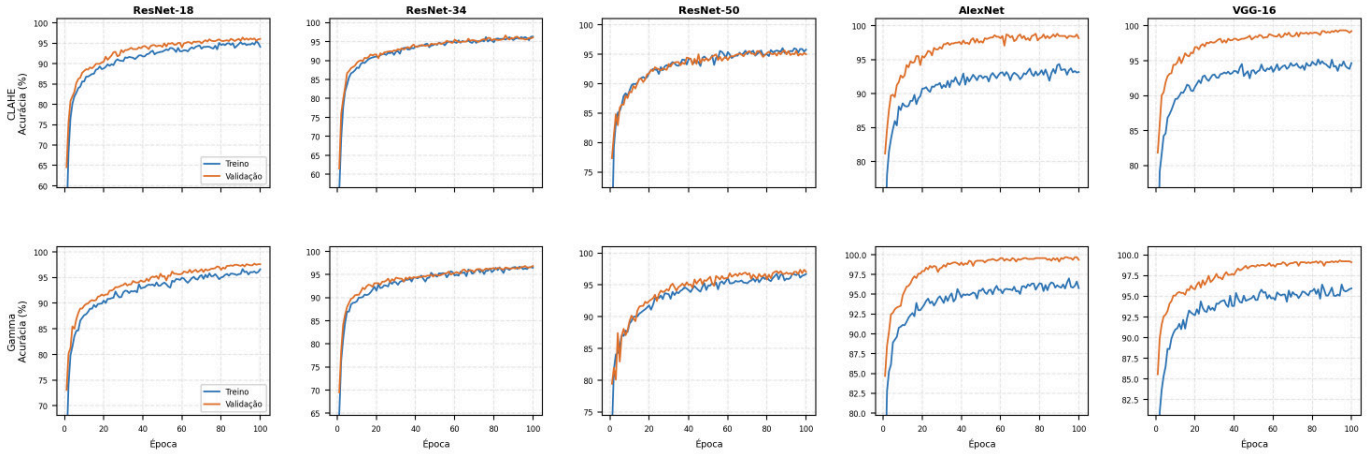

Fig. 2. Curvas de acurácia por época (100 épocas). Linha azul: treino. Linha laranja: validação. Linha superior: condição CLAHE. Linha inferior: condição Gama.

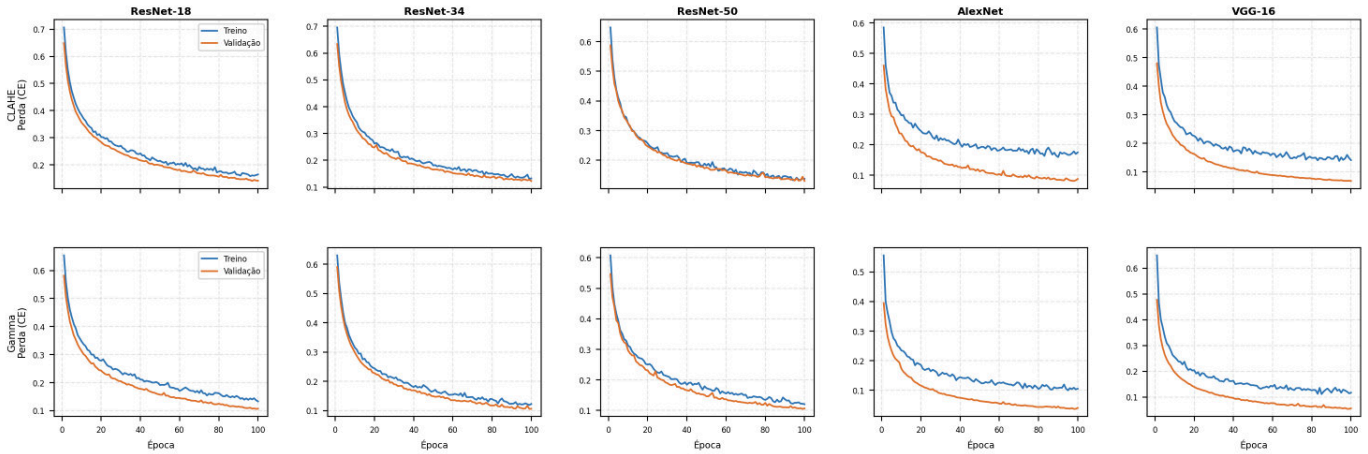

Fig. 3. Curvas de perda (*Cross-Entropy*) por época. Linha azul: treino. Linha laranja: validação. Linha superior: CLAHE. Linha inferior: Gama.

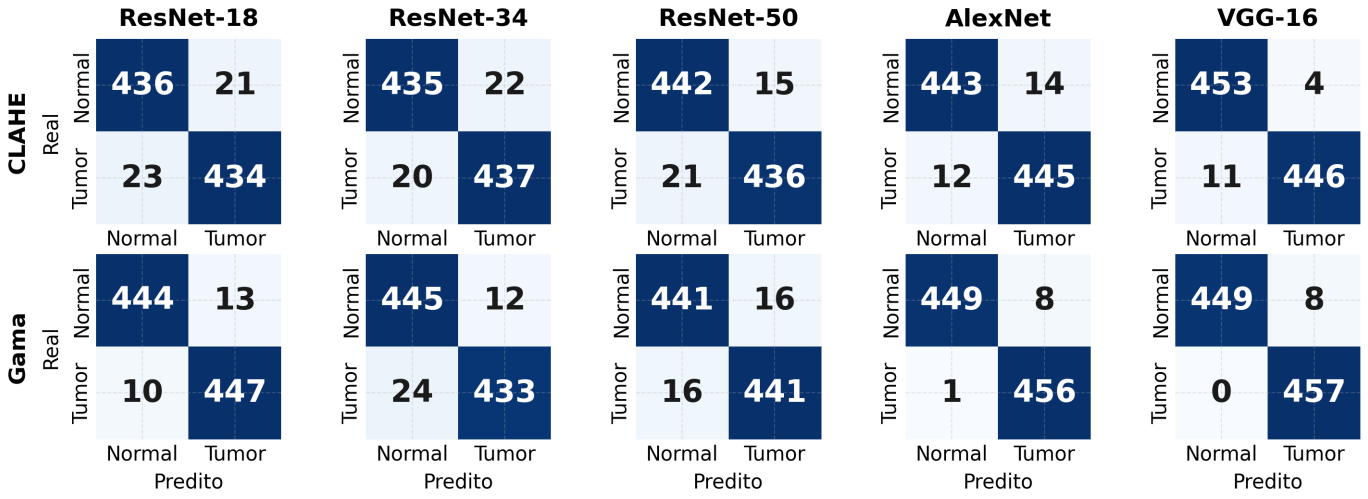

Fig. 4. Matrizes de confusão no conjunto de teste (914 amostras). Linha superior: CLAHE. Linha inferior: Gama. Colunas: ResNet-18, ResNet-34, ResNet-50, AlexNet, VGG-16.

C. Curvas de Treinamento

As Figs. 2 e 3 mostram as curvas de acurácia e perda por época para as condições CLAHE e Gama. Para as ResNets, o Gama antecipa a convergência e eleva o *plateau* de validação, enquanto o CLAHE apresenta maior variabilidade nas épocas intermediárias. Para AlexNet e VGG-16, ambas as condições alcançam acurácias elevadas nas primeiras épocas, evidenciando a eficácia do *transfer learning* mesmo com *backbone* congelado. Em todas as arquiteturas, o reduzido intervalo entre as curvas de treino e validação indica boa capacidade de generalização, sem sinais expressivos de sobreajuste ao longo das 100 épocas avaliadas.

D. Matrizes de Confusão

A Fig. 4 apresenta as matrizes de confusão no conjunto de teste para todas as combinações modelo $\times$ condição (CLAHE e Gama). Para as ResNets, o Gama reduz os falsos negativos (Tumor classificado como Normal) em relação ao CLAHE, propriedade clinicamente relevante em rastreamento oncológico, uma vez que erros nessa direção correspondem a diagnósticos perdidos. AlexNet e VGG-16 apresentam erros próximos de zero na condição base e resultados competitivos com o Gama; em particular, a VGG-16 com correção gama atingiu revocação de 100% na classe Tumor, eliminando completamente os falsos negativos no conjunto de teste.

V. Conclusão

Este trabalho investigou sistematicamente o impacto das técnicas de pré-processamento CLAHE e correção gama sobre o desempenho de cinco arquiteturas CNN na classificação de câncer renal em imagens tomográficas.

A correção gama com $\gamma{=}0{,}7$ demonstrou ser a técnica de pré-processamento mais consistente entre as avaliadas, sendo a única que beneficiou todas as cinco arquiteturas sem exceção: os ganhos variaram de $+0{,}11$ p.p. na AlexNet a $+0{,}87$ p.p. na ResNet-34. O melhor resultado global foi obtido pela VGG-16 com correção gama, que alcançou $99{,}12\%$ de acurácia e revocação de 100% na classe Tumor, evidenciando o potencial da técnica para reduzir falsos negativos em cenários de rastreamento oncológico.

O CLAHE, por sua vez, apresentou comportamento variável: reduziu o desempenho da ResNet-18 e da AlexNet em $-1{,}75$ p.p. cada, enquanto produziu ganhos discretos nas ResNets mais profundas. Esse comportamento sugere que a equalização adaptativa por *tiles* pode introduzir artefatos de borda incompatíveis com os filtros aprendidos na base ImageNet, com impacto mais acentuado em redes com menor profundidade ou maior sensibilidade à distribuição de intensidades.

Como trabalhos futuros, propõe-se avaliar diferentes valores de γ por arquitetura, estender a classificação para as classes Cisto e Pedra presentes no dataset, e investigar estratégias de ajuste fino parcial das camadas convolucionais.

Agradecimentos

Os autores agradecem ao Laboratório LSI pela disponibilização dos recursos computacionais utilizados na condução dos experimentos, sem os quais o treinamento das arquiteturas avaliadas não seria viável no escopo deste trabalho.

***Abstract*—Parkinson's disease is a progressive and incurable neurodegenerative disease that affects millions of people worldwide. Its diagnosis is often time-consuming and expensive, especially in the early stages, which can delay appropriate medical intervention. To increase the accuracy and efficiency of Parkinson's diagnosis, a multi-agent system that leverages machine learning techniques — Random Forest, Neural Networks, and Logistic Regression — was implemented along with optimization methods, including LoRA and Knowledge Distillation. In addition, judging agents were employed to evaluate and compare the results, allowing a voting mechanism to determine the final decision. At the end of the process, it was possible to obtain a 50% reduction in training time when using the LoRA and Knowledge Distillation methods, with only the models that use Logistic Regression having a significant difference in training times. In addition, the accuracy of the methods always remains within a margin of 0.1 either way in all processes, which indicates that, even with the reduction in size for optimization, the models are able to maintain good results. This methodology facilitates the automated selection of the most effective diagnostic approaches, as evidenced by the weighted averages of the agents applied to different data types. Despite initial inefficiencies in identifying Healthy cases, the final aggregated result demonstrates improved diagnostic performance. Consequently, the proposed approach offers a scalable and adaptable solution for the diagnosis of Parkinson's disease, especially in resource-limited settings, highlighting its potential for broader clinical applications.**

***Index Terms*—Multi-Agent, Parkinson's Disease, LoRA, Knowledge Distillation, Random Forest, Neural Network, Logistic Regression**

I. Introduction

According to the World Health Organization (WHO) [1], in 2019, approximately 8.5 million individuals were diagnosed with Parkinson's disease (PD), with an observed increase of over 80% in PD-related mortality since 1990. This trend establishes PD as the fastest-growing neurological disorder worldwide. Furthermore, the WHO emphasizes that Parkinson's disease remains incurable, with available treatments limited to alleviating symptoms and improving patients' quality of life. However, these treatments are not only highly expensive but also incapable of halting disease progression. To address this critical issue, in 2022, the WHO approved a global initiative to promote research efforts focused on Parkinson's disease.

In alignment with this initiative, the present study employs a multi-agent system to enhance the prediction of Parkinson's disease. Four distinct machine learning models were utilized: Random Forest [2], Multi-Layer Perceptron (MLP) Classifier [3], and Logistic Regression [4], each integrated with Principal Component Analysis (PCA) [5] for dimensionality reduction.

Advancements in Parkinson's disease progression prediction have been achieved by integrating diverse data modalities, including clinical, genetic, biomarker, and neuroimaging information. Lei et al. [6] proposed a feature selection model that combines structural magnetic resonance imaging (sMRI) and diffusion tensor imaging (DTI) to predict clinical scores in PD patients. Their methodology, based on sparse multimodal machine learning, demonstrated superior performance compared to single-modality approaches, particularly in predicting sleep disturbances and olfactory impairments. This underscores the efficacy of multimodal data integration in PD prognosis.

Sandhiya et al. [7] investigated PD prediction using motor and speech patterns, employing image processing techniques alongside Random Forest classification. While their model achieved promising accuracy in distinguishing PD patients from healthy individuals, its reliance on a limited set of motor-based features restricts its applicability for disease progression prediction. This study highlights both the potential and limitations of machine learning approaches in PD diagnostics.

Jiang et al. [8] conducted a comprehensive review on multimodal data integration for PD progression prediction, demonstrating that combining multiple data sources significantly enhances predictive accuracy compared to single-modality models. However, they identified key challenges, including data heterogeneity and the necessity for advanced data fusion techniques. Despite these obstacles, such as high computational costs and the requirement for extensive labeled datasets, the study emphasizes the importance of robust, integrative modeling strategies.

The use of an intelligent multi-agent ecosystem in the diagnosis of Parkinson's disease holds great promise, as it enables the integration of data from multiple sources, such as imaging exams, clinical records, and motion sensors, providing a more

precise and comprehensive analysis of the patient's condition. Multi-agent systems play a crucial role in early detection by analyzing motor patterns, interpreting neurological exams, and evaluating therapeutic responses, making the diagnosis faster and more reliable. Recent advances in AI [9], including deep learning for medical imaging and sensor-based monitoring, have further enhanced these capabilities, enabling continuous symptom tracking and improved diagnostic accuracy.

With this adaptive approach, treatments can be personalized in real time, optimizing interventions and improving patients' quality of life. However, challenges remain in integrating heterogeneous data sources and ensuring model interpretability.

Accordingly, this research aims to address these challenges by developing predictive models for early PD diagnosis and treatment optimization. By leveraging advanced machine learning techniques and multimodal data integration, this study not only contributes to the scientific community but also has significant practical implications, facilitating improved clinical decision-making and patient outcomes.

II. Database:

For the execution of this project, the dataset was sourced from the Image and Data Archive (IDA)[1], managed by the Laboratory of Neuro Imaging (LONI) at the USC Mark and Mary Stevens Neuroimaging and Informatics Institute. From this repository, patient information, biospecimens, family history, and polygenic risk scores were extracted for analysis.

This dataset presented two major challenges: a significant amount of missing data and a pronounced class imbalance between instances labeled as Parkinson's Disease and Not Parkinson.

To address the issue of missing data, the K-Nearest Neighbors (KNN) imputation technique was applied. This method operates under the assumption that similar values are spatially close to one another in a multidimensional space. For each missing entry, the algorithm identifies the closest neighbors based on the Euclidean distance and imputes the missing value using a weighted average, mode, or median—whichever is most appropriate. This approach preserves valuable information and increases the number of usable samples, as opposed to simply discarding incomplete rows.

To mitigate the class imbalance, the SMOTEENN (Synthetic Minority Over-sampling Technique combined with Edited Nearest Neighbors) method was employed. This approach integrates SMOTE, which generates synthetic samples for the minority class, with ENN, which removes noisy or borderline instances from the majority class. The application of this technique significantly improved the class distribution across all three data types, as illustrated in Figures 1, 2, and 3.

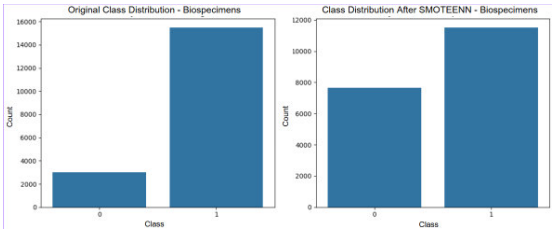

Fig. 1. Biospecimens Class Balance Comparison

Fig. 2. Biospecimens Class Balance Comparison

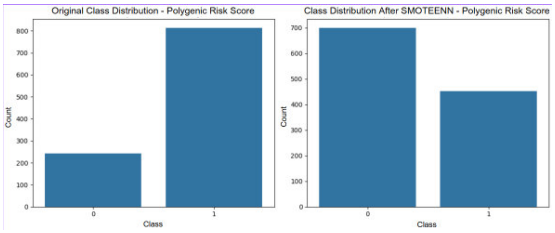

Fig. 3. Polygenic Risk Score Class Balance Comparison

A. Patient Information

This dataset segment categorizes patients into four groups: Healthy Control (HC), SWEDD (Scans Without Evidence of Dopamine Deficit), Prodromal (individuals in the early stages of Parkinson's disease), and Parkinson's Disease (PD) patients.

The SWEDD group [10] comprises individuals who, despite being clinically diagnosed with Parkinson's disease, do not exhibit abnormalities in neuroimaging exams. There is ongoing debate regarding these cases—some researchers suggest that different neurological disorders may be responsible for the diagnosis, while others propose that SWEDD represents a benign variant of Parkinson's disease. However, there is no consensus on a definitive classification. To avoid potential controversy, IDs associated with SWEDD were excluded from this study.

Since the objective of this research was to develop a classification system capable of distinguishing between "Parkinson's" and "Non-Parkinson's" cases, patients in the Healthy Control and Prodromal groups were categorized as "Non-Parkinson's," whereas individuals in the Parkinson's Disease group were classified as "Parkinson's."

B. Biospecimens

The biospecimen data used in this study were obtained through laboratory tests, for the collection of samples of whole

blood, plasma, serum, cerebrospinal fluid (CSF) and urine. In addition, some information is also provided, such as the last date of sample collection and identification of the collection phase. This information is extremely important, because by analyzing it, it is possible to identify biomarkers, among others. Finally, it is worth highlighting that this is one of the main tests for the early detection of Parkinson's, since plasma and serum can contain proteins and metabolites that indicate neurodegeneration, and cerebrospinal fluid (CSF) can be analyzed for biomarkers, which are directly associated with the progression of the disease.

C. Family History

Family history data included information on whether any family members of the participants had neurological conditions of interest, particularly Parkinson's disease and other brain-related disorders. This dataset aimed to assess the hereditary and genetic predisposition associated with PD.

D. Polygenic Risk Score (PRS)

The polygenic risk score (PRS) is a statistical measure that evaluates the genetic predisposition of an individual to develop complex diseases, such as Parkinson's disease. PRS integrates the cumulative effects of multiple genetic variants to quantify an individual's genetic susceptibility to PD, facilitating a more comprehensive risk assessment.

This structured dataset forms the foundation for the predictive modeling framework developed in this study, enabling the integration of multimodal patient data for enhanced Parkinson's disease classification and progression prediction.

III. Methodology

The project was developed using Python 3. A multi-agent system was implemented, structured into four processing layers.

The first layer focuses on data preprocessing, primarily aiming to optimize the training of the Machine Learning models that constitute the second layer. The third and fourth layers consist of evaluation agents responsible for assessing the performance of the models and making a final classification decision—determining whether a patient has Parkinson's disease or is healthy. This workflow is illustrated in Figure 4.

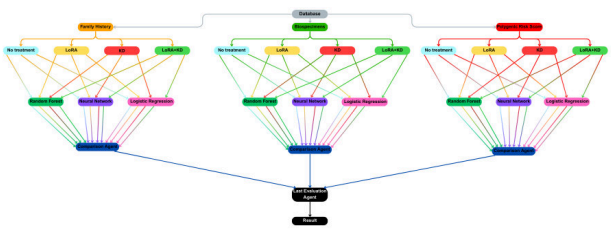

Fig. 4. Workflow

A. Machine Learning and Optimization Agents

As the primary objective of this project is to employ multi-agent systems for the prediction of Parkinson's disease, Machine Learning (ML) plays a fundamental role in achieving accurate and reliable results. To comprehensively address this challenge, four distinct ML models were implemented.

The first selected model was Random Forest [2], a machine learning algorithm that enhances predictive accuracy by aggregating multiple decision trees. It utilizes a technique known as bootstrap aggregation (bagging), in which each decision tree is trained on a randomly selected subset of the dataset. This approach generates a diverse ensemble of decision trees, increasing model robustness and reducing overfitting to the training data.

The second selected model was the MLPClassifier [3], based on a Multi-Layer Perceptron (MLP) Neural Network, a widely used artificial neural network architecture for supervised classification tasks. The implemented network consisted of three hidden layers with 200, 150, and 100 neurons, respectively, allowing the model to capture complex patterns within the dataset.

The activation function selected for this model was the Rectified Linear Unit (ReLU), which introduces non-linearity into the network, enabling it to learn and model complex relationships within the data. Mathematically, the ReLU function is defined as:

$$f(x) = \max(0, x)$$

This means that if the input x is positive, the function returns x, while if x is negative, it outputs zero. The ReLU function was chosen over alternatives like the sigmoid or hyperbolic tangent (tanh) functions due to several advantages. Unlike the sigmoid, which suffers from the vanishing gradient problem—where gradients become extremely small for large or small input values, slowing down training, ReLU maintains a constant gradient for positive inputs, allowing faster learning. Also while the tanh function centers its outputs around zero, it still exhibits saturation effects for extreme input values, leading to slow convergence.

In summary, ReLU was chosen for this model because it helps mitigate the problem of exploding gradients, which can occur in deep networks trained with backpropagation, avoids the vanishing gradient issue, and allows the network to learn more complex patterns effectively. In the context of Parkinson's disease diagnosis, these advantages are particularly relevant, as the model needs to capture subtle patterns across multimodal data, such as genetic markers, clinical records, and neuroimaging features.

The third approach employed a combination of Principal Component Analysis (PCA) [5] and Logistic Regression [4]. PCA is a dimensionality reduction technique that transforms a set of potentially correlated variables into a smaller set of uncorrelated ones, known as principal components, while preserving most of the original information.

After applying PCA, Logistic Regression is used to establish the relationship between the extracted principal components

and the target classes. As a linear classifier, Logistic Regression estimates the probability of a sample belonging to a particular class using the sigmoid function, which plays a fundamental role in converting linear outputs into probability scores. The sigmoid function is defined as:

$$\sigma(x) = \frac{1}{1 + e^{-x}}$$

This function maps any real-valued number to a range between 0 and 1, making it particularly effective for probability estimation. By compressing input values into a bounded interval, it facilitates clear differentiation between distinct classes in a classification task. In the context of Parkinson's disease diagnosis, this property is crucial, as the model needs to distinguish between patients with Parkinson's and those without the disease based on extracted features.

The use of Logistic Regression with the sigmoid function allows the model to output probability scores, that is interpreted as the likelihood of an individual having Parkinson's. This probabilistic interpretation is particularly valuable in medical applications, as it enables clinicians to assess the confidence of predictions rather than relying on rigid binary classifications.

The fundamental distinction between these models lies in the optimization techniques applied. Each algorithm leverages a different computational strategy to extract patterns from the data, ensuring robust and complementary predictive capabilities. The following section further details the comparative evaluation of these methodologies and their respective performance metrics.

1) Base Model Agent: This agent executes the Machine Learning models without any optimization techniques. Its primary purpose is to serve as a baseline model, enabling direct comparison with the optimized agents to assess their effectiveness in improving predictive performance.

2) Knowledge Distillation Agent: Knowledge Distillation [11] is an optimization technique designed to capture complex patterns within the data, thereby enhancing predictive accuracy. This approach is particularly beneficial for neural networks, as they excel in extracting intricate data representations. Similarly, PCA + Logistic Regression benefits from this method by leveraging the distilled knowledge to improve classification performance.

A key advantage of using Knowledge Distillation in this project is its ability to handle imbalanced data, as it provides richer information about class distribution through soft targets. This helps mitigate issues related to biased model training when working with unbalanced datasets.

In the medical field, Knowledge Distillation has been successfully applied to improve disease classification models. Hoang et al. [12] proposed an efficient approach for tuberculosis diagnosis using Knowledge Distillation to transfer knowledge from a complex ensemble of models to a more lightweight and efficient neural network, achieving high classification accuracy while reducing computational cost.

3) LoRA Agent: LoRA (Low-Rank Adaptation of Large Language Models) [13] is a technic to adapt pre-trained models, the mainly idea is to adjust an existing model to a new task or dataset without modifying all of its parameters, but by adding a small number of new parameters that capture the necessary adaptations. Initially it was made by Larguege Language Models (LLMs), but it also can be useful on other types of Machine Learning models. On the project's code, LoRA is responsable for is responsible for making the code more robust and faster, as well as helping with data balancing.

In the healthcare field, LoRA has already shown promising results in improving model performance for real-world medical applications. For example, Gagnon et al. [14] used LoRA to predict vital signs in sepsis patients in intensive care units, helping time-series models adapt to different types of medical data. Their study showed that LoRA improves prediction accuracy without requiring full retraining, making it an efficient way to adapt models.

4) LoRA And Knowledge Distillation Agent: This agent combines both LoRA and Knowledge Distillation, leveraging their complementary properties to enhance model performance, improve data balancing, and accelerate training. While Knowledge Distillation transfers knowledge from a complex model to a simplified one, LoRA efficiently adapts the simplified model without significantly increasing computational costs. This synergy results in a more efficient and scalable approach for Parkinson's Disease prediction.

B. Model Evaluation Agent

The Model Evaluation Agent was designed to assess, compare, and validate the Machine Learning models implemented in the project. Its primary function is to calculate key performance metrics, including: accuracy, precision by class, recall, F1-score, ROC Curve, training time, memory usage.

Additionally, this agent stores results in a local CSV file and generates visual representations for better interpretability. It is applied to each Machine Learning agent, ensuring a direct and systematic comparison of their respective performances.

C. Comparison Agent

This agent plays a crucial role in evaluating the consistency and reliability of the Machine Learning models. It assigns numerical values to the predictions: 2 for "Parkinson's Disease" and 1 for "Not Parkinson"

Beyond simple classification, this agent assesses which model is the most reliable, analyzing precision and accuracy to determine a weighted confidence score. The weighted average of the models' predictions is then computed, assigning a weight of 2 to the most reliable model and 1 to the others. The final decision is made based on the following threshold: If the weighted average is greater than 1.5, so it determine "Parkinson's Disease", however If the weighted average is less than 1.5, so it determine "Not Parkinson".

Since this agent is applied across all data types, three independent predictions are generated by the end of this phase.

D. Last Evaluation Agent

This agent is responsible for delivering the final diagnostic outcome. It consolidates the three predictions obtained from

different data modalities and performs an integrated evaluation based on patient ID.

As in the Comparison Agent, numerical values are assigned to predictions (2 for "Parkinson's Disease" and 1 for "Not Parkinson"), followed by a weighted average computation. However, in this case, the weights are assigned based on the performance of each data type rather than direct model accuracy. Since Polygenic Risk Score (PRS) demonstrated the highest predictive performance, it is given a weight of 2, while the other modalities receive a weight of 1.

Additionally, this agent implements a simple majority voting mechanism, accounting for cases where patient IDs are present in only two of the three models. If data is available from only one model, the patient is classified directly based on that model's prediction without undergoing the voting process.

Finally, the system evaluates the accuracy and precision of the weighted averaging method, as illustrated in Figures 5 and 6, and compares it to the majority voting method, as well as the individual predictions of each agent. The approach that demonstrates superior performance is selected as the final decision-making strategy for Parkinson's disease prediction.

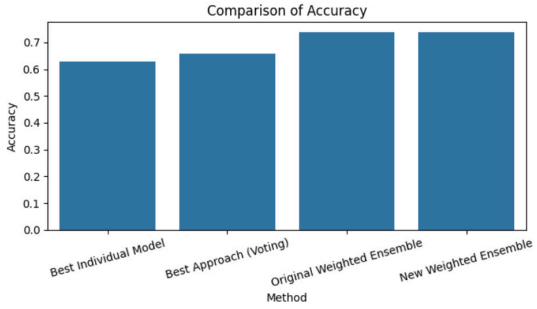

Fig. 5. Accuracy comparison

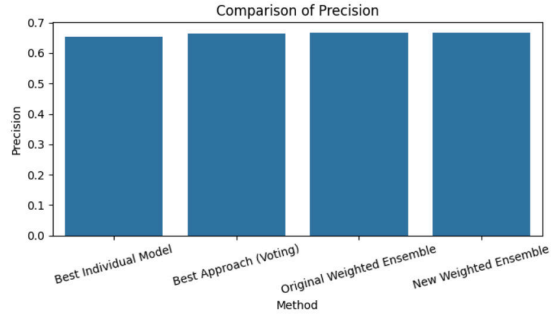

Fig. 6. Precision comparison

In conclusion, the multi-agent system created to predict Parkinson's disease progression includes several agents, each with its own job in the diagnostic process. The Machine Learning agents, like Random Forest, Multi-Layer Perceptron, and Logistic Regression, use different machine learning models on various data types to classify patients. To make the models more accurate, techniques like Knowledge Distillation and Low-Rank Adaptation (LoRA) were used. There's also the Model Evaluation agent, which checks how well the models are performing using metrics like accuracy and sensitivity, and the Comparison agent, which compares the model predictions and calculates a weighted average to decide if the patient has Parkinson's. Lastly, the Last Evaluation agent combines the predictions from all models and uses a majority voting system to make the final call. The way these agents work together to fine-tune predictions makes the system more reliable and accurate, ultimately leading to better early diagnosis.

IV. Results

To better illustrate the results, it is essential to present key numerical data obtained from the program.

Firstly, regarding the training time of the models, a comparison was made between the raw execution time and the time using LoRA and Knowledge Distillation (KD). In practical terms, only the Neural Network model exhibited significant improvements. For the other two models, the reduction in training time ranged from 0.5 to 1 second. However, for the Neural Network model, the training time was reduced by up to 50%, as shown in Table I.

Database	Raw Data	LoRA	KD	LoRA + KD
Family History	25.86 s	22.16 s	15.19 s	10.63
Biospecimens	21.73 s	13.96 s	7.85 s	7.70 s
Polygenic Risk Score	2.52 s	1.32 s	0.87 s	0.43 s

TABLE I
Comparison of Training Time in Neural Network

Furthermore, it is important to highlight that, despite the gain in processing speed, both precision and accuracy were preserved, as demonstrated in the tables II, III and IV.

These are important metrics for measuring the quality of LoRA and KD treatments, since they prove that, even when optimizing the process, they maintain the same level of quality of the raw data.

Database	Raw Data	LoRA	KD	LoRA + KD
Family History	0.9407	0.9390	0.9491	0.9610
Biospecimens	0.9256	0.9272	0.9173	0.9129
Polygenic Risk Score	0.9583	0.9439	0.9524	0.9262

TABLE II
Comparison of Precision in Neural Networks – Parkinson's Disease Classification

Database	Raw Data	LoRA	KD	LoRA + KD
Family History	0.3630	0.3672	0.3109	0.2331
Biospecimens	0.3423	0.3328	0.3472	0.3619
Polygenic Risk Score	0.3101	0.2746	0.2778	0.2835

TABLE III
Comparison of Precision in Neural Networks – Healthy Classification

Regarding the other Machine Learning techniques and their performance across different data types, all methods yielded satisfactory results. Even when applied to an initially highly unbalanced dataset, the models demonstrated efficiency in

Database	Raw Data	LoRA	KD	LoRA + KD
Family History	0.8695	0.8723	0.8367	0.7445
Biospecimens	0.7672	0.7572	0.7784	0.7925
Polygenic Risk Score	0.6225	0.5622	0.5622	0.5984

TABLE IV
COMPARISON OF ACCURACY IN NEURAL NETWORKS

identifying patients with Parkinson's disease. However, they occasionally exhibited limitations in accurately classifying healthy individuals.

Despite this issue, the implementation of a multi-agent system with a multi-stage evaluation process effectively mitigated the error rate for healthy individuals. As shown in the image 7, the percentage of correctly classified healthy individuals demonstrates significantly improved accuracy compared to the results obtained from isolated methods.

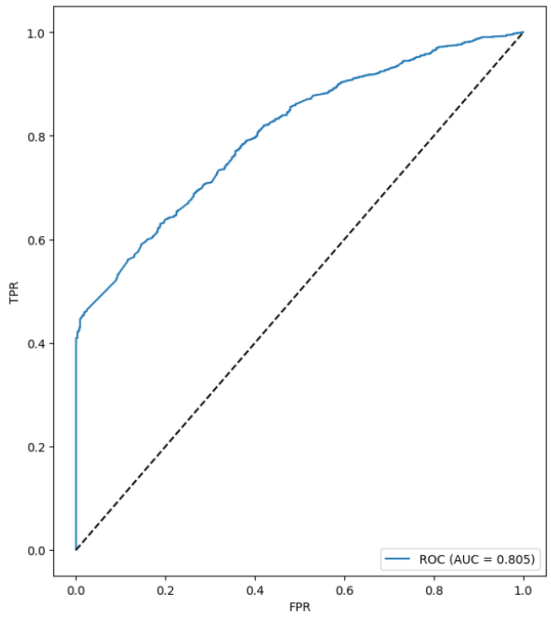

Fig. 7. ROC Curve

With the representation of the ROC curve in image 7, several critical parameters can be highlighted. Since this evaluation method is not influenced by class imbalance, the analyses derived from it are highly reliable. Consequently, it provides a comprehensive assessment of the model's ability to distinguish between classes and its performance across all sensitivity levels.

V. CONCLUSION

It is important to highlight that, despite utilizing a small and unbalanced dataset, the project achieves accuracy levels comparable to those reported in studies comparing Convolutional Neural Networks, Feed-forward Neural Networks, and a hybrid approach combining both [9]. However, the most critical aspect to analyze in this context is the system's ability to generate consistent results, even in the presence of ambiguous or incomplete data. This robustness is primarily attributed to the multi-agent framework and the multi-stage evaluation methodology employed.

Regarding the performance of the models in identifying individuals diagnosed with Parkinson's disease, all trained models achieved accuracy between 0.60 and 0.90. Notably, the precision for this class consistently ranged from 70% to 90%, in stark contrast to the performance observed in identifying healthy individuals. After processing by the Last Evaluation Agent, these performance metrics remained stable.

Therefore, it is important to highlight the significant potential of this project to support the diagnosis of Parkinson's disease, particularly in socially vulnerable contexts, where patients may have limited access to multiple and repeated examinations — especially imaging tests, which are generally costly. In this regard, it is entirely feasible to reach a conclusion that closely approximates clinical reality using only two laboratory tests and an analysis of family history. This feature is further enhanced by the fact that the system can be executed on machines with low computational power. Thanks to the application of optimization and model reduction techniques, such as LoRA (Low-Rank Adaptation) and Knowledge Distillation, the program demonstrates satisfactory performance even under constrained hardware conditions.

Nevertheless, it is essential to emphasize that this system is not intended to replace the assessment conducted by qualified healthcare professionals, but rather to act as a decision-support tool, contributing to the diagnostic process by optimizing both time and available resources.

***Abstract*—Chagas disease, caused by *Trypanosoma cruzi*, remains a major neglected tropical disease for which reliable quantification of intracellular parasite burden is important for investigating infection dynamics and supporting pharmacological screening. Conventional manual inspection of Giemsa-stained cultures is labor-intensive, operator-dependent, and poorly scalable. This work proposes a computer-aided image-processing framework for detecting host-cell nuclei and generating an initial estimate of intracellular amastigote burden in Giemsa-stained HTR8/SVneo cultures. The method combines color deconvolution, Otsu thresholding, marker-controlled watershed segmentation, morphological and intensity feature extraction, unsupervised *k*-means clustering, and centroid-based spatial association. Because automatic parasite detection is sensitive to staining variability, a PySide6 graphical interface is incorporated as a human-in-the-loop validation stage, allowing expert review and correction before final reporting. The framework was evaluated on 22 microscopy images using an independently and blindly obtained manual ground truth. Host-cell detection achieved a Precision of 95.49%, Recall of 96.49%, and F1-score of 95.99%. In contrast, amastigote counting showed a mean absolute percentage error of 29.47% and an aggregated overestimation of 19.77% (2345 automatic versus 1958 manual counts). The observed errors were mainly associated with local Giemsa staining variability and the use of a fixed color-deconvolution matrix, which can cause small basophilic structures or weakly stained nuclear fragments to be classified as parasite candidates. The proposed framework is therefore positioned as a reproducible human-in-the-loop computer-aided quantification approach rather than a fully autonomous parasite-counting system.**

***Index Terms*—Automated detection, Color deconvolution, Digital image processing, Image segmentation, *Trypanosoma cruzi*.**

I. Introduction

Chagas disease is a parasitic disease caused by the protozoan *Trypanosoma cruzi* and remains a major neglected tropical disease, especially in Latin American countries [1]. It is estimated that millions of people are infected worldwide while tens of millions remain at risk of exposure to the parasite, making it a significant public health problem [2]. Although historically associated with endemic regions in Latin America, the disease has come to have a global impact due to migratory flows and the emergence of alternative routes of transmission, including blood transfusion, organ transplantation, and congenital transmission [3], [4].

Clinically, the infection can progress from an acute phase which is often asymptomatic to chronic forms primarily associated with cardiomyopathies and severe gastrointestinal disorders [5]. Furthermore, currently available treatments, based mainly on benznidazole and nifurtimox, still have limitations related to toxicity, adverse effects, and reduced efficacy at certain stages of the disease [6]. This scenario underscores the need to develop new experimental and therapeutic approaches focused on studying parasite-host interactions and screening for antiparasitic compounds.

Investigating these cellular mechanisms requires reliable *in vitro* models. In this context, the HTR8/SVneo cell line, derived from human extravillous trophoblasts, serves as a vital tool for studying the placental microenvironment and host susceptibility to congenital infections [7]. In these experimental assays, precisely quantifying the intracellular parasite burden within cell cultures is a fundamental step to evaluate infection dynamics and conduct pharmacological screening [8], [9].

However, many protocols still rely on manual microscopic inspection, which is considered a labor-intensive, time-consuming procedure that is highly dependent on the operator's experience [10]. Previous studies highlight that this type of analysis has low scalability and high susceptibility to intra- and inter-observer variability, hindering standardization and experimental reproducibility [10]–[12].

With advances in digital image processing techniques, various automated strategies have been explored for the analysis

of intracellular infections [13]–[16]. Methods based on fluorescence and computational segmentation have demonstrated the ability to extract relevant quantitative parameters, such as the number of infected cells, average parasite load, and parasite-to-host-cell ratio [13]. In addition, automated phenotypic approaches have gained prominence in drug discovery for Chagas disease due to the possibility of large-scale analysis and reduced experimental subjectivity [17].

While Giemsa staining remains a cost-effective standard for visualizing intracellular parasites [18], [19], its inherent heterogeneity, nonuniform illumination, and the frequent spatial overlapping of amastigotes with host nuclei severely limit simple thresholding techniques [20], [21]. To address these computational challenges, this study proposes an interpretable image-processing framework, combining color deconvolution, marker-controlled watershed segmentation, and unsupervised *k*-means clustering, to detect host-cell nuclei and associate candidate parasite structures in Giemsa-stained HTR8/SVneo cultures. Every stage of the pipeline relies on explicit, inspectable operations rather than learned parameters, and its output remains editable: the system incorporates a human-in-the-loop PySide6 graphical interface that allows specialists to review the automated detection map and correct false-positive associations before final reporting. The framework is therefore positioned as a reproducible, computer-aided decision tool for pharmacological screening and infection dynamic studies rather than a fully autonomous counting method.

II. Materials and Methods

A. Image Dataset and Ground Truth

For the development and evaluation of the proposed image processing pipeline, 22 images were obtained by optical microscopy (Opton) at $40\times$ magnification from randomly selected fields on the coverslips, with an approximate resolution of 0.16 μm/pixel. The images show Giemsa-stained HTR8/SVneo cells infected with tissue culture-derived trypomastigotes of the *Trypanosoma cruzi* Y strain, in an assay consisting of two independent experiments with three replicates each. The digital photomicrographs were stored in uncompressed TIFF (Tagged Image File Format) with spatial dimensions of 2048×1536 pixels and a 24-bit color depth (RGB standard).

For the computational analysis, host cells were represented by their larger nuclei, whereas small basophilic structures spatially associated with host nuclei were treated as candidate amastigotes. A host cell was considered infected when two or more candidate amastigotes were assigned to its spatial domain.

The reference counts were obtained independently and blindly by a single experienced researcher, who manually evaluated each microscopic field without access to the automated pipeline results. The ground truth contained the absolute number of host-cell nuclei and amastigotes per image. Instance-level masks or centroid coordinates for individual amastigotes were not available; therefore, the parasite ground truth supported per-image counting comparisons but not formal object-to-object validation of the host–parasite spatial association. The complete computational workflow is summarized in Fig. 1.

B. Chromatic Separation

Chromatic separation was performed using the color deconvolution technique proposed by Ruifrok and Johnston [22], which is based on the optical density (OD) model. In this model, the intensity I recorded at each pixel is converted to the optical density space using the logarithmic transformation in (1):

$$OD = -\log_{10}\left(\frac{I}{I_0}\right), \tag{1}$$

where I_0 represents the background intensity (transmitted light without absorption). Each dye present in the sample can be characterized by a three-component vector corresponding to its optical densities in the RGB channels. For a sample stained with two or three dyes, these vectors form a 3×3 optical density matrix M, in which each row represents a dye and each column represents the optical density in the respective channel [22].

The separation of the individual contributions from each dye is then obtained using the deconvolution matrix $D = M^{-1}$, such that the amount of each dye in a given pixel is calculated as in (2):

$$C = D \cdot OD, \tag{2}$$

where C is the vector containing the contributions of each dye and OD is the optical density vector observed at that pixel [22].

The normalized spectral vectors used in this study correspond to the canonical values defined by Ruifrok and Johnston [22] for the combination of hematoxylin, eosin, and a residual channel, forming the matrix M in (3):

$$M = \begin{pmatrix} 0.65 & 0.70 & 0.29 \\ 0.07 & 0.99 & 0.11 \\ 0.27 & 0.57 & 0.78 \end{pmatrix}. \tag{3}$$

The use of this fixed canonical matrix, rather than individual adjustment per image, was motivated by the high variability observed in the manual selection of reference pixels, which led to inconsistencies in the chromatic separation between images of the same cell line. Although originally defined for H&E (Hematoxylin and Eosin), this matrix effectively separates the blue/purple (azure/methylene blue) and pink (eosin) components of the Giemsa stain due to the similar spectral absorption profiles of these dyes [22], [23], as illustrated in Fig. 2.

After deconvolution, the channel corresponding to the blue/purple component (mathematically analogous to the hematoxylin channel in the canonical matrix) was selected for the subsequent steps, as the high affinity of the azure and methylene blue components for nucleic acids provided a clearer view of the cell nuclei and of the basophilic regions relevant for cell identification and for the detection of possible intracellular parasitic structures.

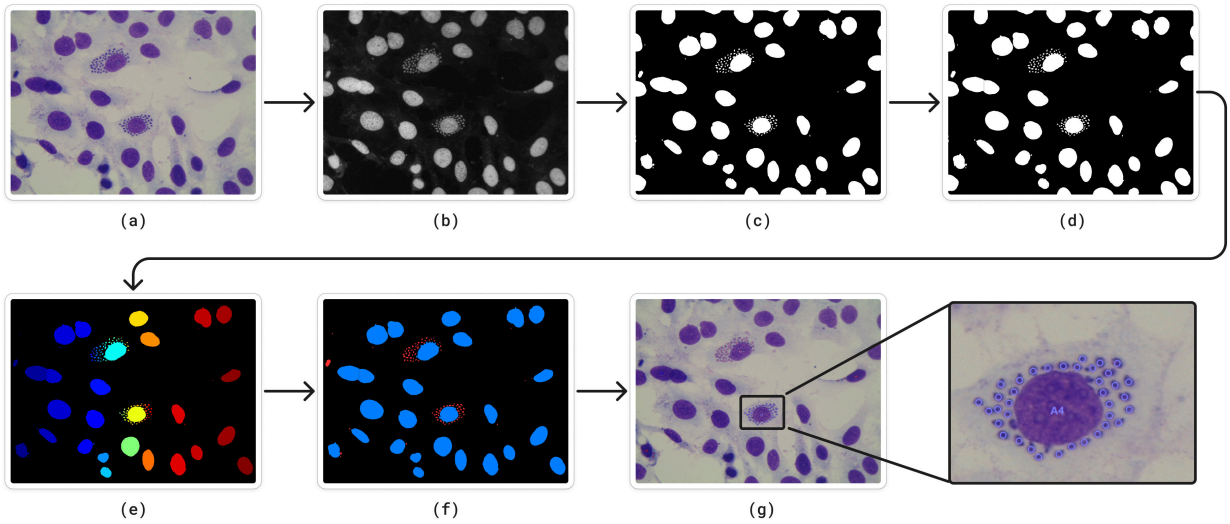

Fig. 1. General flowchart of the proposed methodology. (a) Original Giemsa-stained image; (b) blue/purple channel after color deconvolution; (c) Otsu binarization; (d) watershed segmentation; (e) labeling of cellular structures; (f) *k*-means clustering; (g) automated spatial association of candidate parasite structures. The resulting map is subsequently reviewed in the human-in-the-loop graphical interface before final reporting.

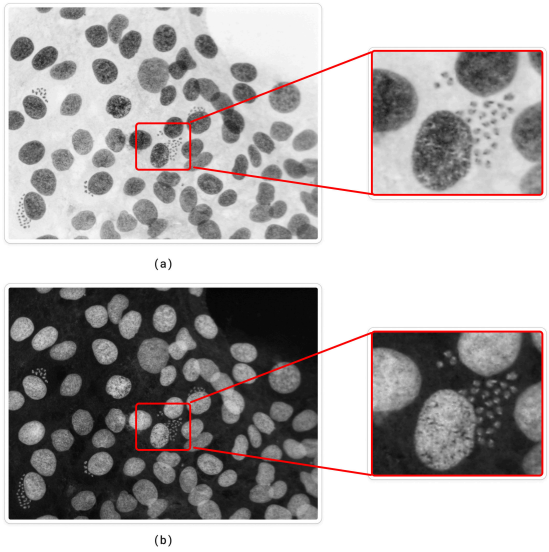

Fig. 2. Chromatic separation achieved by optical deconvolution (OD). (a) Pink channel (eosin component) after deconvolution, predominantly highlighting cytoplasmic structures and extracellular components. (b) Blue/purple channel (azure/methylene blue component) after deconvolution, highlighting cell nuclei and intracellular structures.

C. Cell Segmentation

The first step in segmentation was binarization of the blue/purple channel using the Otsu method [24], since nuclei generally stand out clearly from the background in histopathological images and global histogram-based thresholds yield good results in this setting [25]–[27]. The method divides the image into background (C_1) and nuclei (C_2) and automatically finds the optimal threshold t^* by maximizing the interclass variance σ_B^2, without the need to manually calibrate values for each analyzed image [24], [26].

Although the Otsu method works well, the internal staining of the cell is not always homogeneous, which often results in internal gaps (holes) in the resulting binary mask [27]. To correct these gaps without altering the actual size of the nucleus, the morphological operation of region filling (*imfill*) was applied [28]. The result of this morphological step is the primary binary mask of the cellular structures, shown in Fig. 3(b).

To resolve nuclear clustering, the watershed algorithm [30] was applied by treating the binary mask as a topographic relief. However, direct application of classical watershed leads to severe over-segmentation due to staining noise and minor edge irregularities [28], [31]. To suppress these spurious local minima and preserve the actual morphology of adjacent host cell nuclei, a marker-controlled watershed strategy was implemented, integrated with the Euclidean Distance Transform (EDT) [28], [29]. The EDT calculates the shortest spatial distance from each pixel in the core p to the nearest background pixel q, generating a distance map $D(p)$, as shown in (4):

$$D(p) = \min_{q \in R^c} d(p, q). \tag{4}$$

In this new inverted topographic relief, the highest values (distance peaks) represent the individual centers of mass of each cluster. The algorithm locates these regional peaks and uses them as strict immersion markers (seeds). By restricting the flooding process so that it starts exclusively from these validated seeds, the technique suppresses spurious minima [29]. Thus, the watershed creates dividing lines only at the actual boundary between overlapping nuclei, disaggregating the cellular clusters as illustrated in Fig. 3(c). Next, connected-component labeling is applied, where each nucleus receives a

unique numerical identifier, allowing for individual visualization and analysis, as shown in Fig. 3(d).

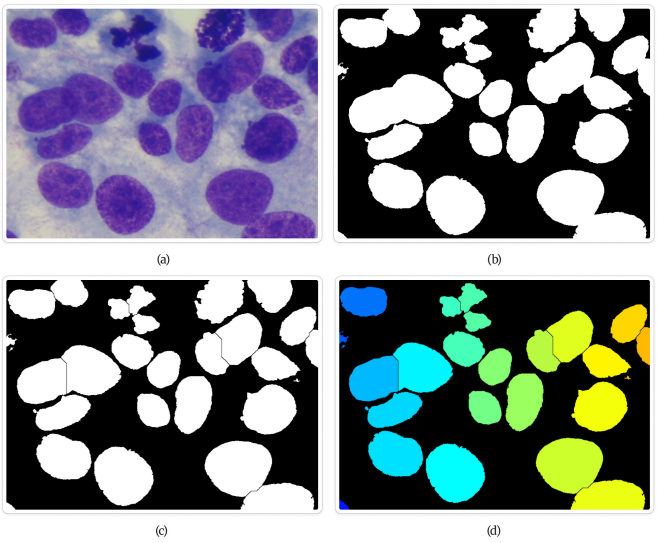

Fig. 3. Stages of nuclear segmentation in the cropped image (777x573 pixels): (a) Original Giemsa-stained image; (b) Consolidated binary mask after global thresholding using the Otsu method and morphological filling; (c) Geometric separation of overlapping nuclei using a marker-controlled watershed transform; (d) Labeling of connected components, assigning unique identifiers to each isolated nucleus for attribute extraction.

D. Detection of Cell and Parasitic Structures

After separating and geometrically labeling the objects in the image, morphological and intensity features were extracted for each one. The main objective of this step is to mathematically differentiate host cells (larger structures) from parasites (smaller structures). For each identified nucleus, we calculated the area, the equivalent diameter (D_{eq}), the solidity, the eccentricity, the coordinates of the geometric centroid, and the average intensity in the blue/purple channel ($\overline{I}_B$). These attributes are widely used in the literature to analyze nuclei in histopathological images [32], [33], as they summarize information regarding cell size, shape, and color.

These two cell populations were classified using the unsupervised *k*-means algorithm [34]. To optimize computational processing and prevent vastly different scales from causing errors in the separation, the clustering used only two variables, forming the two-dimensional space $X = [D_{eq}, \overline{I}_B]$, whose values were previously normalized by the Z-score [33]. The algorithm divided the data into $k = 2$ groups (clusters), iteratively minimizing the sum of the intra-cluster quadratic errors J [34].

Finally, the group with the largest average diameter was classified as the host cell population. The remaining group was classified as the candidate amastigote population. To refine the results and remove small spots or staining artifacts, a morphological filter was applied to remove host cells that were cut off by the edge of the image, since it would not be possible to verify the presence of amastigotes. The visual result of this mathematical separation can be seen in Fig. 4(a).

With the two classes separated, the final step was to map which candidate amastigotes belonged to which host cells. To do this, the code extracted the spatial coordinates (x, y) of all centroids and calculated the matrix of Euclidean distances between them. The distance d between the centroid of a parasite c_p and any other centroid c_t (whether it is another parasite or a cell) is given by (5):

$$d(c_p, c_t) = \sqrt{(x_p - x_t)^2 + (y_p - y_t)^2}. \quad (5)$$

Due to the biology of the infection, amastigotes typically form clustered cellular nests. As a result, it is very common for a parasite to be spatially closer to another parasite than to the center of its own host nucleus [8]. To address this issue, an iterative neighborhood search algorithm (greedy boundary propagation) was implemented. The algorithm tracks the nearest neighbor of each parasite; if it is another amastigote, the two structures are grouped together. This continuous expansion continues until the nearest structure is, in fact, the nucleus of a host cell. When this occurs, the entire cluster of amastigotes is attached to that host, making the cell infected. The use of Euclidean distance combined with neighborhood logic is one of the most robust criteria for analyzing cellular position in dense tissues [32], [35].

This iterative process constructs a final infection map, shown in Fig. 4(b), allowing the system to count, in an automated manner, the number of candidate amastigotes within each identified cell classified as infected.

E. Creation of a Graphical Interface

To support result validation and targeted manual correction, a graphical user interface was developed in PySide6. Considering the overestimation observed in automated amastigote counting, as discussed in Section III, the interface was implemented as a human-in-the-loop curation layer. It enables simultaneous visualization of the original image and the pipeline outputs, allowing the user to inspect, validate, and, when necessary, manually correct the automated detections.

Furthermore, the system provides editing tools that allow users to remove false positives and correct incorrect associations between parasites and infected cells. Undo and zoom features for local inspection were incorporated to assist the specialist during the validation stage [36].

F. Quantitative Analysis

To evaluate the performance of the proposed method, the automatically segmented structures were validated against the manual count performed by an experienced researcher, which served as the experimental ground truth. For each microscopic field, the manual analysis established the absolute number of existing host cell nuclei (true presence).

The classification performance for this specific class was quantified using True Positive (TP), False Positive (FP), and False Negative (FN) metrics. Object matching was performed by side-by-side visual audit of the segmentation map and the corresponding original field: a detected object was accepted as

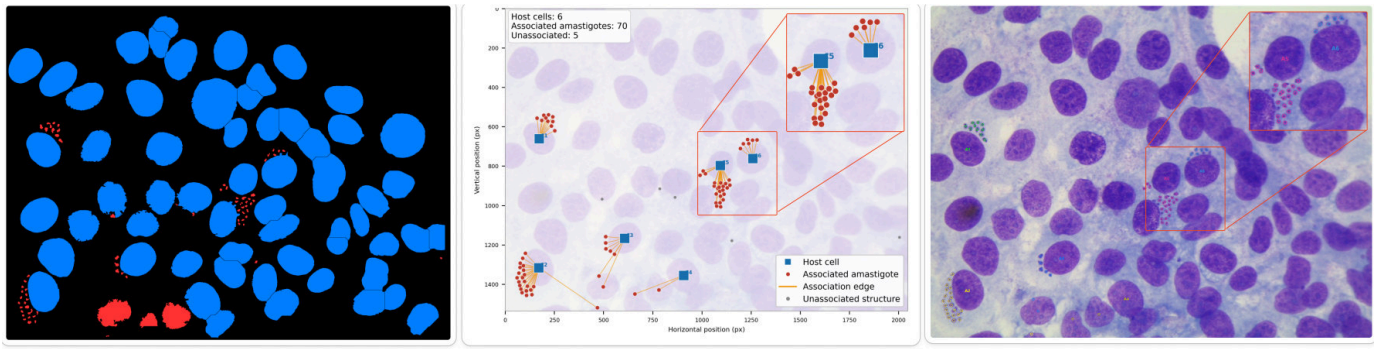

Fig. 4. Final steps of the parasite detection pipeline. (a) Unsupervised classification using k-means ($k = 2$) in the space $[D_{eq}, \bar{I}_B]$: blue cells represent host cell nuclei, and red circles represent parasitic structures (amastigotes). (b) Spatial association map based on Euclidean distance between centroids: gold edges connect each amastigote to its nearest host cell, forming infection clusters. (c) Final result displayed in the graphical interface, where each color identifies a distinct host-parasite cluster.

TP when its segmented region overlapped, partially or completely, a nucleus of the manual reference, under a one-to-one correspondence between detection and reference nucleus. No automatic overlap or centroid-distance criterion was applied. Structures quantified by the automated pipeline that did not overlap any reference nucleus were labeled as FP (artifacts or noise).

Conversely, existing cell nuclei that the system failed to identify were recorded as FN. Based on these audited counts across all 22 images that were visually assessed by an experienced researcher, the system's reliability and sensitivity for nuclear detection were evaluated through cumulative metrics. For amastigotes, only per-image absolute counts were compared, as the ground truth provided total counts only, without spatial location.

True Negatives (TN) were not included in this evaluation: in a detection and counting task they would correspond to every empty region of the image, so their value would be arbitrary. Metrics that depend on TN, such as Specificity, are therefore not meaningful here, and Precision and Recall are the appropriate choices [37].

Using the TP, FP, and FN values accumulated across all 22 images, we calculated three metrics widely used in the literature to evaluate classification systems [38]: *Precision* (P), *Recall* (R), and *F1-score* (F_1), defined in (6)–(8):

$$P = \frac{TP}{TP + FP}, \tag{6}$$

$$R = \frac{TP}{TP + FN}, \tag{7}$$

$$F_1 = \frac{2 \cdot P \cdot R}{P + R}. \tag{8}$$

For the amastigote class, the agreement between automated and manual counts was quantified per image through the signed percentage error, and summarized over the dataset by the mean absolute percentage error (MAPE) and by the aggregated error computed from the total counts.

In addition, in order to investigate possible factors associated with the discrepancies observed between manual and automatic amastigote counts, an analysis was conducted of the chromatic properties of the 22 images evaluated. For each image, the range with the highest concentration of intensities in each RGB channel was identified, and its amplitude (the difference between the maximum and minimum values of that range) was calculated. This metric reflects the heterogeneity of intensities within the channel, with larger amplitudes indicating more scattered distributions and potentially greater variability in the absorption of the corresponding dye.

In addition, the RGB histograms of images IM9 and IM8, representing, respectively, the largest and one of the smallest percentage errors in the dataset, were analyzed comparatively, with the aim of identifying visual differences in the intensity distributions that might be associated with the pipeline's performance in each microscopic field. This analysis was exploratory in nature and sought to relate the chromatic characteristics of the images to the behavior of the pipeline during the binarization and classification of parasitic structures.

III. Results

Table I presents the absolute counts of host cells and amastigotes obtained by manual annotation (gold standard) and by the proposed method for each of the 22 images evaluated, together with the signed percentage error of the automated amastigote count, which ranged from -11.3% (IM3) to $+76.1\%$ (IM9).

For the host cell class, the evaluation was complemented by the analysis of True Positives (TP), False Positives (FP), and False Negatives (FN), whose accumulated values across the 22 images are presented in the confusion matrix in Fig. 5, where the True Negative quadrant is marked as not applicable, since the task consists of object detection and counting.

Based on the TP, FP, and FN values presented in Fig. 5, the Precision, Recall, and F1-score metrics for host cell detection were calculated, as shown in Table II.

To investigate the discrepancies observed in the amastigote count, the chromatic properties of the images were analyzed.

TABLE II
PERFORMANCE METRICS FOR HOST CELL DETECTION

TP Total	Precision	Recall	F1-score
1376	0.9549	0.9649	0.9599

As shown in Fig. 6, the blue channel divided the dataset into two distinct patterns of behavior: images IM1 to IM13 were concentrated in a low-amplitude range (mean of 37.2 units), while images IM14 to IM22 showed a high-amplitude range (mean of 63.2 units). In contrast, the red and green channels remained relatively stable throughout the entire image set.

Additionally, the comparison between the RGB histograms of images IM8 and IM9 showed that, although both belong to the low-amplitude group in the blue channel, they represent opposite extremes in terms of algorithm performance. IM9 presented the highest percentage error in amastigote counting (+76.1%), whereas IM8 presented one of the smallest absolute deviations in the dataset (−4.3%) and the smallest among the images in which the automated count fell below the manual reference. The visualization shows that IM9 has a slightly more dispersed intensity distribution in the blue channel compared to IM8, suggesting that variations in the chromatic distribution, and not just in the amplitude of the highest concentration range, can influence the performance of automatic detection.

IV. DISCUSSION

The results obtained for host cell detection, presented in Section III, demonstrated high and consistent performance, with a precision of 95.49%, a recall of 96.49%, and an F1-score of 95.99%. As shown in the confusion matrix in Fig. 5, of the 1426 host cell nuclei in the manual ground truth, the algorithm detected 1441 structures, comprising 1376 true positives, 65 false positives, and 50 false negatives, indicating that the color deconvolution, binarization, and watershed steps are sufficiently robust for segmenting larger-diameter nuclei despite the variability in contrast and cellular density across the dataset.

In contrast, amastigote counting showed a mean absolute percentage error (MAPE) of 29.47% and an aggregated overestimation of 19.77% (2345 automated versus 1958 manual counts, Table I), indicating that, unlike host cell detection, the amastigote counts should not yet be interpreted as a fully reliable stand-alone measurement of parasite burden. To investigate this behavior, the amplitude of the blue channel was analyzed, Fig. 6, revealing that images IM14–IM22 have a significantly higher amplitude (mean of 63.2) compared to images IM1–IM13 (37.2). However, this discrepancy did not affect the MAPE, which remained close to 29% in both groups. The significant difference occurred only in the mean absolute error (31.4 structures per image in IM14–IM22 versus 10.2 in IM1–IM13), which can be explained by the higher parasite load in the second group (mean of 153.9 amastigotes versus 44.1 in the first), while the number of host cells remained constant. Thus, the greater amplitude in the blue channel reflects the high volume of azure/methylene blue-stained structures (nucleic acids), rather than an isolated metric of pipeline degradation.

Although the overall amplitude is not a direct predictor of error, localized variations in staining affect segmentation. Weakly stained nuclei or fragments with residual

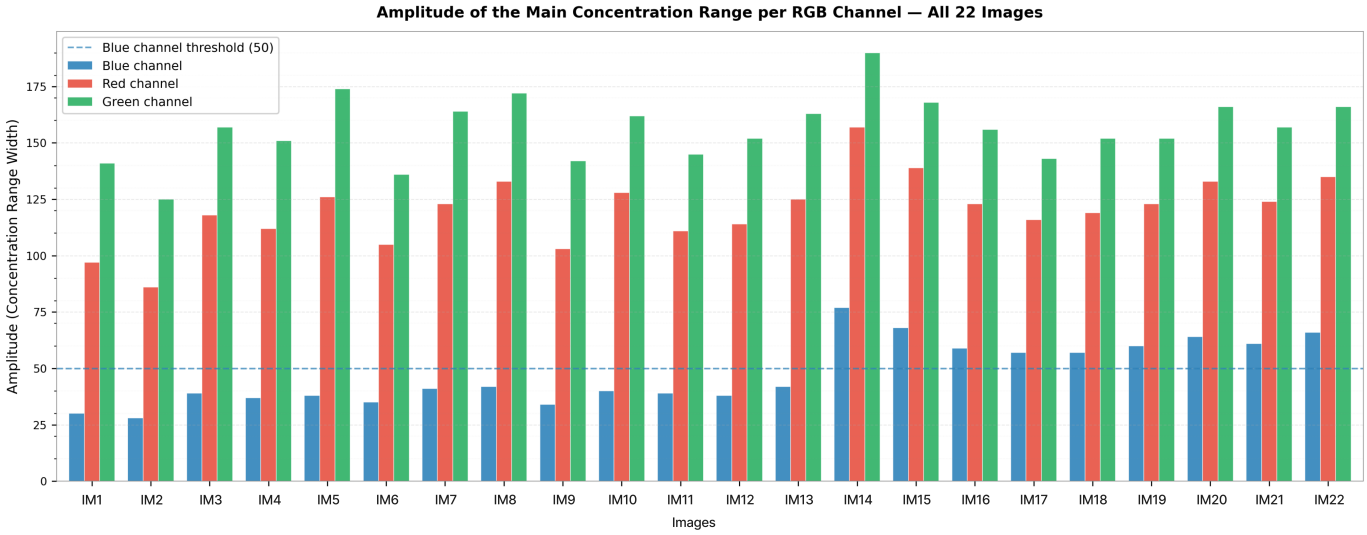

Fig. 6. Range of the band with the highest concentration of intensities in the red, green, and blue channels for the 22 images evaluated, in sequential order. The dashed line indicates the threshold in the blue channel that visually separates two groups with distinct behaviors (IM1–IM13 and IM14–IM22).

azure/methylene blue absorption tend to be segmented independently when they reach the binarization threshold. Due to their small diameter, the *k*-means algorithm incorrectly classifies them as amastigotes. This behavior highlights a limitation of the fixed nature of the color deconvolution matrix defined in (3), which assumes a constant reference intensity and does not adapt to local fluctuations in chromatic density; the overestimation is a direct result of the combination of high amastigote density and these variations in staining.

It is worth noting that the step involving spatial association between amastigotes and host cells was not subjected to formal quantitative validation in this study, since a viable protocol for individualized spatial correspondence between manual annotations and automatically detected structures was not established. The accuracy of this step was verified qualitatively using the graphical interface developed, which allows the expert to visually inspect and manually correct incorrect associations before the final count. The development of a protocol for individualized spatial annotation, which would enable the calculation of association metrics, constitutes a recognized limitation of the present study.

Three further limitations should be acknowledged. First, the reference counts were produced by a single annotator, so inter-annotator agreement could not be estimated and the residual subjectivity of the ground truth remains unquantified. Second, validation was restricted to a single laboratory, staining protocol, microscope, and *T. cruzi* strain; the fixed deconvolution matrix and the derived thresholds were therefore not verified on an independent staining batch, which limits conclusions regarding robustness and generalizability. Third, no comparison against supervised or deep learning segmentation baselines was performed, since training and evaluating such models would require the instance-level annotations that the present ground truth does not provide.

V. Conclusion

This study presented an automated image-processing pipeline for the detection of host cell nuclei and intracellular parasite structures in Giemsa-stained microscopy images of the HTR8/SVneo cell line. The proposed methodology combined color deconvolution, Otsu thresholding, marker-controlled watershed segmentation, morphological feature extraction, *k*-means clustering, and spatial association to estimate the intracellular amastigotes burden.

The proposed approach achieved high performance for host cell detection (Precision of 95.49%, Recall of 96.49%, and F1-score of 95.99%), but amastigote counting showed a mean absolute percentage error of 29.47% and an aggregated overestimation of 19.77%. Automated amastigote counts should therefore be interpreted as an initial estimate, to be confirmed through expert review, rather than a definitive measurement of parasite burden.

The main contribution of the framework is therefore an interpretable and editable pipeline: all decision stages rely on explicit operations that can be inspected and adjusted, and the developed graphical interface provides an efficient tool for visual inspection and manual correction of the automatically generated results, allowing specialists to validate amastigotes-host associations before the final quantification.

Future work includes evaluating the pipeline on larger, multicenter datasets acquired under different staining protocols and microscopes, implementing adaptive stain normalization techniques, establishing a spatially annotated *ground truth* with multiple annotators to enable a quantitative evaluation of amastigotes-host association accuracy, and benchmarking the proposed framework against state-of-the-art supervised and deep learning segmentation methods.

ACKNOWLEDGMENT

The authors are thankful for the received financial support from the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES—Brazil), CNPq—Brazil, FAPEMIG—Brazil, and Universidade Federal de Uberlândia (UFU), as well as the scientific and technical support provided by the Laboratório de Imunofisiologia da Reprodução (LABIFIR).

***Abstract*—Automatic electrocardiogram classification can support clinical decision-making by reducing the burden of manual signal interpretation and improving the consistency of diagnostic screening. However, many high-performing deep learning models for ECG analysis rely on relatively complex architectures, which may increase computational cost and limit reproducibility. This study proposes a compact neural architecture for multi-label ECG classification using the PTB-XL dataset, focusing on the five diagnostic superclasses: normal ECG, myocardial infarction, ST/T changes, conduction disturbances, and hypertrophy. The proposed model is inspired by the hierarchical organization of IMLE-Net but adopts a simpler design composed of a shallow 1D CNN encoder, temporal attention, mean aggregation across signal windows, and inter-lead attention. Each 10-second 12-lead ECG is segmented into partially overlapping windows, allowing the model to capture local temporal patterns while preserving information from different leads. Experiments were conducted using the official PTB-XL stratified folds, with folds 1–8 for training, fold 9 for validation, and fold 10 for testing. The proposed model achieved a macro ROC-AUC of 0.9296 and a mean accuracy of 0.8916 using a fixed threshold of 0.5, outperforming IMLE-Net in both metrics while using fewer trainable parameters. When a validation-optimized threshold was applied, the model reached an F1-score of 0.8103. These results indicate that compact architectures can achieve competitive performance for ECG superclass classification while reducing architectural complexity.**

***Index Terms*—ECG, PTB-XL, Deep Learning, CNN.**

I. Introduction

The electrocardiogram (ECG) is a vital medical tool used to record the heart's electrical activity, providing essential insights for the assessment of cardiac abnormalities. Interpreting these signals requires meticulous observation of complex morphological features, including waves, segments, intervals, and leads, as both signal morphology and temporal organization are critical for accurate diagnosis [1]. Despite its clinical importance, manual analysis of ECG recordings is labor-intensive and susceptible to intra- and inter-observer variability. To address these challenges, machine learning (ML)-based approaches have been developed to automate classification tasks, facilitating more consistent and efficient diagnostic support.

The public datasets available on PhysioNet reflect the diverse scenarios in which ML is applied to ECG analysis. One primary scenario is ambulatory monitoring, exemplified by the MIT-BIH Arrhythmia Database, which consists of 48 half-hour two-lead records primarily designed for arrhythmia detection [2]. In contrast, conventional short-duration clinical ECGs are represented by datasets like PTB-XL. This dataset includes 21,799 ten-second exams across 12 leads from 18,869 patients, serving as a standard benchmark for developing and evaluating automatic classification models, particularly for multi-label tasks such as identifying normal ECGs (NORM), myocardial infarction (MI), ST/T changes (STTC), conduction disturbances (CD), and hypertrophy (HYP) [3]–[5].

Beyond short-duration clinical recordings, large-scale hospital datasets such as MIMIC-IV-ECG have emerged, comprising approximately 800,000 diagnostic 12-lead electrocardiograms sampled at 500 Hz from over 160,000 patients [6]. Due to its scale and integration with clinical metadata, MIMIC-IV-ECG has been instrumental in the development of foundation models for ECG analysis [7]. These models typically employ large-scale self-supervised pre-training to learn generalizable signal representations, as seen in architectures like the transformer-based ECG-FM [8]. Furthermore, the PhysioNet/Computing in Cardiology Challenge 2020 introduced a scenario characterized by significant heterogeneity across datasets, labels, and acquisition conditions by aggregating multiple 12-lead ECG sources [9]. Consequently, the performance of ECG classification models is heavily influenced by factors such as record duration, lead configurations, dataset scale, and the underlying data origin.

In this study, the PTB-XL dataset is utilized, which provides diagnostic annotations organized at different levels of granularity [3], [10]. Specifically, the five diagnostic superclasses, NORM, MI, STTC, CD, and HYP, allow for the evaluation of model performance across broad clinical groups. This organization facilitated its inclusion in international challenges, such as the PhysioNet/Computing in Cardiology Challenge 2020, which focused on 12-lead cardiac abnormality classification, and the 2021 edition, which evaluated algorithms under vary-

ing lead configurations, including 12, 6, 4, 3, and 2 leads [11]–[13].

Thus, PTB-XL has become a relevant dataset for both standardized model comparison and the development of architectures aimed at automatic ECG classification. For instance, IMLE-Net was proposed to explore signal organization at the beat, rhythm, and channel levels, utilizing attention mechanisms to weight relevant information at each processing stage [5]. Other studies reinforce the importance of considering ECG leads during architecture design, as different channels contribute differently to classification performance [14].

Despite the strong results achieved by previous architectures like X-ECGNet, which reported a macro-AUC of 0.936, an F1 score of 0.750, and an accuracy of 0.903 in the diagnostic superclass task, reducing the number of parameters remains a relevant issue [14], [15]. Models with fewer parameters can lower training costs, facilitate experimental reproducibility, and support deployment on resource-constrained devices, such as embedded systems.

In this direction, Reference [16] presented a simplified CNN-VAE-based architecture for PTB-XL, reporting competitive results with only 197,093 trainable parameters. The model achieved 87.01% binary accuracy and a weighted F1 score of 0.7454 in the multi-label classification of the five PTB-XL diagnostic superclasses. These results indicate that compact architectures can indeed be effective in this scenario.

Given this context, this study investigates a compact architecture for ECG signal classification using the PTB-XL dataset, focusing on the five diagnostic superclasses. The proposed approach takes IMLE-Net as a conceptual reference but adopts a shallower structure, featuring a convolutional neural network (CNN) encoder, temporal attention, mean aggregation across windows, and inter-lead attention. The primary objective is to evaluate whether a model with fewer convolutional layers and parameters can still achieve competitive performance.

This work is organized as follows: Section 1 presents the introduction, contextualizing the problem, motivation, objectives, and text organization. Section 2 describes the main concepts related to the study and automatic electrocardiographic signal classification models. Section 3 outlines the proposed methodology, including signal preprocessing, window segmentation, model architecture, and the training and evaluation procedure. Section 4 discusses the obtained results, comparing the proposed model with literature benchmarks. Finally, Section 5 presents the conclusions, limitations, and potential directions for future work.

II. Theoretical Background

This section outlines the foundational concepts supporting this study. We begin with one-dimensional (1D) convolutional neural networks (CNNs), focusing on their application to ECG signals. Subsequently, we detail the hierarchical structure of the IMLE-Net model, which serves as a reference for processing electrocardiographic signals across different levels. Finally, we describe the attention mechanisms within this architecture, highlighting their mathematical formulation and their function in synthesizing representations throughout the model.

A. One-Dimensional Convolutional Neural Networks

Convolutional neural networks utilize shared filters, enabling the application of consistent parameters across different positions of the input. In 1D signals, these positions correspond to consecutive segments of the signal. Applying convolution along a single dimension, referred to as 1D convolution, allows for the extraction of local patterns from ECG traces. These patterns are typically associated with the morphology of waves, complexes, and segments of the signal.

In this context, for ECG signals, 1D convolutions can be used to extract local patterns from the electrocardiographic trace. These patterns may be associated with the morphology of the waves, complexes, and segments of the signal.

B. Hierarchical Models

Reference [5] proposed the IMLE-Net model for anomaly classification in 12-lead ECG signals, structuring the extraction of morphological features and the classification of anomalies into three sequential stages: heartbeat, cardiac rhythm, and ECG lead. This organization is illustrated in Fig. 1.

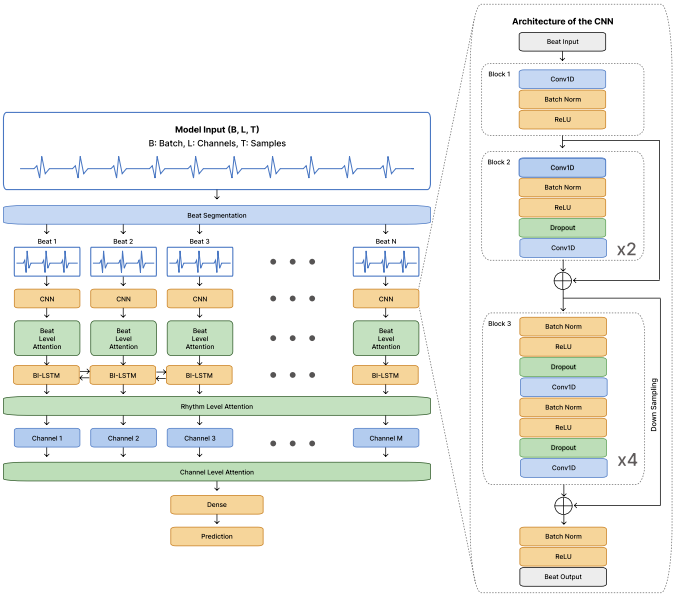

Fig. 1. Hierarchical architecture of IMLE-Net

In Fig. 1, the first stage illustrates processing at the individual ECG lead level. The lead is segmented into short, non-overlapping windows and the input signals with a sampling frequency of 100 Hz are divided into 50-sample windows. Each window is processed by a 1D CNN, followed by a heartbeat-level attention mechanism.

Subsequently, the representations of the windows from the same lead are processed by a BiLSTM, followed by a rhythm-level attention mechanism [17]. Finally, the third stage demonstrates how representations from different leads are aggregated

via a lead-level attention mechanism and forwarded to the dense layer for the final prediction. Consequently, IMLE-Net incorporates attention mechanisms at the heartbeat, rhythm, and lead levels prior to the final classification [5].

The attention functions in IMLE-Net are described below. The equations presented are an adaptation of the model's original mathematical description. Those functions weigh the representations extracted at different stages of ECG processing. At each level, the model assigns greater weight to the most relevant representations, combining this information through a weighted sum. This procedure, applied at the beat, rhythm, and lead levels, allows the model to emphasize specific parts of the signal and particular channels before classification [5].

At the beat level, let (b_k^c) be the (k)-th segment of lead (c). This segment is processed by the 1D CNN, producing the sequence $(\overline{\mathbf{b}}_k^c)$ of intermediate length $(\overline{W})$. The attention function at the beat level is defined as:

$$\boldsymbol{\alpha}_k^c = f_b\left(\overline{\mathbf{b}}_k^c\right) = \operatorname{softmax}\left(\mathbf{V}_b \tanh\left(\mathbf{W}_b \overline{\mathbf{b}}_k^c + \mathbf{b}_b\right)\right). \quad (1)$$

In Equation 1, $\boldsymbol{\alpha}_k^c$ represents the attention weights assigned to the internal positions of segment k from lead c, where $\mathbf{W}_b$, $\mathbf{V}_b$, and $\mathbf{b}_b$ are learned parameters. The segment representation at the beat level is obtained through the weighted sum:

$$\mathbf{B}_k^c = \sum_{i=1}^{\overline{W}} \alpha_{k,i}^c \overline{\mathbf{b}}_{k,i}^c. \quad (2)$$

In Equation 2, i indexes the positions of the sequence produced by CNN, $\alpha_{k,i}^c$ is the attention weight of position i, $\overline{\mathbf{b}}_{k,i}^c$ is the convolutional representation at that position, and $\mathbf{B}_k^c$ is the context vector of segment k from lead c. At the rhythm level, the context vectors of the segments from the same lead are processed by a BiLSTM, generating the sequence $\mathbf{r}^c = \mathbf{r}_1^c, \mathbf{r}_2^c, \ldots, \mathbf{r}_N^c$, where N is the number of segments in lead c. The attention function at the rhythm level is defined as:

$$\boldsymbol{\beta}^c = f_r\left(\mathbf{r}^c\right) = \operatorname{softmax}\left(\mathbf{V}_r \tanh\left(\mathbf{W}_r \mathbf{r}^c + \mathbf{b}_r\right)\right). \quad (3)$$

In Equation 3, $\boldsymbol{\beta}^c$ represents the attention weights assigned to the segments of the lead c, and $\mathbf{W}_r$, $\mathbf{V}_r$, and $\mathbf{b}_r$ are learned parameters. The lead representation at the rhythm level is obtained by:

$$\mathbf{R}^c = \sum_{i=1}^{N} \beta_i^c \mathbf{r}_i^c. \quad (4)$$

In Equation 4, β_i^c is the attention weight of segment (i), $\mathbf{r}_i^c$ is the representation of this segment generated by the BiLSTM, and $\mathbf{R}^c$ is the context vector of lead c. At the lead level, the representations $\mathbf{R}^1, \mathbf{R}^2, \ldots, \mathbf{R}^M$ are considered jointly, where M is the number of available leads. The attention function at this level is defined as:

$$\boldsymbol{\gamma} = f_c\left(\mathbf{R}\right) = \operatorname{softmax}\left(\mathbf{V}_c \tanh\left(\mathbf{W}_c \mathbf{R} + \mathbf{b}_c\right)\right). \quad (5)$$

In Equation 5, $\mathbf{R}$ represents the set of lead representations, $\boldsymbol{\gamma}$ represents the attention weights assigned to these leads, and $\mathbf{W}_c$, $\mathbf{V}_c$, and $\mathbf{b}_c$ are parameters learned. The final signal representation is obtained by:

$$\mathbf{C} = \sum_{i=1}^{M} \gamma_i \mathbf{R}^i. \quad (6)$$

In Equation 6, γ_i is the attention weight assigned to lead i, $\mathbf{R}^i$ is the representation of that lead, and $\mathbf{C}$ is the final context vector of the ECG, used by the linear layer for final prediction.

III. Methodology

This research adopts an experimental design to evaluate a CNN architecture for the multi-disease classification of ECG signals in the PTB-XL database. The objective is to assess the performance of the proposed architecture in classifying the five PTB-XL diagnostic superclasses, considering its organization into convolutional blocks, the resulting temporal receptive field, and the total number of trainable parameters.

A. Dataset

The PTB-XL dataset is a public database of clinical 12-lead ECGs, consisting, in the version used in this study, of 21,799 ten-second exams [3]. The exams include multi-disease diagnostic annotations provided by up to two cardiologists [10]. Notably, not all records have confirmed human validation: approximately 73.7% of the records were validated by a cardiologist, whereas the remaining 26.3% do not have this confirmation [10].

Furthermore, the diagnoses are organized in a hierarchical structure with three levels of granularity. The most specific and detailed level consists of 71 diagnostic statements, such as anteroseptal infarction and diffuse T-wave abnormality, encoded according to the Standard Communications Protocol for Computer-Assisted Electrocardiography [3]. These statements are grouped into 24 intermediate subclasses, such as bundle branch blocks and myocardial infarction, which are subsequently condensed into five general diagnostic superclasses [3].

This hierarchy provides flexibility in the choice of the automatic ECG classification task, allowing anything from the prediction of highly specific diagnoses to the classification of ECG disease groups. Given this, the study adopts the same general superclass classification in IMLE-Net model, as presented in Table I.

TABLE I
DEFINITION OF DIAGNOSTIC SUPERCLASSES

Class	Description
NORM	Normal ECG
MI	Myocardial infarction
STTC	ST/T changes
CD	Conduction disturbances
HYP	Hypertrophy

Table I presents the five PTB-XL diagnostic superclasses. These categories aggregate more specific labels in the dataset;

for example, right bundle branch block and left anterior fascicular block are both subclasses of CD, anterior myocardial infarction is a subclass of MI, and left ventricular hypertrophy is a subclass of HYP.

B. Data Stratification

This study utilizes the official PTB-XL stratified folds, defined in the *strat_fold* metadata field [10]. This stratification was designed to ensure comparability across studies and prevent data leakage between training and test sets. Allocation criteria included diagnosis, patient sex, and age to maintain balanced folds, with the fundamental constraint that all records from a single patient remained within the same fold.

To ensure high label quality, patients whose exam labels had not been validated by human experts were excluded from folds 9 and 10 during stratified sampling. This ensures that all records in these subsets, which are used as the validation and test sets, have undergone at least one confirmed human validation, as recommended in the literature [10]. Consequently, folds 1 through 8 were used for training, fold 9 for validation, and fold 10 for testing, as detailed in Table II.

TABLE II
DATA SPLIT AND DISTRIBUTION OF DIAGNOSTIC SUPERCLASSES

Set	**Folds**	**Number of exams**	**CD**	**HYP**	**MI**	**NORM**	**STTC**
Training	1–8	17,418	3,907	2,119	4,379	7,596	4,186
Validation	9	2,183	495	268	540	955	528
Test	10	2,198	496	262	550	963	521

Table II presents the partitioning of the 21,799 PTB-XL exams. The training set (folds 1–8) comprises 17,418 exams, while the validation (fold 9) and test (fold 10) sets include 2,183 and 2,198 exams, respectively. The table also details the distribution across the five diagnostic superclasses: CD, HYP, MI, NORM, and STTC. The folds 9 and 10 consist exclusively of records with confirmed human validation; they provide a robust foundation for the final evaluation of model performance.

C. Model

This study uses IMLE-Net as a conceptual reference for the hierarchical organization of the ECG while adopting a simpler architecture. The central idea of the proposed model is to process raw signals in three stages: first, a 1D CNN represents each signal window; second, a temporal attention function weights the most relevant points of this representation; finally, an inter-lead attention function determines the contribution of each lead to the classification.

The model input is defined as $x \in \mathbb{R}^{L \times W \times T}$, where L denotes the number of leads, W the number of windows, and T the samples per window. Using 12 leads ($L = 12$), each 10-second record is divided into 1-second segments. We construct 300-sample windows by combining the central 1-second segment with 100 samples from the immediately preceding and following segments, respectively. This approach ensures each window captures the target segment along with surrounding context, as illustrated in Fig. 2. The window slides every two segments, resulting in five windows per lead with a 100-sample overlap between consecutive windows. If no subsequent segment exists for the final window, we apply zero padding to the missing portion.

Fig. 2. ECG signal segmentation

Each window from each lead is processed individually by a 1D CNN encoder shared across all leads and windows. This encoder receives a single lead at a time and consists of three *Conv1D* layers. The first layer transforms the input signal from 1 channel into 64 filters; the second maintains 64 filters to refine the representation; and the third increases the dimension to 128 filters for the attention modules. The three convolutional layers use kernels of size $k_1 = 39$, $k_2 = 19$, and $k_3 = 9$, respectively, all with a stride of $s = 1$ and padding of $p_1 = 19$, $p_2 = 9$, and $p_3 = 4$ samples. The encoder configuration is summarized as follows:

$$1 \xrightarrow[p=19]{k=39} 64 \xrightarrow[p=9]{k=19} 64 \xrightarrow[p=4]{k=9} 128. \tag{7}$$

After each convolution, we apply layer normalization, ReLU activation, and dropout. Layer normalization is preferred over batch normalization to ensure that normalization does not depend on mini-batch statistics, allowing for more independent processing of each example during training.

The temporal attention mechanism follows the beat-level attention formulation of IMLE-Net. Given the feature sequence produced by the CNN, it projects each temporal position into a 64-dimensional attention space, computes normalized attention weights using a softmax function, and obtains the window representation through a weighted sum. Layer normalization, ReLU, and dropout are part of the CNN encoder and not of the temporal attention mechanism.

The representations obtained for windows of the same lead are then aggregated by averaging. This operation reduces the temporal windows into a single per-lead representation without requiring recurrent modules. Unlike IMLE-Net, which models sequences at the rhythm level, this model uses averaging to consolidate representations already processed by the convolutional and temporal attention stages.

Next, the representations from different leads are combined via an inter-lead attention function. This stage assigns weights

to the ECG leads, enabling the model to emphasize the most informative channels for each input. The resulting representation is forwarded to a projection layer consisting of linear layers, layer normalization, ReLU, and dropout to produce the final classification output. In summary, the model flow can be described as:

$$\mathbf{h}_{l,w} = A_t\left(g_\theta(x_{l,w})\right), \tag{8}$$

$$\bar{\mathbf{h}}_l = \frac{1}{W}\sum_{w=1}^{W} \mathbf{h}_{l,w}, \tag{9}$$

$$\mathbf{z} = A_l\left(\bar{\mathbf{h}}_1, \bar{\mathbf{h}}_2, \ldots, \bar{\mathbf{h}}_L\right), \tag{10}$$

$$\hat{\mathbf{y}} = p_\phi(\mathbf{z}). \tag{11}$$

where $x_{l,w}$ represents window w of lead l, g_θ is the 1D CNN encoder, A_t is the temporal attention mechanism, $\mathbf{h}_{l,w}$ is the window representation, $\bar{\mathbf{h}}_l$ is the aggregated representation of lead l, A_l is the inter-lead attention function, $\mathbf{z}$ is the final ECG representation, p_ϕ is the classification head, and $\hat{\mathbf{y}}$ is the predicted output. Reference [5] describes the beat-level attention formulation of IMLE-Net, which is adopted for the temporal attention mechanism A_t in this work. The overall architecture is presented in Fig. 3.

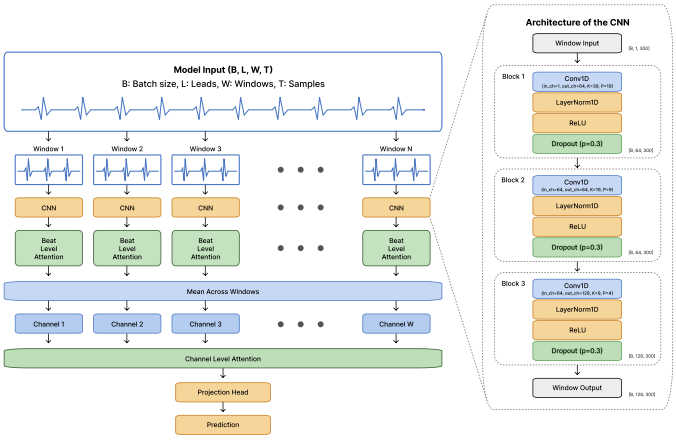

Fig. 3. Architecture of the proposed model

Fig. 3 summarizes the model flow, illustrating the hierarchical processing from the windowed input to the final prediction, with details of the CNN encoder shown on the right.

D. Training and Evaluation

During the main training procedure, a single window is randomly selected for each exam at each iteration. Gaussian noise with zero mean and a specified standard deviation (0.005) is added to this window. In addition, the dropbeat is applied with a probability of 0.2. When applied, a contiguous region corresponding to 20% of the selected window is masked with zeros at a randomly chosen temporal position. Since the last window contains zero padding by construction, the dropbeat introduces zero-valued regions at different temporal positions, reducing the risk that the model associates zeros exclusively with the padded region or treats their position as an informative feature. Furthermore, this temporal masking acts as a regularization strategy by preventing the model from relying on specific local segments and encouraging the temporal attention mechanism to prioritize the remaining informative regions.

Unlike training, the evaluation process incorporates all available windows from each exam. The representations obtained for windows of the same lead are aggregated by averaging before the inter-lead attention stage. Thus, the architecture retains the capability to utilize multiple windows during inference, while maintaining a single-window approach during training to reduce computational costs.

A partial overlap between consecutive windows was adopted to allow the network to observe the same portion of the signal within multiple temporal contexts. This allows segments present in one window to appear in the next, enabling the same part of the signal to be analyzed at two different moments. Conversely, sliding windows with minimal advance were not used; excessive overlap increases processing and memory usage without necessarily yielding significant performance gains [18].

Furthermore, the model does not require processing all windows for every training iteration. While this simplification might slightly reduce performance compared with using full window sequences, it enhances training efficiency and allows for the evaluation of a compact architecture based on its total trainable parameters. Accordingly, comparisons with models from the literature are performed at the level of the complete model, considering total parameter cost and classification metrics, rather than through layer-by-layer equivalence with reference architectures.

1) Model Parameters: Reference [16] presented a simplified CNN-VAE-based architecture for the PTB-XL dataset, using only three convolutional layers and 197,093 trainable parameters. The model reported a binary accuracy of 87.01% and an AUC of 0.8958. Similarly, this study also adopted an architecture with few convolutional layers, avoiding deeper structures with a larger number of convolutional blocks, such as IMLE-Net.

As described in Section III-C, the CNN encoder used in the model is composed of three 1D convolutional layers. In this subsection, this configuration is revisited only to explicitly calculate the temporal receptive field of the encoder. The three layers use kernels of size $k_1 = 39$, $k_2 = 19$, and $k_3 = 9$, respectively, all with a stride equal to $s_1 = s_2 = s_3 = 1$. With this configuration, the final receptive field of the encoder is calculated as:

$$R = 1 + (39 - 1) + (19 - 1) + (9 - 1) = 65. \tag{12}$$

Thus, each position in the final output of the encoder can depend on up to 65 samples from the input window. Since the signals used in this study are sampled at 100 Hz, this receptive

field corresponds to approximately 0.65 seconds. This interval covers durations associated with local ECG components, such as the P wave, whose normal duration is less than 120 ms, and the QRS complex, whose normal duration is approximately between 70 and 100 ms [19], [20]. In addition, it also covers ranges compatible with compound measurements, such as the PR interval, which is normally between 120 and 200 ms [21]. Therefore, the kernels used allow the network to consider isolated deflections as well as regions formed by nearby waves, segments, and intervals.

The last convolutional layer produces 128 filters. This choice was adopted based on IMLE-Net model. Thus, the proposed model maintains this final dimension as a reference before the attention modules. The temporal and inter-lead attention functions use an internal dimension equal to 64. After lead aggregation, the final representation is forwarded to the classification head.

Fig. 4 presents the classification head used in the proposed model. The input to this stage has dimension (B,128), where B represents the batch size. First, this representation passes through a linear layer with 128 units, followed by *LayerNorm* normalization, the *ReLU* activation function, and dropout with a probability of 0.3. Next, a final linear layer projects the representation to five output neurons, corresponding to the five diagnostic superclasses evaluated in this study. The final output has dimension (B,5) and corresponds to the logits used by the *BCEWithLogitsLoss* function.

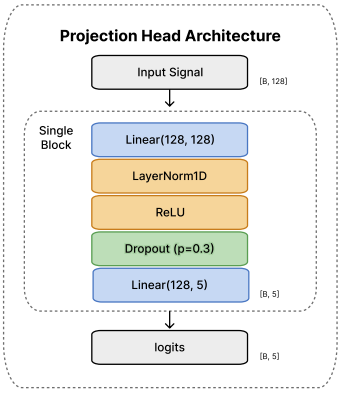

Fig. 4. Classification head of the proposed model

Table III compares the parameter distribution of the proposed model with the official implementation of IMLE-Net.

TABLE III
COMPARISON OF THE PARAMETER DISTRIBUTION BETWEEN THE PROPOSED MODEL AND IMLE-NET

Component	This work	IMLE-Net
CNN encoder	154,816	619,616
Temporal attention	27,456	9,088
Recurrent layer	–	98,816
Rhythm attention	–	9,536
Inter-lead attention	9,024	9,024
Classification head	17,413	645
Trainable parameters	208,709	746,725
Non-trainable parameters	–	1,792
Total	208,709	748,517

In both cases, most of the parameters are concentrated in the convolutional layers. However, this concentration is lower in the proposed model: the CNN encoder has 154,816 parameters, whereas the convolutional block of IMLE-Net has 619,616 parameters. This difference shows that the reduction in parametric cost does not occur only because of the absence of a recurrent stage. IMLE-Net has a specific number of parameters in the recurrent layer and rhythm attention mechanism, but the largest difference between the models lies in the convolutions. Thus, the main factor contributing to the reduction is the use of a more compact CNN encoder, with fewer layers and lower overall depth.

In total, the proposed model has 208,709 trainable parameters, whereas IMLE-Net has 746,725 trainable parameters. Considering the non-trainable parameters, the official implementation of IMLE-Net presents a total of 748,517 parameters. The proposed model, in turn, has no non-trainable parameters counted in this comparison and did not undergo hyperparameter tuning.

2) Training Configuration: To enhance reproducibility, training was conducted using a fixed seed of 42 to initialize random generators. Experiments were executed on an NVIDIA GeForce RTX 3050 Laptop GPU, utilizing a deterministic cuDNN configuration with benchmark mode disabled. The model was trained for up to 256 epochs, incorporating early stopping with a patience of 20 epochs. We adopted the Binary Cross-Entropy with Logits loss function, without class weights or data balancing, consistent with the training of IMLE-Net [5]. Weights were optimized using the AdamW optimizer [22], with a learning rate of 10^{-3} and a weight decay of 10^{-2}. During validation, a fixed threshold of 0.5 was applied to convert predicted probabilities into binary labels. Model selection was based on validation accuracy, and the model yielding the best performance was saved in a checkpoint directory, allowing for the recovery of its weights.

E. Evaluation Metrics

The evaluation of ECG classification models often combines threshold-independent and threshold-dependent metrics. ROC-AUC evaluates the model's discriminative ability without relying on a fixed decision threshold, whereas metrics such as accuracy and F1 depend on the binarization of model outputs and the specific threshold criteria applied. In this study, we employ the same metrics as those reported for IMLE-Net, which achieved notable performance on the PTB-XL dataset [5]. This approach enables a direct comparison between models, allowing for an assessment of both discriminative ability and performance at defined decision thresholds.

IV. RESULTS

This section presents the performance of the proposed model on the PTB-XL dataset, comparing it with established literature. The comparison focuses on the metrics: macro ROC-AUC, average accuracy, and F1 score. For the proposed model, we report two operating points: one with a fixed threshold of 0.5, and another with a global threshold optimized on

the validation set. In the comparative tables, the rank column indicates each model's position relative to the corresponding metric, where 1 denotes the best result.

Table IV presents the class-wise ROC-AUC comparison between the proposed model and the literature values, which are based on the results reported in the IMLE-Net work. The proposed model performs competitively with IMLE-Net across the five PTB-XL diagnostic superclasses, achieving higher ROC-AUC values in CD, HYP, MI, and NORM, and only slightly lower performance in STTC. Among all compared models, the proposed model obtains the best ROC-AUC values in CD, MI, and NORM.

TABLE IV
CLASS-WISE ROC-AUC COMPARISON

Model	CD		HYP		MI		NORM		STTC	
	Value	Rank	Value	Rank	Value	Rank	Value	Rank	Value	Rank

Table V presents the class-wise accuracy comparison. For the proposed model, the values were calculated using the standard 0.5 threshold, consistent with the methodology adopted in the IMLE-Net study. The proposed model performs competitively across the five PTB-XL diagnostic superclasses, achieving higher accuracy than IMLE-Net in CD, HYP, and NORM. Among all compared models, the proposed model obtains the highest accuracy values in CD, HYP, and NORM.

TABLE V
CLASS-WISE ACCURACY COMPARISON

Table VI summarizes the overall performance of the proposed model in comparison with the models evaluated in the IMLE-Net study. For the proposed model, we report both the results obtained with the fixed 0.5 threshold and those obtained at the maximum F1-score threshold.

TABLE VI
OVERALL COMPARISON

Model	Year	Macro ROC-AUC		Mean Accuracy		F1	
		Value	Rank	Value	Rank	Value	Rank
ResNet101	2016	0.8952	5	0.8678	6	0.7558	6
Mousavi et al.	2019	0.8654	6	0.8419	7	0.7315	7
ECGNet	2018	0.9101	4	0.8735	5	0.7712	5
Rajpurkar et al.	2019	0.9155	3	0.8791	4	0.7895	4
IMLE-Net	2022	0.9216	2	0.8885	2	0.8057	2
This work (threshold 0.50)	2026	**0.9296**	**1**	**0.8916**	**1**	0.7969	3
This work (threshold 0.33)	2026	**0.9296**	**1**	0.8851	3	**0.8103**	**1**

Reference [5] report the maximum F1 obtained through a threshold sweep on the test set, which differs from an F1 calculated using a validation-set threshold, we provide our maximum F1 result as an additional reference. This allows for a more equitable comparison with the protocol used in the IMLE-Net study, while the 0.5 fixed threshold remains our primary, reproducible operating point.

Overall, the proposed model achieves a macro ROC-AUC of 0.9296, exceeding the 0.9216 reported by IMLE-Net. Using a 0.5 threshold, it also surpasses IMLE-Net in average accuracy (0.8916 versus 0.8885). Although our F1 score of 0.7969 at this threshold is below IMLE-Net's 0.8057, applying the validation-set optimized threshold of 0.3333 increases our F1 to 0.8103, outperforming the literature. We emphasize that this comparison should be interpreted cautiously due to the differing thresholding methodologies. These results indicate that the proposed simplification maintains competitive performance.

Table VII presents an extended comparison of results from the literature on the PTB-XL dataset, allowing the proposed model to be situated among a broader set of recent architectures. References [14] and [16] are used to construct the extended comparison. When a metric was not reported in the original study, the corresponding field is marked as "–", and no rank is assigned.

TABLE VII
EXTENDED COMPARISON

Model	Year	Macro ROC-AUC		Mean Accuracy		F1	
		Value	Rank	Value	Rank	Value	Rank
Bidirectional LSTM	2020	0.9210	9	–	–	–	–
ResNet1D	2020	0.9300	4	–	–	–	–
Inception1D	2020	0.9210	9	–	–	–	–
XResNet1D101	2020	0.9280	7	0.8850	7	0.7370	8
MLBF-Net	2021	0.9310	3	–	–	–	–
IMLE-Net	2022	0.9216	8	0.8885	5	0.8057	2
IM-ECG	2025	0.9290	6	0.8920	3	0.7700	5
X-ECGNet	2025	**0.9360**	**1**	**0.9030**	**1**	0.7500	6
L5G-Net	2025	0.9357	2	0.8976	2	0.7706	4
Simplified CNN-VAE	2026	0.8958	10	0.8701	8	0.7454	7
This work (threshold 0.5)	2026	0.9296	5	0.8916	4	0.7969	3
This work (threshold 0.33)	2026	0.9296	5	0.8851	6	**0.8103**	**1**

The F1 and accuracy values for the external models are presented as reported in their original studies. Reference [14] addresses the PTB-XL superclass classification task but does not utilize the same threshold-selection procedure as this work. Therefore, the F1 comparison should be interpreted as a compilation of reported literature values rather than a direct comparison of strictly equivalent experimental protocols.

In this extended comparison, X-ECGNet achieves the highest macro ROC-AUC and mean accuracy, with 0.9360 and 0.9030, respectively. L5G-Net also demonstrates strong performance, with a macro ROC-AUC of 0.9357 and a mean accuracy of 0.8976. The proposed model does not outperform these architectures in terms of macro ROC-AUC or mean accuracy. However, with the fixed 0.5 threshold, it achieves an F1-score of 0.7969, outperforming most of the external models with reported F1 values. When the global threshold optimized on the validation set is used, the F1-score increases to 0.8103, representing the highest F1-score among the values included in the comparison.

Compared with the simplified CNN-VAE, the proposed model achieves higher macro ROC-AUC, mean accuracy, and F1-score. This result is significant as both models aim to reduce architectural complexity. However, the proposed model explicitly preserves the organization by windows and leads,

drawing inspiration from the hierarchical structure of IMLE-Net, whereas the simplified CNN-VAE adopts a more direct CNN architecture designed for automatic feature extraction from the ECG signal [16].

V. Conclusion

This work presented a compact deep learning architecture for multi-label ECG classification on the PTB-XL dataset, targeting the five diagnostic superclasses NORM, MI, STTC, CD, and HYP. The proposed model provides a simplified alternative to hierarchical architectures such as IMLE-Net, preserving the organization of ECG signals into windows and leads while removing recurrent components and reducing the depth of the CNN encoder. It combines a shallow 1D CNN, temporal attention, mean aggregation across windows, inter-lead attention, and a classification head.

The proposed simplification maintained competitive performance compared with models from the literature. The model achieved a macro ROC-AUC of 0.9296 and a mean accuracy of 0.8916 at a fixed threshold of 0.5, surpassing the corresponding values reported for IMLE-Net. Although its F1-score at this threshold was slightly lower, optimization of the threshold on the validation set increased the F1-score to 0.8103, the highest value among the compared results. Moreover, the proposed architecture uses 208,709 trainable parameters, substantially fewer than the 746,725 reported for IMLE-Net, supporting the feasibility of compact models for ECG classification.

Some limitations should be considered. The model was evaluated only on PTB-XL and the five superclass labels, limiting conclusions about generalization to other datasets, acquisition protocols, lead configurations, and more specific diagnoses. Comparisons with external models should also be interpreted with caution because threshold selection and evaluation protocols may differ across studies. In addition, extensive hyperparameter optimization was not performed.

Future work should evaluate the architecture on other ECG datasets and reduced lead configurations, as well as investigate alternative aggregation and attention strategies. Further studies may include hyperparameter tuning, calibration, class imbalance handling, and interpretability analyses of the temporal windows and leads emphasized by the attention mechanisms. Overall, the results indicate that compact attention-based CNN architectures can provide a favorable balance between predictive performance, parameter efficiency, and practical applicability in automatic ECG analysis.

***Abstract*—Diabetic retinopathy is a major cause of vision loss, highlighting the importance of developing automated methods to support disease screening and diagnosis. This study evaluated different deep learning architectures for classifying retinal fundus images into five levels of disease severity using the *Diabetic Retinopathy (resized)* dataset. Convolutional neural network and Vision Transformer architectures were compared using transfer learning, fine-tuning, data augmentation, and class weighting to address the substantial class imbalance in the dataset. The results showed that modern architectures, particularly ConvNeXt-Small and EfficientNetV2-S, achieved the highest overall performance. ConvNeXt-Small obtained the highest quadratic weighted Kappa score but showed very low sensitivity to the Mild class, whereas EfficientNetV2-S provided the most balanced trade-off between quadratic weighted Kappa and macro-averaged F1-score across the five severity levels. Because architecture, input resolution, and fine-tuning strategy varied jointly across experiments, these differences should be interpreted as configuration-level rather than purely architectural, and as validation-set results within this study rather than clinically validated performance. An ensemble strategy based on weighted soft voting was also evaluated; however, it did not outperform the individual models under the experimental configuration considered. Overall, the findings indicate that input image resolution, fine-tuning strategy, and appropriate handling of severe class imbalance are key factors affecting performance in multiclass diabetic retinopathy classification.**

***Index Terms*—Diabetic retinopathy, medical image classification, deep learning, convolutional neural networks, Vision Transformers, transfer learning.**

I. Introduction

Diabetic retinopathy (DR) is a microvascular complication of diabetes mellitus that affects the retinal blood vessels and constitutes one of the leading causes of preventable blindness among working-age adults [1], [2]. The continued growth of the global population with diabetes has substantially increased the demand for screening programs and early disease detection. According to Grzybowski [2], the worldwide expansion of diabetes and the increasing incidence of diabetic retinopathy have made the adoption of scalable ophthalmic screening solutions increasingly necessary, particularly in resource-constrained regions with limited access to specialists.

Traditionally, diabetic retinopathy is identified by ophthalmologists through the analysis of retinal fundus photographs. However, the large volume of examinations generated by population-based screening programs makes this process time-consuming, costly, and highly dependent on the availability of qualified professionals. In this context, artificial intelligence techniques, particularly those based on deep learning, have demonstrated considerable potential for automating medical image analysis and supporting clinical decision-making.

Among the pioneering studies in this field, Gulshan et al. [3] developed a system based on deep convolutional neural networks for the automated detection of diabetic retinopathy in retinal fundus photographs. The model achieved high sensitivity and specificity on independent validation datasets, demonstrating that deep learning algorithms can attain performance comparable to that of specialists in disease-screening tasks.

In recent years, architectural advances have further improved the performance of these systems. In addition to conventional Convolutional Neural Networks (CNNs), architectures based on attention mechanisms, known as Vision Transformers (ViTs), have achieved competitive results across several computer vision tasks. In a comparative study involving different retinal diseases, Saygılı and Atıcı [4] reported that the Swin Transformer outperformed conventional CNN architectures and other Transformer-based models, achieving the highest accuracy among the evaluated methods.

In parallel, approaches that combine multiple models have also been investigated to improve prediction robustness. Rajeshwar et al. [5] proposed a hybrid architecture based on deep learning feature extraction and a stacking ensemble, obtaining promising results for diabetic retinopathy detection. These studies reflect the growing interest of the scientific community in exploring different architectures and model-combination

Fig. 1: Examples of retinal fundus images from the dataset according to diabetic retinopathy severity level.

strategies to improve the performance of automated systems for ophthalmic screening.

Despite the advances reported in the literature, automated diabetic retinopathy classification still presents significant challenges. One of the main difficulties is class imbalance, since public datasets frequently contain a substantially larger number of images without signs of the disease than images representing more severe stages. Furthermore, diabetic retinopathy grading is both a multiclass and ordinal task, as the severity levels follow a clinical progression from no diabetic retinopathy (class 0) to proliferative diabetic retinopathy (class 4), according to the International Clinical Diabetic Retinopathy Disease Severity Scale [6], as illustrated in Fig. 1. Consequently, global metrics such as accuracy may not adequately represent model performance for minority classes, making the analysis of metrics such as the macro-averaged F1-score and quadratic weighted Kappa particularly important.

Within this context, this study aims to evaluate and compare different deep learning architectures for diabetic retinopathy classification using retinal fundus images. CNN- and Vision Transformer-based models were investigated, including ResNet50, DenseNet121, DenseNet169, EfficientNet-B0, EfficientNet-B2, EfficientNetV2-S, ConvNeXt-Small, and Swin-Tiny. Different fine-tuning strategies, data augmentation techniques, class-weighting schemes, and ensemble configurations were also evaluated to identify the most suitable approaches for the proposed classification task.

II. Methodology

The methodology consisted of an experimental comparison of different deep learning architectures for the multiclass classification of diabetic retinopathy in retinal fundus images. The experimental workflow included dataset preparation, image preprocessing, training of pretrained models through transfer learning, application of class-imbalance mitigation strategies, and model evaluation using metrics suitable for an ordinal and highly imbalanced classification problem.

A. Dataset

The publicly available *Diabetic Retinopathy (resized)* dataset [7], derived from the Kaggle diabetic retinopathy competition [8], was used in this study. The dataset contains 35,126 retinal fundus images labeled according to five severity levels: class 0, no diabetic retinopathy; class 1, mild diabetic retinopathy; class 2, moderate diabetic retinopathy; class 3, severe diabetic retinopathy; and class 4, proliferative diabetic retinopathy. Because these labels represent internationally established progressive levels of clinical severity [6], the problem was treated as an ordinal multiclass classification task.

The original dataset metadata are provided in a CSV file containing the image identifier and its corresponding severity level. To optimize model training, the images were reorganized into class-specific directories using a structure compatible with the *ImageFolder* data loader. The dataset was divided into training and validation subsets using an 80/20 ratio and stratified sampling according to class. To ensure reproducibility and consistency across all evaluated architectures, a fixed random seed of 42 was adopted. No independent external test set was used. The exact distribution of samples between the training and validation subsets is presented in Table I.

TABLE I: Dataset distribution by class

Class	Description	Total	Training	Validation
0	No DR	25,810	20,648	5,162
1	Mild	2,443	1,955	488
2	Moderate	5,292	4,234	1,058
3	Severe	873	699	174
4	Proliferative	708	567	141
Total	–	**35,126**	**28,103**	**7,023**

A substantial class imbalance can be observed, with class 0, representing images without signs of diabetic retinopathy, accounting for most of the samples. This imbalance motivated the use of evaluation metrics beyond accuracy and the application of class-weighting strategies during training.

B. Data Preprocessing and Class-Imbalance Handling

The images were resized according to the experimental configuration of each model. Input resolutions of 224×224, 256×256, 384×384, 512×512, and 1024×1024 pixels were evaluated. ImageNet mean and standard deviation values were used for normalization because the evaluated models were initialized with weights pretrained on the ImageNet dataset.

To increase the variability of the training data and reduce the risk of overfitting [9], data augmentation techniques were applied, including horizontal and vertical flips, rotations of up to 15°, and color transformations using *ColorJitter*. These transformations were applied exclusively to the training subset.

TABLE II: Summary of the main experimental configurations

Model	Resolution	Backbone	Augmentation	Optimizer (Head LR / Backbone LR)	Epochs	Remarks
EfficientNet-B0	224×224	Frozen	Horizontal/vertical flip	Adam (1e-4 / 1e-5)	25	Baseline
EfficientNet-B2	380×380	85% unfrozen	Flip, 15° rotation, ColorJitter	Adam (1e-4 / 1e-5)	19/25	Class weights applied
ResNet50	256×256	25% unfrozen	Flip, 15° rotation, ColorJitter	Adam (1e-4 / 1e-5)	23/25	Low macro F1-score
ResNet50	256×256	100% unfrozen	Flip, 15° rotation, ColorJitter	AdamW (1e-4)	24/25	Intermediate performance
DenseNet121	256×256	100% unfrozen	Flip, 15° rotation, ColorJitter	AdamW (1e-4)	21/25	High overall accuracy
DenseNet169	512×512	89.6% unfrozen	Flip, 15° rotation, ColorJitter	AdamW (1e-4 / 1e-5)	18/25	Best recall for severe classes
EfficientNetV2-S	384×384	85% unfrozen	Flip, 15° rotation, ColorJitter	Adam (1e-4 / 1e-5)	17/25	Improvement with larger images
EfficientNetV2-S	512×512	85% unfrozen	Flip, 15° rotation, ColorJitter	Adam (1e-4 / 1e-5)	14/25	**Best overall clinical balance**
Swin-Tiny	224×224	100% unfrozen	Flip, 15° rotation, ColorJitter	AdamW (1e-4)	25/25	Strong performance at low resolution
ConvNeXt-Small	512×512	100% unfrozen	Flip, 15° rotation, ColorJitter	AdamW (1e-4 / 1e-5)	29/50	Early stopping triggered
ConvNeXt-Small	1024×1024	100% unfrozen	Flip, 15° rotation, ColorJitter	AdamW (1e-4 / 1e-5)	3/50	**Highest overall Kappa**

Note: All models used a scheduler patience of two epochs and class weights to address class imbalance.

The validation images were not artificially augmented and underwent only resizing and normalization.

To address the observed class imbalance, a class-weighted *CrossEntropyLoss* function was used. The weights were calculated from the distribution of class labels in the training subset. Additional strategies, including *WeightedRandomSampler* and *Focal Loss*, were also explored. However, most of the main experiments relied primarily on class weighting within the loss function.

C. Evaluated Architectures and Experimental Variations

Architectures based on Convolutional Neural Networks and Vision Transformers were evaluated. The convolutional architectures included EfficientNet-B0, EfficientNet-B2 [10], EfficientNetV2-S [11], ResNet50 [12], DenseNet121, DenseNet169 [13], and ConvNeXt-Small [15]. Swin-Tiny [14] was evaluated as the representative architecture based on visual attention mechanisms.

Table II summarizes the main configurations and experimental variations investigated throughout the study. All models were initialized with weights pretrained on ImageNet, thereby characterizing a transfer learning approach [16]. The original classification layer of each architecture was replaced with a new layer containing five output units, corresponding to the five diabetic retinopathy severity levels.

Initially, the architectures were evaluated with a larger proportion of their pretrained layers frozen, providing baseline configurations. The most promising models were subsequently subjected to more specific adjustments, including partial or complete unfreezing of the backbone, increased input resolution, and changes to the optimization algorithm. This strategy enabled an assessment of the effects of fine-tuning and image resolution on classification performance.

D. Training Strategy

The experiments were implemented in Python using the PyTorch and torchvision libraries and were executed on CUDA-compatible NVIDIA GPUs. Because of the available GPU memory limitations, batch sizes were adjusted according to the architecture and input image resolution used in each experiment.

The Adam and AdamW optimization algorithms were used depending on the experimental configuration. In some experiments, different learning rates were assigned to the backbone and classification head, allowing smaller updates to the pretrained layers and greater adaptation of the new classification layer. The *ReduceLROnPlateau* scheduler was also used to reduce the learning rate when no improvement was observed in the monitored validation metric.

The maximum number of training epochs ranged from 25 to 50, depending on the evaluated model. To reduce overfitting, an early stopping strategy was applied, primarily monitoring the quadratic weighted Kappa score on the validation subset. The final version selected for each model corresponded to the best checkpoint obtained during training rather than necessarily the checkpoint from the final executed epoch.

E. Classification and Ensemble Strategy

The task was formulated as a direct multiclass classification problem. For each input image, the model generated a probability distribution across the five classes. The class with the highest predicted probability was assigned as the final classification output.

In addition to evaluating each model individually, an ensemble strategy based on *Weighted Soft Voting* was investigated. In this approach, the probability distributions generated by different models were combined using a weighted average. The weights were proportional to the individual performance of each architecture on the validation subset. The ensemble was evaluated to determine whether combining architectures from different model families could improve prediction robustness compared with the individual classifiers.

F. Evaluation Metrics

Model performance was assessed using accuracy, macro-averaged precision, macro-averaged recall, macro-averaged F1-score, and quadratic weighted Kappa. Accuracy was used as a general measure of the proportion of correct predictions. However, because of the substantial imbalance among the classes, accuracy was not considered sufficient when interpreted in isolation.

The macro-averaged F1-score assigns the same importance to each class regardless of its frequency in the dataset, providing a more appropriate assessment of model performance on minority classes. Quadratic weighted Kappa was adopted as the primary comparison metric because it accounts for the ordinal nature of the classification problem [17] and imposes greater penalties on errors involving classes that are farther apart on the disease-severity scale. Confusion matrices were

also analyzed to identify the main error patterns across diabetic retinopathy severity levels.

III. Results and Discussion

A. Overall Model Comparison

Table III summarizes the main results obtained in the experiments. To provide a concise comparison without including every tested configuration, the table presents the baseline model, the best-performing representative of each architectural family, and the final ensemble.

TABLE III: Comparison of the main evaluated models

Model	Res.	Accuracy	Macro F1	Kappa
EfficientNet-B0 (Baseline)	224	0.74	0.27	0.26
Swin-Tiny	224	0.69	0.52	0.63
DenseNet169	512	0.75	0.55	0.71
EfficientNetV2-S	512	0.80	0.54	0.73
ConvNeXt-Small	1024	0.82	0.53	0.75
Ensemble	–	0.73	0.39	0.47

The EfficientNet-B0 results illustrate a recurrent problem in highly imbalanced datasets. Although the model achieved an accuracy of 0.74, its Kappa score was only 0.26. This result indicates that the model predominantly learned to predict the majority *No DR* class, without adequately distinguishing among the different disease severity levels. This discrepancy reinforces the importance of evaluating the models using quadratic weighted Kappa and macro F1-score rather than relying exclusively on overall accuracy.

B. Best-Performing Individual Models

The three best-performing models, ConvNeXt-Small, EfficientNetV2-S, and DenseNet169, exhibited distinct classification profiles. These differences are particularly relevant when considering the potential application of such models in diabetic retinopathy screening.

ConvNeXt-Small achieved the highest Kappa score in the study (0.7453). However, it presented an important limitation, with a recall of only 0.05 for the *Mild* class and an F1-score of 0.09. This means that the model detected very few cases corresponding to the earliest stage of diabetic retinopathy, for which timely identification may be particularly important. Its high overall performance was strongly influenced by the majority *No DR* class, which represented approximately 73% of the dataset and achieved a recall of 0.93.

EfficientNetV2-S with an input resolution of 512 px provided the most balanced performance across the five classes, achieving a Kappa score of 0.7313 and a macro F1-score of 0.54. Recall values of 0.42 for *Severe* and 0.67 for *Proliferative* indicate that the model was able to identify relevant patterns in the most advanced disease classes despite the substantially smaller number of available samples.

The *Mild* class remained the most challenging, with a recall of 0.34 and an F1-score of 0.27. This result may be related both to the smaller number of samples in this class and to the subtle nature of early retinal abnormalities, which may be difficult to distinguish from healthy retinas or from moderate disease.

DenseNet169 with an input resolution of 512 px completed the group of best-performing models, achieving a Kappa score of 0.7114 and a macro F1-score of 0.55. The model showed slower convergence, reaching its best validation result at epoch 18, which suggests a more gradual optimization process. Its main strength was the performance on the *Proliferative* class, for which it achieved a recall of 0.67 and an F1-score of 0.67. Table IV presents the class-specific metrics for the three models.

TABLE IV: Class-specific metrics for the best-performing individual models

Model	Class	Prec.	Rec.	F1
ConvNeXt-S (1024 px)	No DR	0.90	0.93	0.92
	Mild	0.41	0.05	0.09
	Moderate	0.55	0.48	0.51
	Severe	0.52	0.28	0.36
	Prolif.	0.71	0.55	0.62
EfficientNetV2-S (512 px)	No DR	0.90	0.85	0.88
	Mild	0.22	0.34	0.27
	Moderate	0.59	0.60	0.60
	Severe	0.44	0.42	0.43
	Prolif.	0.57	0.67	0.61
DenseNet169 (512 px)	No DR	0.89	0.85	0.87
	Mild	0.17	0.30	0.22
	Moderate	0.62	0.51	0.56
	Severe	0.39	0.53	0.45
	Prolif.	0.67	0.67	0.67

C. Learning Curves

The convergence curves revealed distinct training behaviors among the evaluated models. Figures 2 and 3 present the training and validation loss and accuracy curves, respectively, for EfficientNetV2-S. The model showed stable convergence over 14 epochs, without a pronounced divergence between the training and validation curves before training was terminated by the early stopping criterion.

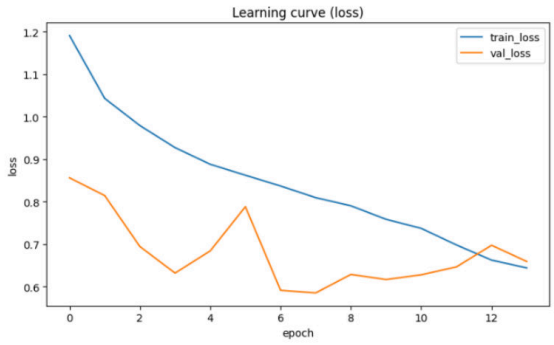

Fig. 2: Training and validation loss curves for EfficientNetV2-S at 512 px.

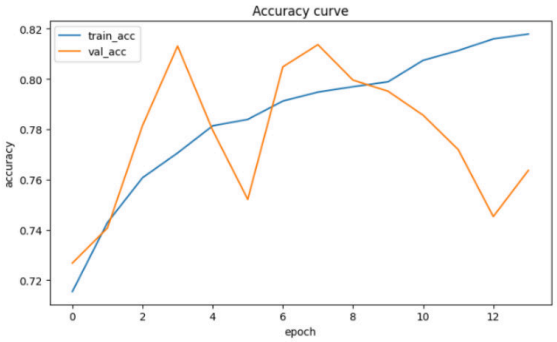

Fig. 3: Training and validation accuracy curves for EfficientNetV2-S at 512 px.

Figures 4 and 5 show the learning curves obtained for DenseNet169. Compared with EfficientNetV2-S, DenseNet169 required more epochs to stabilize but maintained a consistent improvement until approximately epoch 18.

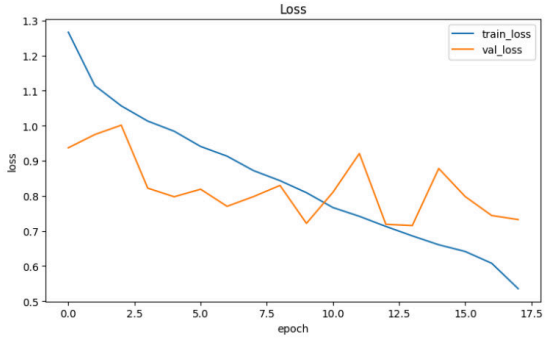

Fig. 4: Training and validation loss curves for DenseNet169 at 512 px.

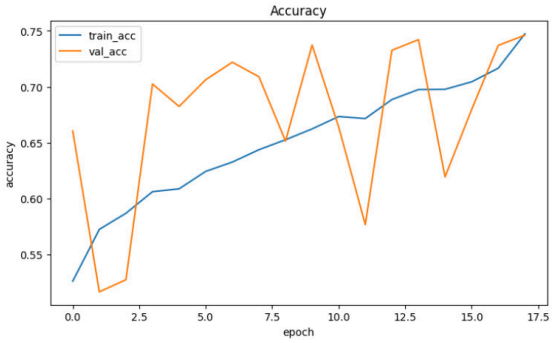

Fig. 5: Training and validation accuracy curves for DenseNet169 at 512 px.

ConvNeXt-Small, whose learning curves are presented in Figs. 6 and 7, achieved its best validation result at epoch 3. This early peak suggests that the combination of a fully unfrozen backbone, high-resolution input images, and the adopted learning-rate configuration led to rapid adaptation during the initial epochs. However, subsequent training did not improve the monitored validation metric, indicating limited additional benefit from further optimization under this configuration.

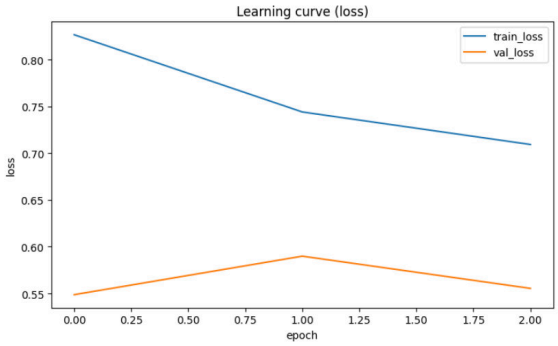

Fig. 6: Training and validation loss curves for ConvNeXt-Small at 1024 px.

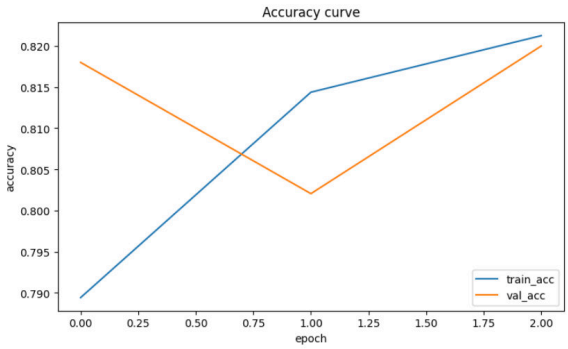

Fig. 7: Training and validation accuracy curves for ConvNeXt-Small at 1024 px.

D. *Confusion Matrices*

The confusion matrices of the three best-performing models provide a more detailed view of how each architecture was affected by class imbalance and highlight their individual strengths and limitations.

The confusion matrix of EfficientNetV2-S at 512 px (Fig. 8) confirms that the *Mild* class was the most challenging for the model. A considerable proportion of these samples was classified as either *No DR* or *Moderate*. This pattern is consistent with the subtle nature of early diabetic retinopathy findings, which may share visual characteristics with both healthy retinas and more evident moderate lesions.

The *Severe* class was also frequently confused with *Moderate* and *Proliferative*. In contrast, the strongest diagonal values were observed for the *No DR* and *Moderate* classes. Compared with the 384 px configuration, the 512 px model produced more consistent predictions for the *Severe* and *Proliferative* classes.

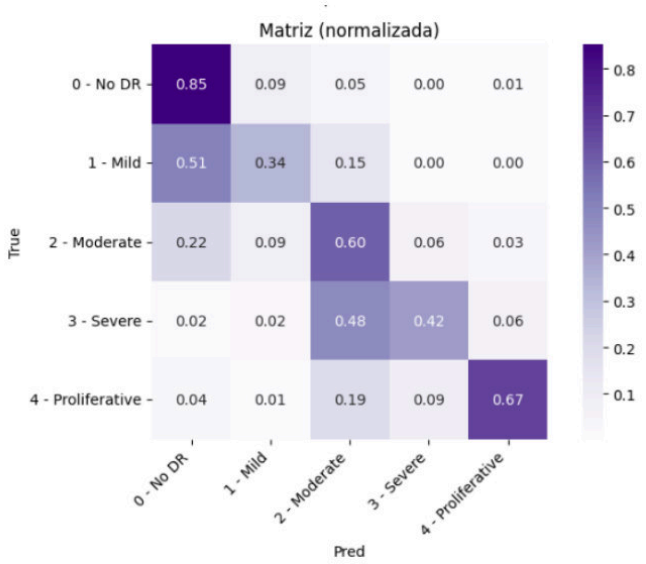

Fig. 8: Confusion matrix of EfficientNetV2-S at 512 px on the validation subset.

ConvNeXt-Small at 1024 px (Fig. 9) showed a pronounced tendency toward the majority *No DR* class, for which it achieved a recall of 0.93. In contrast, its recall for the *Mild* class was only 0.05, indicating that most mild cases were incorrectly classified, particularly as healthy retinas.

Therefore, despite obtaining the highest overall Kappa score, the model showed limited ability to identify the earliest disease severity level. This result demonstrates that a high aggregate metric does not necessarily imply balanced performance across all clinically relevant classes.

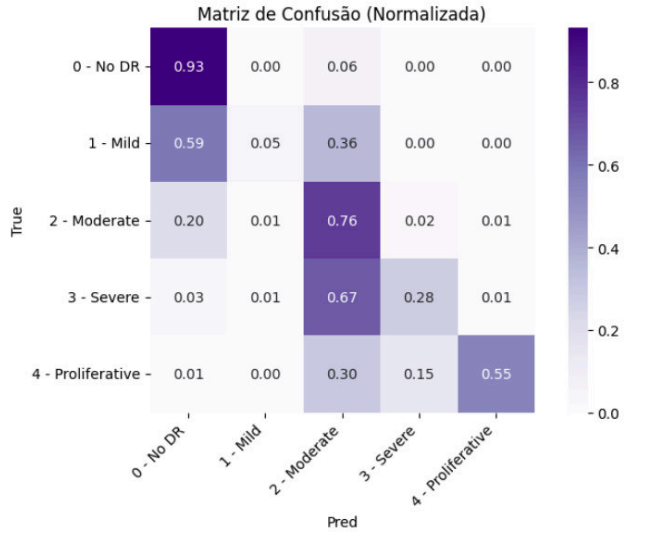

Fig. 9: Confusion matrix of ConvNeXt-Small at 1024 px on the validation subset.

The confusion matrix of DenseNet169 at 512 px (Fig. 10) showed a more distributed prediction pattern among the higher-severity classes. The model achieved a recall of 0.67 for the *Proliferative* class and a recall of 0.53 for the *Severe* class.

However, the low precision of 0.17 for the *Mild* class indicates a substantial number of false-positive predictions. This result suggests that the model frequently confused healthy retinas or samples from adjacent severity levels with mild diabetic retinopathy.

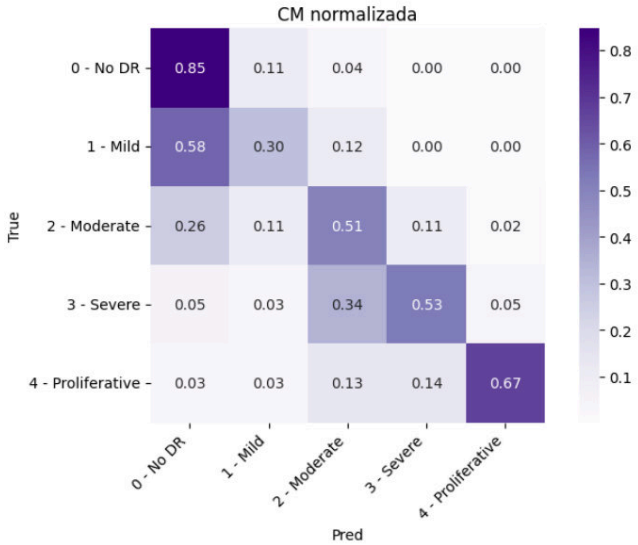

Fig. 10: Confusion matrix of DenseNet169 at 512 px on the validation subset.

E. Ensemble Results

The ensemble based on *Weighted Soft Voting* performed below expectations. Six models were combined using weights proportional to their individual Kappa scores. The resulting ensemble achieved a Kappa score of 0.4691 and a macro F1-score of 0.39, underperforming each of the three best individual models, as shown in Table V.

TABLE V: Comparison between the best individual models and the ensemble

Model	Macro F1	Kappa
ConvNeXt-Small (1024 px)	0.53	0.75
EfficientNetV2-S (512 px)	0.54	0.73
DenseNet169 (512 px)	0.55	0.71
Ensemble	**0.39**	**0.47**

Figure 11 presents the ensemble confusion matrix and shows how the combined model distributed its prediction errors across the five severity classes.

One possible explanation for this result is the lack of calibration among the probability distributions generated by the individual models. When model outputs are not calibrated on comparable scales, a weighted probability average may produce suboptimal predictions. Architectures with overconfident outputs may dominate the combined decision even when their class-specific predictions are less reliable than those of more conservative models.

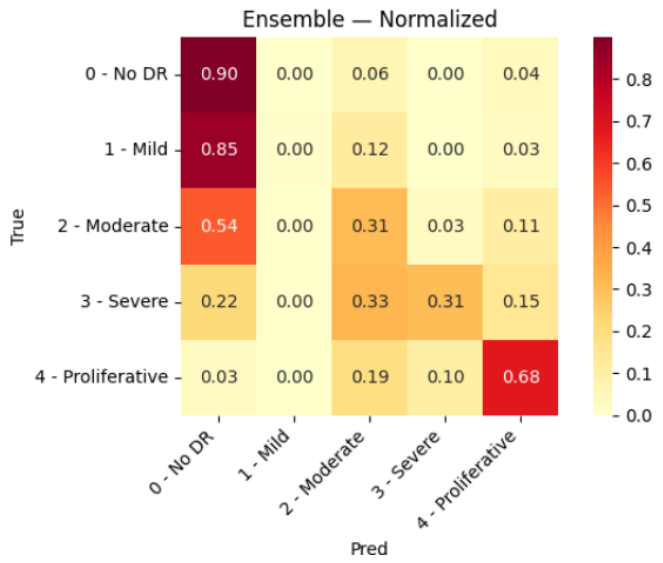

Fig. 11: Confusion matrix of the weighted soft-voting ensemble on the validation subset.

Furthermore, although the ensemble weights were derived from individual validation performance, they were assigned using a fixed empirical rule rather than optimized directly for the combined predictions. More systematic approaches, such as probability calibration, weight optimization, or a stacking meta-classifier, might produce a more effective combination.

Under the evaluated configuration, however, the ensemble did not provide a performance improvement sufficient to compensate for its additional computational cost. Simultaneous inference using multiple deep architectures increases memory requirements and inference latency, which may reduce the practicality of this approach in large-scale screening settings.

F. Discussion of the Main Findings

One of the most relevant findings was the influence of input image resolution. Increasing the EfficientNetV2-S input resolution from 384 px to 512 px raised the Kappa score from 0.57 to 0.73 and increased the recall for the *Mild* class from 0.26 to 0.34. This corresponds to a relative increase of approximately 31% in recall for this class.

A plausible explanation is that microaneurysms, small hemorrhages, and exudates associated with diabetic retinopathy may occupy relatively small image regions. Excessive downsampling can reduce the visibility of these findings and limit the model's ability to learn discriminative features, particularly for the earlier severity levels.

Nevertheless, the results should not be interpreted as evidence that increasing image resolution will systematically improve every architecture. Higher resolutions also increase computational cost and may require adjustments to the batch size, learning rate, regularization, and fine-tuning strategy. Therefore, image resolution must be considered jointly with the characteristics and original training configuration of each architecture.

The evaluated architectures were not compared under identical conditions. As summarized in Table II, input resolution, the proportion of unfrozen layers, the optimizer, the learning rates, and the number of epochs varied across configurations; For example, ConvNeXt-Small was evaluated at 1024×1024 px while the other architectures used lower resolutions (Table III). Isolating the individual contribution of architecture and resolution would require additional same-resolution experiments under otherwise identical settings, which we leave for future work.

Class imbalance remained a major limitation throughout the experiments. Class weighting in the loss function improved the model's sensitivity to minority classes but was not sufficient to compensate for the large difference in the number of samples. The *No DR* class contained approximately 36 times more images than the *Proliferative* class.

The *Mild* class was particularly challenging because it combined two difficulties: limited representation in the dataset and subtle visual differences from neighboring classes. ConvNeXt-Small illustrates the risk of evaluating an imbalanced multiclass model only through aggregate metrics. Although it achieved a Kappa score of 0.7453, its F1-score for the *Mild* class was only 0.09.

Therefore, selecting a model solely on the basis of its overall Kappa score could conceal substantial weaknesses in clinically relevant minority classes. Among the evaluated configurations, EfficientNetV2-S at 512 px provided the most balanced distribution of performance across the five severity levels. However, these results were obtained on the validation subset and should be confirmed using an independent test set before any conclusions regarding generalization or clinical applicability can be established.

IV. Conclusion

This study evaluated different configurations of deep learning architectures, including modern CNNs and a Vision Transformer, for the classification of five diabetic retinopathy severity levels using 35,126 retinal fundus images.

Among the evaluated architectures, EfficientNetV2-S with an input resolution of 512×512 pixels provided the most balanced class-wise performance, achieving a quadratic weighted Kappa score of 0.7313 and a macro F1-score of 0.54. ConvNeXt-Small achieved the highest overall Kappa score (0.7453); however, its recall of only 0.05 for the *Mild* class substantially limits its suitability for early-stage screening. The ensemble approach did not outperform the best individual architectures, indicating that combining model predictions requires appropriate probability calibration and weight optimization to be effective.

Although quadratic weighted Kappa was prioritized over overall accuracy to reduce the influence of the majority class, the substantial class imbalance still concealed important weaknesses in the minority classes. The use of class weights in the loss function improved the learning process but was insufficient to address the structural imbalance of the dataset. More robust imbalance-mitigation strategies should therefore

be investigated to improve the recognition of underrepresented severity levels, particularly the early stages of the disease.

Another relevant technical consideration concerns the effect of input image resolution. The experiments indicated that resolution can substantially affect classification performance, especially when the relevant pathological findings occupy small image regions. However, comparisons involving different input dimensions must be interpreted carefully because resolution changes also affect memory consumption, batch size, optimization dynamics, and the effective scale of the features processed by the network. Although several convolutional architectures can accept variable input dimensions through operations such as adaptive pooling, resolutions that differ substantially from those used during pretraining may alter the behavior of the learned representations. Therefore, comparisons across resolutions should be conducted under controlled experimental conditions and should consider the architectural design and documented preprocessing recommendations of each model.

The main methodological limitation of this study was the absence of an independent test set. Although the fixed random seed of 42 ensured consistent data partitions and prevented overlap between the training and validation subsets, the validation subset was used both to guide early stopping and model selection and to report the final ensemble performance. This repeated use of the same partition may introduce optimistic evaluation bias, since the final experimental decisions may be indirectly adapted to the validation data. Consequently, the reported results may overestimate the ability of the models to generalize to completely unseen data.

Future work should prioritize a rigorous three-way data partition comprising training, validation, and independent test subsets. Patient-level partitioning should also be adopted whenever information about the acquisition subject is available, thereby preventing images from the same patient from being distributed across different subsets. Additional investigations should evaluate model-specific input resolutions under controlled conditions and explore more advanced strategies for extreme class imbalance, including minority-focused data augmentation, *Focal Loss*, balanced sampling, and decision threshold adjustment. Probability calibration and systematically optimized ensemble strategies should also be investigated to determine whether model combination can provide improvements over the strongest individual classifiers.

***Abstract*—The wound healing assay is widely used to evaluate cell migration. However, its quantitative analysis is commonly affected by manual segmentation variability, especially in images with nonuniform illumination, cellular debris, and poorly defined wound borders. This study presents a comparative analysis of three digital image processing pipelines for automatic segmentation of the open wound area in wound healing assays. A total of 225 images with 2048 × 1534 pixels, acquired at 0 h and 24 h, were evaluated. The first pipeline was based on median filtering, local contrast enhancement, texture estimation, and Otsu thresholding. The second pipeline incorporated homomorphic filtering, morphological enhancement, Gabor-based texture extraction, and k-means clustering. The third pipeline introduced an adaptive approach based on image brightness and experimental time, with specific processing strategies for 0 h and 24 h images. The segmented areas were compared with manual annotations performed by specialists, and the signed error, absolute error, percentage error, and processing time were analyzed. The results showed a progressive reduction of segmentation errors across the developed pipelines, with the adaptive method providing the best balance between segmentation accuracy and computational cost. These findings reinforce the importance of standardized image processing procedures to improve reproducibility and support quantitative analysis in wound healing studies.**

***Index Terms*—automatic quantification, digital image processing, image segmentation, morphological processing, wound healing assay.**

I. Introduction

Trypanosoma cruzi and *Toxoplasma gondii* are two intracellular protozoa capable of causing infections of major public health relevance, although they have distinct characteristics, particularly regarding their modes of transmission and immune responses [1], [2]. *Trypanosoma cruzi*, the etiological agent of Chagas disease, is mainly transmitted by triatomine insects, but it can also be transmitted from mother to fetus, although at relatively low rates, ranging from 1% to 12%. In contrast, *Toxoplasma gondii*, the protozoan responsible for toxoplasmosis, has a worldwide distribution, infects a significant proportion of the population, and presents higher rates of congenital transmission, ranging from 22% to 72%. Despite these differences, both parasites are capable of interfering with the host immune response and modulating processes related to gene expression, which may influence the progression of infection [3].

Given this scenario, different studies have been conducted to understand the cellular damage associated with the action of these protozoa, as well as to investigate strategies capable of promoting tissue recovery [4], [5], [6]. Among the methods used, the in vitro assay known as the wound-healing scratch plate assay stands out, as it is employed to evaluate cell migration during the repair process. In this assay, cells such

as human fibroblasts are cultured in plates until they form a continuous cell monolayer, after which a "scratch" is made in this monolayer, simulating a wound. From this point, the ability of the cells to migrate into the injured area and promote the closure of the formed gap is observed. Thus, this model allows for the analysis of the effects of different substances or experimental conditions [7].

Cellular wound healing is monitored through image acquisition over time, allowing tracking of the rate at which the wound area closes. Thus, the faster the reduction of the open region, the greater the cell migration capacity tends to be in response to the treatment being analyzed. For this evaluation, images can be processed and quantified using specific software tools, which enable the measurement of parameters such as wound area, percentage of closure, mean width, and width standard deviation. Therefore, image processing techniques contribute to making the analysis of cellular wound healing more objective and reproducible [7], [8].

Some software tools are commonly used for image analysis in cellular wound healing assays, such as MATLAB and tools developed as plugins for ImageJ/Fiji. In this context, Suarez-Arnedo et al. developed their own ImageJ/Fiji plugin, called the Wound Healing Size Tool, with the objective of automating the analysis of images obtained from these assays. For this purpose, the images underwent processing steps as contrast enhancement, filtering, and binarization, allowing the automatic segmentation of the region corresponding to the wound. After this step, the plugin calculated important metrics, such as wound area, percentage of closure, and mean width. As a result, the authors observed that the tool showed performance similar to existing methods for area quantification. The plugin also reduced the analysis time, being faster than the manual method [9]. These software tools are developed with the objective of automating the process of wound area quantification, a step that is traditionally performed manually and is time-consuming, especially when the analysis involves large images datasets.

Therefore, the objective of this study is to perform a systematic comparative analysis of three digital image processing pipelines designed to automate the segmentation of open wound regions in vitro scratch assays under parasite infection. Specifically, this work introduces a novel, adaptive framework that adjusts filtering, enhancement, and region-of-interest constraints based on experimental time (0 h vs. 24 h) and image brightness levels. The ultimate goal is to establish a standardized, computationally efficient workflow that minimizes human subjectivity and mitigates the artifacts caused by cellular debris and non-uniform illumination, thereby enhancing quantitative accuracy and reproducibility in biomedical research.

II. MATERIALS AND METHODS

A. Image dataset

The study was performed with three wound healing assay image datasets from the Institute of Biomedical Sciences (ICBIM). Human fibroblasts were cultured to confluence in multi-well plates and infected with either T. cruzi or T. gondii. Mechanical scratch wounds were created across the monolayer using a sterile 200 µL pipette tip, followed by washing to remove unattached cells. Wound healing was monitored at 0 h and 24 h post-scratch using an EVOS XL Core inverted microscope (Thermo Fisher Scientific) under a 4× (or 10×) objective in brightfield mode, capturing uncompressed 2048×1534 pixel frames. The first dataset consisted of 47 images in TIF format, with 22 corresponding to the 0 h time point and 25 to the 24 h time point, contaminated with *Trypanosoma cruzi*. The second dataset consisted of 76 images in JPG format, 34 of which were from 0 h and 42 from 24 h. The third dataset contained 102 images in JPG format, equally distributed between the 0 h and 24 h time points, both contaminated with *Toxoplasma gondii*. The distribution of the images used in each dataset, considering the file format and experimental time points, is presented in Table I.

TABLE I
DESCRIPTION OF THE IMAGE DATASET USED IN THE STUDY

Dataset	Format	0 h	24 h	Analyzed
Dataset 1	TIF	22	25	47
Dataset 2	JPG	34	42	76
Dataset 3	JPG	51	51	102
Total	–	**107**	**118**	**225**

B. Overview of processing

The computational approach was based on the comparison of three automatic segmentation pipelines P1, P2, and P3. The first two versions were developed in MATLAB® (The MathWorks, Inc., Natick, MA, USA; institutional license no. 41224224), while the current version was developed in Python. All these tests were performed on the same computer, equipped with an Intel(R) Core(TM) i5-1035G1 @ 1.00 GHz processor and 16 GB of DDR4 RAM, in order to ensure that processing time comparisons were conducted under equivalent computational conditions.

To support reproducibility and facilitate independent evaluation of the proposed methods, the complete source code of the three processing pipelines is publicly available at https://github.com/anahaula/wound-healing-segmentation.git. The repository includes the implementation of the preprocessing, segmentation, morphological refinement, and quantitative evaluation stages, together with the parameter configurations adopted in each approach. The experimental microscopy images used for development and validation are not publicly distributed and are therefore not included in the repository.

In all approaches, images were first converted to grayscale intensity matrices, as wound delineation relies primarily on intensity gradients, local contrast, and textural variance rather than chrominance [10]. To overcome acquisition artifacts, CLAHE was employed for local contrast enhancement while limiting noise amplification [11]. Spatial smoothing, including Gaussian, median, and edge-preserving bilateral filtering, was

applied to attenuate local intensity fluctuations prior to segmentation [11], [13]. Following binarization, morphological operators (opening, closing, and hole-filling) were used to eliminate spurious detections, reconnect fragmented regions, and smooth boundary contours [12]. Finally, the open wound area was quantified by counting the remaining foreground pixels in the binary mask, as formulated in 3.

Finally, the wound area was calculated by counting the pixels belonging to the final binary mask, as shown in (2). Thus, after processing, each image was represented by a quantitative area measurement in pixels, allowing comparison with the manual delineation performed by specialists.

C. Pipeline P1: Initial approach

The first pipeline was developed as a strategy to assess the feasibility of automatic segmentation of wound healing images. Initially, the images were converted to grayscale and filtered using a median filter with an 11x11 window. This filtering step aimed to reduce local noise and small isolated intensity variations before the enhancement and segmentation stages.

Next, CLAHE was applied to enhance local contrast. This step was important because some images presented poorly defined borders between the open wound region and the area occupied by cells. After contrast enhancement, local texture was estimated through the standard deviation calculated within image neighborhoods. The local standard deviation measures the variation in intensity levels around each pixel. Regions with a higher cellular presence tend to present a more irregular texture, whereas the open wound region usually exhibits a more homogeneous pattern. Thus, the texture map was used to assist in differentiating the wound area from the cellular background. Segmentation was performed using Otsu thresholding, generating an initial binary mask.

The Otsu method automatically calculates a threshold based on the distribution of grayscale levels, and it was used in the first approach because it does not depend on a manually defined fixed value [14].

After binarization, the image underwent a post-processing step, that was used to remove small isolated regions. Morphological closing, composed of dilation followed by erosion, was applied to connect nearby regions and correct small discontinuities. Hole filling was used to correct internal gaps in the mask, and the removal of small components eliminated detected regions that did not correspond to the wound. This pipeline made it possible to obtain the first consistent automatic segmentations.

D. Pipeline P2: lighting correction and segmentation by textural features

The second pipeline was developed to reduce the influence of non-uniform illumination and improve the separation between the wound region and the cellular background. Initially, the image was normalized, standardizing the intensity range to reduce differences between brighter and darker images.

After normalization, homomorphic filtering was applied. This technique assumes that the image can be modeled as the product of an illumination component and a reflectance component. Illumination is associated with slow brightness variations, whereas reflectance is related to structural details, edges, and texture [10]. In the code, the image was transformed into the logarithmic domain, smoothed using a Gaussian filter to estimate the illumination component, and then this component was subtracted from the image [11]. In this work, the filter was defined as shown in (1):

$$H(u,v) = (\gamma_H - \gamma_L)\left[1 - e^{-c\frac{D^2(u,v)}{D_0^2}}\right] + \gamma_L \qquad (1)$$

Where γ_H controls the gain of the high frequencies, γ_L controls the gain of the low frequencies, c controls the slope of the filter transition, D_0 is the cutoff frequency, and $D(u,v)$ represents the distance from the point (u,v) to the center of the frequency spectrum. Thus, this step aimed to reduce the effects of shadows and irregular brightness while preserving information associated with the wound edges.

In addition to intensity information, textural features were extracted using Gabor filters. These filters respond to specific frequency and orientation patterns and were applied at multiple wavelengths and directions to highlight textural structures and edges with different orientations [10]. In the code, the responses of the Gabor filters were combined with the processed image, forming a feature set used in the clustering step.

Segmentation was performed using k-means, an unsupervised clustering method that separates data into classes with similar characteristics [10]. In this work, each pixel was represented by the features extracted from the image, and k-means grouped the pixels with similar intensity and texture patterns. The class most compatible with the wound region was then selected as the binary mask.

Finally, the mask is further refined by filling holes, removing small objects, selection of the largest connected component, and edge smoothing. The selection of the largest connected component retained only the largest continuous region of the mask, reducing false detections scattered throughout the image.

E. Pipeline P3: current adaptive approach

The third pipeline corresponds to the current version of the algorithm implemented in Python. Unlike previous approaches, this method eschews a single fixed set of parameters for all images. Instead, the processing was adapted according to the experimental time point and the mean intensity of the grayscale image.

The images were classified as bright, intermediate, or dark. We chose this division as images with different illumination levels have different responses to enhancement, filtering, and thresholding steps. For each group, specific parameters were defined for gamma correction, homomorphic filtering, CLAHE, smoothing, and morphological operations.

Gamma correction is a transformation on the intensity levels of an image. This technique allows the brightness distribution

to be adjusted before segmentation, making image regions brighter or darker according to the value of the gamma parameter [10]. In the code, this step was used to make bright or dark images more suitable for the subsequent enhancement and binarization steps.

Homomorphic filtering was maintained to reduce slow illumination variations (1), with only the parameters being adjusted. CLAHE was used to improve local contrast, while Gaussian, bilateral, and median filters were applied for smoothing and noise reduction. The combination of these filters made it possible to reduce small image irregularities without completely eliminating the main wound edges.

For the 24 h images, we included an additional step of cellular texture suppression based on the local standard deviation. This step was necessary because, after 24 h of the assay, cell migration may partly fill the open wound region, making the internal texture more similar to the cellular background. Therefore, the local standard deviation was used to identify regions with greater intensity variation and reduce the influence of cellular patterns that could be incorrectly interpreted as edges or as part of the wound area.

After adaptive processing, the mask was refined using multi-scale morphological operations. Morphological closing was used to connect nearby regions and correct continuity gaps; opening removed small isolated detections; hole filling corrected internal gaps; and the choice of the largest connected component preserved the main region associated with the wound. Edge smoothing was applied at the end to reduce abrupt irregularities in the segmented contour

For the 24 h images, segmentation was also spatially constrained based on the region detected at the 0 h time point, when this information was available. This constraint was adopted to avoid estimates that were incompatible with the original wound area, such as segmentations much larger than the original open region. Fig. 1 shows the workflow of the developed code.

F. Calculation of the wound area and closure

After segmentation, the wound area was calculated from the final binary mask generated by the algorithm. Considering $B_t(x, y)$ as the mask obtained at the experimental time point t, in which wound pixels are assigned a value of 1 and all other pixels are assigned a value of 0, the area in pixels was defined as (2):

$$A_t = \sum_{x=1}^{M} \sum_{y=1}^{N} B_t(x, y) \tag{2}$$

where A_t represents the segmented wound area at time point t.

For sequential images of the same sample, the wound closure percentage was calculated (3) to evaluate the reduction of the open area between 0 h and 24 h.

$$F_{0h \to 24h}(\%) = \left(1 - \frac{A_{24h}}{A_{0h}}\right) \times 100 \tag{3}$$

where A_{0h} corresponds to the initial wound area and A_{24h} to the remaining area after 24 h.

G. Quantitative Validation

The algorithm was validated by comparing the automatically segmented area with the area manually delineated by specialists. For each image, the signed error, absolute error, and absolute percentage error were calculated, as described in (4), (5), and (6), respectively.

$$E_s = A_{auto} - A_{manual} \tag{4}$$

$$E_a = |A_{auto} - A_{manual}| \tag{5}$$

$$E_p(\%) = \frac{|A_{auto} - A_{manual}|}{A_{manual}} \times 100 \tag{6}$$

where A_{auto} represents the area obtained by the algorithm and A_{manual} represents the reference area defined by the specialists.

To evaluate the overall performance of each pipeline, the mean absolute percentage error and the mean processing time per image were computed in (7) and (8), respectively.

$$\overline{E_p} = \frac{1}{n} \sum_{i=1}^{n} E_{p,i} \tag{7}$$

$$\overline{T} = \frac{1}{n} \sum_{i=1}^{n} T_i \tag{8}$$

where n represents the number of images evaluated and T_i corresponds to the processing time of image i.

In addition to area-based error metrics, spatial agreement between the automatic and manual segmentations was evaluated using the Dice coefficient:

$$Dice = \frac{2|M_{auto} \cap M_{manual}|}{|M_{auto}| + |M_{manual}|} \tag{9}$$

where M_{auto} and M_{manual} represent the automatic and manual wound masks, respectively. Dice values range from 0 to 1, with higher values indicating greater overlap. The coefficient was calculated for each image and summarized by pipeline and time point using mean, median, and standard deviation.

III. Results

A. Visual Segmentation Assessment

Fig. 2 presents a representative comparison of the segmentation boundaries generated by the three pipelines. P1 produced fragmented contours and was strongly affected by local artifacts, especially at 24 h. P2 improved the overall wound tracking but showed oversegmentation in some cellular regions. In contrast, P3 provided more coherent boundaries and better agreement with the manual reference, including in the more challenging 24 h images.

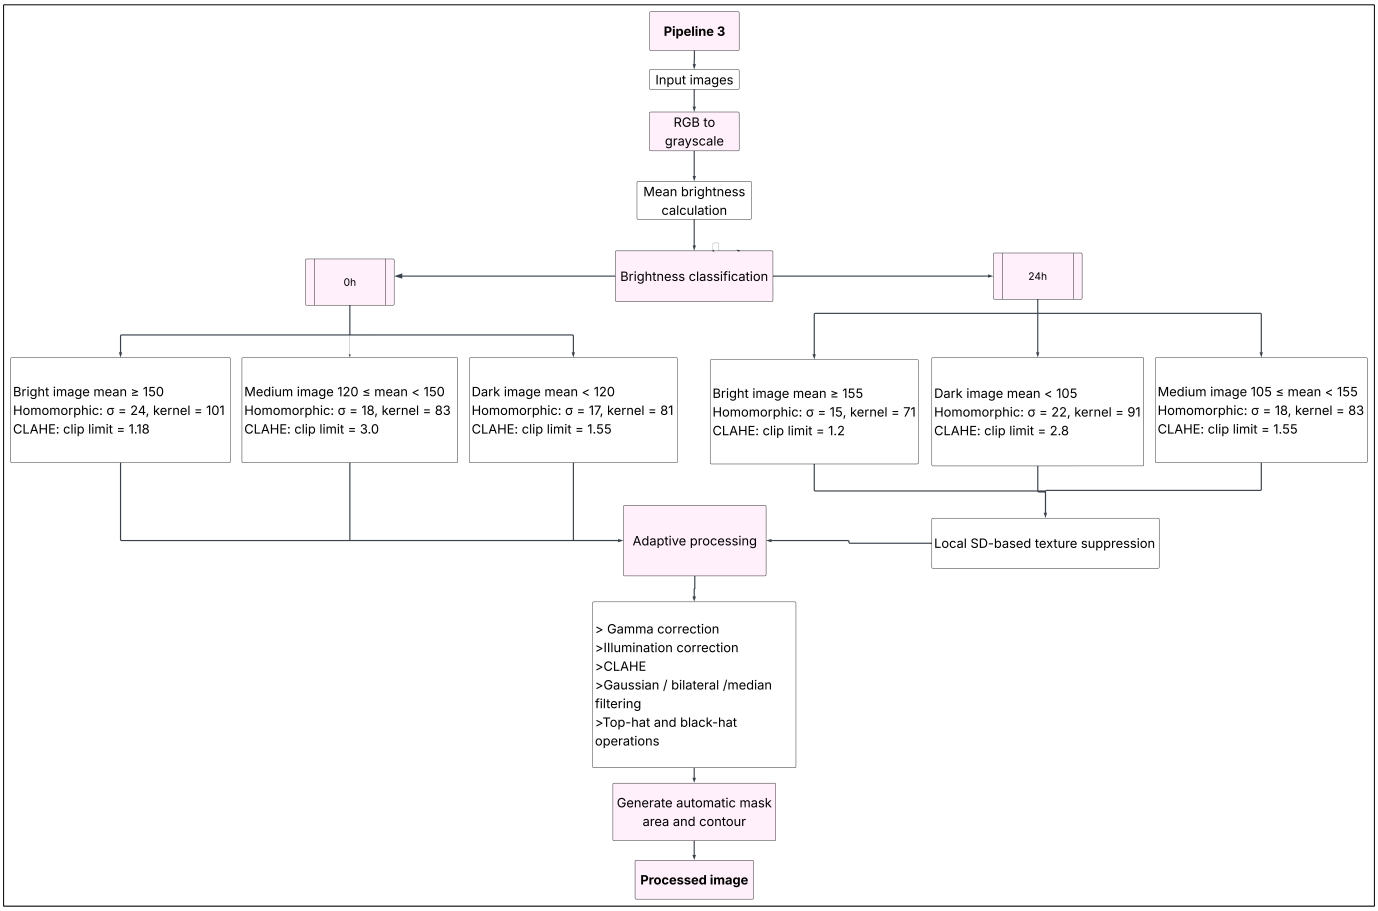

Fig. 1. Architectural flowchart of the proposed adaptive framework (Pipeline 3). The schematic maps the dynamic execution routing where input matrices are automatically stratified by experimental time points (0 h vs. 24 h) and specific mean brightness thresholds (bright, intermediate, or dark) to select optimal parameters for gamma correction, homomorphic filtering, and local contrast enhancement (CLAHE).

B. Error Distribution Analysis

The distribution of absolute percentage errors across designated ranges highlights a progressive optimization through the algorithmic iterations (Fig 3,Fig 4, and Fig 5).

For Pipeline 1 (Otsu-based), a critical vulnerability to undersegmentation was confirmed, with a massive concentration of images falling into the extreme error range (100%), encompassing 89 images at 0 h and 36 images at 24 h (Fig. 3).

Pipeline 2 (Gabor/k-means) successfully mitigated undersegmentation, shifting the majority of 0 h images to lower error tiers (29 images in 0–20% and 19 in 20–40%). However, it introduced widespread positive errors at 24 h, with 21 and 22 images scattered in the 60–80% and 80–100% ranges, respectively, due to a lack of illumination tolerance (Fig. 4).

Pipeline 3 (Adaptive) achieved the most robust error control. At the critical baseline condition (0 h), it concentrated 57 images in the lowest negative error tier (0–20%) and 25 images in the lowest positive tier (Fig. 5). At 24 h, despite the biological noise of cell proliferation, severe failures (100%) were restricted to a minimal subset (9 images), maximizing the number of samples within acceptable clinical tolerances (Fig. 5).

Table II presents the descriptive statistics of the absolute percentage discrepancy and the Dice coefficient obtained for the three processing pipelines at 0 h and 24 h. The table includes the mean and median values for each metric, together with the corresponding standard deviation. In this context, the standard deviation indicates the dispersion of the measurements within each group, allowing the variability of the segmentation results to be observed in addition to the central tendency represented by the mean and median. The Dice coefficient complements the area-based discrepancy by providing a spatial similarity measure between the automatic segmentation and the manual reference.

TABLE II
QUANTITATIVE EVALUATION OF THE PROCESSING PIPELINES AT 0H AND 24H

Metrics	P1	P2	P3
Mean error 0h (%) ± SD	82 ± 0.23	27 ± 0.31	17 ± 0.26
Mean error 24h (%) ± SD	173 ± 3.11	242 ± 3.23	100 ± 0.26
Median error 0h (%) ± SD	91 ± 0.23	14 ± 0.31	6 ± 1.74
Median error 24h (%) ± SD	94 ± 3.11	97 ± 3.23	35 ± 1.74
Median Dice 0h ± SD	0,03 ± 0,03	0,73 ± 0,34	0,84 ± 0,27
Median Dice 24h ± SD	0,05 ± 0,04	0,45 ± 0,32	0,64 ± 0,22

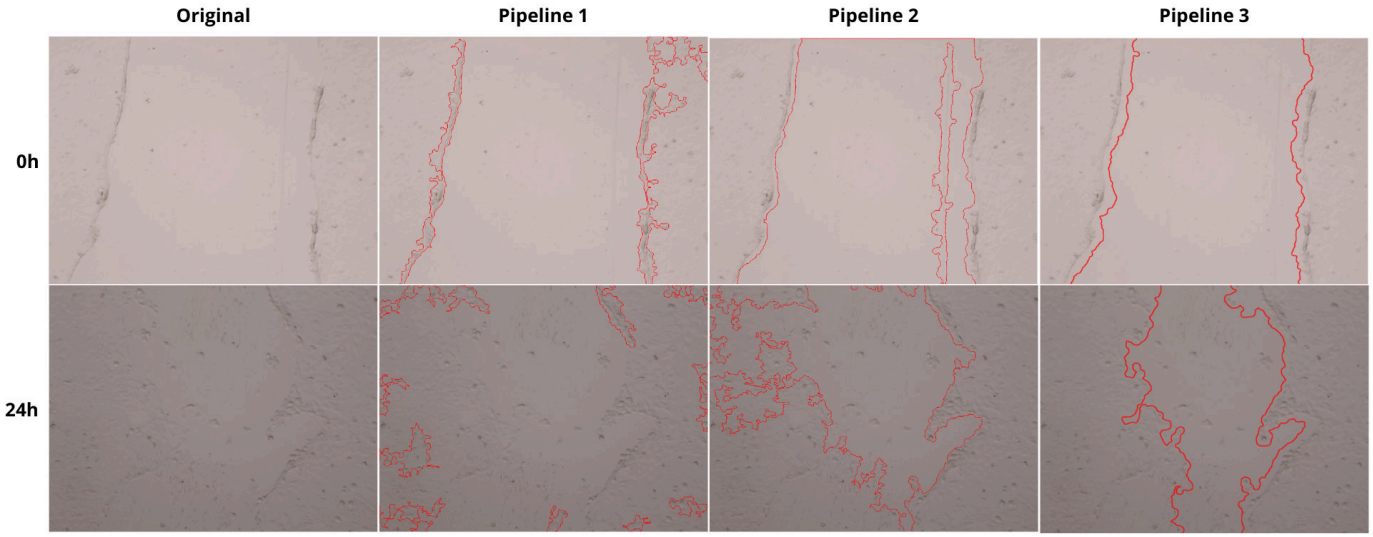

Fig. 2. Representative visual comparison of the automated segmentation boundaries (red contours) generated across the three development stages against the specialist's ground truth. The top row illustrates baseline tracking (0 h), contrasting Pipeline 1's sensitivity to structural noise with the progressive optimization of Pipelines 2 and 3. The bottom row (24 h) highlights the performance under active cellular migration, showcasing Pipeline 3's superior spatial coherence and topological stability when biological debris and low boundary contrast mislead conventional thresholding strategies.

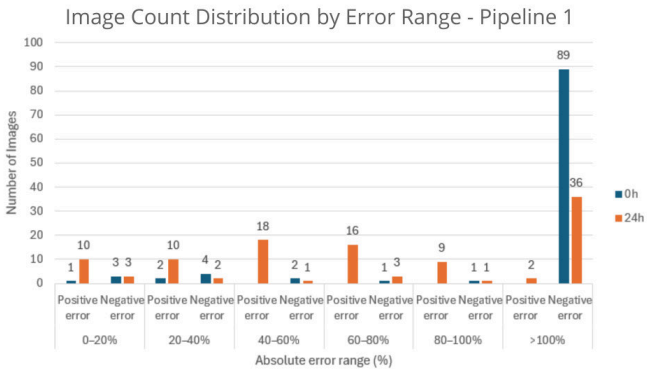

Fig. 3. Distribution of the image dataset analyzed across absolute percentage error ranges for Pipeline 1 (Otsu based) at 0 h and 24 h. The bars categorize the cumulative counts into positive and negative deviation tiers, highlighting the method's accuracy and error control compared to the specialists' manual annotations.

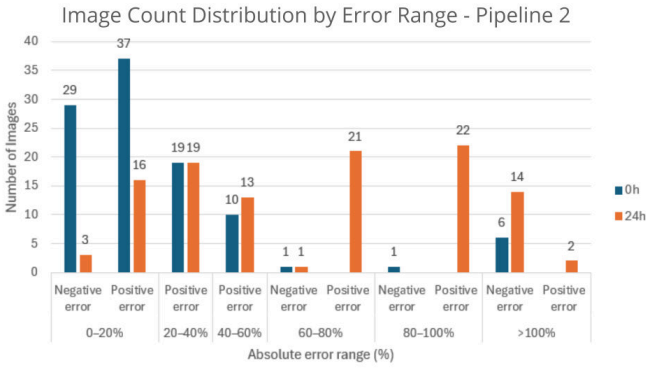

Fig. 4. Distribution of the image dataset analyzed across absolute percentage error ranges for Pipeline 2 (Gabor/k-means) at 0 h and 24 h. The bars categorize the cumulative counts into positive and negative deviation tiers, highlighting the method's accuracy and error control compared to the specialists' manual annotations.

C. Computational Efficiency

The computational throughput per image revealed an explicit trade-off between algorithmic complexity and processing time (Fig. 6). Pipeline 1 was the fastest, with a negligible median execution time below 1 seconds, but at the expense of segmentation viability. Pipeline 2 recorded the worst computational overhead and the highest dispersion (median 28 s), driven by multi-orientation Gabor filter convolutions and iterative k-means clustering. Pipeline 3 successfully restricted the computational cost (median 17 s), representing a significant speedup compared to Pipeline 2 while achieving superior accuracy through its dynamic parameters.

TABLE III
PROCESSING TIME STATISTICS FOR THE THREE EVALUATED PIPELINES

Metrics	P1	P2	P3
Mean time (s) $\pm$ SD	1 $\pm$ 0.48	28 $\pm$ 7.94	17 $\pm$ 3.22

IV. Discussion

The image dataset was processed using three pipelines developed progressively to address the main difficulties observed during segmentation. The images were acquired in wells containing liquid medium, without complete standardization of illumination, and also contained artifacts related to the experimental procedure and to the blade used during scratch generation. These limitations became even more evident at 24 h, when cells partially occupied the initially open region,

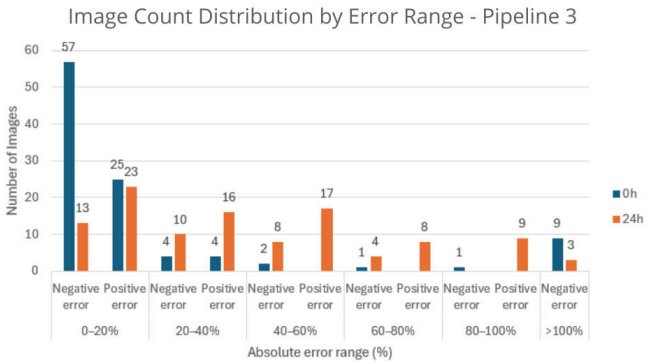

Fig. 5. Distribution of the image dataset analyzed across absolute percentage error ranges for Pipeline 3 (Adaptive Approach) at 0 h and 24 h. The bars categorize the cumulative counts into positive and negative deviation tiers, highlighting the method's accuracy and error control compared to the specialists' manual annotations

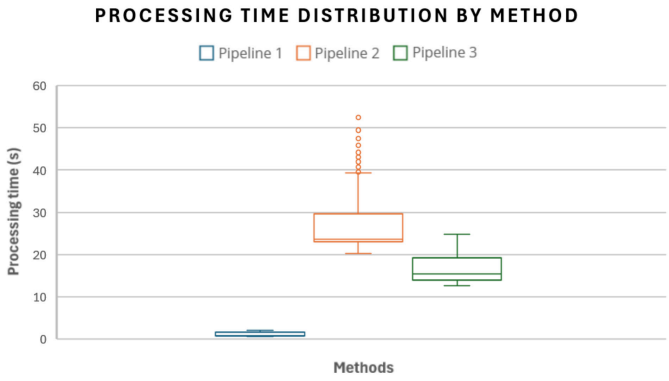

Fig. 6. Boxplot distribution of the computational processing time (in seconds) per image across the three evaluated segmentation pipelines. The whiskers and outliers illustrate the operational throughput and complexity trade-offs, highlighting the intermediate efficiency achieved by the dynamic Python framework (Pipeline 3).

reducing the contrast between the wound and the surrounding cellular area. Under these conditions, distinguishing cells, artifacts, and the remaining open region became more challenging for both automatic segmentation and manual reference delineation. Therefore, each pipeline was developed to address limitations identified in the previous one and progressively reduce segmentation errors.

P1 showed the expected behavior of an initial approach. Its main advantage was its low computational demand, with an average processing time of approximately 1 s per image. However, it presented the highest errors among the three pipelines, as shown in Table II. This behavior is mainly related to the dependence of Otsu thresholding on a global separation between foreground and background, a condition that is not always present in wound healing images. Since the open region does not exhibit uniform intensity and its boundaries may be smooth or discontinuous, local texture variations can be incorrectly interpreted as independent regions. This limitation is also reflected in the low Dice coefficient values obtained by P1.

P2 showed a clear improvement over P1 by incorporating homomorphic filtering to reduce illumination variations and Gabor-based features combined with k-means clustering. In Fig. 4, a reduction in extreme deviations can be observed at 0 h, with a greater concentration of images within the 0–20% and 20–40% error ranges. However, P2 still showed important limitations at 24 h. In these images, regions containing dispersed cells, debris, or textures similar to the open area were frequently incorporated into the segmentation. Thus, although texture analysis reduced some of the failures observed in P1, it was not sufficient to consistently distinguish the wound region in images with poorly defined boundaries and irregular cellular coverage.

P3 was developed to directly address these limitations. In Fig. 5, a greater concentration of 0 h images can be observed within the lowest discrepancy ranges, indicating greater stability in identifying the initial wound region. This result is particularly relevant because the area measured at 0 h serves as the reference for the subsequent calculation of wound closure. For the 24 h images, the corresponding 0 h mask was used to restrict the region analyzed, reducing the possibility of identifying areas outside the original scratch. Even with this strategy, the presence of cells within the open region and the reduced definition of its boundaries remained important sources of error. Therefore, the improvement observed with P3 does not eliminate the difficulties associated with 24 h images, but it reduces the occurrence of severe failures compared with the previous pipelines.

The statistics presented in Table II reinforce this behavior. At 0 h, P3 achieved a mean error of 17%, compared with 82% for P1 and 27% for P2, as well as a median error of only 6%, compared with 91% and 14%, respectively. The median Dice coefficient was also higher for P3, reaching 0.84, whereas P2 and P1 presented values of 0.73 and 0.03, respectively. At 24 h, despite the greater complexity of the images, P3 achieved a median error of 35%, lower than the 94% obtained by P1 and 97% by P2, while its median Dice coefficient reached 0.64, compared with 0.45 and 0.05 for P2 and P1, respectively. However, the mean error of 100% observed for P3 at 24 h indicates that a subset of particularly challenging images still produced large discrepancies, substantially increasing the mean. In this context, the difference between mean and median highlights the heterogeneity of the 24 h condition and the importance of considering the overall distribution of the results when evaluating pipeline performance.

When stratifying the P3 performance by pathogen, median Dice scores at 0 h and 24 h were 0.82 and 0.61 for T. cruzi (n=47), compared to 0.85 and 0.65 for T. gondii (n=178), respectively. Although T. cruzi assays presented higher debris from parasite motility, the adaptive brightness and multi-scale morphological filtering maintained robust boundary delineation across both infection models, demonstrating the method's versatility regardless of parasite type.

Regarding computational efficiency, P1 remained the fastest pipeline due to its simpler structure, whereas P2 presented the highest computational cost, mainly because of the Gabor filters

and k-means clustering. P3 required an intermediate processing time while maintaining a lower computational cost than P2 and a more favorable segmentation performance than the other pipelines. Therefore, when area error, Dice coefficient, and processing time are considered together, P3 provided the most favorable balance among the methods evaluated for this image dataset. This observation, however, should not be interpreted as evidence of statistical superiority or as an indication that the method will necessarily generalize to other datasets.

Despite the improvements achieved, the 24 h results show that there is still substantial room for further development. Future work should include the expansion and diversification of the image dataset to encompass different cell lines, laboratories, microscopy systems, and acquisition conditions, as well as manual references generated by multiple annotators. Additional spatial metrics, such as IoU and boundary-based measures, should also be considered, together with validation of the adaptive rules of P3 using images not involved in parameter definition. Automatic parameter optimization and comparisons with deep-learning approaches, including U-Net, DeepLabV3+, and SAM, are also relevant next steps. These evaluations will provide a stronger basis for assessing the robustness and generalizability of the proposed approach.

Overall, the results demonstrate a consistent progression across the three pipelines. P1 established an initial, computationally inexpensive approach but showed a high occurrence of segmentation errors. P2 reduced part of these discrepancies through illumination correction and texture analysis, although important limitations remained, particularly at 24 h. P3 achieved the lowest errors and highest Dice values among the evaluated pipelines while requiring less processing time than P2. Thus, under the experimental conditions and image dataset evaluated in this study, P3 showed the most favorable performance for segmentation and quantification of the open region in wound healing assays, while the 24 h images remain the main challenge to be addressed in future improvements.

V. Conclusion

This study compared three progressively developed classical image-processing pipelines for the segmentation of *wound healing images. P1 was the fastest approach but presented the highest segmentation errors, while P2 improved the results through illumination correction and texture analysis at a higher computational cost.

P3 showed the most favorable overall performance among the evaluated pipelines, reaching a mean area error of 17% and a median Dice coefficient of 0.84 at 0 h, as well as a median area error of 35% and a Dice coefficient of 0.64 at 24 h. Although the 24 h images remained more challenging, P3 reduced severe segmentation failures and provided a better balance between accuracy and processing time within the evaluated dataset.

Future work should focus on improving segmentation at 24 h and validating the method on more diverse and independent datasets. The use of multiple annotators, automatic parameter optimization, and comparisons with deep-learning approaches may further assess the robustness and generalizability of the proposed pipeline.

***Abstract*—This work presents a comparative and qualitative analysis of the performance of analog and digital band-stop filters applied to electromyographic (EMG) signal processing. The primary objective is to improve EMG signal quality by reducing power-line interference while preserving physiologically relevant characteristics. Five printed circuit boards were developed in Proteus software, each implementing a distinct notch filter topology: Fliege, Multiple Feedback (MFB), Sallen-Key, Tow-Thomas, and Twin-T. These were integrated into a custom acquisition system to evaluate hardware-based filtering effectiveness. In parallel, the same topologies were implemented digitally in MATLAB via bilinear transformation and applied to raw signals in which 60 Hz interference was deliberately retained. Evaluation was conducted through power spectral density analysis, windowed RMS, signal-to-noise ratio, and spectral preservation metrics. Results indicate that the analog Sallen-Key achieved the best 60 Hz rejection among analog topologies (20.37 dB), while the digital Twin-T yielded the highest attenuation (79.62 dB) and SNR (77.46 dB), although at the cost of the lowest in-band spectral preservation of the digital set (60.44 %). These findings support a hybrid architecture combining analog pre-filtering with digital refinement, with the digital topology selected according to whether maximum line rejection or maximum spectral fidelity is required. All *in-vivo* results were obtained from a single healthy volunteer in a single acquisition session, without independent replication, and should therefore be read as a proof-of-concept characterization rather than a statistically validated ranking.**

***Index Terms*—Power line artifacts, signal conditioning, notch filter, biomedical instrumentation, electromyographic signal.**

I. Introduction

The accurate acquisition and interpretation of electromyographic (EMG) signals are strictly dependent on the capability of the instrumentation system to isolate weak physiological biopotentials from surrounding environmental noise [1], [4]. Electromyography is highly susceptible to diverse types of degradation, including motion artifacts, baseline wander, and cross-talk from adjacent bioelectric sources [1]. Among these perturbations, power-line interference (PLI)-manifesting at 60 Hz or 50 Hz depending on the geographic region-constitutes one of the most pervasive and critical challenges in biomedical instrumentation.

In contrast to other electrophysiological signals (e.g., electrocardiography), attenuating PLI in EMG data presents unique technical difficulties. The dominant power spectrum of a surface EMG signal is distributed between 10 Hz and 150 Hz, often extending up to 500 Hz [2]. Because primary physiological components lie directly in the vicinity of the line frequency, conventional high-pass or low-pass filtering strategies are inadequate, as they inevitably clip meaningful neuromuscular data. Consequently, the selective suppression of this interference requires targeted band-stop (notch) filtering techniques alongside meticulous hardware design choices [3].

The fundamental design decision between implementing an analog notch filter within the early signal conditioning stage or applying a digital notch filter during post-processing involves critical trade-offs [4]. Hardware-based filters operate directly in the continuous-time domain, treating the signal before digitization. This approach prevents out-of-range saturation of Analog-to-Digital Converters (ADCs) and optimizes the dynamic range allocation [5]. However, physical analog components are inherently restricted by manufacturing tolerances, thermal drift, and parasitic impedances, which can displace the nominal center frequency ($f_0 = 60$ Hz) and alter the quality factor (Q) [6]. Conversely, discrete-time digital filters provide steep attenuation slopes, high numerical stability, and flexible coefficient tuning without hardware modification [7]. Nonetheless, digital alternatives increase the computational load and are strictly bound to the constraints of the prior sampling process, risking quantization noise amplification if the raw signal is heavily contaminated [5], [9].

Recent studies emphasize that unoptimized notch filter architectures can induce unwanted attenuation in adjacent frequency bands, distorting the morphological structure of Motor Unit Action Potentials (MUAPs) and skewing fundamental parameters such as median frequency and muscle firing rates

[8]. Therefore, a comprehensive comparative evaluation of distinct filter topologies is essential for the standardization of reliable biomedical acquisition protocols.

This paper presents a systematic comparative performance analysis of five classical notch filter topologies-Fliege, Multiple Feedback (MFB), Sallen-Key, Tow-Thomas, and Twin-T-implemented in both physical printed circuit boards (PCBs) and as digital IIR filters mapped via the bilinear transformation. The evaluation is conducted using a custom-developed biomedical acquisition system and validated through experimental surface EMG data collected from the *biceps brachii* muscle under controlled dynamic contractions. Performance is quantified across four rigorous criteria: absolute attenuation at 60 Hz, signal preservation index (P_{EMG}), temporal RMS attenuation impact, and resulting Signal-to-Noise Ratio (SNR).

II. Materials and Methods

A. EMG Biopotential Acquisition System Architecture

A high-fidelity hardware conditioning chain was developed to amplify and adapt the raw microvolt-level muscular potentials before digitization. The structural topology of the custom-developed frontend is organized into the following sequential blocks, summarized in Fig. 1:

1) *Primary Instrumentation Stage:* Centered around the precision INA128 instrumentation amplifier, selected for its high input impedance ($10^{10}\,\Omega$) and excellent Common-Mode Rejection Ratio (CMRR $>$ 120 dB). The primary differential gain G is governed by an external resistor R_g according to:
$$G = 1 + \frac{50\ \text{k}\Omega}{R_g} \tag{1}$$
An arrangement using a fixed $51\,\Omega$ resistor coupled to a 10 kΩ precision potentiometer enabled accurate gain adjustments.
2) *Active Bandpass Cascading Structure:* To isolate the neuromuscular spectrum, a 4th-order active high-pass Sallen-Key filter (cutoff frequency $f_c = 10$ Hz) was cascaded with a 4th-order active low-pass Sallen-Key filter ($f_c = 300$ Hz). Both sections utilize a maximally flat Butterworth response topology ($Q = 0.707$). The high-pass component values were dimensioned via:
$$4\pi\frac{f_c}{Q} = \frac{2}{R_2}\left(\frac{1}{C_1} + \frac{1}{C_2}\right) \tag{2}$$
yielding $R_2 = 2.25$ kΩ, $R_1 = 1.125$ kΩ for $C_1 = C_2 = 10\,\mu$F. The low-pass section component calculations resulted in $C_1 = 250$ nF and $C_2 = 125$ nF for a fixed $R = 3$ kΩ.
3) *Baseline Restorer (BLR):* An active integrator loop feeds the output offset voltage back into the reference pin of the INA128. This forms a continuous-time high-pass loop to eliminate DC drift without attenuating metabolic AC signals. With loop constants $R = 2.2$ MΩ and $C = 20$ nF, the equivalent cutoff satisfies:
$$f_{eq} = \frac{1}{2\pi RC} = 3.61\ \text{Hz} \tag{3}$$
4) *Driven Right Leg (DRL) Active Loop:* Common-mode voltage is sensed at pins 1 and 8 of the input buffer, inverted, amplified, and actively reinjected back to the subject through a safety-limiting resistor (1 MΩ). Frequency compensation via a parallel network ($R = 10$ kΩ, $C = 1.6$ nF) ensures loop stability against body capacitance.
5) *Level-Shifter and Safe Clipper Frontend:* Operates as a non-inverting scaling stage ($A_v \approx 101$) providing a fixed 2.75 V DC offset to align the biopotential centered inside the $0 - 5$ V unipolar range of the ADC. A low-voltage Zener barrier (1N4731A, $V_Z = 4.3$ V) tied to a biased voltage divider restricts potential spikes to a rigorous $0.075\ \text{V} - 4.925\ \text{V}$ absolute window to safeguard the microcontroller input.

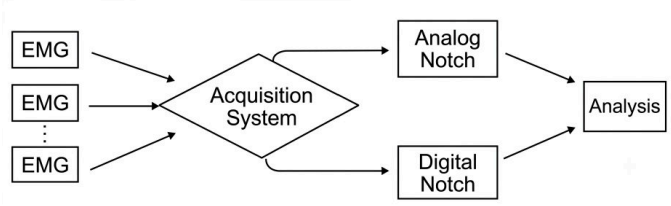

Fig. 1. Comprehensive architectural block diagram of the custom-developed electromyographic signal acquisition chain, highlighting the analog frontend blocks, filtering stages, and digital interface.

B. Analog Notch Filter Topologies

To establish an equitable baseline for structural comparison, the target line attenuation frequency was set to $f_0 = 60$ Hz, and the targeted quality factor was fixed at a reference value of $Q = 3.0$ across all continuous-time networks. Five architectures were constructed, two of which are illustrated in Fig. 2:

1) *Fliege Architecture:* Renowned for its highly selective band-rejection performance, this topology permits independent tuning of Q and f_0. Modeled using component constraints $R_5 = R_6 = 10$ kΩ, $C = 330$ nF, where $R_3 = R_4 = 8$ kΩ models the notch center frequency, and $R_1 = R_2 = 2QR_3 = 48$ kΩ tunes the selectivity.
2) *Multiple Feedback (MFB) Topology:* Employs the active op-amp within an integrator-based configuration. Resistor choices were derived from standard mathematical transfer definitions: $R_1 = Q/(2\omega_0 C) = 26.5$ kΩ, $R_2 = R_1/(Q^2 - 1) = 3.31$ kΩ, and $R_4 = 4R_1 = 106.08$ kΩ given a scaled baseline capacitance of $C = 150$ nF.
3) *Sallen-Key Notch Filter:* Configured as a voltage-controlled voltage source (VCVS) network where the active node functions strictly as a buffer. For a target capacitance $C = 220$ nF, the structural parameters evaluate to $R = 12$ kΩ with op-amp scaling feedback values set to $R_1 = 30$ kΩ and $R_2 = 20$ kΩ to yield an active gain of approximately 1.6.
4) *Tow-Thomas State-Variable Network:* Implemented as a continuous-time analog biquad integrating layout. The

discrete combination of parallel high-pass and low-pass output nodes forms the notch response. Choosing $C = 100$ nF and scaled parameters $R_1 = R_2 = R_3 = 100$ kΩ fixes the central tuning resistor to $R_4 \approx 7$ kΩ.

5) *Twin-T Passive-Active Configuration:* Employs a dual-path passive resistive-capacitive network inside an active feedback loop dedicated to scaling the sharpness of the notch. Component dimensioning based on $C = 220$ nF yields a baseline loop resistance of $R = 12$ kΩ.

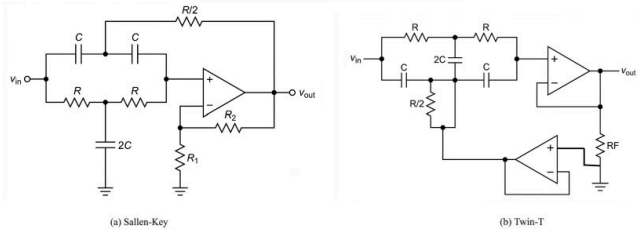

Fig. 2. Conceptual circuit diagrams of the two main topologies of active analog band-rejection filters evaluated.

C. Digital Filter Derivation and Post-Processing

The software-based counterparts were derived directly from the continuous-time Laplace transfer equations $H(s)$ of each physical circuit rather than standard canonical forms. Mapping into the discrete-time z-domain was performed via Bilinear Transformation (Tustin's method) to ensure exact preservation of stability boundaries:

$$s = \frac{2}{T_s}\frac{1 - z^{-1}}{1 + z^{-1}} \tag{4}$$

where $T_s = 1/f_s$ represents the sampling period ($f_s = 1200$ Hz, satisfying oversampling conditions equal to four times the low-pass cutoff frequency). To eliminate computational phase distortion, the derived Infinite Impulse Response (IIR) digital structures were executed via forward-backward filtering operations (`filtfilt`), rendering a strict zero-phase implementation.

D. Experimental In-Vivo Acquisition Protocol

Validation data were gathered from a single healthy adult volunteer using standard surface Ag/AgCl electrodes. The targeted neuromuscular anatomical area was the *biceps brachii* muscle body, mapped according to the SENIAM framework guidelines [12]. Local dermis preparation included mechanical abrasion and isopropyl cleansing to minimize the skin-electrode impedance boundary layer. The active differential pair was placed along the structural midline of the muscle fibers, while a reference electrode was secured over the low-activity acromion process. The movement sequence mandated five consecutive isometric voluntary muscle contractions, executed evenly within a fixed 15-second tracking window, maintaining a strict relaxation interval between bursts to eliminate neuromuscular fatigue variables. The five contractions were recorded as one continuous segment and processed as a single record; they were not treated as independent repetitions, and no dispersion statistics were derived from them (see Section III-E).

E. Ethical Considerations and Informed Consent

The experimental record analyzed in this work was obtained from one healthy adult volunteer, who is also one of the authors of this study and who provided informed consent prior to the acquisition, having been fully informed of the procedure, of its purpose, and of the intended use of the resulting data. The protocol was entirely non-invasive: it involved only surface Ag/AgCl electrodes applied to intact skin, with no pharmacological agent, no electrical stimulation, and no invasive procedure of any kind. Subject safety in the acquisition chain is enforced at the hardware level by the current-limiting resistor (1 MΩ) in series with the DRL reinjection path and by the Zener clamping network described in Section II-A. No clinical, demographic, or otherwise identifiable personal data were recorded, stored, or transmitted; only the anonymized biopotential waveform was retained, and it was used exclusively for the signal-processing analysis reported here. The study was conducted in accordance with the principles of the Declaration of Helsinki and with the IEEE EMBS Code of Ethics. The protocol was submitted to the Research Ethics Committee *Wladirson Ronny da Silva Cardoso* (Universidade do Estado do Pará, UEPA) on 6 August 2026 under protocol no. 2865255; committee approval was still pending at the time of manuscript submission, and the corresponding document will be provided to the editors as soon as it is issued.

F. Quantitative Performance Metrics

1) *Absolute Spectral Attenuation (A_{60Hz}):* Estimated using Welch's modified periodogram method with a non-overlapping Hanning window setup to suppress spectral leakage. Line attenuation was calculated across a locked ± 1 Hz band centered on the power network component:

$$A_{60\text{Hz}}\ [\text{dB}] = 10\log_{10}\left(\frac{\overline{P_{xx}}(59 - 61\ \text{Hz})}{\overline{P_{yy}}(59 - 61\ \text{Hz})}\right) \tag{5}$$

Acceptance criteria reported in the surface EMG denoising literature are adopted here as the reference scale: attenuation above 20 dB is regarded as adequate for the suppression of power-line interference, and attenuation above 30 dB as excellent [10], [11].

2) *Signal Preservation Coefficient (P_{EMG}):* Assesses structural integrity across the primary integration window ($10-300$ Hz), verifying that out-of-band energy profiles are preserved:

$$P_{\text{EMG}} = \frac{\int_{10}^{300} P_{yy}(f)df}{\int_{10}^{300} P_{xx}(f)df} \tag{6}$$

Note that the integration window contains the line component itself, so a fraction of the observed reduction in P_{EMG} corresponds to the interference that the filter was designed to remove rather than to lost physiological content.

3) *Temporal Global RMS Shift (Δ_{RMS}):* Quantifies time-domain energy attenuation using sliding windows ($W = 100$ ms, 50% overlap).
4) *Resulting Signal-to-Noise Ratio (SNR):* Determined by treating the difference vector $r[n] = x[n] - y[n]$ as the baseline noise floor:

$$\text{SNR [dB]} = 20 \log_{10} \left(\frac{\overline{\text{RMS}}_{filtered}}{\text{RMS}_{noise}} \right) \tag{7}$$

III. Results and Discussion

A. Hardware Validation Benchmark: Protoboard vs. PCB

Initial testing compared temporary protoboard assemblies against the finalized custom-fabricated PCBs using a deterministic 1 V_{pp} 60 Hz sinusoidal test signal. The empirical results are compiled in Table I.

The migration from temporary breadboard assemblies to fabricated PCBs did not produce a uniform improvement, and the results must be reported as mixed. The residual 60 Hz amplitude decreased for three of the five topologies (Fliege, $176 \rightarrow 130$ mV; Multiple Feedback, $136 \rightarrow 110$ mV; Tow-Thomas, $152 \rightarrow 130$ mV), remained essentially unchanged for the Sallen-Key ($116 \rightarrow 120$ mV), and degraded severely for the Twin-T, whose residual rose from 44 mV to 140 mV. The topology that produced the deepest null on the breadboard therefore became one of the shallowest once transferred to a board. Center-frequency placement follows an equally mixed pattern: the mean absolute deviation from the 60 Hz target decreased only marginally, from 0.22 Hz to 0.18 Hz, with three topologies moving closer to nominal and two moving further away. The measured bandwidth widened in four of the five circuits, indicating a general reduction of the effective quality factor after fabrication.

For the three topologies that improved, the gain is consistent with the elimination of long jumper wires and unstable contact resistances inherent to breadboard layouts, which introduce stray capacitive coupling and parasitic impedances capable of displacing the pole-zero placement of high-Q active networks. The Twin-T behaves differently because its rejection mechanism is fundamentally different: the null arises from the cancellation of two nearly equal signals travelling through the complementary R-$2C$ and $2R$-C arms, and the depth of that null is theoretically unbounded only while the two arms remain exactly balanced. The residual at f_0 is thus a small difference between large quantities, so even a modest absolute asymmetry produces a large relative change in the measured residual. On a PCB, the distributed capacitance of the copper traces and of the ground plane at the internal T node, the leakage paths across the board surface, the input capacitance of the active device, and a different realization of component tolerances all act to unbalance the arms. The breadboard build happened to sit close to balance, which explains its 44 mV residual; the fabricated board did not. This makes the Twin-T the least layout-tolerant of the five topologies evaluated, and its PCB implementation is consistent with this interpretation, exhibiting simultaneously the shallowest null degradation and the widest bandwidth of the set (22 Hz, i.e. an effective $Q \approx 2.7$ against the nominal $Q = 3.0$). Practical implementation of a Twin-T on a board therefore requires guarded routing at the T node, matched or trimmable arm components, and post-assembly tuning, none of which were applied here.

B. Analog Filtering Performance Characterization

Following the in-vivo experimental acquisition protocol, the continuous-time notch filtering systems were evaluated. Quantitative signal processing results are detailed in Table II, and the corresponding spectral comparison is shown in Fig. 3.

The Sallen-Key architecture outperformed all alternative hardware-based filters, achieving an absolute 60 Hz attenuation of 20.37 dB. This is the only analog topology reaching the 20 dB level adopted in the surface EMG literature as the threshold of adequate power-line suppression [10], [11]. The Tow-Thomas network achieved a comparable attenuation of 18.74 dB, marginally below that level, but introduced a higher signal distortion profile, reducing the structural preservation index to a low value of 54.60%. Given that the two figures differ by less than 2 dB and originate from separate single-trial acquisitions, this ordering should not be treated as a resolved ranking (Section III-E). The low relative performance of the remaining hardware topologies can be attributed to out-of-band phase distortions and component value drift. The negative SNR calculations arise from the strict evaluation method used, which treats any out-of-band attenuation or phase deviation within the raw baseline signal as noise.

C. Digital Filtering Performance Characterization

The discrete-time IIR filters, mapped via exact bilinear discretization, were executed on the raw (unfiltered) digital EMG signal vectors. The processing metrics are summarized in Table III, with the corresponding spectral comparison shown in Fig. 4.

In the software domain, the Twin-T digital configuration demonstrated the deepest line suppression of the set, rendering a notch depth of 79.62 dB coupled with a reconstruction SNR of 77.46 dB. This sharpness is a direct result of digital execution, which operates with absolute coefficient precision and is immune to physical component tolerances, temperature variations, or contact degradation. The digital Sallen-Key and Tow-Thomas filters also formed a highly effective processing tier, achieving strong line attenuation (> 54 dB) while maintaining superior out-of-band signal preservation compared to the Twin-T structure.

The Multiple Feedback result requires separate comment, as it is a clear outlier. Its digital attenuation at 60 Hz (0.44 dB) lies two orders of magnitude below every other digital implementation ($42.07 - 79.62$ dB) and is also inconsistent with the behavior of the same topology in hardware, where the fabricated MFB board reduced a 1 V_{pp} test tone to 110 mV (Table I) and reached 10.28 dB of attenuation on the in-vivo record (Table II). The remaining digital metrics reinforce this reading rather than contradicting it: the highest preservation

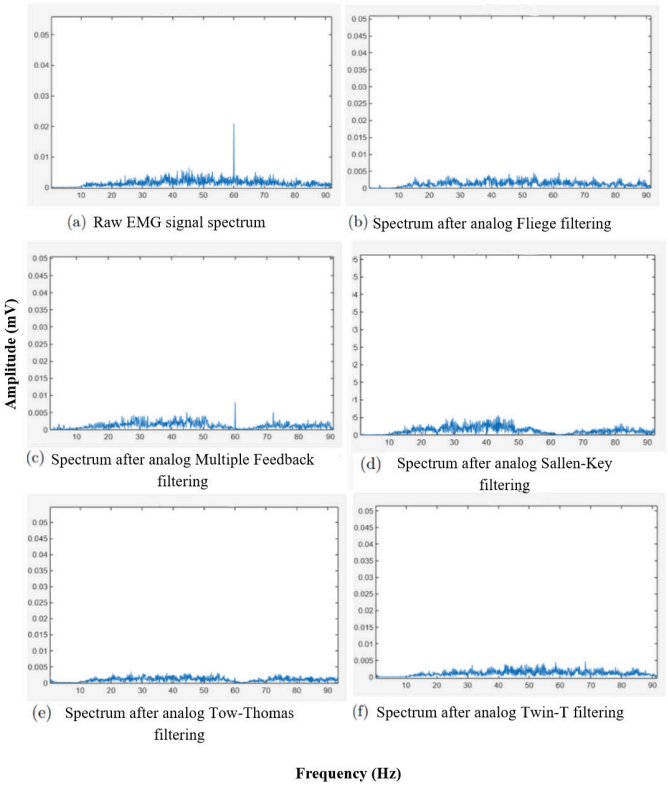

Fig. 3. Frequency spectra comparison of the raw surface electromyographic (EMG) signal against the five evaluated active analog notch filter implementations.

index of the entire set (94.90%) combined with the smallest global RMS shift (0.45 dB) describes a transfer function that is close to transparent across the whole band, which is the signature of a filter that removes almost nothing, not of a selective band-stop response. We therefore interpret this value as an implementation artifact rather than an intrinsic limitation of the MFB architecture. The most probable cause is an error in the symbolic derivation of $H(s)$ for this particular network. The MFB notch response is formed by combining a band-pass path with the direct input path, so an incorrect gain, sign, or resistor ratio in that combination displaces the transmission zeros off the imaginary axis and leaves a shallow dip in place of a true null. This network is especially exposed to such an error because the zero placement depends strongly on the ratio $R_2 = R_1/(Q^2-1)$, which for $Q = 3.0$ implies a factor of eight between the two resistors. A secondary hypothesis is numerical degradation in the discretization, although the absence of frequency pre-warping alone displaces the discrete notch by less than 0.5% at $f_s = 1200$ Hz, which cannot account for a 0.44 dB result given the nominal notch bandwidth of approximately 20 Hz. Verification of the numerator coefficients, confirming that the discrete zeros lie on the unit circle at $\omega_0 T_s$, and re-implementation as cascaded second-order sections with pre-warping, are required before this topology can be ranked fairly. Until that verification is performed, the digital MFB figure is reported here as inconclusive and is excluded from the comparative ordering.

The rejection advantage of the digital Twin-T carries a measurable cost in spectral fidelity that must be stated explicitly, since this is the topology recommended for the digital stage of the architecture proposed in Section IV. Its preservation index (60.44%) is the lowest of the digital set, between 19 and 34 percentage points below the other digital implementations, and its global RMS shift (4.37 dB) is the largest. Because P_{EMG} is integrated over $10 - 300$ Hz, that is, over the band

that carries the neuromuscular information, the loss is not cosmetic: MUAP morphology, median and mean frequency estimators, and amplitude-based activation indices are all derived from this band and are therefore susceptible to bias, a mechanism already reported for aggressive notch filtering [8]. Part of the reduction necessarily corresponds to the removal of the interference itself, which also lies inside the integration window, and separating the two contributions would require recomputing P_{EMG} over $10 - 300$ Hz with the $59 - 61$ Hz band excluded; this refinement was not performed here and is left for future work. In practical terms, applications whose objective is the removal of a dominant line component with limited sensitivity to spectral shape, such as onset detection or gross activation timing, can accommodate this trade-off. Applications in which spectral parameters are themselves the measured quantity, such as fatigue monitoring through median-frequency shifts, conduction-velocity estimation, or MUAP-based indices, are better served by the digital Sallen-Key (56.73 dB, 79.28%) or Tow-Thomas (54.16 dB, 82.32%), which still exceed 54 dB of line rejection while retaining approximately 80% of the in-band energy.

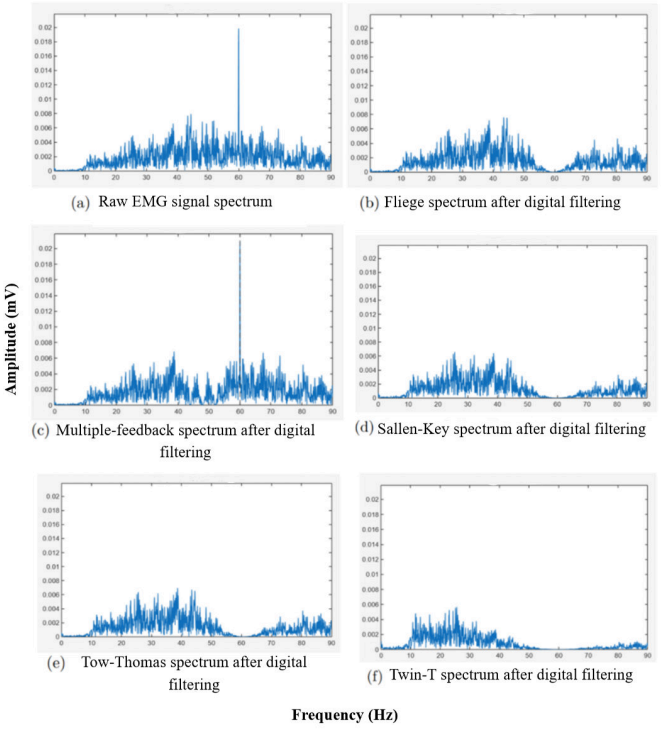

Fig. 4. Frequency spectra comparison of the raw surface electromyographic (EMG) signal against the five evaluated discrete-time zero-phase IIR notch filter implementations.

D. Analog vs. Digital Architectural Discussion

Comparing the two analytical frameworks reveals that digital implementations provide significantly deeper, more stable, and more precise line frequency attenuation than physical hardware filters. However, this comparison must be interpreted within the context of a complete biomedical acquisition system.

Relying entirely on digital post-processing means the input frontend must handle heavily contaminated raw signals. If power-line noise magnitudes exceed the limits of the ADC frontend, it can lead to signal saturation, clipping, and irreversible quantization distortion. Conversely, incorporating an analog notch stage (such as the Sallen-Key topology) minimizes noise amplification early in the conditioning chain, preserving the full dynamic range of the ADC. The optimal solution for high-fidelity electromyographic instrumentation is therefore a hybrid architecture, combining early analog filtering to prevent saturation with digital IIR processing for final spectral cleanup. Within that architecture, the analog stage is best served by the Sallen-Key, which was both the only analog topology to reach the 20 dB criterion and the one whose bench behavior proved least sensitive to the transition from breadboard to fabricated board. The digital stage admits two defensible choices: the Twin-T when maximum line rejection is the priority, and the Sallen-Key or Tow-Thomas when preservation of in-band spectral content is critical to the intended measurement.

E. Study Limitations

The scope of the conclusions that can be drawn from this comparison is bounded by the experimental design. All in-vivo results reported in Tables II and III and in Figs. 3 and 4 originate from a single healthy volunteer, a single muscle, and a single acquisition session. The five contractions were performed within one continuous 15-second window and were processed as one record rather than as independent repetitions, so no standard deviations, confidence intervals, or significance tests accompany the reported metrics. Every value in the tables is consequently a point estimate from one realization, and differences of a few decibels between adjacent topologies fall within a margin that the design cannot resolve. Large separations, such as that between the digital Twin-T and the remaining digital filters, are robust to this limitation; close comparisons, such as the 1.63 dB gap between the analog Sallen-Key and Tow-Thomas, are not.

A second constraint concerns the asymmetry between the two comparisons. The digital topologies were applied to a common raw record, so the differences among them reflect the filters alone. Each analog topology, in contrast, required its own acquisition, since only one board could be inserted in the conditioning chain at a time; the analog comparison therefore carries the natural physiological variability between contractions of the same subject, arising from motor unit recruitment patterns and small differences in electrode-skin conditions across trials. Future evaluations should adopt a programmable generator reproducing a synthetic EMG signal with known spectral and temporal characteristics, so that an identical stimulus can be replayed through every topology, and should extend the in-vivo protocol to multiple volunteers, muscle groups, contraction levels, and fatigue conditions before any topology ranking is presented as generalizable.

IV. Conclusion

This study evaluated and compared five active notch filter configurations across both the continuous analog hardware domain and the discrete digital software domain. The experimental results show that the Sallen-Key configuration provides the most effective analog hardware implementation, and the only one reaching the 20 dB attenuation criterion adopted in the literature [10], [11], while the digital IIR implementation of the Twin-T topology offers the deepest line rejection, achieving an attenuation of 79.62 dB. That advantage is not free: the digital Twin-T also exhibits the lowest in-band preservation of the digital set (60.44%), so the digital stage of a hybrid conditioning chain should be selected according to the intended measurement, with the Twin-T reserved for applications dominated by line interference and the Sallen-Key or Tow-Thomas preferred where spectral fidelity governs the result. The digital Multiple Feedback result remains inconclusive and requires verification of its transfer function derivation before it can be ranked. These findings derive from a single-subject, single-session acquisition without independent replication and are therefore offered as a proof-of-concept characterization. Future research will focus on validation against a synthetic reference signal with known spectral content, on automated adaptive digital filtering algorithms, and on the evaluation of hybrid conditioning systems across a broader, multi-subject clinical testing group.

Acknowledgment

The authors express their gratitude to the Federal University of Pará (UFPA) and the team at the Biomedical Engineering Laboratory (E.Bio) for providing the experimental infrastructure and technical support critical to the completion of this study.

***Abstract*—Breast cancer is the leading cause of female mortality related to cancer in the world, with histopathological analysis of lymph nodes tissue the gold standard technique for metastasis detection. The existence of digitalization of Whole Slide Images (WSI) and availability of public datasets such as PatchCamelyon (PCam) has enabled the development of autonomous applications for diagnosis using deep learning algorithms. Convolution Neural Networks (CNNs) are well known for its capabilities of local features extraction while Vision Transformers (ViTs) capture global dependencies, but a comparative evaluation of ensemble and fusion of both architectures are scarce or inexistent in the literature. This paper aims to present a comprehensive analysis of CNNs and ViTs architectures for metastatic breast cancer detection using the original PCam dataset and evaluate ensemble and fusion of both models. We investigated three strategies for models' selection to the ensemble and fusion experiments (lowest validation loss, loss per architecture type, and mean correlation error - MCE) combined with four techniques (average ensemble, weighted ensemble, MLP fusion, and Transformer fusion), resulting in 60 experiments. Our results indicate that the Swin Transformer achieves the best individual performance with 92.51% accuracy and 0.9734 of AUC, while the Top4-LpAT-MLP achieves the highest AUC and the Top6-MCE-Transformer achieves a stable overall performance with 92.39% accuracy and 0.9771 of AUC. The MCE strategy of selection achieved stable metrics and is also competitive to other evaluated fusion techniques, supporting the premise that model complementarity could be useful in fusion and ensemble design. Furthermore, our best configuration surpasses slightly the state-of-the-art for AUC metric from works using the original PCam dataset.**

Keywords—breast cancer, lymph node metastasis, deep learning, convolutional neural networks, vision transformers, ensemble learning, histopathological image classification, PatchCamelyon

I. Introduction

Breast cancer is the most diagnosed cancer among women and is still the leading cause of cancer related mortality. According to the World Health Organization (WHO), approximately 2.3 million new cases and 670,000 deaths were registered in 2022. These figures highlight the importance of early diagnosis and effective treatment [1]. Histopathological examination of whole slide images (WSI) of lymph node tissue is the gold standard approach for detection of metastasis in patients with breast cancer; however, this procedure is labor-intensive, time-consuming, and extremally dependent on the experience and condition of pathologists [2]. The availability of public datasets with WSI, such as Camelyon16 and its variants PatchCamelyon (Pcam) have accelerated the development of diagnosis systems [2].

Convolutional Neural Networks (CNNs) have managed to achieve an overall good performance in WSI images classification by learning local tissue patterns, whereas Vision Transformer (ViT) comes to provide a global contextual relationship through self-attention [3][4][5]. Even though hybrid CNN-Transformer architectures were proposed to exploit these characteristics, they generally increase model complexity [4][5]. Conversely, ensemble and fusion offer an alternative solution that combines the usage of well-known trained models from literature while preserving their individual strengths. Nevertheless, comparative studies that investigated ensembles of CNNs and ViTs for metastasis detection of breast cancer lymph node samples remain limited.

This paper aims to show a comprehensive comparison of CNN and ViT architectures and their combination for ensemble and fusion techniques for metastatic breast cancer detection using the original PCam dataset. The proposed approach investigates whether combining models with their features representation can improve the classification while avoiding the complexity of hybrid solution designs.

II. Related works

The accelerated usage of Whole Slide Images (WSI) has led to advances in digital pathology making it possible the development of computer-aided diagnostic. Alongside this technological development, public WSI datasets for deep learning research emerged. The Cancer Metastases in Lymph Nodes Challenge 2016 Competition (Camelyon16) provided a large annotated WSI dataset, 399 whole-slide images, for breast cancer lymph node metastasis detection. This competition indicates that deep learning solutions could achieve diagnostic performance close to experienced pathologists while maintaining consistent performance under time constraints [2].

To enable an easy usage of patch wise classification and reproducibility of Camelyon16 dataset, Veeling et al. introduced the patch variant, named PatchCamelyon (PCam), containing 327,680 labeled image patches. In addition to establishing one of the most widely used benchmarks for histopathology classification, the authors also demonstrated that rotation and reflection equivariant models optimizes the usage of their internal kernel filters to efficiently classify the samples [3].

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

After the release of PCam, some studies investigated the usage of Convolutional Neural Networks (CNNs) for breast cancer metastasis detection. Several approaches relied on models such as VGG, ResNet, DenseNet and Inception, indicating that CNNs could extract tissue features effectively from image patches [6][7], while others incorporated transfer learning, data augmentation and attention mechanisms to improve the classification performance. Liang et al. presented the Convolutional Block Attention Module (CBAM) to emphasize the relevant regions achieving an AUC of 0.976 on PCam dataset [8]. Additionally, Ahmad et al. used preprocessing and transfer learning techniques with CNNs, achieving an accuracy of 98% on PCam [9] and Shi et al. proposed the CSAM-ResNet, that integrates channel and spatial attention mechanisms to enhance contextual feature extraction [10]. Even though CNNs remain effective for local feature extraction, their limitation for global context affects their performance [4][5].

Vision Transformers (ViTs) have managed to deal with this limitation by applying the self-attention mechanisms capable of learning global relationships. Wang et al. presented LGViT, which is a hybrid model that combines CNN layers with a Local-Global Multi-head Self-attention mechanism to capture both local and global features while also keeping the computational cost relatively low [4]. More recently, Mukadam et al. using image enhancement and multi-attention CNN modules illustrates these advances for classification on PCam [11].

Ensemble has also appeared as an effective technique for improving the diagnostic by combining complementary models. Jaiswal et al., shown that ensembles of DenseNet models outperform individual networks on PCam [12]. Rane et al. proposed an attention fusion network that combines the DenseNet201, InceptionV3, and ResNext-50 through an attention module, achieving an AUC of 0.9816 [13]. Additionally, Ge et al. presented DECENN, an ensemble architecture integrating VGG16 and DenseNet121 with multi-scale feature extraction and feature harmonization modules achieving an AUC of 0.9970 [14]. However, both Rane and Ge used a deduplicated version of PCam dataset, which makes it hard to fairly compare with approaches using the original PCam.

Despite these advances, most of existing works aim on improving individual CNNs, ViTs, proposing hybrid CNN-ViT architectures, or presenting a design of ensemble composed exclusively by CNN models. Little attention has been given to ensemble that combines independently trained CNNs and ViTs while keeping the simplicity of these architectures. Such approach offers the potential to explore the complementary strengths of CNN based local feature extraction and ViT global representation without introducing additional complex hybrid architecture. Motivated by this gap, this work presents a unified comparison of representative CNN and ViT architectures and investigates the ensemble and fusion strategy for breast cancer lymph node metastasis detection on the original PCam dataset.

III. Materials and Methods

A. Materials

The PatchCamelyon (PCam) database [3], used in this work, consists of 327680 labeled images (96x96 pixels) extracted from histopathologic lymph node tissue (normal and metastasis samples), which are already publicly available with the training, validation and test proportion of, respectively, 80:10:10. The experiments were executed using an A100 NVidia® GPU with 164GB of RAM from Google Collab environment.

B. Methods

For the following training experiments, AdamW was the selected optimizer, with a weight decay of 0.05 and the initial learning rate for each architecture following the results presented in Table I. The best checkpoint for each model is selected based on the lowest validation loss.

Fig. 1 shows the framework designed to achieve the goal of this work, which will be presented below:

a) Data augmentation: The data augmentation techniques applied are: random horizontal and vertical flip, random erasing, and default operations from RandAugment from TorchVision. A sampling of augmented dataset is used for each epoch, resulting in different samples for each epoch.

b) Training of single models: The trained single models are: EfficientNets, Resnets, VGG, Inception, Xception, ViTs, ConvNext.They are trained using the train split from PCam dataset and all validation metrics are stored to support the selection and combination of models for the ensemble and fusion approachs.

c) Selection of models for ensemble and fusion: For the ensemble and fusion experiment the following strategies of selection is used, resulting in 3 sets of top 6 models:

- Loss: For this approach the simple selection of lowest validation loss is used to get the ideal set of models for ensemble/fusion experiments.
- Loss per Architecture type (LpAT): This strategy of model selection uses a similar approach compared to the loss described above, but in this case only one – the best based on validation loss – model for each type of architecture is selected.
- Mean Correlation Error (MCE): For this strategy, a mean correlation error matrix is generated to know how similar models tend to make mistakes. The idea is to select the models that usually fail differently from the other models. Therefore, the models for MCE were selected using the lowest mean correlation error from the validation split of PCam.

d) Experiment of ensemble and fusion: For ensemble and fusion, the following techniques are used: average ensemble, weighted ensemble Table VII (each weight is calculated by its AUC metric divided by the sum of all selected models), multilayer perceptron (MLP) fusion, Transformer Fusion. In the ensemble approaches, a simple average ensamble and a weighted ensemble are used. The MLP fusion ilustrated on *Fig. 2* works by basically concatenating the features, classification logits, and classification probabilities from each model and feeding them to the MLP classifier. Transformer fusion on *Fig. 3* also uses the concatenated features, logits, and probabilities considering each model as a token and adding a classification token at the beginning to use its adjusted embeddings at the end for the classification step. Finally, the train split was used for training both MLP and Transformer fusion.

e) Performance metrics for comparison: A total of 22 individual models and the 60 ensemble and fusion

combinations were evaluated on the PCam test set, by computing the following performance metrics: accuracy, precision, recall, f1-score, and AUC. Then, all ensemble and fusion experiments were then compared to the individual models.

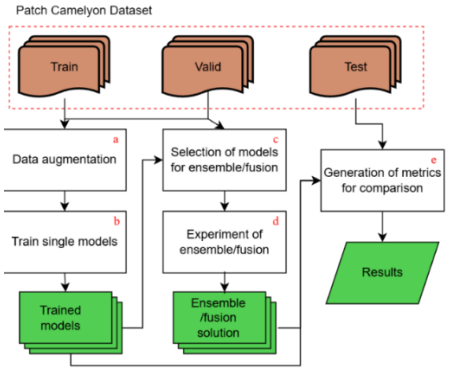

Fig. 1 Framework for classification experiments on lymph node images (normal or metastasis tissue).

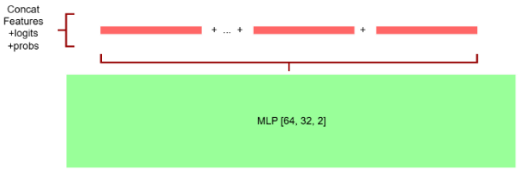

Fig. 2 Experiment of fusion: MLP fusion

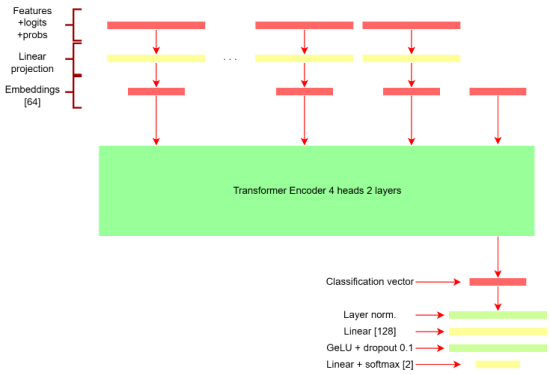

Fig. 3 Experiment of fusion: Transformer fusion

IV. Results and Discussion

A. Hyperparameter tuning for individual models

The first experiment executed was about the ideal configuration of hyperparameter for each architecture to achieve the maximum potential for all models.

From the results summarized on Table I we concluded that for almost all type of architecture the native dimension – 300x300 for inception/xception and 224x224 for the others – achieved better results based on validation loss. Only VGG had a better result for dimension of 96x96. Also, the learning rate of 1E-3 achieved better results, except for VGG and Xception (1E-4). Finally, all these results were used to match the ideal setup for each model in the following experiments.

B. Training of individual models

The results for individual models are summarized on Table II. Swin transformer achieved better results for most metrics, except Recall and AUC, for which the best models where ViT Large and Resnet101, respectively. Also, it is noteworthy that the performance of Swin transformer was nearly two points higher than other models.

Additionally, the Fig. 4 shows that there is no correlation between the better AUC results with number of parameters of each architecture (number of weights + biases), and bigger models like the ViT Large are getting worst results. This suggests that the number of training samples from PCam may not be sufficient to train such complex models even with the already applied data augmentation.

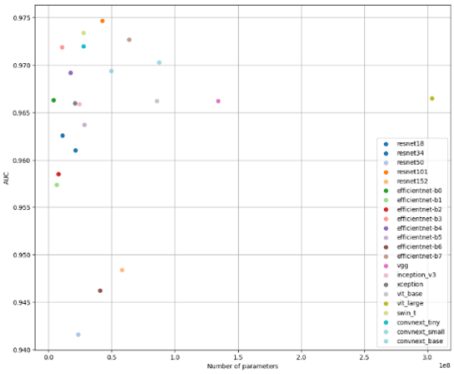

Fig. 4 AUC vs number of parameters of each architecture (number of weights + biases).

C. Selection of models for ensemble and fusion

The following set of models were used for the ensemble and fusion experiments.

a) Loss: By analyzing the 0and selecting the Top 6 models by validation loss we selected following models:

- EfficientNet-B7: 0.2036;
- ViT Base: 0.2142;
- EfficientNet B0: 0.2174;
- Resnet34: 0.2242;
- EfficientNet B3: 0.2244;
- EfficientNet B6: 0.2335.

b) Loss per Architecture Type (LpAT): Also, from 0the following of Top 6 models were selected:

- EfficientNet B7: 0.2036;
- ViT Base: 0.2142;
- Resnet34: 0.2242;
- ConvNext Small: 0.2494;
- Inception: 0.2499;
- VGG: 0.2580.

c) Mean Correlation Error (MCE):

For model i and sample k, the error is defined as bellow, where $\hat{y}_{i,k}$ is the predicted class and y_k is the ground-truth class.

$$e_{i,k} = \begin{cases} 1, if\ \hat{y}_{i,k} \neq y_k \\ 0, otherwise \end{cases}, \quad (1)$$

According to the calculated error, the MCE is generated with the *Pearson correlation coefficient* between the error vectors of models *i* an *j*:

$$p_{ij} = corr(e_i, e_j) \quad (2)$$

Based on MCE for each model from *Fig. 5* and correlation error matrix, ilustrated by *Fig. 6*, the Top 6 models with MCE were sselected:

- Resnet50: 0.4092;
- EfficientNet B6: 0.5092;
- Resnet152: 0.5258;
- Resnet101: 0.5336;
- EfficientNet B5: 0.5485;
- Resnet34: 0.5491.

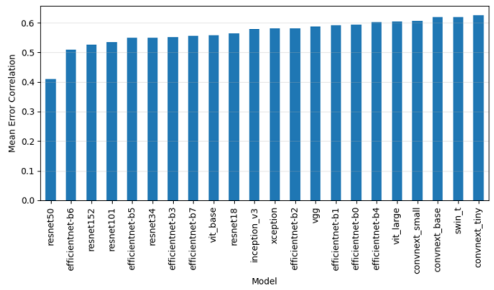

Fig. 5 Mean Correlation Error (MCE) sorted from lowest to highest.

D. *Results for Ensemble and Fusion techniques*

The results for average and weighted ensemble are summarized on Table IV and Table VII while the MLP and transformer fusion results are shown on Table V and Table VI.

Among the approaches for the ensemble and fusion, the Top6-MCE-Transformer achieved the best results for accuracy, precision and F1-score, while the Top4-LpAT-MLP achieved the best AUC and Top6-loss-MLP achieved the best recall.

Considering the better result for the most monitored metrics, the more stable technique is Top6-MCE-Transformer, that achieves the best values for 3 of 5 metrics and not being too distant from the top results for the other 2 metrics. However, a statistical comparison of AUC using DeLong's test indicated that the Top4-LpAT-MLP was indeed higher than the Top6-MCE-Transformer (0.9800 vs. 0.9771, $p < 0.001$), showing its superiority for AUC metric compared to Top6-MCE-Transformer.

E. *SOTA comparison*

The comparison of all experiments and the state-of-the-art solutions identified at the time this paper was written is summarized in Table VIII. TABLE VII. Our experiments achieved the best (Top4-LpAT-MLP) and second (Top6-MCE-Transformer) AUC and kept competitivity with the other metrics.

The Custom CNN [9] model achieved better accuracy even if it got a slightly inferior result for AUC. For medical diagnostic tasks, AUC is a much more robust and relevant metric than raw accuracy, because it measures the model's discriminative capability independently of the classification threshold.

Other papers that used a different version of PCam dataset [13][14], like the deduplicated variant, were filtered out for a fair comparison.

V. Conclusion

The results presented on previous topics indicate that the evaluated experiments achieved competitive performance with previously reported approaches for detection of metastasis using the PCam dataset. Also, the best individual model was Swin transformer that managed to achieve results close to ensemble/fusion techniques. Additionally, the highest AUC was obtained by the Top4-LpAT-MLP configuration with 0.9800 and DeLong's test indicating its superiority to Top6-MCE-Transformer in terms of AUC. However, the Top6-MCE-Transformer strategy achieved competitive and more stable results across most of the monitored metrics and achieved AUC inferior, but close, to those of the Top4-LpAT-MLP approach. These results suggest that complementarity of models could be a useful criterion for construction of ensemble and fusion strategies.

***Abstract*—This study presents a comparative evaluation of three neural network architectures (EEGNet, ResNet, and VGG16) for the automatic classification of ADHD, using raw EEG signals from a public dataset comprising 121 participants. The proposed end-to-end pipeline was developed, integrating per-patient preprocessing, windowing, and data augmentation. The results, evaluated based on accuracy, AUC, and channel importance analysis, show that EEGNet stood out as the most viable and robust architecture, demonstrating stable training behavior and consistently high performance (with accuracy and AUC remaining above 80%) across different windowing strategies. In contrast, ResNet and VGG16 suffered from severe overfitting, especially with larger windows. These findings highlight the efficiency of compact models such as EEGNet for ADHD classification based on EEG signals under participant-held-out internal evaluation.**

***Index Terms*—EEG, ADHD classification, Neural Networks, EEGNet**

I. Introduction

Attention-Deficit/Hyperactivity Disorder (ADHD) is one of the most common neurodevelopmental disorders in childhood, affecting children and adolescents across different social and educational contexts [1]. It is characterized by persistent symptoms of inattention, hyperactivity, and impulsivity, which can impair academic performance, executive functions, and social interactions [2]. In this context, early diagnosis is important to enable appropriate interventions and reduce the disorder's impact throughout development [3].

Currently, ADHD is diagnosed primarily through clinical evaluations based on criteria established by reference manuals, such as the DSM-5 and the ICD-10 [4]. This process involves behavioral observations, clinical interviews, and questionnaires administered to parents, teachers, and patients. Although widely used in clinical practice, this model relies on professionals' interpretation and can be influenced by the heterogeneity of symptoms and the presence of comorbidities, making the search for more objective complementary measures a recurring theme in the literature [4], [5].

Among the techniques investigated for this purpose, electroencephalography (EEG) has received significant attention. EEG records brain electrical activity using electrodes placed on the scalp, allowing for noninvasive monitoring of neural dynamics [6]. One of its main characteristics is its high temporal resolution, which makes it possible to track variations in brain activity on the millisecond scale; the signals obtained can be analyzed in both the time domain and the frequency domain and are often represented by spectral bands such as delta, theta, alpha, beta, and gamma [2], [5].

Several studies report differences in the electrophysiological patterns observed in individuals with ADHD when compared to control groups [7]. Changes in the power distribution across frequency bands and in other EEG-derived indicators suggest that these signals may contain information relevant to characterizing the disorder; for this reason, the EEG has been explored as a data source for computational systems to aid in diagnosis [6].

At the same time, advances in machine learning and deep learning techniques have expanded the capacity for automatic analysis of biomedical signals. In the case of EEG, different neural network architectures have been employed to identify patterns associated with ADHD and to aid in classification

To the Graduate Program in Electrical Engineering (PPGEE) and the Federal Institute of Para´ıba (IFPB) for their financial support

tasks [8].

However, modeling these signals remains a challenge due to their nonstationary nature, the presence of noise and physiological artifacts, and high inter-individual variability [1]. Furthermore, results reported in the literature can vary considerably depending on the architecture used, the preprocessing strategies adopted, and the characteristics of the analyzed dataset [1]–[4], [7], [8] .

Given this scenario, it is important to investigate the performance of different neural network architectures in classifying individuals with ADHD based on EEG signals. Thus, this study conducts a comparative evaluation of three neural networks using a public EEG dataset, analyzing their ability to identify patterns associated with the disorder and their performance in the automatic classification task.

II. Related Works

Studies on ADHD classification based on EEG signals predominantly use databases consisting of children and adolescents, obtained from both public repositories and specific clinical data collections. Although acquisition protocols vary between resting-state recordings and cognitive tasks, there is relative convergence in the preprocessing steps employed. In general, the signals undergo filtering to remove noise, reduce artifacts, and segment them into time windows for analysis. In addition, frequency-domain or time-frequency representations are frequently employed to highlight relevant patterns of brain activity prior to the classification stage [3], [4], [6], [8].

Convolutional Neural Networks (CNNs) are among the most widely used approaches for ADHD classification based on EEG signals, and are applied to both time series and representations derived from the signals. Initially, deep architectures adapted from the field of computer vision—such as variants inspired by VGG and ResNet—were explored due to their capacity for hierarchical learning. However, the limited availability of data in clinical applications has driven the development of more compact and specialized architectures for EEG, such as EEGNet, designed to reduce computational complexity while maintaining good classification performance [2], [4], [6], [7], [9].

In addition to purely convolutional architectures, the literature also presents hybrid models that combine CNNs with recurrent or attention mechanisms to simultaneously explore the spatial and temporal relationships of brain signals. Although different strategies have been proposed, research in this field highlights the ongoing challenge of balancing representational capacity, computational cost, and performance on often small datasets [1], [4], [6].

The limited amount of available data has led to the adoption of various data augmentation strategies in EEG applications. Among the most common approaches are the segmentation of signals into multiple time windows, class balancing techniques, and transformations applied directly to the signals during training. These strategies aim to increase the variability observed by the models and reduce overfitting issues, especially in scenarios where the number of participants is small and inter-subject variability is high [6], [10].

In addition to more traditional techniques, some studies explore approaches based on regularization and representation sharing during training, seeking to improve the models' generalization ability without the need for large volumes of additional data. In general, the literature has prioritized relatively simple methods for data augmentation and class balancing, which can be incorporated into existing processing workflows. Despite the advances made, generating samples capable of adequately preserving the neurophysiological characteristics of EEG signals remains a significant challenge, especially when seeking to increase data diversity without compromising the patterns present in the original signals [7], [8], [10], [11].

Despite the growing adoption of neural networks for ADHD classification based on EEG signals, direct comparisons between the proposed models remain limited. The literature presents a wide variety of architectures, including conventional CNNs, specialized EEG models, residual networks, and hybrid approaches. However, the reported results are often obtained from distinct datasets, using different preprocessing strategies, signal segmentation, data partitioning, and validation protocols. This heterogeneity makes it difficult to identify the factors that effectively contribute to model performance and limits objective comparison among the proposed architectures [1], [3], [4], [7], [8].

Furthermore, although compact architectures and deeper models have been extensively investigated, there is still no consensus on the optimal balance between representational capacity, computational cost, and generalization for applications involving EEG data from patients with ADHD. Thus, it remains important to conduct comparative studies under standardized experimental conditions, allowing for a more consistent evaluation of the behavior of different neural architectures when subjected to the same dataset and the same processing steps [4], [7]–[9].

To consolidate the state of the art that will serve as the basis for the performance discussions presented in this paper, Table I summarizes the approaches that will serve as a reference for a comparative evaluation of the results. Among traditional machine learning methods, the use of AdaBoost-based models operating on the same dataset [12] and analyses of regional hemispheric contributions for feature selection [13] stand out. In the context of hybrid architectures, recent research proposes coupling signal decompositions using VMD (Variational Mode Decomposition) and RLMD (Robust Local Mean Decomposition) [14], with MI (*Mutual Information*) integrated with stacked classifiers [15], and the extraction of feature maps from CNNs in conjunction with classical machine learning models [16]. Based on this, the methodological parameters and performance metrics from these references will be used to analyze the contrasts with the architectures proposed in this paper. However, direct performance comparisons between studies should be made with caution due to methodological differences. In particular, the way data are partitioned (by window or by participant) drastically affects the results.

III. METHODOLOGY

The development of the ADHD classification system based on EEG signals was carried out entirely in a computer simulation environment, using three neural network architectures (EEGNet, ResNet, and VGG16). The choice of these distinct architectures is justified by the need to evaluate the trade-off between generalization ability and the risk of overfitting on small datasets.

Fig. 1 illustrates the complete flowchart, consisting of six sequential steps for building the neural networks. The workflow begins with data acquisition and loading, followed by preprocessing per patient, overlapping windowing, splitting into training and validation sets, stochastic data augmentation in the training set, and, finally, model training and evaluation.

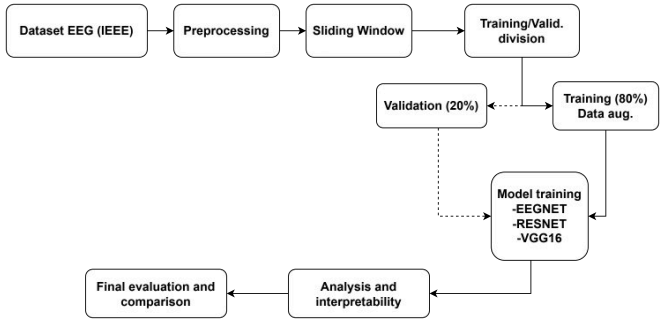

Fig. 1. Proposed EEG classification pipeline.

A. Dataset

The experiments were conducted using the public EEG dataset introduced by Nasrabadi et al. [17], collected at Shahed University and made available through IEEE Open Access. The dataset comprises electroencephalographic (EEG) recordings from 121 participants, including 61 children diagnosed with ADHD and 60 healthy control subjects, aged between 7 and 12 years.

EEG signals were acquired using 19 scalp electrodes positioned according to the international 10–20 system (Fp1, Fp2, F3, F4, C3, C4, P3, P4, O1, O2, F7, F8, T7, T8, P7, P8, Fz, Cz, and Pz), with a sampling frequency of 128 Hz. The reference electrodes were placed on the earlobes (A1 and A2).

The ADHD diagnosis was established by clinical specialists according to the diagnostic criteria of the DSM-IV, while the control group consisted of participants with no history of neurological or psychiatric disorders. During data acquisition, participants performed a visual attention task in which they were instructed to count specific elements presented in a sequence of images. This protocol was designed to engage attentional processes and to highlight EEG patterns associated with ADHD.

Each recording includes the EEG signals from all 19 channels, together with the participant identifier and the corresponding class label (ADHD or control).

B. Signal Preprocessing

Each patient record undergoes a filtering and normalization chain applied individually, preventing data leakage between patients.

During the filtering stage, a second-order IIR notch filter centered at 50 Hz is applied to suppress power line noise. Next, a fourth-order Butterworth bandpass filter with cutoff frequencies $f_{\text{low}} = 0.5\,\text{Hz}$ and $f_{\text{high}} = 40\,\text{Hz}$ isolates the clinically relevant EEG rhythms (delta, theta, alpha, and beta), discarding motion artifacts and high-frequency components. Both filters are applied with zero-phase to preserve temporal information.

After filtering, the signal for each patient p is normalized channel by channel using the z-score:

$$\hat{x}_c^{(p)} = \frac{x_c^{(p)} - \mu_c^{(p)}}{\sigma_c^{(p)} + \epsilon}, \tag{1}$$

where $\mu_c^{(p)}$ and $\sigma_c^{(p)}$ are the mean and standard deviation of channel c, calculated exclusively from the samples of that patient, and $\epsilon = 10^{-8}$ prevents division by zero.

Because the normalization parameters are estimated using the complete recording of each participant before window segmentation, the proposed preprocessing pipeline should be interpreted as an offline classification procedure. In a real-time implementation, normalization would need to be performed using only the signal samples available up to the current time, for example through adaptive or causal normalization strategies.

C. Windowing

Continuing the workflow, the next step consisted of segmenting each patient's continuous signal into windows of lengths W equal to 256, 512, 768, and 1024 samples (2 s, 4 s, 6 s, and 8 s at 128 Hz), with the step size calculated as:

$$\text{step} = \lfloor W(1-r) \rfloor, \tag{2}$$

corresponding to an overlap of $r = 50\%$. Each window produces an input tensor $\mathbf{X} \in \mathbb{R}^{C \times W}$, with $C = 19$ channels and W time points. An extra channel of unit dimension is added before training, resulting in $\mathbf{X} \in \mathbb{R}^{1 \times C \times W}$, consistent with the 2-D input convention for convolutional networks.

In this process, segments of the continuous signal at the end of each recording that were shorter than the W window were discarded, avoiding incomplete signals in the model's input. Although the total duration of each patient's EEG recordings

varied, due to differences in the completion time of the visual attention task, windowing standardizes the temporal dimension of all inputs.

D. Training/Validation Split

The data is split according to patient identity using group split, ensuring that all windows from the same individual belong exclusively to either the training set or the validation set. The ratio adopted is 80% training and 20% validation. This prevents windows from the same participant from appearing in both subsets and provides an internal estimate of performance on participants held out from training.

The validation subset was also used for early stopping and model selection. Therefore, the reported results represent an internal development estimate rather than performance on an independent external validation set.

To address class imbalance at the window level, a weight inversely proportional to the frequency of each class in the training set is assigned to each window, ensuring that each mini-batch contains balanced proportions of ADHD and Control subjects.

E. Data Augmentation

Once the group division and class balancing have been defined, data augmentation is applied to the training set at each epoch. The goal is to artificially expand the diversity of the training set, exposing the model to possible variations in the signal that reflect the natural variability of the EEG across sessions and individuals, without the need to collect new recordings.

The transformations are applied stochastically at each epoch; thus, with each pass through the training set, each window may be altered differently, preventing the model from memorizing fixed examples. There are four transformations in total, each of which is applied independently with a 50% probability. The first consists of signal inversion, which reverses the polarity of the signal within the window; since the absolute polarity of the EEG depends on the electrode reference used during acquisition, this operation does not compromise the diagnostic information contained in the signal. Next is the technique of altering the amplitude scale, in which the amplitude of the window is multiplied by a random value between 0.8 and 1.2, simulating the variations in electrode impedance and amplifier gain that naturally occur between different data collection sessions.The third technique is temporal shifting, which consists of a cyclic shift of up to 50 samples to the left or right, performed without zero-padding. Finally, temporal reversal inverts the temporal sequence of the window; since the analyzed brain rhythms do not exhibit significant temporal asymmetry on the order of seconds, the reversed window remains physiologically acceptable as a training example. Figure 2 shows a visual example of the application of these transformations:

With the dataset properly balanced and enhanced by the transformations, the resulting samples are used to train the neural network architectures.

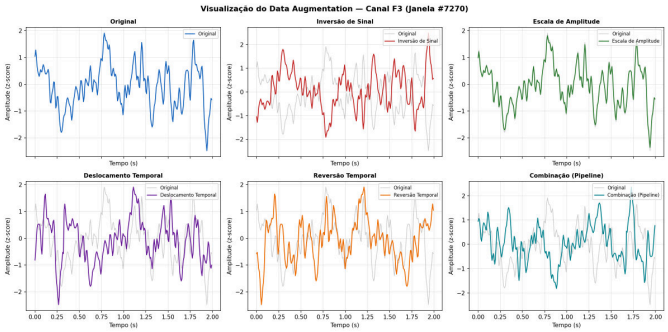

Fig. 2. Data augmentation visualization.

F. Neural Network Architectures

As mentioned earlier, the three neural networks were trained under the same conditions, allowing for a direct comparison between representational capacity and the tendency toward overfitting.

1) EEGNet: The first architecture used was EEGNet, a compact network proposed specifically for EEG signal classification based on depthwise separable convolutions. The initial block of this network applies a 1×64 temporal convolution with $F_1 = 16$ filters, followed by a 19×1 depthwise spatial convolution with depth $D = 2$, which learns one spatial filter per input channel, totaling $F_1 \times D = 32$ feature maps. The second block applies a separable convolution to refine the features extracted by the preceding block. Finally, batch normalization, ELU, average pooling, and progressive dropout (0.25/0.50) complement the blocks, with classification performed by a dense layer of 64 neurons, producing the output for the two classes (ADHD/Control).

2) ResNet: The second network implemented is ResNet, a 1-D residual network of intermediate complexity, designed with Squeeze-and-Excitation (SE) attention blocks. This architecture was constructed using the principles of residual learning and modified to process EEG time series. Initially, a spatial convolution merges the 19 EEG channels into 64 1-D feature maps. Subsequently, the signal passes through four stages, each consisting of two residual blocks with decreasing kernel sizes and increasing numbers of filters (kernels 7, 7, 5, 3; filters $64 \rightarrow 64 \rightarrow 128 \rightarrow 128 \rightarrow 256$), interspersed with average pooling operations that progressively reduce the temporal resolution. At the end of the four stages, adaptive Global Average Pooling (GAP) reduces the temporal dimension to four positions, followed by two fully connected layers (256 and 64 neurons) produces the classification.

3) VGG16: The third and final neural network was a custom 1-D adaptation of VGG16. The original VGG16 architecture was developed for the classification of two-dimensional images and was not specifically designed for EEG signals. In this study, its general structure of convolutional blocks was maintained the classic depth of five convolutional blocks with 2, 2, 3, 3, and 3 convolutions of kernel size 3, respectively, and an increasing number of filters ($64 \rightarrow 128 \rightarrow 256 \rightarrow 512 \rightarrow 512$) while its operations were modified for processing

multichannel EEG time series. As in ResNet, an initial spatial convolution merges the 19 EEG channels before they enter the 1-D convolutional blocks. Due to the high number of parameters in this type of network, regularization measures were adopted to mitigate overfitting, such as a dropout rate of 0.6 in all convolutional blocks, the use of GAP instead of direct flattening before the classifier, a learning rate reduced by half, and a weight decay rate quadrupled compared to other architectures.

G. Training and Optimization

The three architectures were trained using the AdamW optimizer with a learning rate of 10^{-4}, reduced to 5×10^{-5} for the VGG16 network, a weight decay of $= 5\times10^{-4}$, increased to 2×10^{-3} for the VGG16, and cross-entropy with label smoothing of 0.1. The learning rate followed a linear warmup for 15 epochs, followed by cosine annealing until epoch 150, to avoid abrupt updates at the beginning of training. Each network was trained for up to 150 epochs, with early stopping after 25 epochs if there was no improvement in the AUC on the validation set.

H. Evaluation Metrics

Performance was evaluated on the validation set using accuracy, AUC-ROC, and F1-score per class, supplemented by confusion matrices, the number of parameters in each model, gradient-based channel importance—which measures the sensitivity of the model's output to perturbations in each input channel—and by channel permutation, which assesses the drop in performance when randomly shuffling the values of a specific channel, relating complexity and performance.

IV. RESULTS AND DISCUSSION

We will present the performance results of the EEGNet, ResNet, and VGG16 networks, discussing the impact on classifier metrics for different time window lengths of the EEG signal and evaluating the convergence and biological interpretability of the EEGNet model, which showed the best performance.

A. Windowing

Table II shows the average of each metric calculated at the end of each network's execution using different windowing strategies. Regarding the number of parameters, EEGNet varies proportionally to the size of the input vector; thus, larger windows generate more points. Meanwhile, the ResNet and VGG16 models exhibit a stable number of parameters due to GAP, which prevents variation in the number of parameters despite changes in windowing.

This information can be crucial for identifying overfitting in complex models that operate on small datasets; in the literature, highly parameterized architectures using long windows on clinical datasets are indicative of vulnerability. According to the literature [16], it is necessary to balance the model's capacity with the volume of samples. The VGG16 model serves as a specific example, achieving satisfactory results with 2-second windows (76.66% accuracy) but failing with 4-, 6- and 8-second windows (39.07%, 41.69% and 38.61% accuracy, respectively) due to its high number of parameters combined with a small number of samples.

TABLE II
PERFORMANCE COMPARISON ACROSS DIFFERENT WINDOW LENGTHS.

Win.	Model	Params	Acc.	AUC	F1-score	
					ADHD	Control
2 s	EEGNet	19.9k	80.72%	83%	85%	74%
	ResNet	1.91M	81.48%	86%	85%	76%
	VGG16	5.07M	76.66%	82%	81%	70%
4 s	EEGNet	36.3k	81.55%	87%	85%	76%
	ResNet	1.91M	79.08%	83%	83%	72%
	VGG16	5.07M	39.07%	81%	1%	56%
6 s	EEGNet	52.6k	80.80%	88%	84%	76%
	ResNet	1.91M	64.27%	82%	64%	65%
	VGG16	5.07M	41.69%	83%	9%	57%
8 s	EEGNet	69.06k	80.94%	83%	85%	74%
	ResNet	1.91M	66.43%	83%	67%	65%
	VGG16	5.07M	38.61%	78%	0%	56%

In the study conducted by Chauhan and Choi [15], an 8-second signal segmentation is used, requiring tools such as PCA (Principal Component Analysis) to reduce dimensionality and avoid overfitting. Therefore, the use of 2-second windows in this study effectively manages this computational complexity, ensuring sufficient data so that high-capacity networks—which depend on data density—can converge. For this reason, the following figures will present the results for this windowing scheme.

Despite the change in windowing, the AUC metric remained stable at above 80% across all configurations. Although the accuracy of VGG16 declines with the use of larger windows, the AUC reinforces the ability of these architectures to distinguish between classes. Based on the literature, this metric is essential for evaluating the classification performance of the model and, in benchmark studies, presents values between 86% and 96% [16]. In line with this perspective, EEGNet demonstrated a considerable increase in performance with larger windowing, supporting the view that an increase in patterns and biomarkers aids in feature separation.

B. Model Evaluation

When evaluating network performance, it is necessary to examine the behavior of all windows. By comparing the number of parameters and the AUC values shown in Table II, it is clear that using too many or too few parameters can affect the ability to distinguish between classes—that is, it affects accuracy. Thus, although the ResNet network outperforms the others with an accuracy of 81.58% for a 2-second windowing, the EEGNet model stands out, demonstrating a robust architecture that provides relatively high AUC and accuracy (both metrics above 80%) for different windowing strategies.

The literature review allowed us to contextualize these results, noting that the 80.72% accuracy achieved by EEGNet

proves to be competitive with approaches and models based on AdaBoost (Adaptive Boosting), which reach 84% accuracy using the same dataset [12].

Although recent studies report significantly higher results—such as the use of stacked classifier architectures with 92% accuracy [15] and hybrid architectures like VMD and RLMD with results exceeding 95% [14], the model proposed in this work demonstrates a methodological advantage. The approach involves applying the end-to-end method to the raw EEG signal, eliminating the need for manual feature extraction and mathematical decompositions, which increase computational cost. Furthermore, this study employs a strict data split (80/20) by patient rather than by window, preventing the results from being affected by data leakage. Thus, the results achieved by the EEGNet model (80.72%) demonstrate a generalization to patients not seen within the evaluated validation set, raising its methodological robustness to the results of studies such as [16], which reports 95.83% accuracy.

Focusing on the results of the EGGNet model, Figure 3 illustrates the convergence behavior and the extent to which the gradient stabilization strategies performed adequately. In the work by [16], overfitting is considered one of the most prominent problems in training neural networks, and two strategies are used to mitigate it: early stopping with a patience of 30 epochs and the selection of the model with the best validation accuracy. For comparison, this study implements early stopping and dropout, ensuring that the training (blue line) and validation (orange line) curves follow similar trajectories, as well as providing greater robustness in classifying patients not seen during training. Furthermore, the model checkpoint corresponding to the highest validation AUC was maintained; to make this clearer, Figure 3 highlights the maximum validation accuracy of 80.72% achieved by this checkpoint. This ensures that the final result demonstrates comparable capacity and data density, overcoming the instability of highly parameterized networks.

The training curves show a progressive decrease in training loss accompanied by an increase in training accuracys in Figure 3 indicates convergence when using Linear Warmup and Cosine Annealing, thereby validating the effectiveness of the training protocol adopted in this study.

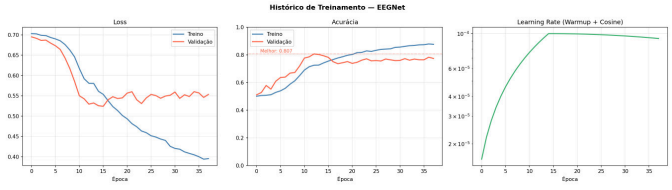

Fig. 3. EEGNET training history.

Figure 4 shows that the ResNet network achieves the best balance between sensitivity and specificity, while maintaining a high ADHD accuracy rate above 80%. EEGNet performs similarly to ResNet even though it uses fewer parameters, demonstrating robust discriminatory power. Meanwhile, VGG16, which has the lowest AUC among the other networks, shows a curve that falls below the others due to a lack of sufficient data for the classifier.

In comparison with the literature, [16] presents comparative tables using AUC as a key metric for analyzing hybrid models, achieving 86% in the base CNN architecture and 96% when combined with logistic regression. Thus, it is noted that EEGNet in this study was the most reliable model due to its preservation of separability between classes.

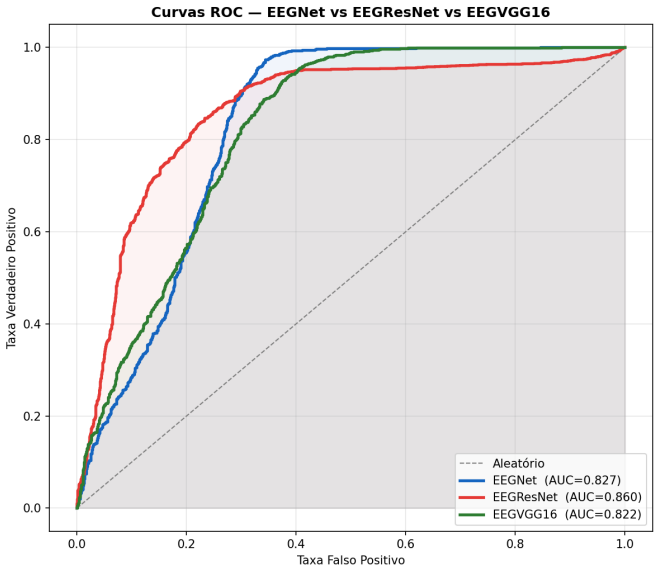

Fig. 4. ROC curve and Area Under the Curve (AUC) for EEGNet, ResNet and VGG16.

C. Classification

Upon analyzing Figure 5, the EEGNet model proved to be the most balanced among the networks in this study, achieving an accuracy rate for the Control class (TN — True Negative) of 71.6% (958 windows) and maintaining a high accuracy rate for ADHD (TP — True Positive) at 86.5% (1,822 windows). These results are reflected in the F1 scores obtained for the two classes, as shown in Table II, indicating a reduction in bias toward the majority class (ADHD).

When comparing these results with the literature, the work by [16] demonstrates an approach with an average accuracy of 86.33% using a basic CNN architecture. On the other hand, the work by [15] demonstrates that approaches using architectures that combine multiple different models (stacked classifiers) can achieve 92% accuracy, with 93% specificity, indicating a high ability to distinguish healthy patients. Therefore, we conclude that the EEGNet architecture offers significant competitive discriminatory power in identifying healthy cases, with a low incidence of false positive diagnoses.

D. Biological Relevance of the Model

To mitigate the “black box” effect and validate the EEGNet model using ADHD biomarkers, gradient-based analysis and

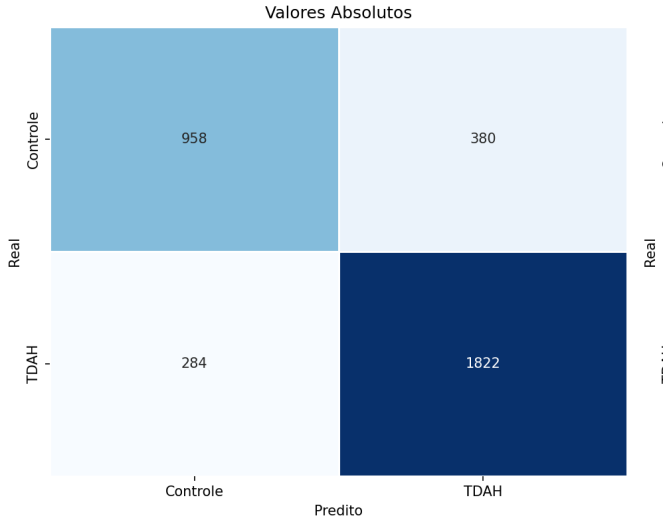

Fig. 5. EEGNET confusion matrix mapping classification for the 2 s window topology.

Permutation Feature Importance (PFI) will be applied. According to Figure 6, the EEGNet model identifies the Fz channel in the frontal region as the most relevant, while also showing that the frontal region (F3) is particularly prominent, as illustrated in Figure 7.

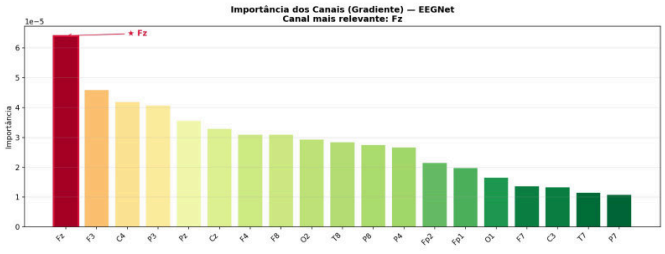

Fig. 6. Channel importance based on the gradient method for the EEGNet model (2 s window).

Based on a review of the literature, the results presented in this study tend to align with studies involving regional mapping and channel relevance. In this context [15], the MI technique was used to measure the dependence between two variables, concluding that there was no consistent concentration of ADHD at a single point and suggesting that the syndrome is complex because it affects different regions of the brain simultaneously. From another perspective, studies such as [13] and [12] identified the region of the right hemisphere with the highest concentration of discriminatory features, achieving metrics such as 96% sensitivity and 84% accuracy, encompassing the Fp2, F4, F8, T4, P4, T6, and O2 channels. Meanwhile, according to [14], the Fz channel is considered one of the most critical in distinguishing between individuals with ADHD and healthy individuals, due to its association with attention deficits. Thus, it is noted that the channel selected by EEGNet (Fz), obtained through gradient-based analysis,

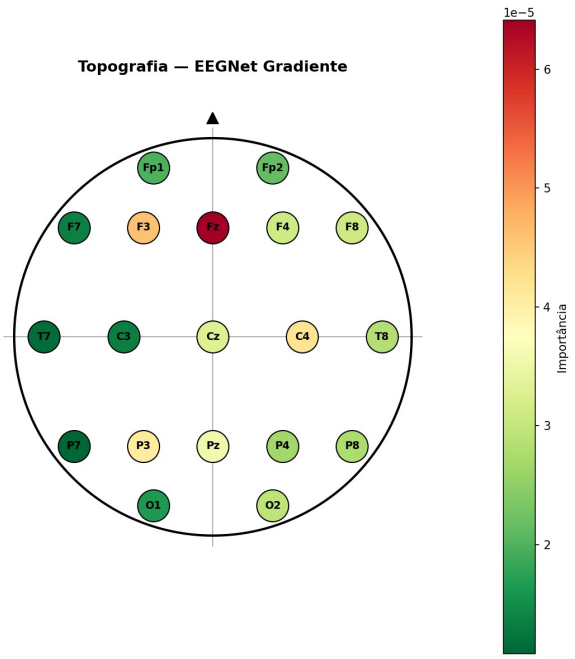

Fig. 7. Topographic relevance maps based on gradients for the EEGNet model.

validates the model, indicating frontal impairment similar to that reported by the authors.

Meanwhile, Figure 8 illustrates the EEGNet results, indicating that the Fz channel is the critical factor in classification; its absence would reduce accuracy by approximately 34% (original accuracy – accuracy with the channel swapped), in addition to the significant impact of the Pz, P3 and F3 channels.

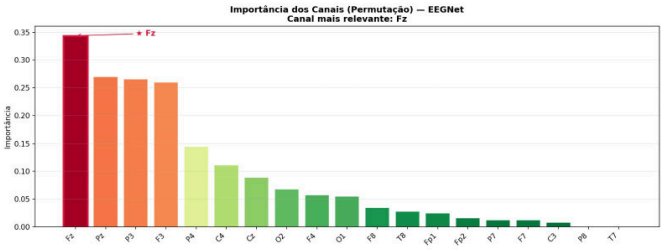

Fig. 8. Channel importance based on the PFI method for the EEGNet model (2 s window).

Using the permutation method, the Fz channel (frontal lobe) was identified as a critical region for classification. This channel supports the findings of [14], which argue that the frontal midline electrodes are the most discriminative in channel-by-channel analysis. From another perspective, the work in [15] points out that the Fz channel reflects activity in the frontal lobe of the brain, which is involved in executive functions, including planning, decision-making, and attention. Furthermore, in studies such as [12] and [13], traditional methods are used, such as manually selecting channels or isolating hemispheres to guide the classifiers, grouping specific regions

to assess their impact on diagnosis. In contrast, the EEGNet model was able to automatically analyze the channels and identified the Fz channel as the critical factor in diagnosis. This finding, obtained through the permutation method, indicates that the trained EEGNet model depends on the Fz channel, representing a decrease in accuracy of approximately 34% in its absence. This internal dependence of the model shows high consistency with the literature, which associates ADHD with executive impairment of the frontal lobe. Furthermore, this method was performed at the window level, and one of the objectives for future work is the implementation of permutation at the participant level.

V. CONCLUSIONS

This study presented a comparative evaluation of three neural network architectures for ADHD classification based on raw EEG signals, using an end-to-end approach applied directly to the signal and a split between training and validation data per patient. EEGNet demonstrated better overall performance due to its ability to handle the EEG signal across different windowing strategies, while ResNet and VGG16 suffered from overfitting in larger windows due to their high number of parameters relative to the limited size of the dataset. Furthermore, EEGNet, despite having approximately 100 times fewer parameters, outperforms ResNet due to its methodological robustness, highlighting the efficiency of compact architectures in scenarios with limited data.

The interpretability analysis of EEGNet highlighted the Fz channel (gradient and permutation), a result consistent with previous studies linking ADHD to the frontal region of the brain. Limitations include the small size of the dataset and performance that is still inferior to that of methods based on manual feature extraction. For future work, we propose testing the same networks and more complex architectures using an offline augmented dataset that combines synthetic and real patients, with an expected improvement in performance.

***Abstract*—Electroencephalographic (EEG) signals are highly susceptible to physiological artifacts and instrumental interference, making preprocessing choices critical for Autism Spectrum Disorder (ASD) classification. This study compared EEG processing pipelines to investigate the influence of Blind Source Separation (BSS) and temporal segmentation strategies on classification performance. A dataset with 28 individuals, 14 ASD and 14 controls was used. Fast Independent Component Analysis (FastICA) and SecondOrder Blind Identification (SOBI) were tested. Temporal, spectral, and nonlinear features were extracted, selected using Minimum Redundancy Maximum Relevance (mRMR), and classified using a Support Vector Machine (SVM). The highest observed performance was obtained with SOBI, reaching an accuracy of 0.741, an area under the receiver operating characteristic curve (AUC) of 0.730, and an F1-score of 0.771. The work also includes an analysis of the features that were more often selected by mRMR. These exploratory findings indicate that source separation, signal segmentation, and feature representation can affect EEG-based ASD classification and motivate further evaluation using participant-wise repeated validation.**

***Index Terms*—autism spectrum disorder; blind source separation; signal classification; electroencephalography.**

I. Introduction

Autism Spectrum Disorder (ASD) is a neurodevelopmental condition associated with persistent alterations in social communication, restricted interests, and repetitive behavioral patterns [1]. Although clinical assessment remains the reference standard for diagnosis, it usually involves behavioral observation, structured interviews, standardized instruments such as CARS-2, ABC, ADOS-2, CHAT, and ADI-R, and interpretation by experienced professionals [2]. As a consequence, the diagnostic process may be time-consuming and dependent on the availability of specialized services, which can delay early identification and intervention.

Because of these limitations, increasing attention has been directed toward complementary approaches capable of providing objective neurophysiological information. Among them, electroencephalography (EEG) has been widely investigated due to its non-invasive nature, relatively low cost, high temporal resolution, and ability to capture rapid fluctuations in cortical activity [3]. EEG records brain electrical oscillations through electrodes placed on the scalp, commonly arranged according to standardized acquisition systems [4].

In ASD research, EEG has been used to investigate neurophysiological patterns related to spectral organization, regional activation, and the stability of neural rhythms under resting-state and task-based conditions [3]. Previous studies have reported differences in frequency bands such as delta, alpha, and gamma, suggesting that spectral characteristics may provide information relevant to the comparison between individuals with ASD and neurotypical controls [2], [5].

Blind Source Separation (BSS) techniques provide a strategy for decomposing multichannel recordings into latent components, allowing neural and non-neural contributions to be analyzed separately [6]. Among these techniques, Fast Independent Component Analysis (FastICA) estimates components based mainly on statistical independence and non-Gaussianity, whereas second-order Blind Identification (SOBI) exploits second-order statistics and the temporal correlation structure of the signals [7], [8]. Because these methods rely on different statistical assumptions, their use may produce different representations of the EEG signal and consequently affect the classification performance.

In addition to the source separation method, other methodological choices may also affect EEG-based classification results. Previous studies have adopted different preprocessing procedures, feature extraction strategies, dimensionality reduction methods, and classification algorithms [2], [9], [10]. Such methodological variability makes direct comparison between studies difficult and indicates that classification performance should be interpreted considering the complete signal-processing pipeline rather than the final classifier alone.

In this context, the present study investigates the influence of BSS and temporal segmentation strategies on EEG-based classification of individuals with ASD and neurotypical controls. Specifically, FastICA and SOBI were evaluated in combination with three temporal processing conditions: no windowing of the EEG signals, non-overlapping windows, and 50% overlapping windows. Temporal, spectral, and nonlinear features were subsequently extracted, selected using Minimum Redundancy

Maximum Relevance (mRMR), and classified using a Support Vector Machine (SVM). The objective was to compare these methodological configurations and identify the pipeline that achieved the highest classification performance in the analyzed dataset.

The remainder of this paper is organized as follows. Section II presents the theoretical background on Blind Source Separation, including the FastICA and SOBI algorithms evaluated in this study. Section III describes the dataset and methodological pipeline, including preprocessing, artifact identification, segmentation, feature extraction, dimensionality reduction, and classification. Section IV presents and discusses the experimental results. Finally, Section V summarizes the main findings and limitations of the study.

II. Blind Source Separation

Independent Component Analysis (ICA) is a multivariate Blind Source Separation (BSS) technique widely employed in EEG signal processing. Its objective is to decompose the observed signals into statistically independent latent components, allowing neural activity to be separated from physiological and instrumental interferences. In the context of this work, the classical linear model is adopted, in which the observed EEG is described as a linear mixture of independent sources [7].

The model can be expressed as:

$$\mathbf{x}(t) = \mathbf{A}\mathbf{s}(t), \tag{1}$$

where $\mathbf{x}(t)$ represents the vector of observed signals, $\mathbf{s}(t)$ corresponds to the independent sources, and $\mathbf{A}$ is the mixing matrix. The objective of ICA is to estimate a separation matrix $\mathbf{W}$ such that:

$$\mathbf{y}(t) = \mathbf{W}\mathbf{x}(t), \tag{2}$$

so that the components of $\mathbf{y}(t)$ are as mutually independent as possible. By doing so, $\mathbf{y}$ will be an estimate of $\mathbf{s}$. In EEG applications, this decomposition favors the identification and removal of artifacts, contributing to more robust analyses.

A. FastICA

FastICA (*Fast Independent Component Analysis*) is a BSS algorithm based on the maximization of the non-Gaussianity of the estimated sources. This principle follows from the Central Limit Theorem, according to which linear combinations of independent variables tend to present a distribution closer to a Gaussian one. Thus, by searching for maximally non-Gaussian projections, FastICA recovers estimates of the independent components [7].

The measure of non-Gaussianity employed in FastICA is based on negentropy, given by:

$$J(y) = H(y_{\text{gauss}}) - H(y), \tag{3}$$

where $H(\cdot)$ denotes differential entropy, and y_{gauss} is a Gaussian variable with the same mean and variance as y. In practice, the algorithm uses computationally efficient approximations of this measure through nonlinear functions, leading to a fixed-point method recognized for its fast convergence and numerical stability [7].

B. SOBI

SOBI (*Second-Order Blind Identification*) is a BSS algorithm based on the analysis of second-order statistics, with emphasis on the temporal correlations of the signals. Its separation strategy relies on the joint diagonalization of autocorrelation matrices at different time delays, which makes it particularly suitable for EEG signals, whose temporal structure carries relevant information [8].

The SOBI cost function can be expressed as:

$$J(\mathbf{U}) = \sum_{\tau_k \in D} \operatorname{off}\left(\mathbf{U}^{\mathrm{T}} \mathbf{R}_z(\tau_k) \mathbf{U}\right), \tag{4}$$

where $\mathbf{R}_{\mathbf{z}}(\tau_k)$ represents the autocovariance matrix of the whitened signals at time delay τ_k, D denotes the set of time delays considered, $\mathbf{U}$ corresponds to the orthogonal matrix estimated during joint diagonalization, and $\operatorname{off}(\mathbf{M})$ denotes the sum of the squared off-diagonal elements:

$$\operatorname{off}(\mathbf{M}) = \sum_{i \neq j} m_{ij}^2. \tag{5}$$

The complete SOBI separation matrix is given by:

$$\mathbf{W}_{\text{SOBI}} = \mathbf{U}^T \mathbf{V}, \tag{6}$$

where $\mathbf{V}$ represents the whitening matrix, and $\mathbf{U}$ is the orthogonal matrix estimated through the joint diagonalization procedure.

III. Materials and Methods

This section presents the stages that compose the methodological *pipeline* of this study, as illustrated in Figure 1. Each stage of the process is described in detail in the following subsections, in order to clarify the technical decisions adopted and their relevance to the processing and analysis of EEG signals in the context of ASD classification.

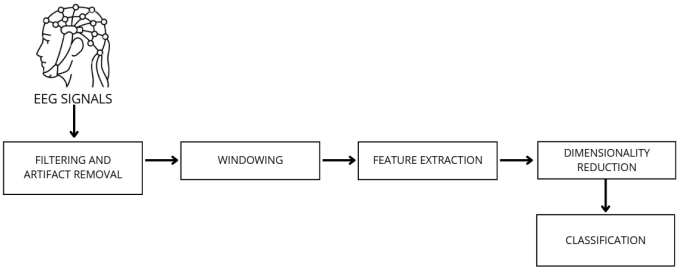

Fig. 1. Overview of the methodological pipeline.

A. Dataset

The EEG signals used in this study were obtained from the Data for Electrophysiological Signatures of Brain Aging in Autism Spectrum Disorder dataset. The original dataset comprises 56 adult participants, including 28 individuals diagnosed with autism spectrum disorder (ASD) and 28 neurotypical controls. The recordings were acquired at the

University of Cambridge using the BioSemi ActiveTwo system with an original 64-electrode montage, under resting-state eyes-closed conditions, with an approximate duration of 2.5 minutes and an original sampling rate of 2048 Hz.

Although the original acquisition protocol employed 64 electrodes, differences in channel availability, naming, and organization were identified across the analyzed files. To ensure identical input dimensionality and direct comparability between participants, all subsequent analyses were restricted to the following 15 channels: AF3, C3, C4, CP4, F3, F4, F7, Fz, O1, O2, P1, P10, P5, P8, and POz.

The final sample comprised 28 participants, including 14 individuals with ASD and 14 neurotypical controls, aged between 36 and 74 years. Participants were included when their EEG recordings contained the complete set of selected channels and when they satisfied the age-matching and group-balancing criteria adopted in the study. The remaining participants did not jointly meet these criteria. Therefore, in the reamining of this work, only 28 participantes were considered.

B. Signal Preprocessing

The preprocessing procedure was applied independently to each participant. First, the 15 common EEG channels were selected, ordered consistently across recordings, and band-pass filtered between 1 and 100 Hz, to preserve the gamma frequency band (from 30Hz to 100Hz) information, which we would also like to exploit in this work. A 50 Hz notch filter was subsequently applied to attenuate power-line interference. The filtered signals were then re-referenced using the common average reference calculated across the 15 retained channels.

After filtering and channel harmonization, the EEG signals were re-referenced using the *Common Average Reference* (CAR) method [11]. CAR was applied independently to each participant using only the 15 channels retained for analysis. At each time sample, the mean electrical potential across these channels was calculated and subtracted from the signal of each individual channel:

$$V_i^{\text{CAR}}(t) = V_i(t) - \frac{1}{N}\sum_{j=1}^{N} V_j(t), \tag{7}$$

where $V_i(t)$ represents the potential recorded at channel i at time t, and $N = 15$ represents the number of channels included in the analysis. Thus, the reference was not calculated using the original 64-channel montage [3], [11].

This procedure ensured that all participants were referenced using the same channel set and channel ordering. CAR was applied before the Blind Source Separation stage and, consequently, before the application of FastICA or SOBI.

C. Artifact Identification and Signal Reconstruction

After filtering and common average referencing, the EEG signals were decomposed using either FastICA or SOBI, according to the evaluated pipeline. The resulting components were subsequently analyzed in EEGLAB using the ICLabel plugin for automatic component classification [12].

ICLabel assigns to each component a probability of belonging to different classes, including Brain, Muscle, Eye, Heart, Line Noise, Channel Noise, and Other. In this study, a probability threshold of 80% was adopted. Components for which ICLabel assigned a probability equal to or greater than 80% to a specific artifact class were considered representative of that category. Components classified with a probability equal to or greater than 80% as Muscle, Heart, Line Noise, or Channel Noise were excluded during signal reconstruction, whereas components classified as Eye were retained.

Artifacts identified through FastICA and SOBI components were recorded separately and used to characterize the distribution of artifact types identified for each source separation method. Ocular components were retained as part of the exploratory methodological protocol but were not considered specific biomarkers of ASD.

The results presented in Fig. 2 were obtained from the ICLabel classifications that satisfied the adopted 80% probability threshold and represent the distribution of non-ocular artifact categories identified for each BSS method.

D. Segmentation and Feature Extraction

In the segmented configurations, the EEG signals were resampled to 256 Hz and divided into fixed-length windows of 60 s, corresponding to 15,360 samples per segment. Two segmentation strategies were evaluated: non-overlapping windows and 50% overlapping windows. In the overlapping condition, the step between consecutive windows was 30 s, corresponding to 7,680 samples. Segmentation was performed after filtering, re-referencing, and artifact removal. A Hann window was subsequently applied to each segment before feature extraction to reduce spectral leakage associated with spectral estimation [13].

In the feature extraction stage, temporal, spectral, and nonlinear features were obtained from the EEG signals to characterize different properties of brain activity. Temporal features included variance, kurtosis, skewness, peak-to-peak amplitude, Root Mean Square (RMS), and Hjorth mobility and complexity parameters [14].

Nonlinear features included the Hurst exponent, Detrended Fluctuation Analysis (DFA), Higuchi fractal dimension, and Petrosian fractal dimension. The Hurst exponent was used to characterize persistence and long-range dependence in the signal, whereas DFA was used to quantify long-range correlations and scaling behavior [15]. Higuchi and Petrosian fractal dimensions were included as measures of temporal signal complexity.

In the frequency domain, the power spectral density (PSD) was estimated using Welch's method. Absolute and relative spectral powers were extracted for the classical EEG frequency bands (δ, θ, α, β, and γ), together with total spectral power. Additional spectral measures included Peak Alpha Frequency (PAF) [16] and Spectral Edge Frequency 95 (SEF95) [17].

Entropy-based features included approximate entropy, permutation entropy, Singular Value Decomposition (SVD) entropy, and spectral entropy. Approximate entropy was computed

directly from the temporal EEG signal using the Python library `AntroPy` implementation and was used to quantify signal regularity and complexity. Permutation entropy was included as an ordinal measure of temporal complexity, whereas SVD entropy was used to characterize the distribution of information across the singular values of the time-delay representation of the signal.

Spectral entropy was computed from the PSD estimated using Welch's method. The PSD was normalized by its total power to obtain a probability distribution over frequencies, from which Shannon entropy was calculated using a base-2 logarithm. For the segmented pipelines, the features were computed separately for each channel and each 60-second window. For the non-segmented pipelines, they were computed separately for each channel using the complete recording of each participant.

E. Dimensionality Reduction

To minimize redundancy among features and reduce the risk of overfitting, the Minimum Redundancy Maximum Relevance (mRMR) method was applied [9]. The method was applied to the extracted feature matrix rather than directly to the raw EEG samples. Each column of the matrix represented a candidate temporal, spectral, or nonlinear feature.

For the segmented pipelines, each observation corresponded to a channel-window pair associated with a participant. For the non-segmented pipelines, each observation corresponded to a channel from the complete recording of a participant. Mutual information was estimated between each candidate feature and the ASD or control class label, while redundancy was evaluated among the candidate features. The resulting feature subset was subsequently used as input to the SVM classifier.

F. Classification and Evaluation

After feature selection, the classification stage was performed using the *Support Vector Machine* (SVM) algorithm, which is widely employed in biomedical signal classification tasks due to its robustness in high-dimensional spaces [9]. The implementation was carried out in Python using the *scikit-learn*, *pandas*, and *NumPy* libraries.

The features were standardized using the `StandardScaler` method, and classification was performed using a Support Vector Machine (SVM) with a radial basis function (RBF) kernel, configured as `SVC(kernel='rbf', C=1, gamma='scale', probability=True)`. The RBF kernel and its hyperparameters were defined *a priori* and maintained unchanged across all evaluated pipelines. No comparison with alternative kernels or systematic hyperparameter optimization was performed. This fixed configuration was adopted to evaluate the effects of the source separation and segmentation strategies under the same classification conditions. The RBF kernel was used to allow nonlinear decision boundaries in the space of the extracted EEG features.

A single stratified hold-out evaluation was adopted, with 70% of the observations assigned to the training set and 30% to the test set. The partition was performed using a fixed random seed (`random_state=42`) to ensure reproducibility while preserving the proportion of ASD and control observations in both subsets.

The performance of the *pipelines* was evaluated using accuracy, precision, *recall*, F1-score, and the area under the receiver operating characteristic curve (AUC). The final comparison considered different combinations of artifact removal methods and signal segmentation strategies, aiming to identify the most consistent methodological configuration for discriminating between individuals with ASD and neurotypical controls.

IV. Results and Discussion

Initially, the artifact classes obtained after FastICA and SOBI decomposition were descriptively compared based on the ICLabel classification. Ocular components were identified but retained during signal reconstruction, according to the methodological procedure described in Section III-C.

Different distributions of artifact classes were observed between the two source separation methods. FastICA produced a higher number of components classified as channel noise, whereas SOBI produced a higher number of components classified as muscle activity. Both methods also yielded a smaller number of components classified as cardiac activity, as illustrated in Fig. 2. These results provide a descriptive comparison of the component classes obtained after each decomposition and should not be interpreted as a formal evaluation of artifact-detection sensitivity.

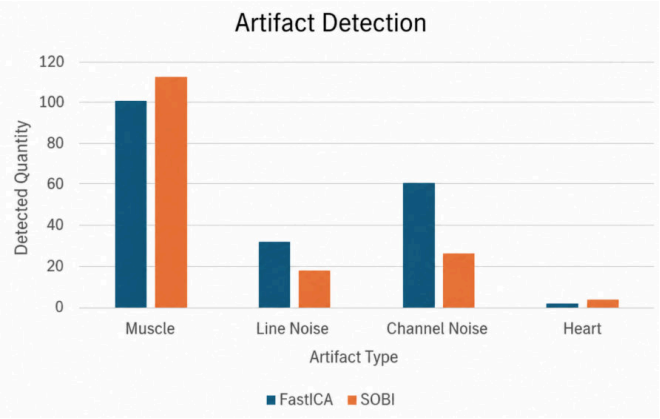

Fig. 2. Distribution of artifact classes identified by ICLabel after FastICA and SOBI decomposition.

The mRMR analysis showed that the most relevant attributes were not restricted to spectral power measures. The 15 highest-ranked features were, respectively, Higuchi fractal dimension, Detrended Fluctuation Analysis (DFA), Petrosian fractal dimension, Hurst exponent, relative beta power, relative alpha power, approximate entropy, peak-to-peak amplitude, total spectral power, absolute beta power, Hjorth complexity, permutation entropy, SVD entropy, spectral entropy, and Hjorth mobility.

The predominance of nonlinear measures among the highest-ranked features suggests that signal complexity, self-similarity,

and long-range temporal organization contributed relevant information to the distinction between ASD and control observations in the analyzed dataset. Higuchi and Petrosian fractal dimensions characterize signal complexity, whereas DFA and the Hurst exponent provide information related to scaling behavior and long-range temporal dependencies [15]. The presence of approximate, permutation, SVD, and spectral entropy among the selected attributes also indicates a contribution from measures associated with signal regularity and dynamical complexity [14]. At the same time, the presence of relative beta power, relative alpha power, total spectral power, and absolute beta power demonstrates that spectral information also contributed to the feature-selection process.

Complementarily, absolute and relative spectral power across the classical EEG frequency bands was explored as a descriptive analysis, independently of the mRMR ranking. The exploratory analysis suggested higher delta power in the ASD group and higher alpha power in the control group. Differences in alpha activity have also been reported in previous resting-state EEG studies involving ASD [5], [18], [19].

In the gamma band, similar central tendencies were observed between groups, although the ASD group showed greater dispersion and higher extreme values. Theta and beta power showed less evident group differences in this descriptive analysis. However, relative beta power and absolute beta power occupied the fifth and tenth positions, respectively, in the mRMR ranking. This apparent difference is not necessarily contradictory, since the spectral analysis considered each frequency-domain measure descriptively, whereas mRMR evaluates feature relevance to the class label while also accounting for redundancy among features. No inferential statistical tests were performed for these band-wise comparisons; therefore, the spectral findings should be interpreted as exploratory.

Following the feature analysis, the classification performance of the six evaluated pipelines was compared. Table I summarizes the results obtained by combining FastICA and SOBI with the no-windowing, non-overlapping, and 50% overlapping configurations. In the adopted hold-out evaluation, classification performance differed according to the source separation and segmentation strategies.

TABLE I
COMPARATIVE PERFORMANCE OF THE EVALUATED PIPELINES.

Method	Windowing	Acc	AUC	Prec.	Rec.	F1
FastICA	No windowing	0.674	0.657	0.712	0.693	0.703
FastICA	No overlap	0.615	0.566	0.635	0.720	0.675
FastICA	50% overlap	0.622	0.610	0.645	0.710	0.676
SOBI	No windowing	**0.741**	**0.730**	**0.756**	0.787	**0.771**
SOBI	No overlap	0.596	0.544	0.612	0.747	0.673
SOBI	50% overlap	0.659	0.649	0.653	**0.823**	0.729

Among the FastICA-based pipelines, the highest overall performance was obtained in the no-windowing condition, with an accuracy of 0.674, AUC of 0.657, precision of 0.712, recall of 0.693, and F1-score of 0.703. Both segmented configurations presented lower accuracy than the no-windowing condition, although the 50% overlapping configuration showed a slight improvement over the non-overlapping strategy for some metrics.

Among the SOBI-based pipelines, the highest overall performance was also obtained without windowing, with an accuracy of 0.741, AUC of 0.730, precision of 0.756, recall of 0.787, and F1-score of 0.771. Although the 50% overlapping configuration achieved the highest recall of the evaluated pipelines (0.823), its accuracy, AUC, precision, and F1-score remained below those obtained with SOBI without windowing. The non-overlapping SOBI configuration presented the lowest accuracy and AUC among the SOBI-based conditions.

In the adopted hold-out evaluation, neither segmentation strategy provided a consistent improvement over the corresponding no-windowing configuration. For both FastICA and SOBI, the highest accuracy and F1-score were obtained when the complete recording was used for feature extraction. Thus, within the conditions evaluated in this study, temporal segmentation did not provide a consistent classification advantage.

The higher overall performance observed for SOBI without windowing suggests that the combination of a source separation method based on second-order temporal statistics with feature extraction from the complete recording may be advantageous for this dataset. However, considering the exploratory design of the study, these results should not be interpreted as evidence of the general superiority of SOBI over FastICA.

Because this study was designed as an initial exploratory analysis, classification performance was evaluated using a single stratified hold-out partition. In addition, participant-wise separation was not explicitly enforced during the original classification protocol. Therefore, the reported performance should be interpreted as preliminary, and future studies should employ participant-wise repeated validation strategies to provide a more robust estimate of generalization performance.

V. CONCLUSION

This work compared EEG signal processing pipelines applied to individuals with Autism Spectrum Disorder and neurotypical controls. Among the evaluated configurations, SOBI without temporal segmentation showed the highest observed classification performance. Exploratory spectral analysis also indicated group-related patterns in delta, alpha, and gamma activity.

Overall, the findings show that source separation and segmentation choices were associated with differences in classification performance in the analyzed dataset. Considering the exploratory nature of the study and the adopted hold-out evaluation, these results should be interpreted as preliminary. Future studies should evaluate the proposed pipeline using participant-wise validation and larger datasets.

Abstract*—This paper presents the development and validation of a modular computational pipeline for electroencephalography (EEG) signal processing and automated spectral modulation detection. Implemented in Python with MNE-Python, the system integrates EDF file reading, channel standardization, temporal segmentation, Welch power spectral density (PSD) estimation, extraction of five spectral features, aggregation, statistical analysis, and automated report generation. The pipeline was validated through two complementary strategies. First, a physiological control based on alpha reactivity between eyes-open and eyes-closed resting states confirmed that the software preserves genuine spectral changes: across 109 participants from the EEG Motor Movement/Imagery Dataset (3,052 epochs at the Oz channel), all five metrics differed significantly between conditions after Holm correction, with large effect sizes. Second, a controlled synthetic-signal protocol tested whether the pipeline specifically detects and quantifies a modulation at the target frequency (12 Hz): EEG signals with known 12-Hz amplitude and known signal-to-noise ratio (six SNR levels from −10 to +20 dB, five modulation levels, 15 synthetic subjects per condition) were processed and compared against their known ground truth. Recovered target-band power matched the theoretical value with a mean absolute relative error of 1.8% at the strongest modulation level, and the modulation was statistically detected across all paired post-vs.-pre test conditions, including low-SNR scenarios. No EEG recordings from binaural-stimulation experiments or individuals with Alzheimer's disease were analyzed in the present study; these results indicate that the pipeline reproduces a known physiological effect and recovers a specific, quantitatively known spectral modulation, providing the computational infrastructure required for future EEG studies of 12-Hz binaural stimulation.

***Keywords*—computational pipeline, binaural beats, electroencephalography, spectral modulation, power spectral density, synthetic validation, ground truth.**

I. INTRODUCTION

Electroencephalography (EEG) provides a noninvasive, time-resolved measure of brain electrical activity and is widely used to study spectral and connectivity changes associated with aging and neurodegeneration [2], [3]. Comparing EEG recordings across experimental conditions, however, requires a processing chain that reads raw signals, extracts frequency-domain features in a standardized way, and applies appropriate statistical comparisons — components that are often implemented ad hoc and inconsistently across studies, hindering reproducibility.

This work is part of a broader project investigating whether a 12-Hz binaural acoustic protocol can produce a measurable electrophysiological response in the context of Alzheimer's disease research. The broader project adopted 12 Hz as a predefined experimental target for subsequent investigation; however, the present article does not evaluate the biological rationale, therapeutic efficacy, or clinical effects of that stimulation. Its scope is limited to the computational infrastructure required to objectively identify and quantify changes in the spectral content of EEG recordings acquired before, during, and after stimulation.

The central contribution of this work is computational, not clinical: an automated, modular pipeline that reads raw EEG recordings, preserves sample traceability, estimates the frequency-domain power distribution, extracts spectral biomarkers, and statistically compares experimental conditions. Because the pipeline is intended to eventually support the 12-Hz binaural protocol, it must be validated not only on a phenomenon with a known direction of change, but specifically on its ability to recover a modulation of known frequency, amplitude, and noise level.

To that end, the pipeline underwent two independent validation strategies. The first is a physiological control with a well-documented, reproducible effect: alpha reactivity between eyes-open and eyes-closed resting states [4], [5]. This test confirms that reading, segmentation, spectral estimation, feature extraction, and statistical testing operate correctly as an integrated chain, but — because its expected direction, not its magnitude, is known in advance — it cannot by itself establish that the pipeline correctly quantifies an arbitrary spectral modulation. The second validation strategy is a controlled synthetic-signal protocol in which the amplitude and the signal-to-noise ratio of a 12-Hz component are set explicitly and compared against the pipeline's recovered estimates, directly measuring detection and quantification error.

This study aims to develop and validate this modular pipeline for detecting and quantifying spectral modulation in EEG. Its main contribution is a reusable computational infrastructure, validated against both a known physiological effect and a known synthetic ground truth, capable of processing public datasets and future experimental recordings, generating biomarkers, performing statistical comparisons, and producing standardized outputs for auditory neuromodulation studies — including, but not limited to, the 12-Hz binaural protocol.

II. BACKGROUND

A. Spectral Modulation in EEG

Scalp EEG mainly reflects the spatiotemporal summation of postsynaptic potentials from cortical neuronal populations. In this study, spectral modulation is defined as a quantifiable difference between two conditions, expressed through the integrated energy of a frequency band (absolute power), that energy normalized by the total analyzed power (relative power), or properties of the dominant oscillatory component (peak frequency and peak PSD amplitude). For the 12-Hz protocol, the 10–14 Hz range was defined as the target band. Alpha reactivity to eye closure — a well-documented increase in occipital alpha power upon closing the eyes [4], [5] — was used as a physiological control because its direction is known in advance, allowing verification that the software chain preserves a genuine spectral change.

B. Project Context: 12-Hz Binaural Stimulation

Binaural beats are perceived when each ear receives a pure tone at a slightly different frequency; the difference is processed along the auditory pathway and, in some protocols, has been associated with changes in cortical oscillatory activity, although reported effects are inconsistent and depend strongly on stimulation parameters [6]–[9]. In the broader project supported by this pipeline, a 12-Hz binaural difference is the predefined stimulation condition selected for future EEG investigation in the context of Alzheimer's disease research [1]–[3]. The present study does not test therapeutic efficacy or Alzheimer's-specific effects; it provides the infrastructure to later compare EEG recordings obtained before, during, and after exposure to the 12-Hz protocol, quantifying any resulting spectral modulation with the architecture validated in this paper.

III. MATERIALS AND METHODS

A. Pipeline Architecture

The pipeline was developed in Python using MNE-Python [12] as a modular processing sequence, separating data acquisition, file reading, standardization, preprocessing, spectral estimation, feature extraction, statistical aggregation, and output generation into independent stages. Each stage receives a defined input, performs one function, and passes its output forward; participant, condition, channel, and epoch identifiers are preserved throughout, ensuring traceability from any aggregated result back to its source recording. The complete modular processing sequence is summarized in Fig. 1. Parameterization (channels of interest, epoch duration and overlap, band limits, compared conditions) is kept separate from the analysis logic, so the same core processing chain is reused across the PhysioNet dataset (Section III.B), the synthetic ground-truth signals (Section III.E), and, in future work, recordings from the 12-Hz binaural protocol, with only source-specific acquisition parameters (e.g., sampling rate) supplied through configuration.

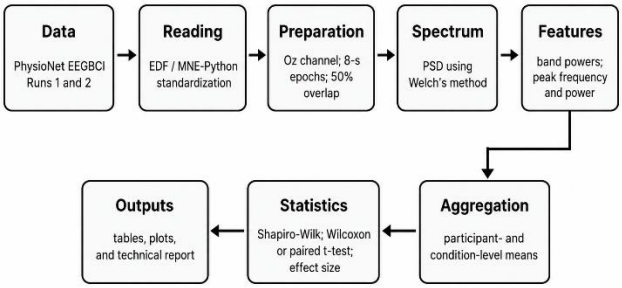

Fig. 1. Modular workflow of the EEG processing and analysis pipeline.

B. Physiological Validation Dataset

The EEG Motor Movement/Imagery Dataset, version 1.0.0, from PhysioNet [10], acquired with the BCI2000 system [11], was used for the physiological control. The dataset contains 109 participants, 64 channels, and a sampling frequency of 160 Hz; baseline Run 1 (eyes open) and Run 2 (eyes closed) were selected. The Oz channel, over the occipital region where alpha reactivity is typically most pronounced, was used. Prior to spectral analysis, recordings were band-pass filtered between 1 and 40 Hz (4th-order Butterworth, zero-phase); a 60-Hz notch filter was applied beforehand as a preprocessing safeguard against strong power-line interference, although it is not strictly necessary for the reported 1–40 Hz analysis band once the band-pass filter is applied. Results reported here use the single Oz channel without additional re-referencing. Signals were segmented into 8-s epochs with 50% overlap, yielding 3,052 epochs (1,526 per condition).

C. Spectral Processing and Feature Extraction

For each epoch, PSD was estimated using Welch's method [13] with 4-s Hann windows, 50% overlap between segments, and nfft = nperseg (no zero-padding), averaging modified periodograms to reduce estimation variability. This corresponds to nperseg = nfft = 640 samples at the 160-Hz PhysioNet sampling rate and nperseg = nfft = 1024 samples for the 256-Hz synthetic signals (Section III.E) — both yielding the same frequency resolution, $\Delta f = 0.25$ Hz. PSD is reported in V^2/Hz for the PhysioNet recordings and in

arbitrary-units squared per hertz (a.u.²/Hz) for the synthetic signals.

Five features were extracted per epoch: absolute alpha power (8–13 Hz); alpha power relative to the total power integrated between 1 and 40 Hz, matching the upper edge of the preprocessing band-pass filter (Section III.B) — the same reference band is used for both the PhysioNet physiological validation and the synthetic ground-truth validation (Section III.E), as this normalization is applied by a single shared function with no dataset-specific branching; integrated power in the 10–14 Hz target band; and, searched within that same 10–14 Hz target band (not the 8–13 Hz alpha band), the frequency and amplitude of the largest spectral peak. For the PhysioNet data, integrated powers are reported in V² and peak PSD amplitude in V²/Hz; for the synthetic validation, the corresponding units are a.u.² and a.u.²/Hz. Peak PSD amplitude is read directly from the PSD at a single frequency bin rather than integrated over a band, consistent with the PSD representation shown in Fig. 2.

D. Physiological Validation Statistics

The functional validation criterion was recovery of the expected alpha increase at Oz during eyes-closed rest. Metrics were calculated per epoch and summarized per participant; normality of paired differences was assessed with Shapiro–Wilk [14], and the Wilcoxon signed-rank test [15] (rank-biserial effect size) or the paired t-test (Cohen's dz [16]) were applied accordingly, with $\alpha = 0.05$ and Holm correction for five outcomes.

E. Controlled Synthetic Validation Protocol

A physiological control such as eyes-open/eyes-closed alpha reactivity confirms that the pipeline detects a genuine spectral change in the expected direction, but its magnitude is not known in advance, so it cannot alone establish whether the pipeline correctly quantifies an arbitrary modulation — the requirement for the 12-Hz binaural protocol, where the size of any effect is unknown a priori. To address this, a second, independent validation used synthetic EEG signals in which the amplitude and signal-to-noise ratio (SNR) of a 12-Hz component are explicit, known parameters.

Each synthetic signal (60 s, 256 Hz) combines a fixed ~10-Hz background rhythm of amplitude 1.0 a.u., additive 1/f-shaped noise, and, in post-stimulus conditions, a pure 12-Hz sinusoidal component of controlled amplitude A, all expressed in arbitrary units (a.u.). Five modulation levels were defined as fractions of a reference amplitude Aref = 1.0 a.u.: pre-stimulus (0%), and post-stimulus very weak (15%, A = 0.15 a.u.), weak (35%, A = 0.35 a.u.), moderate (65%, A = 0.65 a.u.), and strong (100%, A = Aref = 1.0 a.u.). Six SNR levels were tested (−10, −5, 0, 5, 10, and 20 dB), computed relative to Aref, where noise_amp is the standard deviation of the generated zero-mean 1/f noise and therefore equals its RMS amplitude. The generator normalizes the pink-noise sequence to unit standard deviation before scaling it by noise_amp:

$$SNRdB = 10 \cdot \log10[(Aref^2/2) / noise_amp^2] \qquad (1)$$

Within each SNR group, the same background-noise level was used across all five signal-generation levels, isolating the effect of modulation amplitude from the effect of the noise floor. The six SNR levels and five generation levels produced 30 signal-generation configurations; with 15 independent synthetic subjects per configuration, 450 signals were generated in total. Statistical pre-vs.-post detection, however, involved only the four nonzero modulation levels at each of the six SNRs, yielding 24 post-vs.-pre comparisons. Every signal was processed through the same preprocessing, epoching, and Welch PSD pipeline used for the physiological validation.

Within each (SNR, subject) pair, the pre-stimulus and all post-stimulus signals share the same random seed, containing an identical background-noise realization and differing only in the amplitude of the added 12-Hz component. This design supports paired pre-vs.-post comparisons for the same synthetic subject — analogous to how the future 12-Hz protocol will compare the same individual before and after stimulation — while controlling the background-noise realization. Normality of within-subject differences was assessed with Shapiro–Wilk; a paired t-test was used when the normality criterion was met and the Wilcoxon signed-rank test otherwise. The minimum detectable modulation was defined as the lowest nonzero modulation level producing a significant paired post-vs.-pre difference ($p < 0.05$) in target-band power at each SNR level.

The theoretical power added by a pure 12-Hz sinusoid of amplitude A is, by Parseval's theorem:

$$Pexpected = A^2 / 2 \qquad (2)$$

The power actually recovered by the pipeline was computed as the paired difference in target-band power between the post- and pre-stimulus signals of the same synthetic subject, canceling the shared noise floor and background rhythm. The peak-frequency error was computed as the recovered peak frequency (searched within the 10–14 Hz target band, as in Section III.C) minus the inserted frequency (12.00 Hz).

IV. RESULTS

A. Physiological Validation

Across the 109 participants (3,052 epochs), all five spectral metrics differed significantly between eyes-open and eyes-closed conditions after Holm correction (Table I). The four power-related metrics increased upon eye closure — relative alpha power rose from 18.39% to 42.41% (Wilcoxon, $p = 4.29\times10^{-19}$, $|r| = 0.985$) — whereas peak frequency shifted downward, from 11.32 to 10.74 Hz (paired t-test, $p = 4.63\times10^{-15}$, $|dz| = 0.874$). Fig. 2 shows the expected concentration of PSD energy within the alpha/target band upon eye closure, and Fig. 3 shows the corresponding epoch-level distribution. This physiological control confirms that the software chain — reading, segmentation, Welch PSD, feature extraction, and statistical testing — preserves a real spectral difference. Because only its direction, not its magnitude, was known beforehand, it is complemented by the synthetic ground-truth validation below, which provides a quantitative test of recovery accuracy under known conditions.

TABLE I. PHYSIOLOGICAL VALIDATION (EYES-OPEN → EYES-CLOSED)

Metric	Mean EO→EC	p-value	Effect
Abs. alpha power ($\times10^{-10}$V²)	1.652→8.856	3.54×10^{-19}	0.988
Rel. alpha power (%)	18.39→42.41	4.29×10^{-19}	0.985
Target-band power ($\times10^{-10}$V²)	1.018→4.825	2.48×10^{-19}	0.992

Metric	Mean EO→EC	p-value	Effect
Peak PSD ampl. ($\times 10^{-10}$V²/Hz)	0.840→6.575	2.06×10^{-18}	0.966
Peak frequency (Hz)	11.32→10.74	4.63×10^{-15}	0.874

EO: eyes open; EC: eyes closed. All outcomes remained significant after Holm correction (Wilcoxon signed-rank, except peak frequency: paired t-test). Relative power is referenced to total power integrated over 1–40 Hz, as described in Section III.C.

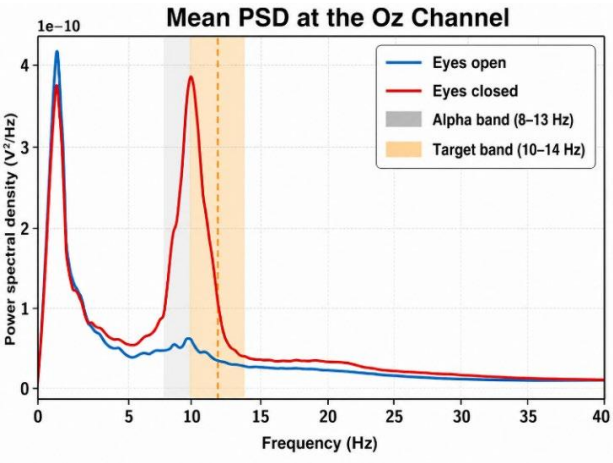

Fig. 2. Mean PSD at the Oz channel, eyes open vs. eyes closed.

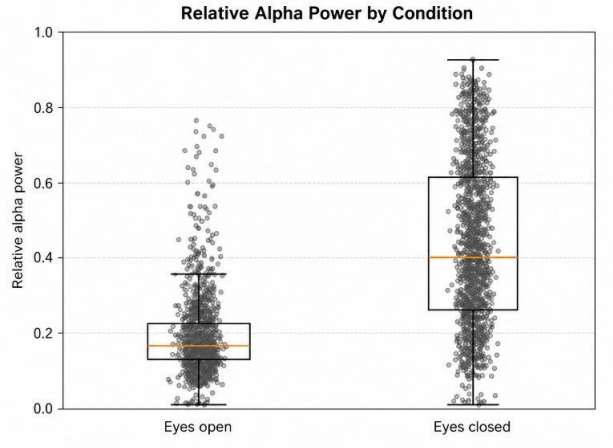

Fig. 3. Distribution of relative alpha power by epoch, eyes open vs. eyes closed.

B. Controlled Synthetic Validation

Fig. 4 shows the recovered target-band power (mean ± SD across 15 synthetic subjects) as a function of the inserted 12-Hz amplitude, for all six SNR levels, together with the theoretical curve Pexpected = A²/2. Recovered power closely tracks the theoretical curve across the entire tested range.

Averaged across all SNR levels, the mean relative power error decreased monotonically with modulation strength (Table II), from −3.4% (|error| 12.1%) at the very weak level to −0.5% (|error| 1.8%) at the strong level. At the strong level specifically, the mean relative error ranged from −1.9% ± 6.3% at the most adverse SNR (−10 dB) to −0.03% ± 0.15% at the most favorable SNR (+20 dB).

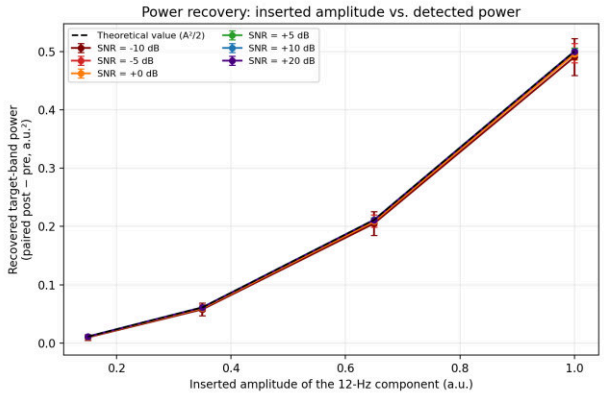

Fig. 4. Inserted 12-Hz amplitude vs. recovered target-band power, by SNR.

TABLE II. MEAN RECOVERY ERROR BY MODULATION LEVEL (ALL SNR POOLED, n = 90/LEVEL)

Level	Freq. err (Hz)	Pow. err (%)	|Pow. err| (%)
Very weak (15%)	−2.00	−3.4	12.1
Weak (35%)	−2.00	−1.5	5.2
Moderate (65%)	−2.00	−0.8	2.8
Strong (100%)	−1.05	−0.5	1.8

Fig. 5 shows the corresponding peak-frequency error. At the very weak, weak, and moderate modulation levels, the recovered peak remained close to the background ~10-Hz rhythm (error near −2 Hz) across the tested SNRs. An appreciable shift toward the inserted 12-Hz component became evident at the strong modulation level, where the mean error decreased to approximately −1.05 Hz. This does not indicate a failure of target-band-power detection; rather, it reflects that the peak-frequency metric identifies the largest local maximum within the 10–14 Hz band, which remains dominated by the ~10-Hz background component at lower modulation amplitudes — target-band power (Table II, Fig. 4) already detects the added modulation at those same levels, so the two metrics are not in conflict. Fig. 6 illustrates this transition for a representative synthetic subject: the pre- and post-stimulus PSD curves coincide throughout the spectrum except for the additional 12-Hz peak introduced by the modulation.

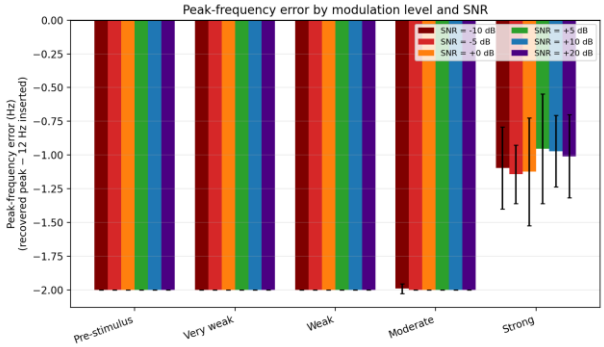

Fig. 5. Peak-frequency error by modulation level and SNR.

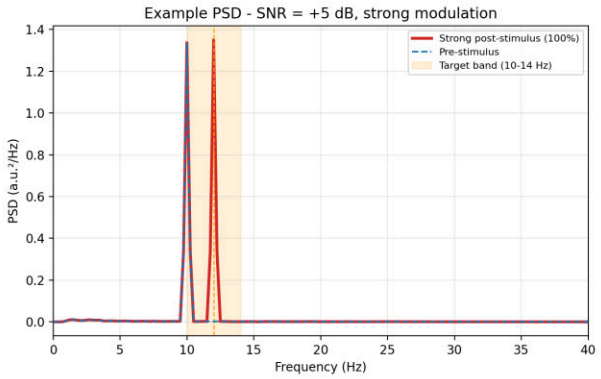

Fig. 6. Example PSD, pre- vs. strong post-stimulus (SNR = +5 dB, one synthetic subject).

Statistical detection followed the same pattern. Using the target-band-power metric, the paired comparison against the matched pre-stimulus condition (same synthetic subject, same noise realization) was significant ($p < 0.05$) for all 24 tested post-vs.-pre combinations (six SNR levels × four nonzero modulation levels), including the weakest modulation at the lowest SNR ($p = 1.2\times10^{-6}$). Consequently, the minimum detectable modulation in the paired analysis was the very weak level (15% of Aref) at every tested SNR, as summarized in Table III. This result characterizes sensitivity under the controlled matched-noise design used for the synthetic validation and should not be interpreted as a detection limit for real EEG recordings.

TABLE III. MINIMUM MODULATION LEVEL DETECTED IN PAIRED COMPARISONS ($p < 0.05$, TARGET-BAND POWER)

SNR (dB)	Minimum detected level (paired)
−10	Very weak (15%)
−5	Very weak (15%)
0	Very weak (15%)
5	Very weak (15%)
10	Very weak (15%)
20	Very weak (15%)

C. Pipeline Performance Summary

Together, the two validations characterize complementary aspects of pipeline performance: the physiological control confirms that a real, direction-known spectral change is preserved end-to-end; the synthetic ground-truth protocol confirms that a modulation of known frequency and amplitude is both detected with statistical significance and quantified with a small, SNR-dependent relative error. Neither result establishes, by itself, that the eventual 12-Hz binaural protocol will produce a detectable effect in real EEG recordings — that remains an open empirical question the validated pipeline is now positioned to answer.

V. DISCUSSION

A. Integrated Validation

The convergence of two independent validation strategies — one based on a real physiological effect of known direction, the other on synthetic signals of known magnitude — provides stronger evidence than either alone that the pipeline's reading, spectral estimation, feature extraction, and statistical modules operate correctly as an integrated chain. Had a systematic error existed (e.g., incorrect PSD normalization, misaligned band integration, or mismatched participant/condition bookkeeping), it is unlikely that both the direction of the physiological effect and the quantitative magnitude of the synthetic modulation would be recovered simultaneously across the tested range of SNR and amplitude.

B. Toward the 12-Hz Binaural Protocol

These results establish the pipeline as ready to process recordings from the 12-Hz binaural protocol once available, but they do not constitute evidence of a neuromodulatory effect of that protocol. The synthetic validation deliberately used an idealized additive signal model (a pure sinusoid over structured background noise) and does not capture the artifacts, inter-individual variability, or unknown effect size that a real binaural-stimulation recording may present; the true minimum detectable amplitude in real EEG may differ from Table III. The Alzheimer's-related context should therefore be interpreted only as a planned application domain for future investigation, not as an outcome of the present study [1]–[3]. This pipeline neither confirms nor tests a disease-specific, therapeutic, or electrophysiological effect of 12-Hz stimulation; it only provides the infrastructure to look for spectral modulation with a characterized detection and quantification error under known conditions. Any future claim about a specific neuromodulatory or Alzheimer's-related effect would require applying this validated pipeline to real pre-/post-stimulation recordings and interpreting the result on its own terms, not by extrapolation from the validations reported here.

C. Limitations and Future Work

Both validations share limitations. The physiological validation used a single channel (Oz) and healthy participants only; multichannel analysis, automated artifact rejection, and topographic mapping were not implemented. The synthetic validation used an idealized 1/f-noise-plus-sinusoid model that does not capture non-stationary artifacts, electrode/impedance variability, or physiological confounds present in real recordings, and tested a single target frequency (12 Hz) and background alpha amplitude; results at other frequencies, montages, or noise structures were not characterized. Future work should extend the synthetic protocol to multichannel signals and alternative noise models, apply the validated pipeline to real pre-, during-, and post-stimulation recordings from the 12-Hz binaural protocol, and incorporate automated artifact handling, functional connectivity, and individual alpha frequency adjustment.

VI. CONCLUSION

A modular computational pipeline was developed for reading, organizing, spectrally processing, and statistically analyzing EEG signals, and was validated through two complementary strategies: a physiological control with a known direction of effect (alpha reactivity to eye closure) and a controlled synthetic protocol with known modulation amplitude and SNR. The synthetic validation showed that the pipeline recovers the inserted 12-Hz power with a mean absolute relative error of 1.8% at the strongest tested modulation and detects the modulation with statistical significance across all paired post-vs.-pre conditions in the tested range of amplitude and SNR, including adverse noise conditions.

The pipeline therefore provides the infrastructure required to analyze EEG signals before, during, and after 12-Hz binaural stimulation, supporting future studies on whether measurable neurophysiological modulation occurs in the context of Alzheimer's disease research. Beyond this application, its parameterizable, dataset-independent architecture and its characterized detection/quantification error under known conditions support reuse in other neuromodulation studies, with future extension to multichannel analysis, connectivity, automated artifact handling, and validation on real stimulation recordings.

***Abstract*—This study presents the development and evaluation of an unsupervised computational framework tailored for the automated detection and segmentation of demyelinating brain lesions in patients with multiple sclerosis (MS) using fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI). To enhance dataset heterogeneity and improve external validity, a total of 60 brain MRI examinations were obtained from two distinct sources: the Hospital de Clínicas of the Federal University of Paraná (UFPR), Brazil, and a public international repository from the University of Ljubljana, Slovenia. Comparative tests against the LS Segmenter extension in 3D Slicer software demonstrate that while standard methods suffer from significant lesion overestimation, the proposed tool isolates focal periventricular and juxtacortical plaques more effectively, providing instant quantitative spatial metrics . This framework represents a scalable and objective tool suitable for clinical diagnostic support and longitudinal tracking of MS lesion burden.**

***Index Terms*—K-means clustering, lesion segmentation, magnetic resonance imaging (MRI), multiple sclerosis (MS), unsupervised machine learning framework**

I. Introduction

Multiple sclerosis is a complex and chronic inflammatory demyelinating and immune-mediated disorder that affects the central nervous system and leads to progressive neurological impairment [1] . The disease is characterized by focal areas of demyelination, neuroaxonal injury, and gliosis, which result in heterogeneous neurological manifestations including visual, sensory, motor, sphincteric, and cognitive dysfunction. Although the precise mechanisms underlying the disease remain incompletely understood, current evidence suggests the interaction of genetic susceptibility, environmental exposure, and dysregulated immune responses, culminating in inflammatory damage to the myelin sheath and disruption of axonal conduction [1] [2]. In total, approximately 2.8 million individuals are estimated to be affected by multiple sclerosis, with a higher prevalence observed in populations located at higher latitudes and among young adults, specifically women [1] [2] [3]. Recently, deep learning approaches, particularly convolutional neural networks, have demonstrated significant potential for automated lesion detection and segmentation in brain magnetic resonance imaging. Architectures derived from U-Net, originally proposed for biomedical image segmentation, have become one of the most widely used frameworks for this purpose [4].

Studies have demonstrated encouraging results in the application of deep learning models to detect demyelinating lesions and quantify the burden of the injury in brain magnetic resonance images [5] [6].

Magnetic resonance imaging plays a central role in the diagnosis and follow-up of the disease. The technique provides high sensitivity for the detection of demyelinating lesions in both the brain and the spinal cord and has become essential to demonstrate the dissemination of lesions in time and space, a key element in the diagnostic criteria for multiple sclerosis [1] [7]. In addition, magnetic resonance imaging is widely used for longitudinal monitoring of disease activity, allowing the identification of new lesions or the progression of existing ones, as well as the evaluation of therapeutic response. Early identification of disease activity is particularly relevant because

multiple sclerosis represents one of the main causes of non-traumatic neurological disability in young adults.

Typical lesions appear as hyperintense areas on T2-weighted images and FLAIR(Fluid-attenuated inversion recovery) sequences, usually oval or round in morphology and measuring at least 3 mm in diameter, corresponding to focal inflammatory demyelinating processes within the central nervous system. Their spatial distribution follows characteristic anatomical patterns that reflect diagnostic criteria for dissemination in space. The most relevant locations include the periventricular region, cortical/juxtacortical white matter, infratentorial compartment, optic nerves, and spinal cord [1]. These patterns reflect the preferential involvement of the perivenular white matter pathways, which represent a key pathological feature of the disease. Among the most characteristic imaging features are the "Dawson's fingers", which represent lesions oriented radially and perpendicular to the lateral ventricles. These lesions correspond to inflammatory demyelination along the medullary veins and are considered a classic imaging hallmark of multiple sclerosis [1]. Their presence, particularly when associated with the "central vein sign", significantly increases the specificity of magnetic resonance imaging to differentiate multiple sclerosis from other white matter disorders, such as small vessel disease of the brain. For lesions to be classified as juxtacortical, they must directly contact the cortical ribbon and involve the subcortical U-fibers. This imaging feature is particularly relevant for the differential diagnosis, as many vascular white matter lesions spare these fibers.

Despite the critical role of imaging in disease management, lesion identification and comparison across serial examinations remain largely dependent on manual evaluation by radiologists. This process may be time-consuming and subject to variability between observers, particularly when dealing with subtle changes or large data sets of images [8]. The increasing demand for neuroimaging examinations in clinical practice has further intensified the workload of neuroradiologists, highlighting the need for computational tools capable of assisting image interpretation and improving workflow efficiency. Recently, advances in machine learning and deep learning techniques have enabled the development of computational systems capable of extracting complex patterns from medical images and performing automated segmentation of pathological structures [9] [10]. In the context of multiple sclerosis, these approaches have shown promising results in detecting and quantifying white matter lesions on magnetic resonance imaging. Automated lesion segmentation methods have the potential to improve reproducibility, reduce observer variability, and facilitate an objective evaluation of the disease burden over time [1] [9] [10].

More recently, research has increasingly focused on automated longitudinal analysis of magnetic resonance examinations, with the aim of identifying new or enlarging lesions in follow-up studies and supporting clinical decision-making in patient monitoring. However, several challenges remain for the clinical implementation of these systems. Differences in acquisition protocols, scanner characteristics, and image quality between institutions can significantly affect algorithm performance and limit generalization between datasets. Consequently, contemporary research has emphasized the development of robust segmentation pipelines and the use of large heterogeneous datasets for algorithm training and validation [10]. Modern deep learning architectures, including convolutional neural networks and self-configuring segmentation frameworks, have demonstrated improved performance in medical image analysis tasks [11].

Approaches based on automated pipeline configuration and external validation have shown encouraging results in the segmentation of multiple sclerosis lesions in FLAIR magnetic resonance sequences [12]. In addition, ensemble strategies that combine predictions from multiple algorithms have been proposed to improve robustness and reliability in heterogeneous clinical scenarios. Emerging methodologies have also explored the integration of foundation-model concepts and prompt-guided segmentation frameworks, reflecting a broader trend toward more adaptable artificial intelligence systems for medical imaging applications.

Another important aspect addressed in recent studies concerns the variability of lesion appearance and imaging protocols in multicenter datasets, which represents a major obstacle to the generalization of automated methods. Large collaborative datasets and international segmentation challenges have demonstrated that algorithm performance may vary substantially depending on the characteristics of the imaging data and patient population. These findings reinforce the importance of developing computational tools capable of maintaining adequate performance in real-world clinical conditions. In this context, the development of automated systems capable of identifying and quantifying demyelinating lesions in magnetic resonance imaging represents an important strategy to improve diagnostic support and longitudinal monitoring of patients with multiple sclerosis. Such tools may contribute to reducing the workload of neuroradiologists while enabling a more objective and reproducible assessment of disease activity. Therefore, the guiding research question of this study is whether machine learning–based computational approaches can reliably identify typical multiple sclerosis lesions on brain magnetic resonance imaging examinations.

To address these limitations, the objective of this research is to develop and evaluate an unsupervised machine learning computational framework tailored for the automated detection and segmentation of demyelinating lesions in patients with multiple sclerosis using FLAIR magnetic resonance imaging. Instead of relying on data-hungry supervised deep learning architectures, the proposed methodology integrates a robust image processing pipeline—combining N4 bias field correction, skull stripping, and Z-score intensity normalization with K-means clustering for multi-tissue classification and localized statistical anomaly detection for focal plaque identification. This framework provides an accessible, fully automated tool capable of generating objective, real-time quantitative spatial metrics of lesion burden without requiring manually labeled ground-truth datasets. Ultimately, this approach aims to sup-

port specialists in longitudinal disease monitoring and clinical follow-up, particularly within public healthcare environments such as the Brazilian Unified Health System (Sistema Único de Saúde - SUS)

II. Method

This study was designed as a methodological investigation aimed at the development and evaluation of a computational system for medical image analysis using machine learning techniques applied to the detection and segmentation of demyelinating lesions in brain magnetic resonance imaging.

The dataset used consisted of brain MR examinations obtained from two independent sources. The first source included scans of patients diagnosed with multiple sclerosis who underwent clinical follow-up at the Hospital de Clínicas of the Federal University of Paraná (UFPR), located in Curitiba, Brazil. A total of 30 examinations from this institution were included in the study. Before inclusion in the study, all examinations were anonymized to ensure protection of patient identity and compliance with ethical standards for clinical data research. All identifying information contained in the imaging files was removed before data processing and analysis. The use of examinations obtained from the Hospital de Clínicas of the Federal University of Paraná was approved by the institutional Research Ethics Committee, in accordance with national ethical guidelines for research involving human subjects (CAEE 86677324.9.0000.0096 - Approval Number 7.582.336 in accordance with Resolution 466/2012 of the Brazilian National Health Council). The second source consisted of a publicly available international dataset provided by the Laboratory of Imaging Technologies of the University of Ljubljana, Slovenia, available online (http://lit.fe.uni-lj.si/tools). From this database, an additional 30 MRI examinations were selected.

Therefore, the final dataset comprised a total of 60 brain MRI examinations from patients diagnosed with multiple sclerosis. Only volumetric FLAIR images were used for algorithm development and training, due to their well-established sensitivity to targeting demyelinating lesions. The model was able to detect and segment demyelinating lesions on FLAIR images, generating masks that could be late compared to expert annotations.

To process these MRI acquisitions, a complete desktop-integrated pipeline was developed for automated preprocessing, multi-tissue segmentation, and quantitative lesion analysis tailored for FLAIR sequences. The image processing workflow ingests raw DICOM directories or NIfTI volumes, applying SimpleITK-based N4 Bias Field Correction to eliminate radiofrequency field inhomogeneities, followed by Otsu thresholding, 3D morphological operations, and largest-connected-component analysis for robust skull stripping.

After executing a voxel-wise Z-score normalization within the isolated brain mask, the pipeline feeds the data into a K-means clustering algorithm to segment the brain into distinct anatomical tissue classes—specifically suppressing cerebrospinal fluid (CSF) while isolating gray matter, normal white matter, and hyperintense white matter. Furthermore, it incorporates a dual-strategy anomaly detection mechanism that flags global statistical intensity outliers alongside a localized white matter hyperintensity detector to efficiently map lesions, MS plaques, and vasogenic edema while discarding microscopic noise using size-filtering thresholds.

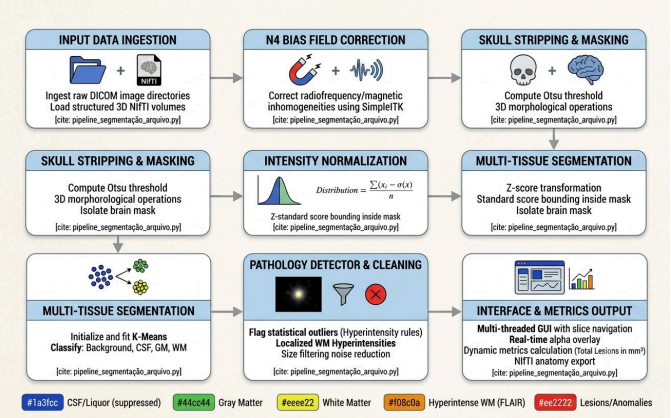

Fig. 1. Flowchart summarizing the unsupervised brain MRI segmentation pipeline. Image generated with the assistance of Imagen 3 (Google, 2026) using a text prompt detailing the step-by-step processing from raw DICOM/NIfTI ingestion, N4 bias field correction, skull stripping, Z-score normalization, to K-means multi-tissue classification and anomaly detection.

To facilitate clinical workflow and interpretation, the processing pipeline was coupled with a desktop Graphical User Interface (GUI) implemented in Python using Tkinter and Matplotlib. The interface features a side-by-side display that pairs original grayscale FLAIR MRI slices with customizable segmentation overlays. Clinicians can dynamically navigate through 3D volumes, adjust real-time opacity blending, and manipulate an interactive sensitivity slider that rescales Z-score intensity thresholds to refine lesion boundaries on-the-fly. In addition, the software automatically computes per-slice tissue statistics, quantifies total lesion volume in cubic millimeters, counts independent lesion clusters, and supports exporting segmented maps into standardized 3D NIfTI format.

III. Results

First of all, our MRI DICOM dataset was anonimized, and analysed by an specialist. We carried out reconstruction of images and data visualization using the 3D Slicer version 5.10.0 Software [13]. Figure 2 shows an original patient MRI DICOM file from our dataset, shown on three views : axial, sagital and coronal, and 3D reconstruction renderized volume. Figure 3 shows an original patient MRI file obtained from University of Ljubljana, Slovenia (available online (http://lit.fe.uni-lj.si/tools), shown on three views: axial, sagital and coronal ,and 3D reconstruction renderized volume. As shown, the brain images were cropped to exclude the nasal region, as the nasal mucosa exhibits high signal intensity that may be erroneously identified as hyperintense regions with signal characteristics similar to multiple sclerosis lesions or normal gray matter.

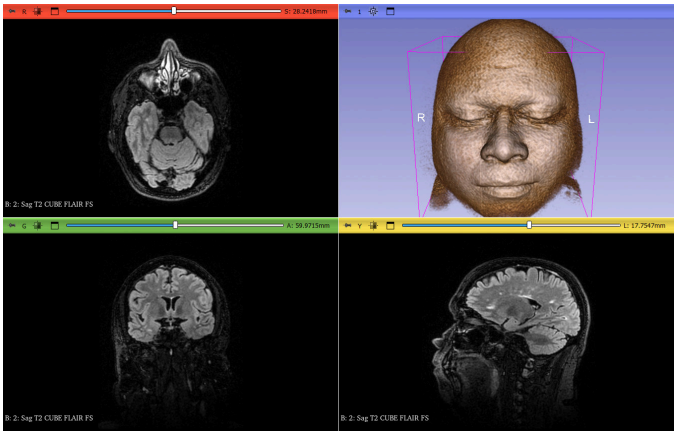

Fig. 2. MRI analysis presenting from volume renderization in 3D Slicer software-patient from our dataset.

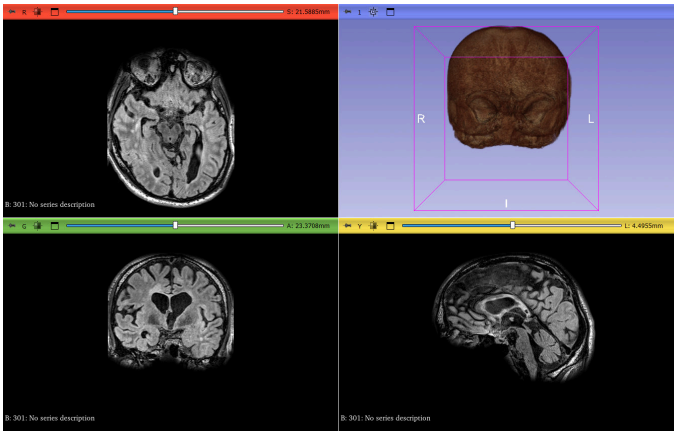

Fig. 3. 3D slicer volume renderization from an original patient MRI file obtained from University of Ljubljana, Slovenia.

Finally, Figure 4 shows data analysis run through the MRI tool segmentation, available in [14]. Patient selection, pipeline processing, lesions area and processing loading are shown on top bar. Control parameters such as : MRI slices, opacity, lesion sensibility, lesion and classes of tissues segmentation are shown on the right. This slice refers to the same patient shown on figure 2.

Average sensibility values and lesion area in mm3 for both datasets set by an specialist in our pipeline to obtain the most accurate lesion segmentation are shown on Table I.

TABLE I
STATISTICAL SUMMARY OF SENSITIVITY AND LESION VOLUME

Class Group	**Metrics and Standard Deviation**	
	Sensitivity	***Lesion Volume (mm^3)***
Hospital de Clínicas UFPR Dataset	0.283 ± 0.076	1637.42 ± 1056.58
University of Ljubljana Dataset	0.287 ± 0.064	1545.39 ± 1050.47

DISCUSSION

1) UI Description and Comparative Analysis: Custom Segmentation Viewer vs. 3D Slicer modules and Extentions [15]:

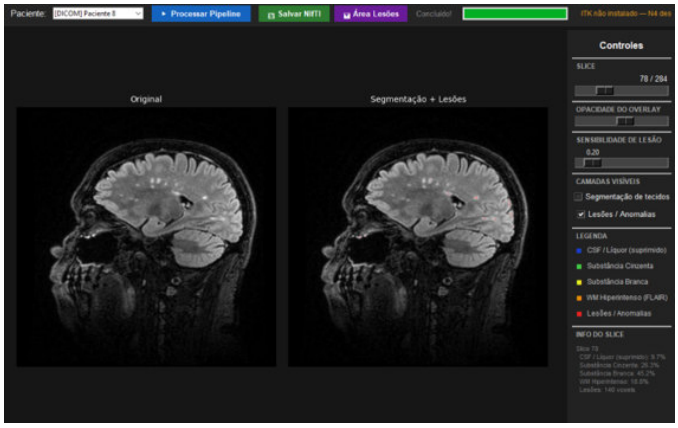

Fig. 4. Data analysis run through the MRI tool segmentation. Patient selection, pipeline processing, lesions area and processing loading are shown on top bar. Control parameters such as : MRI slices, opacity, lesion sensibility, lesion and classes of tissues segmentation are shown on the right. This slice refers to the same patient shown on figure 2

The custom application's Graphical User Interface (GUI) serves as an interactive clinical dashboard tailored specifically for brain MRI segmentation. Below is a technical description of its core functionalities and its comparative advantages over the generic multi-purpose output obtained from 3D Slicer.

2) Functional Description of the Custom Pipeline Viewer: The custom GUI is divided into an asynchronous top control bar, a dual-pane interactive canvas, and a right-hand parametric control panel:

- **Asynchronous Processing Top Bar:** It allows the user to select specific patient exams from organized DICOM or NIfTI directories. Clicking **"Processar Pipeline"** triggers a multi-stage background thread (N4 Bias Correction, Otsu skull stripping, and K-means clustering) while updating a live progress bar to prevent UI freezing. It also includes quick buttons to export the results directly into medical NIfTI files or generate standalone lesion statistics windows.
- **Dual-Pane Interactive Canvas:** The software renders a side-by-side comparative screen using Matplotlib. The left pane displays the original raw grayscale MRI slice (such as a sagittal FLAIR view showing hyperintense plaque regions), while the right pane dynamically projects the exact same slice with customizable segmentation overlays.
- **Parametric Right Control Panel:** * *Slice Navigation:* A precision slider allows the user to traverse through the entire 3D volume, with synchronized hotkey tracking (Arrow keys).
  - *Overlay Opacity:* Real-time alpha blending control lets clinicians adjust how transparently the tissue colors or lesion masks are mapped over the anatomical structure.
  - *Lesion Sensitivity Adjustment:* A critical real-time slider that inversely rescales the global Z-score and intra-White Matter standard deviation thresholds.

Moving this slider dynamically recalculates and filters lesion masks on the fly to fit a specific patient's contrast constraints.

- *Layer Visibility & Live Info:* Checkboxes isolate specific tissue classes or anomaly maps, while the bottom section computes live, voxel-by-voxel percentage distributions of CSF, Gray Matter, White Matter, and lesion load for the active slice.

3) Advantages over the 3D Slicer Output: While 3D Slicer is an industry-standard powerhouse for generalized multi-planar medical rendering and 3D volume reconstruction, the custom application offers distinct workflow and clinical advantages for this specific task:

a) Tailored Specialization for Multiple Sclerosis (MS) & FLAIR Sequences:

The Custom Application Advantage: The custom pipeline is clinically optimized for FLAIR sequences. Its entire color palette and mathematical logic are engineered to suppress CSF and isolate "Hyperintense White Matter". Instead of just masking a large general region of the brain, it flags focal periventricular and juxtacortical plaques—crucial for multiple sclerosis monitoring—highlighting them in bright, recognizable red over the structures.

b) Dynamic, Real-Time Pathology Tuning (Sensitivity Slider):

- **The 3D Slicer Limitation:** Refining a segmentation in 3D Slicer typically requires diving into complex multi-module parameters (such as Segment Editor or thresholding filters) and manually recalculating the label maps, which can be computationally slow and counter-intuitive for a quick clinical review [15].
- **The Custom Application Advantage:** The right panel's **"Sensibilidade de Lesão" (Lesion Sensitivity)** slider operates as an interactive thresholding tool. If the initial unsupervised calculation overestimates the multiple sclerosis lesions (due to artifact noise or blood vessel hyperintensities), the clinician can immediately adjust the slider to reduce sensitivity. The application instantly updates the viewport slice without requiring the user to recalculate the entire machine learning or backend pipeline, allowing immediate correction of overestimation errors.

c) Instant Quantitative Metrics and Focused Diagnostics:

- **The 3D Slicer Limitation:** To get volumetric metrics or area projections out of 3D Slicer, a user must add specific quantitative extensions, run statistical modules on selected segments, and parse broad spreadsheet tables. [15].
- **The Custom Application Advantage:** The custom GUI minimizes clicks. The **"Info do Slice"** section shows real-time tissue composition changes as you scroll. Clicking the **"Área Lesões"** button opens a focused dialog that translates voxel counts straight into total lesion volume in cubic millimeters and tracks individual lesion clusters sorted by size. It bridges the gap between deep image segmentation and immediate diagnostic feedback.

A central strength of this work lies in evaluating the unsupervised framework across a multicenter pilot dataset comprising 60 volumetric FLAIR MRI examinations sourced from two distinct clinical environments: a public tertiary hospital in Brazil (UFPR) and an international public repository (University of Ljubljana, Slovenia). By processing acquisitions from different scanners and protocols without requiring retraining or manual ground-truth annotations, the algorithm demonstrated high cross-institutional consistency. This stability is reflected in the comparable average lesion volumes ($1,637.42 \pm 1,056.58$ mm^3 for UFPR vs. $1,545.39 \pm 1,050.47$ mm^3 for Ljubljana) and sensitivity metrics presented in Table I. This capability addresses a well-documented challenge in automated neuroimaging, where inter-scanner heterogeneity frequently degrades segmentation reliability [16] [10].

Compared to established unsupervised toolboxes such as the Lesion Growth Algorithm (LGA) and Lesion Segmentation Tool (LST) proposed by Roura et al. [12][14] and Schmidt et al. [8][10], which rely on intensity thresholding within SPM environments, our pipeline combines SimpleITK-based N4 bias correction with dynamic Z-score outlier filtering. While supervised deep learning architectures (e.g., 3D U-Nets) achieve high segmentation accuracy on standardized benchmarks [4], [16] they require extensive, pixel-wise expert annotations that are difficult to scale in daily practice. The proposed framework bridges this gap by offering instant, deterministic multi-tissue segmentation without training overhead, presenting an accessible and scalable tool well-suited for public healthcare infrastructures like the Brazilian Unified Health System (Sistema Único de Saúde - SUS).

The volumetric output generated by the software (averaging $1,545.39$ mm^3) aligns with expected clinical lesion burdens for patients with mild-to-moderate MS under active neurological surveillance ($1,000$ mm^3 to $4,000$ mm^3) [1] [7]. Importantly, computing integrated 3D spatial volumes avoids the overestimation typical of simple 2D slice summation. A recognized limitation of this pilot study is the sample size and the reliance on volumetric yield and sensitivity for validation. Future research will expand the validation cohort across additional centers and incorporate spatial overlap metrics—such as the Dice Similarity Coefficient (DSC) and Lesion False Positive Rate (LFPR)—to enable direct benchmarking against international MS challenges [16]. Furthermore, developing longitudinal registration tools will allow automated tracking of new, enlarging, or regressing plaques over serial MRI studies.

***Abstract* – Eye movement and eyelid dynamics analysis plays an important role in Biomedical Engineering; however, access to assessment tools that combine low cost and high precision remains a challenge. In this context, this work aimed to develop a non-invasive eye monitoring system capable of processing conventional videos obtained from image capture devices. The system was developed in Python using the OpenCV and dlib libraries, allowing real-time facial mapping through 68 reference points. Among the implemented functionalities, the following stand out: dimensional calibration based on pupillary distance, continuous calculation of the Ocular Aspect Ratio (EAR) for automatic blink detection, and iris trajectory tracking, with the generation of structured reports for analysis. The tests performed demonstrated that the system was able to process conventional videos and continuously extract the proposed biometric metrics, making them available in structured reports for later analysis. The results obtained indicate that the initial functional validation demonstrated the feasibility of the pipeline's computational architecture for extracting structured metrics. As this is a technical proof of concept focused on software development, the validation of biomedical performance, the generalization of the method, and its clinical applicability depend on future studies with larger sample sizes and ethical approval. The developed software obtained registration as a Computer Program with the National Institute of Industrial Property (INPI), consolidating itself as a technological product resulting from this work.**

Keywords: Computer Vision; Eye Movement; Eyelid Dynamics; Eye Tracking; Biomedical Engineering.

I. Introduction

The continuous assessment of eyelid dynamics and eye movement provides relevant biomarkers for the investigation of cognitive disorders, neurodegenerative diseases and fatigue states. Traditionally, the quantitative extraction of these metrics depends on high-cost eye tracking equipment, often based on infrared sensors [1] and dedicated hardware. This technological and financial requirement restricts the application of these analyzes to laboratory environments and large clinics, limiting the population's access to preventive assessments and making it difficult to expand remote monitoring.

In this scenario, the integration of computer vision with digital health emerges as a promising technological alternative to overcome these barriers. Applying image processing algorithms to conventional videos enables the non-invasive analysis of eye movement, eliminating the need for specific equipment and expanding the possibilities for using the technology in different clinical and research contexts. This software-based approach facilitates the acquisition of biometric data using conventional RGB (Red, Green, Blue) cameras [2].

Although computer vision-based solutions for eye analysis exist, many focus on specific functionalities or rely on particular experimental configurations, highlighting the need for systems that integrate different biometric metrics into a single, low-cost application.

Given this scenario, this work presents the development of a computer vision system for analyzing eye movement and eyelid dynamics. Unlike approaches focused on isolated functionalities, the system integrates, in a single application, techniques for dimensional calibration, calculation of the Eye Aspect Ratio (EAR), iris tracking, and automatic generation of structured reports, using conventional videos obtained by RGB cameras.

II. Materials and Methods

A. General system architecture

The proposed system was developed with the objective of analyzing eye movement and eyelid dynamics from conventional videos, using computer vision techniques for the automatic extraction of metrics related to eye movement and eyelid dynamics. The architecture was structured in a modular way, encompassing the stages of data acquisition and calibration, facial detection, extraction of biometric metrics, and generation of results. This organization allows for the sequential pro-

cessing of information, from video reading to data export for analysis. Fig. 1 shows the general system architecture and the implemented processing flow.

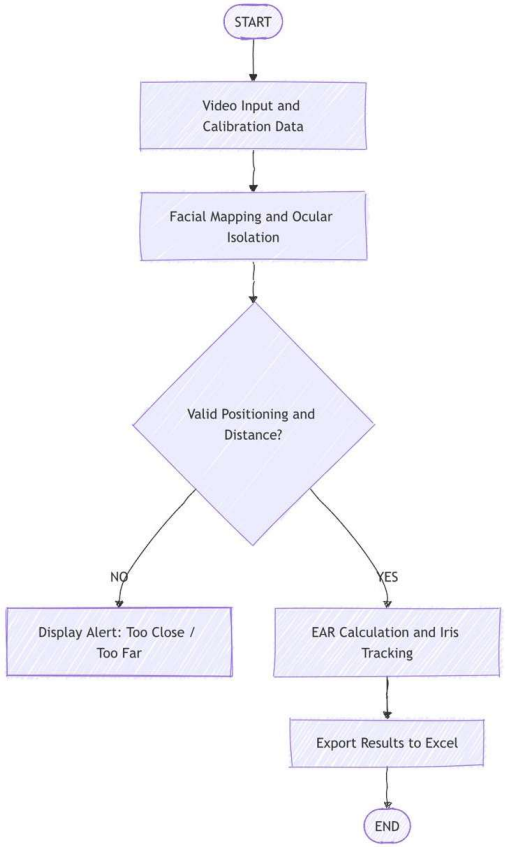

Fig. 1 – Flowchart of the system's architecture and general operation.

As illustrated in Fig. 1, the system's operation is organized into four main modules. Initially, video acquisition and calibration of the parameters necessary for processing are performed. Next, the system executes facial detection and ocular region localization, allowing the extraction of biometric metrics related to eye movement and eyelid dynamics. Finally, the results obtained are organized and exported into structured reports for later analysis.

B. Data acquisition and calibration

The system was developed to process conventional videos containing the user's face, captured by devices equipped with RGB cameras, such as webcams and smartphones. Before processing begins, the necessary parameters for system calibration are provided, including user identification, the video file, the approximate distance between the face and the camera, and the actual pupillary distance, expressed in millimeters. This information is used to establish the spatial scale of the image, allowing the conversion of measurements obtained in pixels to values in millimeters during analysis.

Dimensional calibration is an essential step in processing, as it allows measurements extracted from images to be represented in physical units. To achieve this, the system uses the actual pupillary distance provided by the user as a reference to determine the conversion factor between pixels and millimeters, reducing the exclusive reliance on relative measurements and allowing the acquisition of quantitative metrics related to eyelid opening.

C. Facial detection and localization of eye regions

After the calibration stage, each video frame is processed for face identification and eye region localization. Initially, the frames are converted to grayscale, reducing computational complexity and improving the performance of facial detection algorithms. Then, face identification is performed using the dlib library [3], widely used in computer vision applications for providing highly efficient facial detectors and anatomical landmark estimators [4].

After face detection, the system performs facial mapping using 68 anatomical landmarks, automatically identifying facial structures such as eyebrows, nose, mouth, and eyes. For this task, points corresponding to the ocular regions are used, serving as the basis for calculating the Eye Aspect Ratio (EAR) and for tracking the iris trajectory in subsequent processing steps.

D. Extraction of eye movement and eyelid dynamics metrics

After locating the eye regions, the system automatically extracts the metrics used to characterize eye movement and eyelid dynamics. Eye region location is performed using the facial landmark estimation model shape predictor 68 face landmarks, which identifies six two-dimensional reference points for each eye. Eyelid dynamics are quantified using the Eye Aspect Ratio (EAR), calculated from the geometric relationship between the vertical and horizontal Euclidean distances of the points that delimit the eye region. Eq. (1) presents the expression used to calculate this metric.

$$EAR = \frac{||p_2 - p_6|| + ||p_3 - p_5||}{2 \cdot ||p_1 - p_4||} \quad (1)$$

In this expression, P_1 a P_6 represent the facial reference points obtained during the mapping of the ocular region. The vertical distances are compared to the horizontal distance of the eye, producing an approximately constant value when the eye remains open and significantly reduced during eyelid closure.

The temporal variation of the EAR throughout processing allows for the automatic identification of blink events. Fig. 2 shows the temporal evolution of the Ocular Aspect Ratio, highlighting the threshold used for the automatic detection of eyelid closure.

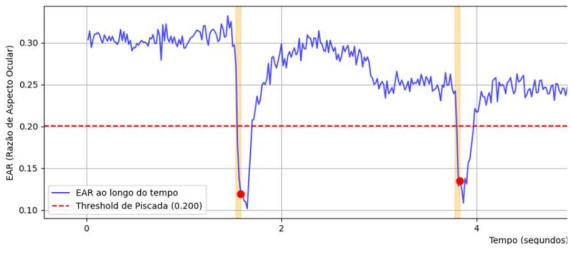

Fig. 2 – Temporal evolution of the ocular aspect ratio with blink threshold.

As observed in Fig. 2, EAR values remain relatively stable during periods when the eyes are open, showing sharp reductions at times corresponding to eyelid closure. The threshold defined during the calibration step is used to automatically

identify these events, allowing the detection of blinks throughout video processing.

E. Generation and export of results

After extracting the metrics related to eye movement and eyelid dynamics, the information obtained during processing is organized into a tabular structure, allowing for the sequential storage of data for each frame of the video. This structure, implemented using the Pandas library, gathers the parameters calculated throughout the analysis, preserving the temporal correspondence between the extracted metrics and facilitating their subsequent processing [5].

At the end of the analysis, the system automatically consolidates the information obtained, generating graphical representations of the temporal evolution of the Ocular Aspect Ratio (OAR), eyelid opening, and iris trajectory. The data are also exported in spreadsheet format (xlsx), allowing for organization, consultation, and use in subsequent analyses, as well as facilitating the documentation and reproducibility of the results obtained.

F. Spatial Iris Tracking

Spatial tracking of the iris is performed by applying an elliptical mask over the Region of Interest (ROI) to suppress peripheral noise and isolate the pupil region. Subsequently, the Canny Filter is used to map the edges, and the Hough Circular Transform is used to identify the iris contour and determine its geometric center [6]. The combination of these techniques allows for the continuous extraction of the iris's spatial coordinates (X, Y) in each processed frame. Fig. 3 and 4 show, respectively, the trajectories of the iris coordinates in horizontal and vertical directions.

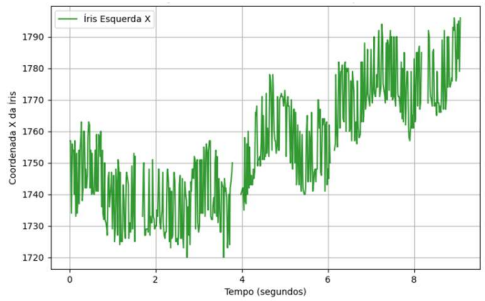

Fig. 3 – Spatial trajectory of the X and Y coordinates of the iris in the left eye in the horizontal position.

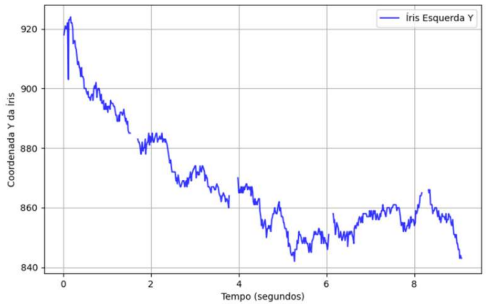

Fig. 4 – Spatial trajectory of the X and Y coordinates of the iris in the left eye in the vertical position.

Trajectory analysis makes it possible to characterize iris displacements over time, complementing the information obtained from the Ocular Aspect Ratio and allowing an integrated assessment of eye movement and eyelid dynamics.

G. Generation and export of results

After extracting the metrics related to eye movement and eyelid dynamics, the data obtained during processing are organized into a tabular structure, implemented using the Pandas library. This structure sequentially stores the information for each processed frame, preserving the temporal correspondence between the calculated metrics and facilitating their consolidation for later analysis.

Upon completion of processing, the system automatically exports the data to a spreadsheet in .xlsx format, containing the metrics extracted throughout the analysis. This organization enables structured documentation of the results, facilitating their consultation, reproducibility, and use in research activities and support for clinical evaluation.

IV. Results And Discussion

The experimental validation of the system was performed using a primary database composed of videos of a healthy adult volunteer, obtained in a real-world capture environment. The processing was performed automatically, allowing for facial detection, ocular region localization, and continuous extraction of metrics related to eyelid dynamics and eye movement.

In the analysis of eyelid dynamics, the system continuously calculated the Eye Aspect Ratio (EAR), automatically identifying the baseline value of the metric and determining the threshold used for blink detection. During processing, a sharp reduction in EAR was observed at the instants corresponding to eyelid closure, allowing for the automatic identification of these events and the extraction of the respective image segments. Fig. 5 shows the record of the first blink detected automatically by the system.

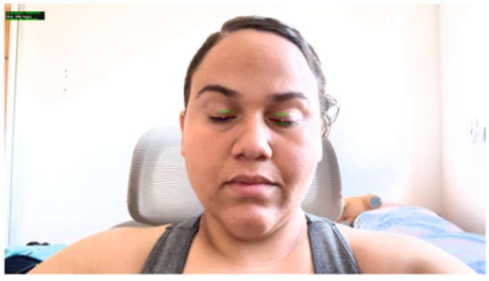

Fig. 5 – Visual cutout of automatic detection of the first blink during processing.

The temporal behavior of the Ocular Aspect Ratio for the right and left eyes is shown in Fig. 6. It can be observed that the EAR values remain relatively stable during periods of eye opening, showing simultaneous reductions during blinks, when the automatic threshold is exceeded. Independent analysis of the two eyes demonstrates the consistent functioning of the detection algorithm throughout the processing.

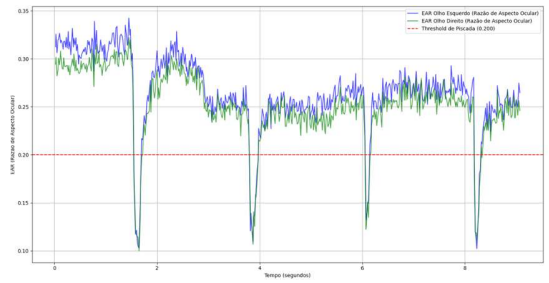

Fig. 6 – Temporal evolution of the Ocular Aspect Ratio (OAR) for the right and left eyes, highlighting the automatic blink threshold.

Spatial calibration allowed the conversion of measurements originally obtained in pixels to physical units (millimeters), making it possible to quantitatively represent the vertical opening of the eyelids throughout the image sequence. During rest periods, values close to 8 mm of eyelid opening were observed, with progressive reductions during blinking. Fig. 7 shows the continuous evolution of these measurements for the left eye (Fig. 7(a)) and right eye (Fig. 7(b)), demonstrating the system's ability to track dimensional variations in eye opening throughout the video.

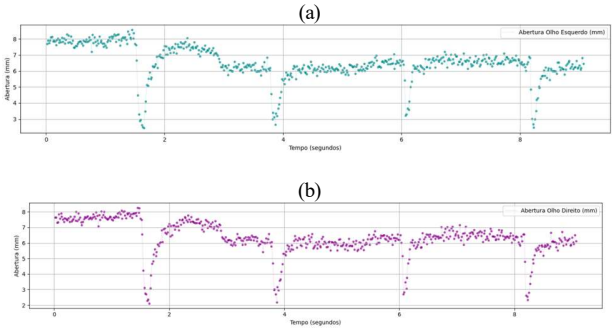

Fig. 7 – Continuous vertical opening of the eyelids (in millimeters) extracted by the system: (a) left eye and (b) right eye.

In addition to eyelid dynamics, the system performed continuous iris tracking using the Hough Circular Transform, allowing the extraction of spatial coordinates (X, Y) throughout the entire image sequence. The horizontal and vertical trajectories obtained made it possible to quantitatively represent eye movement independently for each eye, complementing the information provided by the EAR analysis.

Upon completion of processing, all extracted metrics—including EAR values, iris spatial coordinates, and eyelid opening measurements in millimeters—were automatically organized and exported to a spreadsheet in .xlsx format. This structure preserves the temporal sequence of the obtained data, facilitating its documentation, statistical analysis, and use in experimental studies in the field of Biomedical Engineering.

The results obtained demonstrate that the integration between the calculation of the Ocular Aspect Ratio (EAR), dimensional calibration in millimeters, and spatial tracking of the iris allowed for the simultaneous extraction of different metrics related to eyelid dynamics and eye movement. The automatic organization of this information in a structured format expands the possibilities of using the tool in experimental studies in the field of Biomedical Engineering, providing quantitative data that can support future research and applications to aid clinical evaluation.

Although the pipeline has proven fully functional, the current system operates as a technical proof of concept with limitations to be overcome. Dimensional calibration, for example, is susceptible to scaling variations if unpredictable facial displacements occur in the depth axis. Similarly, environmental factors, such as light reflections and partial eyelid occlusions, pose challenges to the optimal extraction of coordinates by the Hough Transform. Consequently, the validation of parameters of clinical interest requires additional experimental steps. The future timeline of this project will include ethics review (CEP) for the inclusion of a diverse sample—encompassing different age ranges, phenotypic variations, and neurological conditions—as well as statistical performance validation. It is planned to measure the spatial error of iris tracking using a commercial eye tracker as the gold standard, in addition to verifying the sensitivity and specificity of the EAR algorithm through cross-validations with independent manual markings (ground truth).

V. Conclusions

This work achieved the objective of developing a non-invasive and low-cost computational system for the analysis of eye movement and eyelid dynamics from conventional videos. The proposed solution integrated computer vision techniques to automatically perform facial detection, calculation of the Eye Aspect Ratio (EAR), spatial tracking of the iris, and dimensional calibration of measurements in millimeters. The functional validation performed demonstrated the system's ability to extract, organize, and export quantitative metrics related to eye behavior, bringing together different functionalities in a single computational platform.

Although the results obtained demonstrate the proper functioning of the proposed architecture, some limitations should be considered. The system's performance is influenced by image acquisition conditions, such as inadequate lighting, intense reflections, and video quality, factors that can affect the accuracy of iris and ocular structure detection. Furthermore, the dimensional calibration process still depends on the user's manual input of the pupillary distance. The experimental evaluation was conducted using videos from a single healthy adult volunteer, representing an initial stage of functional validation. Therefore, studies with a larger number of participants will be necessary to evaluate the system's performance under different acquisition conditions and anatomical characteristics.

Looking to the future, the intention is to incorporate automatic depth estimation or stereo vision methods to eliminate the need for manual pupillary distance calibration. The integration of Machine Learning techniques for identifying patterns associated with ocular changes is also planned, as well as adapting the system for mobile devices, allowing for real-time metric processing. Additionally, future studies should consider validating the system in a broader population, including participants with different anatomical characteristics and clinical conditions, expanding the evidence on its applicability in research and in clinical assessment support scenarios.

As a result of technological development, the system obtained the Computer Program Registration Certificate from the National Institute of Industrial Property (INPI), under process number BR512026004319-0, issued on June 16, 2026, with the Federal University of Rio Grande do Norte (UFRN) as the rights holder. This registration demonstrates the originality of the developed solution and reinforces its contribution as a technological product for Biomedical Engineering. Thus, the developed system consolidates itself as a computer vision platform for analyzing eye movement and eyelid dynamics, integrating eye tracking techniques, dimensional calibration, and structured data organization, with the potential to support future research and applications in Biomedical Engineering.

***Abstract*—Ischemic stroke is one of the leading causes of death and disability worldwide, requiring early diagnosis. The scarcity of annotated medical images limits the performance of deep learning models. This study investigates the use of Generative Adversarial Networks (GANs) to synthesize computed tomography (CT) images and evaluates whether these images improve an Xception-based stroke classifier. The generated samples obtained an SSIM of 0.80 and an FID of 6.5. Under five-fold stratified cross-validation at the slice level, combining classical augmentation with GAN-generated images increased the aggregated Xception accuracy from 88.12% to 91.99% and sensitivity from 86.19% to 91.71%, while reducing false negatives from 25 to 15. These results indicate a potential benefit from synthetic augmentation; however, they are descriptive because the experiment did not employ patient-level separation or an independent test set.**

***Index Terms*—GAN, images, stroke, ischemic**

I. Introduction

Stroke is among the leading causes of mortality and long-term disability worldwide, representing a major public health challenge. According to the World Health Organization, millions of individuals suffer a stroke every year, often resulting in severe neurological impairment or death. Early diagnosis and timely intervention are critical factors for improving patient outcomes and reducing the burden associated with the disease.

Approximately 87% of all stroke cases are ischemic, occurring when cerebral blood flow is interrupted due to vascular occlusion [1]. The effectiveness of treatment is strongly dependent on the time elapsed since symptom onset, making rapid and accurate diagnosis essential [2]. Ischemic stroke (IS) is commonly categorized into acute, subacute, and chronic stages according to its temporal evolution [3].

Computed tomography (CT) and magnetic resonance imaging (MRI) are the most frequently used imaging modalities for stroke assessment [4]. Although MRI generally provides greater sensitivity for detecting ischemic lesions in the early stages, CT remains the most widely adopted imaging technique due to its lower cost, faster acquisition time, and broader availability in clinical settings [5]. However, ischemic lesions often appear as subtle hypodense regions in CT images, making their identification challenging, particularly during the acute phase.

To address these limitations, computer-aided diagnosis systems based on machine learning and deep learning have been increasingly investigated. Convolutional Neural Networks (CNNs) have demonstrated remarkable performance in medical image classification and segmentation tasks. Nevertheless, the development of robust deep learning models is often hindered by the limited availability of annotated medical datasets, especially in specialized clinical domains such as stroke imaging.

Recent advances in Generative Artificial Intelligence (Generative AI) have introduced promising solutions for mitigating data scarcity. In particular, Generative Adversarial Networks (GANs) have emerged as one of the most effective approaches for generating realistic synthetic medical images. Comprehensive reviews have highlighted the growing adoption of GANs in medical image analysis, including image synthesis, segmentation, classification support, and data augmentation [6].

Motivated by these advances, this work investigates the use of GAN-generated synthetic CT images of ischemic stroke to augment training datasets and improve the performance of a CNN-based classification model. By combining synthetic image generation with transfer learning, the proposed approach seeks to alleviate dataset limitations and contribute to more reliable computer-aided stroke diagnosis.

II. Related Work

The application of generative models in medical imaging has received considerable attention in recent years. A comprehensive review by Yi et al. [6] highlighted the growing role of deep learning and Generative Adversarial Networks in medical image analysis, demonstrating their effectiveness in

image synthesis, segmentation, reconstruction, and classification support.

Several studies have investigated GAN-based image synthesis for neurological disorders. Sun et al. [7] proposed a multimodal framework combining GANs and 3D residual U-Nets for brain tumor and stroke image generation and lesion segmentation. Their results demonstrated improvements in segmentation accuracy, highlighting the benefits of synthetic image generation for medical image analysis.

Li et al. [8] explored the generation of synthetic MRI images from CT scans of ischemic stroke patients using GANs. Their approach improved lesion visualization and achieved a Peak Signal-to-Noise Ratio (PSNR) of 24.4 dB and a Structural Similarity Index Measure (SSIM) of 0.78. Similarly, studies investigating CT-based synthetic MRI generation for acute ischemic stroke have shown that GAN-generated images can improve lesion detectability and support clinical decision-making by enhancing image contrast and anatomical detail.

GANs have also been employed directly in ischemic stroke lesion modeling and segmentation. Ghnemat et al. [9] proposed a mutation model combined with a GAN architecture for ischemic stroke lesion segmentation, demonstrating that synthetic lesion generation can improve segmentation robustness and lesion representation. These findings suggest that generative models are capable of capturing clinically relevant stroke patterns and anatomical variability.

Despite the progress achieved by previous studies, most existing works focus on image synthesis, lesion segmentation, or classification as isolated tasks. Comparatively fewer studies investigate the integration of GAN-based synthetic image generation with transfer learning classifiers for ischemic stroke detection in CT images. Therefore, this work proposes the generation of realistic synthetic ischemic stroke CT images using GANs and evaluates their impact on the performance of an Xception-based classification model, aiming to improve generalization and diagnostic accuracy in scenarios with limited data availability.

III. Methodology

The workflow of the proposed approach is illustrated in Fig. 1 and Fig. 2. First, the GAN is trained to generate realistic synthetic CT images from latent noise vectors through an adversarial process involving the Generator and the Discriminator, as illustrated in Fig. 1. Subsequently, the generated synthetic images are combined with real CT images to train and evaluate an Xception-based classifier using transfer learning. The corresponding classification workflow is presented in Fig. 2 and includes dataset balancing, image preprocessing, prediction, and performance evaluation.

A. Dataset Used

The database used in this project consists of computed tomography (CT) images of the head from 292 patients. This database was provided by the Center for Imaging Studies and Research (NEPI) at the Federal University of Paraíba (UFPB), in accordance with the ethics committee's approval number

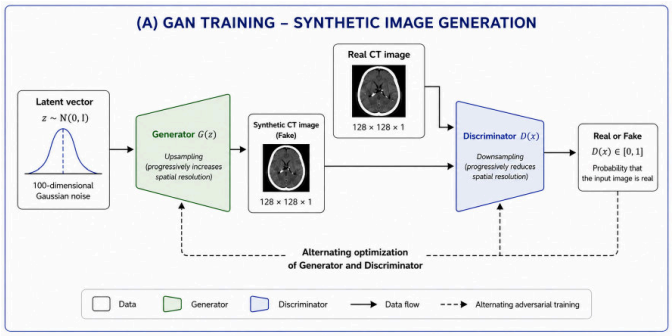

Fig. 1. Workflow of the GAN training process for synthetic CT image generation.

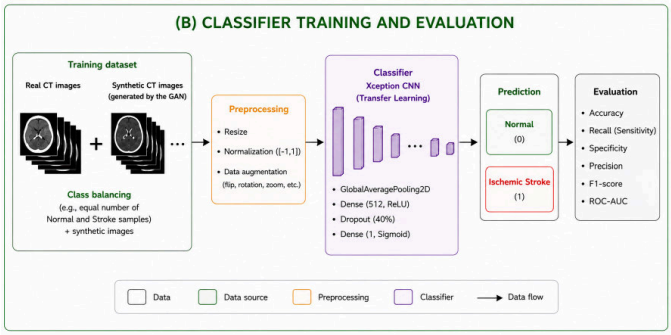

Fig. 2. Workflow of the classifier training and evaluation pipeline using real and GAN-generated CT images.

1,293,095. All images comply with the DICOM standard for medical imaging and have original dimensions of 512×512.

Each patient's CT scan contains approximately 20 images with an 8-mm spacing between the axial slices of the head. The images of these patients were obtained at random from a clinic specializing in diagnostic imaging.

The reports for each patient were prepared by a physician specializing in radiology, who marked on the CT images of the skull the gray-scale intensity levels characteristic of areas of chronic, acute, and subacute ischemic stroke, so that stroke detection could be performed.

Each scan consists of multiple axial slices, so the complete set of 292 patients resulted in a total of 11,142 two-dimensional images. Fig. 3 presents a summary of the process of compiling the database used in this study, from the scans obtained from the 292 patients to the acquisition of the images used to train the GAN. After analyzing the medical reports and identifying the regions of interest, the images were divided into 10,821 images classified as normal and 322 images showing signs of ischemic stroke, with the latter subdivided into 186 subacute cases, 62 acute cases, and 74 chronic cases.

Each scan consists of multiple axial slices, so the complete set of 292 patients resulted in a total of 11,142 two-dimensional images. Figure 3 summarizes the database construction workflow. Starting from the 292 head CT examinations, each scan was decomposed into axial slices, resulting in 11,142 two-dimensional images. After reviewing the radiology

reports and identifying the regions of interest, the images were classified as either normal or containing ischemic stroke. The ischemic stroke images were further categorized according to the disease stage into subacute, acute, and chronic cases. Finally, all images were resized from 512×512 to 128×128 pixels and normalized before being used for GAN training.

Although the original images have a resolution of 512×512 pixels, they were resized to 128×128 pixels due to computational limitations and the high cost associated with training Adversarial Generative Networks. This reduction shortens training time and decreases the amount of memory required, making it feasible to use the model under the available computational conditions. However, the reduction in resolution may result in a loss of fine details and the smoothing of lesion edges, affecting the visual quality of the synthesized images. Therefore, the results obtained should be interpreted while considering the trade-off between computational cost and the preservation of the anatomical features present in the original images.

B. GAN Architecture

Generative Adversarial Networks (GANs) are a class of deep learning models consisting of two neural networks that compete with each other: the generator and the discriminator. The generator aims to create synthetic images that resemble the real images in the dataset, while the discriminator attempts to distinguish between real images and those generated artificially. During training, the generator learns to produce increasingly realistic images, while the discriminator improves its ability to differentiate between real and fake images [12].

To train the Generative Adversarial Network (GAN), an image dataset was used following the preprocessing steps described below. To facilitate training and stabilize the data distribution, the images were normalized to the interval [-1,1] using Equation 1. Where, I represents the pixel intensity in the original image.

$$I_{norm} = \frac{I}{127.5} - 1 \tag{1}$$

The GAN's input signals were organized into batches of 128 images to ensure diversity during training. The GAN architecture developed in this study consists of two models: a Generator and a Discriminator. The Generator is responsible for synthesizing realistic images from a random noise vector, while the Discriminator distinguishes between real and generated images.

The Generator receives as input a random noise vector $z \in \mathbb{R}^{100}$, which is initially projected by a dense layer onto a $4 \times 4 \times 256$ tensor. This tensor is then reshaped by a *Reshape* layer and progressively expanded using transposed convolution layers (*Conv2DTranspose*), combined with batch normalization (*Batch Normalization*) and *LeakyReLU* activation functions. This process of gradually increasing the resolution allows for the synthesis of computed tomography images of size $128 \times 128 \times 1$ with normalized values in the range ([-1,1]). The complete architecture of the Generator is presented in Table II.

The Discriminator follows a progressive dimension-reduction approach, using convolutional layers (*Conv2D*) combined with *LeakyReLU* activations. The model's goal is to

C. Training setup

The GAN was trained using the binary cross-entropy (BCE) loss function, since the Discriminator acts as a binary classifier responsible for distinguishing real images from synthetic images. During training, real images were assigned label 1, while images generated by the Generator were assigned label 0.

The Discriminator's loss was calculated by considering both real and synthetic images simultaneously, as shown in Equation (2).

$$\mathcal{L}_D = -\mathbb{E}_x \left[\log D(x)\right] - \mathbb{E}_z \left[\log\left(1 - D(G(z))\right)\right] \quad (2)$$

The generator loss was calculated using the equation (3).

$$\mathcal{L}_G = -\mathbb{E}_z \left[\log D(G(z))\right] \quad (3)$$

In Equations (2) and (3), x represents a real image, z represents the input noise vector, $G(z)$ corresponds to the synthetic image produced by the Generator, and $D(\cdot)$ indicates the probability assigned by the Discriminator that the sample is real.

Both the Generator and the Discriminator were optimized using independent Adam optimizers with a learning rate of 1×10^{-4}, $\beta_1 = 0.9$, and $\beta_2 = 0.999$. The latter corresponds to the default value adopted by TensorFlow/Keras. The models were trained using a batch size of 128 for 1000 epochs. A random seed of 42 was used, and model checkpoints were saved every 50 epochs. No *early stopping* strategy was employed. The model weights were randomly initialized using the default Keras initializers.

The experiments were conducted on a computer equipped with 16 GB of RAM and an NVIDIA GeForce RTX 4060 GPU with 8 GB of VRAM. The implementation was developed using Python version 3.11.9, TensorFlow version 2.21.0, CUDA version 12.5, and cuDNN version 9.3.

D. Xception Classification Protocol

The downstream classification experiment used a balanced subset of 362 complete axial CT slices obtained from the NEPI database and the head CT database described by Chilamkurthy et al. [13]. The subset contained 181 slices with visible ischemic stroke findings and 181 slices without visible ischemic abnormalities. Among the positive slices, 55 were labeled as hyperacute, 66 as acute, 15 as subacute, and 45 as chronic. The examinations were reviewed by a radiology technologist and a physician, and the final labels were assigned by consensus. Only complete axial slices with sufficient brain parenchyma were retained; lesion-centered crops were not used.

The DICOM pixel values were converted to Hounsfield units using the *RescaleSlope* and *RescaleIntercept* attributes. A brain window with a window level of 0 HU and a window width of 150 HU was applied, followed by skull removal and min–max normalization to $[0, 1]$. For Xception, the images were resized to 299×299 pixels and the grayscale channel was replicated three times to obtain an input of $299 \times 299 \times 3$.

The Xception model [14] used an ImageNet-pretrained backbone with frozen weights. Its original classification layer was replaced by a *GlobalAveragePooling2D* layer, a dense layer with 512 neurons and ReLU activation, a dropout layer with a rate of 0.4, and a single sigmoid output neuron. The classifier was optimized using Adam with a learning rate of 10^{-3} and binary cross-entropy loss. Training was performed

for up to 50 epochs with a batch size of 128. Early stopping monitored the validation loss with a patience of 10 epochs and restored the weights associated with the lowest validation loss.

Four training conditions were evaluated: (i) real images only; (ii) real images with classical data augmentation; (iii) real images supplemented with GAN-generated samples; and (iv) real images with both classical and GAN-based augmentation. Five-fold stratified cross-validation was used, and the same folds were retained across all four conditions. In each iteration, four folds were used for training and the remaining fold was used for validation and performance estimation. For the GAN conditions, the GAN was reinitialized and trained using only the real images from the four training folds. Synthetic samples were added only to the classifier training data at a real-to-synthetic ratio of 1:1 and with equal class proportions; the validation folds contained real images only. The predictions from the five validation folds were concatenated to construct the aggregated confusion matrices.

E. Evaluation Metrics

This subsection presents the metrics used to evaluate the quality and fidelity of computed tomography images containing ischemic stroke lesions generated by the GAN-based model.

The quantitative evaluation of the quality of the synthetic images was performed using two complementary metrics: the Fréchet Inception Distance (FID) and the Structural Similarity Index (SSIM). The combined use of these metrics allows for the evaluation of both the statistical similarity between the sets of real and synthetic images and the preservation of the structural features present in the images.

FID is a metric widely used in the evaluation of generative models and quantifies the distance between the feature distributions extracted from the sets of real and generated images [15]. To do this, feature vectors are obtained from the activations of the *global average pooling* layer of the Inception-v3 network, which was previously trained on the ImageNet dataset. The Fréchet distance between the Gaussian distributions associated with the real and synthetic images is calculated according to Equation (4).

$$FID = |\mu_r - \mu_g|^2 + Tr\left(\Sigma_r + \Sigma_g - 2(\Sigma_r\Sigma_g)^{1/2}\right) \quad (4)$$

In Equation (4), μ_r and Σ_r represent the mean and covariance matrix of the features extracted from real images, while μ_g and Σ_g correspond to generated images. Lower FID values indicate greater similarity between the two feature distributions.

SSIM evaluates perceptual similarity between a reference image and a compared image by considering luminance, contrast, and local structure [16]. It is calculated according to Equation (5).

$$SSIM(x,y) = \frac{(2\mu_x\mu_y + C_1)(2\sigma_{xy} + C_2)}{(\mu_x^2 + \mu_y^2 + C_1)(\sigma_x^2 + \sigma_y^2 + C_2)} \quad (5)$$

In Equation (5), μ_x and μ_y are the local means, σ_x^2 and σ_y^2 are the local variances, σ_{xy} is the local covariance, and C_1 and C_2 are stabilization constants. Higher SSIM values indicate greater structural similarity. Because the proposed GAN does not generate paired reconstructions, SSIM is interpreted only as an auxiliary structural measure and not as evidence of anatomical correspondence.

IV. Results

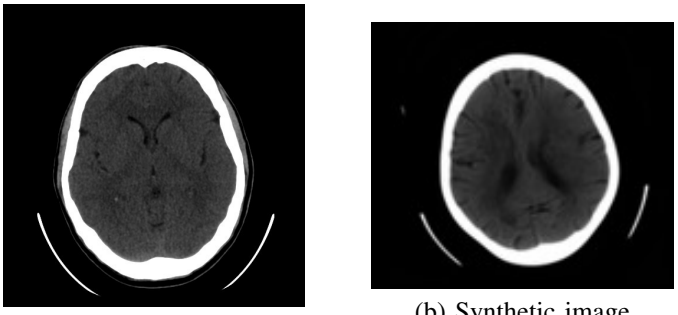
A. GAN Image Evaluation

This section presents the results obtained from the evaluation of the proposed model for generating synthetic computed tomography (CT) images showing ischemic stroke lesions, using Generative Adversarial Networks (GANs). The analysis was conducted using quantitative metrics and visual qualitative assessment.

The quality of the synthetic images was evaluated using two metrics widely recognized in the literature: the Structural Similarity Index (SSIM) and the Fréchet Inception Distance (FID). The experiments were conducted using a subset of 500 generated images. Table IV presents the observed mean values and standard deviations.

TABLE IV
AVERAGE SSIM AND FID SCORES FOR GENERATED IMAGES

Metric	Average	standard deviation
SSIM	0,8002	±0,037
FID	6,52	±0,83



The results indicate a high degree of structural similarity between the real and generated images, as compared to the studies cited above. The FID value was less than 7, which was lower than in other studies.

The qualitative evaluation was performed through visual inspection of the synthesized images. Figure 5 presents a comparison between a real computed tomography image containing an ischemic lesion and a synthetic image generated by the proposed model. Although the original images have a resolution of 512×512 pixels, the GAN was trained using images resized to 128×128 pixels. For visual comparison purposes, both images are presented at the same scale.

The generated images preserved relevant visual characteristics, such as the contrast between the lesion and the brain parenchyma, and did not present recurring visual artifacts. These findings suggest that the model was able to learn relevant structural patterns from the training set.

B. Xception Classification Results

Table V summarizes the Xception results across the five folds. Training with GAN-generated images increased all reported metrics relative to the real-only baseline. The combined use of classical and GAN-based augmentation achieved the highest aggregated performance, with 167 true negatives, 14 false positives, 15 false negatives, and 166 true positives. This corresponds to an aggregated accuracy of 91.99%, precision

(a) Actual image (b) Synthetic image

Fig. 5. Comparison between a real computed tomography (CT) image showing an ischemic stroke and a synthetic image generated by the proposed model. Although the GAN was trained using images resized to 128×128 pixels, both images are presented at the same scale to facilitate visual comparison.

of 92.22%, sensitivity of 91.71%, specificity of 92.27%, and F1-score of 91.97%.

TABLE V
XCEPTION PERFORMANCE UNDER FIVE-FOLD STRATIFIED SLICE-LEVEL CROSS-VALIDATION. VALUES ARE MEAN ± STANDARD DEVIATION; FN IS THE AGGREGATED NUMBER OF FALSE NEGATIVES.

Training condition	Accuracy	Sensitivity	F1-score	FN
Real only	$88.12 \pm 1.21\%$	$86.19 \pm 1.97\%$	$87.88 \pm 1.29\%$	25
Classical augmentation	$89.50 \pm 0.84\%$	$88.93 \pm 2.84\%$	$89.42 \pm 1.03\%$	20
GAN augmentation	$90.88 \pm 0.83\%$	$90.60 \pm 1.57\%$	$90.86 \pm 0.76\%$	17
Classical augmentation + GAN	$91.98 \pm 1.21\%$	$91.71 \pm 0.10\%$	$91.97 \pm 1.12\%$	15

Relative to the real-only baseline, the combined condition increased aggregated accuracy by 3.87 percentage points, sensitivity by 5.52 percentage points, specificity by 2.21 percentage points, and F1-score by 4.08 percentage points. The number of false negatives decreased from 25 to 15, a descriptive reduction of 40%. Because no hypothesis tests or confidence intervals were calculated for the paired differences, these gains should not be interpreted as statistically significant.

The combined condition reduced the global false-negative rate from 13.81% to 8.29%. Relative to the real-only baseline, false negatives decreased from 11/55 (20.00%) to 5/55 (9.09%) for hyperacute slices, from 8/66 (12.12%) to 6/66 (9.09%) for acute slices, from 4/15 (26.67%) to 3/15 (20.00%) for subacute slices, and from 2/45 (4.44%) to 1/45 (2.22%) for chronic slices. The subacute estimate is particularly unstable because this subgroup contains only 15 slices.

V. DISCUSSION

This study investigated GAN-based synthesis of CT images with ischemic stroke findings and its use for augmenting an Xception classifier. The synthetic images achieved a mean Structural Similarity Index (SSIM) of 0.8002 ($\pm$0.037) and a mean Fréchet Inception Distance (FID) of 6.52 ($\pm$0.83). These metrics characterize structural and feature-distribution similarity under the adopted protocol, but do not demonstrate clinical correctness because SSIM depends on the image-pairing procedure and FID uses ImageNet features from Inception-v3.

In the Xception experiment, the addition of GAN-generated images increased aggregated accuracy from 88.12% to 90.88% and sensitivity from 86.19% to 90.60%. Combining classical and GAN-based augmentation produced the best descriptive result, with 91.99% accuracy, 91.71% sensitivity, and 15 false negatives, compared with 25 false negatives in the real-only condition. The stage-stratified analysis also suggested fewer false negatives in hyperacute, acute, subacute, and chronic slices under the combined condition.

***Abstract*—This work presents a methodology for the correction of characteristic contrast curves and a post-processing routine for contrast improvement in digital mammography images. The study revolves around 4 systems, from which images of an anthropomorphic breast phantom were extracted. This phantom contains a grayscale step wedge that enables the extraction of the characteristic curves from each image using Piecewise Cubic Hermite Interpolating Polynomial (PCHIP). These curves allowed for the calculation of a conversion curve that transforms a contrast curve into a reference curve, defined by the characteristic curve of a radiographic film. Furthermore, a post-processing routine was established, consisting of 3 steps: pre-processing for noise removal; equalization based on quality assessment metrics, specifically the Modulation Transfer Function (MTF), the Noise Power Spectrum (NPS), and the Detective Quantum Efficiency (DQE); and enhancement filtering. Through this process, it was possible to generate an image similar, and of even better quality, compared to those from commercially available digital mammography systems. This makes the method a great ally in the objective of improving and standardizing digital mammography images, a factor that can significantly aid the diagnostic process of such a complex exam, especially regarding Computer-Aided Diagnosis (CAD).**

***Index Terms*—contrast, digital mammography, characteristic curve, post-processing.**

I. Introduction

Breast cancer is one of the most incident type of cancer among women. An estimated 73,000 new cases were projected for 2025 [1], representing one of the highest female mortality risks worldwide. Most deaths occur in low- and middle-income countries, where diagnoses are often delayed due to misinformation or limited access to screening services. The best way to prevent and increase treatment success rates is through periodic examinations and early-stage detection [2].

Thus, the importance of mammography screening is undeniable; however, it is also essential that the exam can accurately detect any anomalies. The correct detection of different breast structures depends on several factors, with image contrast being one of the most critical [3].

In current digital acquisition systems, there is an important distinction between ”Raw” and ”Processed” images. Raw images are derived directly from X-ray attenuation information and correspond to a linear relationship between the logarithm of exposure and the pixel value, featuring low contrast and a wide dynamic range, as seen in Fig. 1b. Because of this, subtle contrast differences essential for a correct diagnosis are difficult for the human eye to perceive, given its logarithmic response to contrast. Processed images are obtained after applying processing steps to the raw image to improve quality or enhance regions of interest, and this is the image presented to the radiologist for diagnosis.

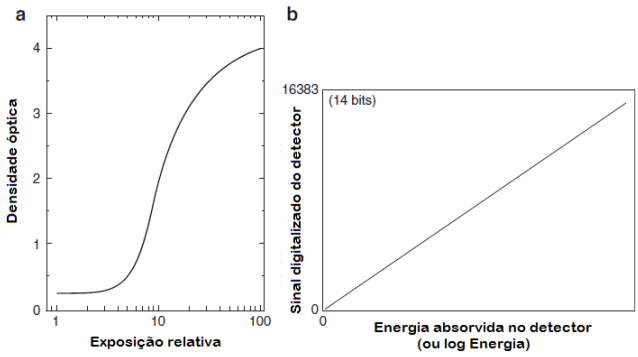

Fig. 1. Comparison between the characteristic curve of a screen-film acquisition system (a) and a digital system (b). Source: [4]

Although the diagnosis is performed on processed images, raw images are used for analysis, study, and treatment to avoid the influence of already applied processing methods.

Having established the importance of a coherent image and the relationship between exposure and acquisition system response, this work analyzes the characteristic contrast curves of digital mammography images, as well as inherent acquisition system metrics, such as the Modulation Transfer Function (MTF), the Noise Power Spectrum (NPS), and the Detective Quantum Efficiency (DQE). Based on the extracted data, the objective is to correct possible deficiencies in the studied systems and achieve image standardization. This facilitates auxiliary diagnosis by Computer-Aided Diagnosis (CAD) systems in conjunction with a healthcare professional.

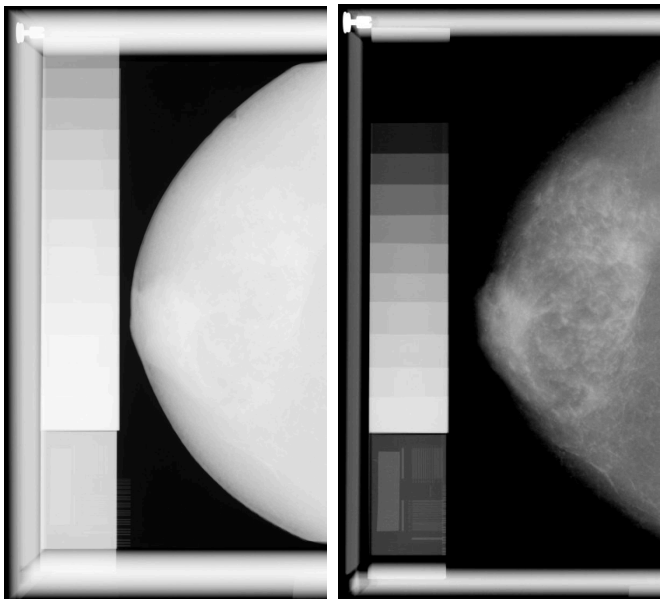
The correction occurs through the adjustment of the images' contrast curves and the application of a post-processing routine to match the contrast quality presented in commercially available and widely used systems.

II. Methodology

For the tests, an anthropomorphic breast phantom was used, specifically Model 18-226 from Nuclear Associates, nicknamed phantom Rachel, measuring $19.6 \times 11.7 \times 6.1$ cm. The model simulates a compressed breast of 5 cm thickness, consisting of 50% glandular tissue and 50% adipose tissue, and includes a grayscale step wedge on the side, used to extract the characteristic contrast curves of the studied systems.

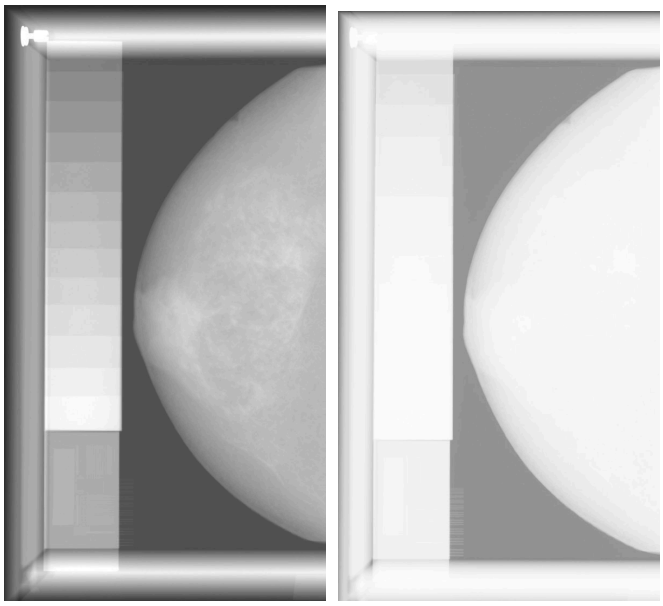
Fig. 2. Phantom Rachel used in the study.

Images of the phantom were acquired at various hospitals and radiological clinics under predefined exposure metrics (kVp and mAs values) across 4 different systems:



- System 1: CsI scintillator + Si detectors (0.1 mm/pixel); Mo or Rh target; Mo or Rh filter.
- System 2: a-Se detectors (0.07 mm/pixel); W target; Rh or Ag filter.
- System 3: a-Se detectors (0.05 mm/pixel); W target; Rh filter.
- System 4: CsI scintillator + Si detectors (0.1 mm/pixel); W target; Rh filter.

The studies were conducted on one image from each system, acquired under the following parameters:



- IMG01: acquired from System 1, with 30 kVp and 100 mAs;
- IMG02: acquired from System 2, with 30 kVp and 100 mAs;
- IMG03: acquired from System 3, with 29 kVp and 99 mAs;
- IMG04: acquired from System 4, with 30 kVp and 80 mAs.

The equipments were not calibrated by the research team, however, as they are utilized by medical facilities on the day to day life, they are calibrated by the manufacturer and the hospitals' maintenance teams. They are up to standards following the periodic quality evaluations required for them to be legally used.

Given that all the images were obtained using the same phantom and under the same kVp and mAs parameters (or at least as close as possible), it is safe to say that the data obtained is comparable between different systems.

(a) IMG01. (b) IMG02.

(c) IMG03. (d) IMG04.

Fig. 3. Raw images acquired from the 4 different systems.

A. Characteristic Curves Determination

Using the grayscale present on the side of the phantoms, the average value of each of the 12 steps was extracted to perform interpolation and generate the corresponding curve for the studied system.

The interpolation type used is PCHIP (Piecewise Cubic Hermite Interpolating Polynomial), which allows joining the points using third-degree functions, ensuring curve smoothness. Furthermore, the method guarantees monotonicity while connecting the points with great flexibility and without oscillations.

B. Reference Curve Selection

To correct the obtained contrast curves, it was necessary to define a reference curve so that the images could be processed to match it. Keeping in mind the human eye's logarithmic response to contrast, a curve that benefits from this fact was sought.

Given the logarithmic relationship between optical density and relative exposure of a radiographic film's characteristic curve, shown in Fig. 1a, a radiographic film curve was defined as the reference to adapt the image to the human eye's contrast perception. In [3], a set of 20 points describing the used curve was extracted, which were then connected using PCHIP.

As a characteristic curve carries the informations that relate the darkening degree of the image with the values of incident exposure, it represents a relation of input-output of the imaging system. In this sense, the choice of a radiographic film's characteristic curve intends on avoiding the linear relationship observed in digital systems, as represented by Fig. 1b, that is not perceived well by humans.

By the same logic, a transformation of the image by utilizing a different characteristic curve is not capable of eliminating information useful for the diagnosis, since it only affects how light or dark a different part of the breast is. This transformation never attributes the same value of gray level to different regions, hence, never losing information, which is granted by the monotonicity of the curve, that never assumes the same output values for different inputs. It is also worth noting the fact that the post-processing routine utilized by the manufacturers includes a characteristic curve transformation.

C. Contrast Correction Curves Calculation

Once the characteristic curves of the studied systems and the reference curve were obtained, it was possible to calculate contrast correction curves. When applied to the original image, these curves can convert its contrast curve to the reference one.

Each correction curve is unique to each image and can only be generalized for images from the same system acquired under the same kVp and mAs parameters. Thus, its calculation is performed using the previously defined reference curve and the characteristic curve of the image to be corrected.

The goal is to obtain a curve that, instead of relating grayscale steps to gray levels, relates the gray levels of the image to be corrected with those of the reference curve. For this, both used curves had their domains normalized (allowing the use of curves obtained from grayscales with different numbers of steps), and then several equidistant points were extracted from each curve. Both sets of points were obtained for the same domain values, thus allowing the relation of an image's gray level to the reference based on the same X-axis value.

With the points relating gray levels, PCHIP was applied to generate the actual correction curve. Its application occurs in a pixel-by-pixel transformation of the image to be corrected, making its contrast curve approaching the reference used.

D. Quality Control Metrics

To be used in the post-processing step, quality control metrics were extracted from the image detection systems, specifically MTF, NPS, and DQE, following the international standard protocols for digital mammography [5]. The calculation for each metric follows these equations:

$$MTF(f) = \frac{|\mathcal{F}\{LSF(x)\}|}{|\mathcal{F}\{LSF(x)\}|_{f=0}}, \tag{1}$$

where:

- f: Spatial frequency (in cycles/mm).
- $\mathcal{F}$: Fourier Transform operator.
- $LSF(x)$: Line Spread Function, obtained by the derivative of the Edge Spread Function ($ESF(x)$), defined as $LSF(x) = \frac{d}{dx}ESF(x)$.

$$NPS(u,v) = \frac{\Delta x \Delta y}{N_x N_y M} \sum_{i=1}^{M} |\mathcal{F}\{I_i(x,y) - B_i(x,y)\}|^2, \tag{2}$$

where:

- u, v: Spatial frequencies in the horizontal and vertical axes (cycles/mm).
- $\Delta x, \Delta y$: Pixel spacing in the x and y directions (in mm).
- N_x, N_y: Dimensions (number of pixels) of each evaluated sub-region.
- M: Total number of sub-regions extracted from the image to compose the statistical mean.
- $I_i(x,y)$: Pixel intensity matrix of the i-th original sub-region.
- $B_i(x,y)$: 2nd-order polynomial background fit (detrending) of the i-th sub-region, subtracted to isolate noise fluctuations.

$$DQE(f) = \frac{\bar{S}^2 \cdot MTF^2(f)}{NPS(f) \cdot Q} \tag{3}$$

where:

- $\bar{S}$: Average image signal, calculated from a Region of Interest (ROI) in the flat-field image.
- Q: Incident photon fluence on the detector (photons/mm^2).

To perform the calculation correctly, specific images obtained by the digital mammography systems are required. MTF requires an abrupt transition to be calculated with minimal errors, which was achieved by placing a lead plate (completely white in the final image) over the image acquisition system, ensuring a clean and abrupt transition relative to the image background (completely black). NPS, on the other hand, requires a large, uniform region for noise detection, achieved by placing an acrylic plate over the system, providing a uniform image from which noise can be extracted with minimal interference.

These metrics are a measure of the image acquisition system, and not only of the images utilized for their calculation, since they extract information that does not depend on any

acquisition parameters. This means that only a handful of images are recquired to define a whole system, and the data can be used on the processing of any other images extracted from the same system.

E. Post-Processing

By applying the correction curve, an equalized image is obtained, with well-distributed gray levels to leverage the human eye's natural contrast perception. However, a post-processing stage is still necessary to match the contrast level displayed in processed images from current digital mammography systems. The developed post-processing can be divided into 3 steps:

The first step consists of pre-filtering, responsible for removing the noise present in the image which, although not perceptible to the naked eye, is drastically amplified in the subsequent steps. Since the breast is a highly complex organ and the image is rich in details, it is necessary to use a filter that loses as few details as possible. Thus, an NLM (Non-Local Means) filter was used [6]. Instead of comparing a pixel with its immediate neighbors for noise removal, a process performed by simpler filters like the Gaussian, this filter compares blocks of pixels across large neighborhoods to preserve more image details.

The second step consists of correcting potential image defects using the quality control metrics extracted from the images, specifically MTF and DQE. The gain of the filter $G(f)$ is composed of the product of a damped inverse restoration term (H_{inv}) and a Wiener-based attenuation mask (W_{norm}) [7]:

$$G(f) = H_{inv}(f) \cdot W_{norm}(f) \tag{4}$$

where the spatial modulation restoration is given by:

$$H_{inv}(f) = \min\left[\left(\frac{1}{MTF(f)}\right)^{\alpha}, G_{max}\right] \tag{5}$$

and the signal reliability mask (normalized Wiener fraction), which limits the values the filter can assume, is expressed as:

$$W_{norm}(f) = \frac{1}{\max(W)} \cdot \left(\frac{DQE(f)}{DQE(f) + C}\right) \tag{6}$$

where:

- α: Enhancement strength.
- G_{max}: Maximum gain limit.
- C: Damping constant.

The filter acts by amplifying the frequencies where the MTF is poorest, using the DQE as a brake to prevent over-amplifying high frequencies, which could reveal a large amount of noise. At frequencies where the DQE drops, there is high noise in the image. By using this information, the filter can be calibrated to enhance frequencies with information loss in a controlled manner.

The third and final step consists of enhancement filtering, designed to highlight glandular tissue and darken adipose tissue, ensuring good contrast values in the final image. First, a Gamma correction is applied, capable of deepening dark areas and reducing the prominence of adipose tissue. Next, CLAHE (Contrast Limited Adaptive Histogram Equalization) [8] is used, an image histogram equalization technique responsible for increasing local contrast and revealing hidden structures, such as microcalcifications. It is worth noting that CLAHE degrades the overall image contrast at the expense of local contrast, which is why a blending between the pre and post-application images is performed to mitigate this issue.

F. Numerical Validation

To quantify the results, the RMS contrast [9] (referred to as Crms for abbreviation) and the Carneiro Contrast Index (ICC) [10] metrics were used. The Crms is defined by the following equation:

$$C_{rms} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(I_i - \bar{I})^2} \tag{7}$$

where:

- N: Total number of pixels in the evaluated Region of Interest (ROI).
- I_i: Intensity value of the i-th pixel contained in the ROI.
- $\bar{I}$: Average intensity of all pixels present in the respective ROI.

It is important to highlight that Crms is not calculated over the entire image, but in 64×64 pixel windows, in order to capture only the local contrast [9], which is the focus of this work. Calculating Crms for the whole image yields a very high value for RAW images and a very low one for processed images. This is because RAW images have a very high low-frequency gradient (attributed to the thickness gradient between the breast base and the nipple) that artificially inflates the Crms value. This is corrected in post-processing, which equalizes these values and drastically reduces the global contrast value.

The ICC is based on calculating the standard deviation of each pixel relative to its neighborhood. The method generates a standard deviation map that reveals the regions of highest contrast. By averaging all the found values, it is possible to quantify the contrast in a single number. To perform the calculations on the studied images, a 3×3 kernel was used; that is, the neighborhood consists of all eight adjacent pixels.

The numbers found only have meaning when compared to each other and under the same conditions. It is also worth mentioning that the image's bit depth does not influence the results, as ICC takes this parameter into account and Crms is not influenced by it.

Regarding the application methodology, in both cases, only the part containing the breast was cropped from the image, leaving out the "frame" containing the grayscale. Specifically for the Crms calculation, an Otsu algorithm was applied to the image, responsible for separating the breast from the black background behind it, which can considerably influence the results. Since the method considers the average intensity level of all pixels, it is sensitive to the proportion of black pixels

in the image, causing small changes in image cropping to yield measurement errors. For the ICC, however, the black background is not a concern, as it is practically uniform and the ICC only cares about a pixel's standard deviation relative to its neighborhood.

III. Results and Discussion

The previously described methods were applied only to System 1, the only one from which the images necessary for the correct calculation of quality control metrics could be obtained. This system has some of the poorest metrics when compared to the other three, therefore, although the complete processing procedure can only be applied to System 1, a worst-case scenario was simulated, verifying the full potential of the processing technique. The IMG01 that underwent the described processes will be referred to as "converted".

First, the characteristic curves of all systems were extracted, shown in Figures 4 and 5. Comparing the curves in both graphs, it is notable, firstly, how the post-processing performed by the mammography systems inverts the curves' trend, so that the scale goes from a darker to a lighter shade, and the image has a black background with white enhancements, except for System 3. Despite this, in this work, all images with decreasing characteristic curves are displayed with an inverted LUT (Look-Up Table) as a form of standardization.

Another important characteristic to observe is the change in the curves' shapes, as well as their histogram widths, represented by the Y-axis width admitted by the curve. All systems tend to give the curve a sigmoid shape during their processing stage; however, there is an increase in histogram width only in Systems 2 and 3, with a persistence and even decrease in Systems 1 and 4. This reveals a greater poverty of detail and poor utilization of the available grayscale range, which goes from 0 to 4095 since the images are 12-bit.

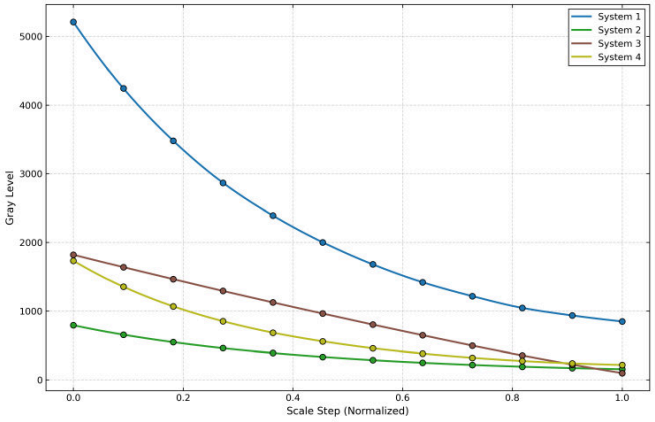


Fig. 4. Comparison between characteristic curves of the RAW images from the studied systems.

Taking IMG01 as the baseline to be improved, the conversion curve shown in Fig. 6 was generated. It is notable that it has a very complex shape to achieve with a single function, which justifies the choice of PCHIP as the interpolation method used, since it provides great flexibility in joining the points. Note that the graph has values up to the order of 16000 on the X-axis, which contradicts Fig. 4, that shows the curve only going up to values in the order of 5000. This is due to the fact that, in addition to the 12 values of the grayscale, the values of the phantom background and the image background were used to generate the correction curve, ensuring that not only the scale but the entire image conforms to the used curve. If these values were not used, the background regions of the image would not have values to be converted to, which would generate a faulty and noisy image.

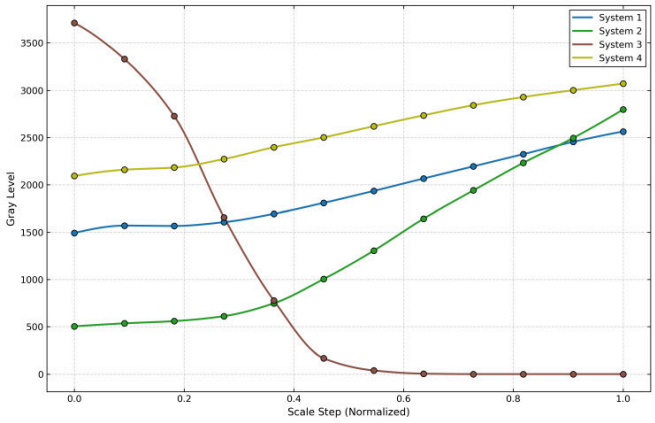

Fig. 5. Comparison between characteristic curves of the processed images from the studied systems.

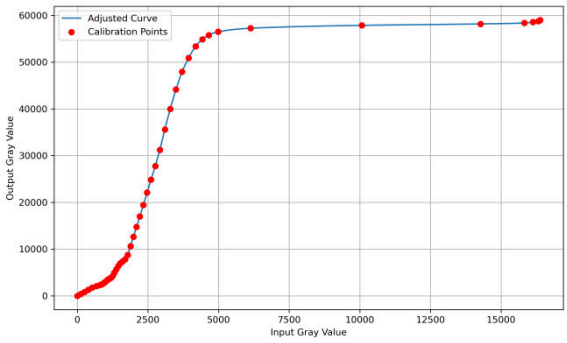

Fig. 6. Conversion curve generated for IMG01 processing.

In Fig. 7, there is a comparison between the processed curves from Fig. 5, along with the converted and post-processed IMG01 curve. Due to the inclusion of out-of-scale points, the converted image curve is noticeably shifted relative to the reference curve; however, it presents the same shape, demonstrating that the method was applied successfully.

Next, the 3-step post-processing was performed on IMG01 with its converted characteristic contrast curve. The resulting image is present in Fig. 8 and can be visually compared with the processed images from each of the 4 mammography systems present in Fig. 9. It reveals itself to be a kind of inter-

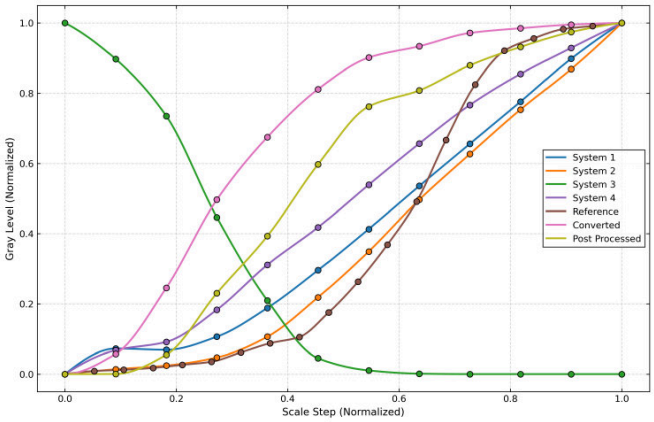

Fig. 7. Comparison between all curves in the study, excluding the raw images.

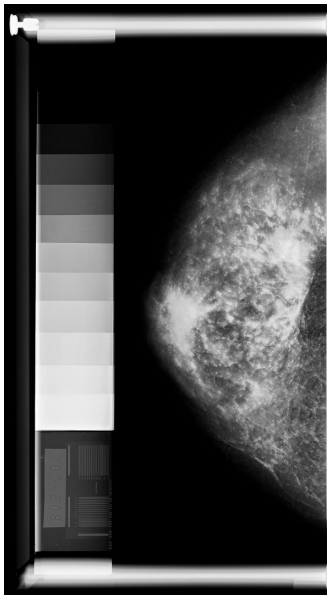
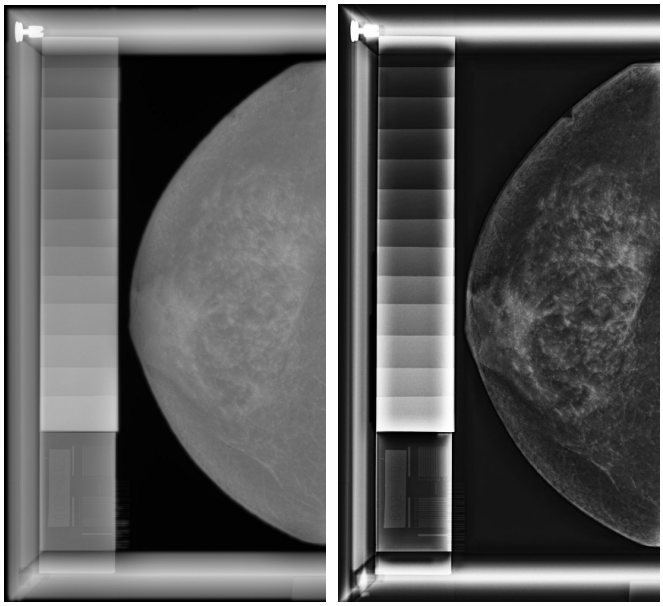
mediate between the IMG02 and IMG03 images, appearing to have better contrast than the IMG01 and IMG04 images, which are more grayish and with little perceptible differentiation between glandular and adipose tissues.

An evident difference between the converted image and those processed by the mammography systems is the absence of a well-defined breast contour. This can be attributed to the application of the Gamma correction, responsible for darkening the parts that tend more towards black, which correspond to the adipose tissue. Thus, the breast ends up losing its contour, which is made almost entirely of fat and holds little value in the exam's analysis. However, it is worth noting that if there were any abnormality in that region, it would not be erased but rather enhanced, mainly due to the influence of CLAHE. Since the phantom used does not have any type of lesion or microcalcification, this region is certainly free of such structures in the presented examples.





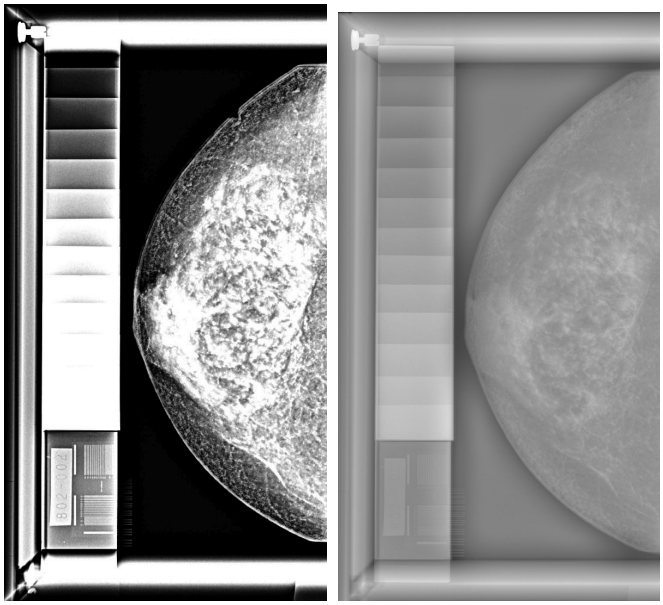


Fig. 8. Post-processed IMG01.

(a) Processed IMG01. (b) Processed IMG02.

(c) Processed IMG03. (d) Processed IMG04.

Fig. 9. Comparison between processed images (performed by the manufacturer softwares) from the 4 systems.

To confirm what was visually assessed, ICC and Crms measurements were taken for all images, both RAW and processed from all systems, as well as the System 1 image submitted to the developed methodology (called "converted"). The results are found in Tables I and II.

First, it is noted that the ICC and Crms values of the raw images are lower than almost all the processed ones and the converted one, as expected, since the intention of processing is to improve the image's contrast. This can be verified visually when comparing Figures 8, 9, and 3, given that glandular tissue is difficult to perceive in raw images, in addition to the fact

TABLE I
ICC VALUES OF THE STUDIED IMAGES

Image	RAW	Processed	Converted
IMG01	0.3036	0.4798	2.8303
IMG02	0.3282	1.6602	-
IMG03	0.2487	4.2219	-
IMG04	0.1297	0.5906	-

TABLE II
CRMS VALUES OF THE STUDIED IMAGES

Image	RAW	Processed	Converted
IMG01	0.061028	0.0941	0.240856
IMG02	0.050542	0.220715	-
IMG03	0.048721	1.072499	-
IMG04	0.072192	0.043850	-

that most present a grayish and unhighlighted image, requiring some processing to improve their display.

Focusing only on Systems 2 and 3, which provide a stronger competition to the converted one, a standout fact is the large difference in the values of both metrics between the IMG02 and IMG03 images. This demonstrates a great example of how one should not blindly trust contrast quantification metrics, but rather use them as an impartial aid to visual analysis. Comparing Figures 9d and 9c, it is verified that the processed IMG02 has a more subtle and well-distributed enhancement of the glandular tissue, giving a good idea of which areas are more or less dense. Meanwhile, the processed IMG03 has a very aggressive enhancement that highlights all the glandular tissue, including a region known to be primarily adipose, such as the breast contour. Thus, it is difficult to differentiate the density of each region and point out if there is any abnormality amidst a sea of white highlights.

Keeping this discussion in mind, now comparing the processed IMG02 with the converted IMG01, there is an improvement in both metrics: a considerable one in ICC and a small one in Crms. Combining the numerical values with visual inspection, the converted image gives greater prominence to the glandular tissue, justifying the higher ICC value. However, it still maintains a more balanced enhancement, with regions clearly showing more and less highlight depending on the amount of glandular tissue, performing a job similar to System 2 in this regard, something that can be related to the close Crms values between the images.

Regarding the converted image, it presented good results, being able to match and even surpass the contrast quality of current digital mammography systems available commercially, validating the effectiveness of the methodology developed in this work. One of the most concerning aspects in the processing of this image is noise, since there is a very large amount of enhancement filtering applied to the image, which makes noise that was previously imperceptible visible. However, it is believed that a very satisfactory result has been achieved, presenting a slightly higher noise level than the processed IMG02, which was taken as a reference during the work due to the previously discussed factors.

IV. CONCLUSION

From the collected data, both visual and numerical, it was possible to develop a mammographic image processing method capable of achieving results similar to and even better than those of digital systems currently available on the market.

By extracting and comparing the contrast curves, it was possible to better adapt it to the human eye's perception. Passing the result through an extensive and intensive post-processing routine made it more presentable and suitable for diagnostic analysis, presenting the difficulty of noise removal as a minor adversity that does not distance the final image, in quality, from images generated by professional systems.

In addition to the good results, the method has an undeniable advantage: knowledge of the type and amount of processing being applied to the raw images, as well as control over it. This enables personalized processing to highlight specific structures or to better suit the personal opinion of the professional performing the diagnosis. This feature, coupled with the fact that it is still possible to standardize the images so they are better diagnosed by CAD systems, makes the developed methodology very powerful as a potential diagnostic auxiliary.

It is important to acknowledge that this is a methodology proposition. The conclusions were drawn by visual inspection of the research team as well as the quality metrics, to ensure a more unbiased and objective view. It is clear that the method was tested in a limited ammount of samples and needs further testing, including different systems, different phantoms and different acquisitons parameters. Testing with clinical cases and studies with CADx systems and radiologists will be carried in the future to solidify the approach suggested in this work.

***Abstract*—Invasive Blood Pressure (IBP) monitoring is a cornerstone of hemodynamic management in Intensive Care Units (ICUs). However, the accuracy of continuous IBP measurements heavily relies on the dynamic response of the catheter-transducer system. Waveform distortions can lead to significant clinical misinterpretations. This study outlines the creation of a clinical database comprising real hemodynamic records annotated via standardized fast-flush tests. Data from ICU patients were acquired at 125 Hz and digitally upsampled to precisely determine the system's natural frequency and damping coefficient. Out of 11 evaluated patients, 8 systems were fully characterized, revealing 3 inadequate setups according to Gardner's criteria. This database establishes an essential foundation for the future validation of artificial intelligence algorithms designed to automatically detect IBP waveform distortions, ultimately enhancing patient safety within the Brazilian Sistema Único de Saúde (SUS) context. This study does not evaluate algorithm performance; it establishes a pilot dataset against which such evaluation will later be conducted.**

***Index Terms*—Invasive Blood Pressure, Fast-Flush Test, Signal Processing, Intensive Care Unit, Artificial Intelligence, Hemodynamic Monitoring**

I. Introduction

Invasive Blood Pressure (IBP) monitoring is considered the gold standard for hemodynamic assessment in Intensive Care Units (ICUs) [1]. In contrast to non-invasive methods such as oscillometry, IBP provides continuous measurements, allowing for the accurate determination of Mean Arterial Pressure (MAP), an essential parameter for adjusting vasopressor therapies and fluid infusion in patients with hemodynamic instability [2]. Critical clinical conditions such as septic, cardiogenic, or distributive shock require rapid and accurate decisions, in which obtaining a precise and trustworthy MAP in real-time is central to goal-directed resuscitation protocols, such as those proposed in international sepsis guidelines [3].

However, even though it is a highly accurate method, the reliability of IBP depends on the integrity of the catheter-transducer system. Alterations in the physical properties of this system, such as the presence of air bubbles, clots, excessively long tubes, or loose connections, can modify its dynamic response, resulting in waveform distortions [5]. An underdamped response, for instance, characterized by a low damping ratio (ζ), leads to overestimation of systolic pressure and underestimation of diastolic pressure, that could impact the clinical management of the patient. [1], potentially inducing both unnecessary drug administration and failure to recognize true hypotension.

Recent studies highlight the current relevance of the problem. Damping disturbances are observed in up to one-third of the catheter-transducer systems used by patients undergoing IBP monitoring in the intensive care setting, often going unnoticed [4]. Furthermore, relying solely on qualitative visual inspection makes error identification inherently subjective and error-prone, compromising the consistent detection of dynamic distortions at the bedside. These limitations point to the urgent need for objective, automated, and reliable methods for detecting IBP distortions at the bedside [6].

The fast-flush test is the classic method for verifying system fidelity, but its application depends on technical availability, standardized execution, and subjective interpretation [5]. In this context, several computational approaches have been proposed, with machine learning-based algorithms being particularly noteworthy. Rinehart et al. demonstrated that neural networks trained with distorted waveforms can achieve high

accuracy in identifying calibration errors [6]. Recent advances in generating synthetic databases through one-dimensional modeling of the cardiovascular system have allowed for realistic representation of circulation at different ages and pathophysiological conditions, such as different phases of septic shock [7], [8].

Within the Laboratório de Engenharia Biomédica (LEB-USP) of the Escola Politécnica da USP, a convolutional neural network model is being developed in a doctoral project, aiming to automatically detect distortions such as underdamping based exclusively on the IBP waveform in the context of ICUs. This model was trained with over 10,000 simulations performed with the Nektar1D solver [7], covering various hemodynamic conditions. However, to be clinically validated, the algorithm needs to be tested with real signals from critically ill patients. This project aims to fill this gap by performing standardized data acquisition in the ICU of the Hospital Universitário da Universidade de São Paulo, simultaneously addressing the scarcity of data within the Brazilian context, applying flush tests, curating the signals, and creating the initial structure of a database to evaluate the model's performance in the future. This translational step aims to consolidate a robust and clinically applicable tool with the potential to positively impact the safety and effectiveness of invasive monitoring in intensive care.

II. Objective

The main objective of this project is to collect, structure, and annotate real clinical Brazilian data from an ICU environment to create a database tailored for the future performance evaluation of an AI algorithm (developed at LEB-USP). By systematically identifying cases of underdamping in the catheter-transducer system (analyzing the damping coefficient and the natural frequency from the fast-flush test transient response) the dataset will serve as a ground truth to verify the AI's ability to detect failures autonomously, using exclusively morphological characteristics extracted from the continuous signal waveform.

III. Methods

A. Study Design and Ethical Approval

This is a prospective observational study conducted in the adult ICU of the Hospital Universitário da Universidade de São Paulo (HU/USP). The proposal was approved by the HU/USP Comitê de Ética em Pesquisa (CAE 86650625.3.0000.0076), incorporating family authorization via a deferred consent model, as established by CNS Resolution 466/12.

B. Population and Inclusion Criteria

Data were included from adult patients (age $\geq$ 18 years) admitted to the ICU of the HU/USP who had an arterial catheter inserted in the radial or femoral arteries as clinically indicated by the clinical team. Patients with high-response atrial arrhythmias, peripheral vasculitis, or conditions that prevented the performance of the fast-flush test were excluded.

C. Signal Acquisition

The pressure signals were acquired using a disposable pressure transducer (REF 7004, Zammi Instrumental Eireli, ANVISA (Agência Nacional de Vigilância Sanitária) registration 10216350082), connected to the arterial line via either a single-lumen central venous catheter (16 Ga, 20 cm; REF CV-50016-BZ, Arrow International/Teleflex, ANVISA registration 80117580569) inserted at the femoral site, or a dedicated arterial catheterization kit (20 Ga, 8 cm; REF CA 2008, Alive Heart Material Médico LTDA., ANVISA registration 80415440015) inserted at the radial site. The signals were obtained directly from the bedside monitors (Nihon Kohden Lifescope, Tokyo, Japan) installed in 14 ICU beds, with a sampling frequency of 125 Hz, between September 2025 and April 2026. These monitors are connected to the catheter-transducer system and integrated to the hospital network, transmitting data in real time via a proprietary protocol. Acquisition was performed using a customized algorithm developed by LEB-USP, which accesses and extracts data packets directly from the network, eliminating the need for additional physical interfaces.

At each ICU visit, photographic records of the vital signs and other values were made on all active bedside monitors, as well as of the chart registering of the patients present in the unit on that date, which contained their respective bed numbers. After identifying patients with active blood pressure monitoring, the following data were tabulated: the bed number of each patient, the current date, the channel of the signal collected by the monitor (ART or P1), and the anatomical site of catheter insertion (radial or femoral). Numerical data and waveforms were obtained continuously during hospitalization and temporally synchronized with five flush tests performed by the care team. All records were stored with precise timestamping (the start and end times of the flush tests were also tabulated) in a format compatible for later processing and analysis in a Python environment. Patient identifiers (name, medical record number) were not retained in the digital dataset; records were linked only by bed number, date and time during acquisition, with this mapping stored separately from the signal files. Data are currently maintained on institutional storage and the Open Science Framework (OSF), with public deposition on Zenodo planned to support future validation studies.

D. Study of Signals and Definition of the Flush Test

The signal segments containing the fast-flush test were manually identified using a graphical interface developed in Python, based on the collection times recorded during signal acquisition. The criteria adopted for what characterizes a successful flush test were defined empirically:

- Rise and fall of the flush with a duration of less than 300 ms, distinguishing the test initiation and termination from slow valve manipulations or low-frequency artifacts;
- High-pressure plateau with a duration of 1 to 15 seconds, filtering out spurious impulse noise or prolonged system

maintenance procedures (such as line washing or blood sampling);
- Presence of a cardiogenic component before and after the flush test, aiming to ensure that the catheter was appropriately connected to the arterial system;
- Existence of cardiogenic components superimposed on the plateau of the flush test, verifying active connection to the patient's arterial system.

E. Natural Frequency and Damping Coefficient Acquisition

The transient response caused by the fast-flush test was modeled as a second-order mass-spring-damper system, whose underdamped analytical solution is expressed as:

$$y(t) = A\, e^{-\zeta \omega_n t} \sin\left(\omega_d t + \phi\right). \tag{1}$$

Following the methodology described by Gardner [5], the damping ratio and damped frequency were estimated through visual identification of the response peaks' amplitudes and periods. Because this approach relies strictly on manual peak detection, the temporal resolution of the original signal, acquired at 125 Hz, may be insufficient. To overcome this limitation and ensure a more reliable identification of the local extrema, the signal was digitally upsampled to a higher frequency prior to the analysis via polyphase low-pass FIR (Finite Impulse Response) filtering interpolation. This technique increases the density of data points without altering the underlying frequency content, thereby enhancing the precision of the visual peak detection.

The natural frequency of each system, ω_n, was calculated using the equation:

$$\omega_n = \frac{\omega_d}{\sqrt{1-\zeta^2}}, \tag{2}$$

where the damping ratio is represented by ζ and the damped frequency by ω_d.

Each of the five flush tests performed for every catheter-transducer system was analyzed individually. Considering that the pulsating pressure waveform superimposes on the flush results [5], only the parameters obtained from the responses placed during diastole were considered to calculate the average value of the damping ratio and the natural frequency of each system. Hence, performing five flushes increases the chances of having at least one measurable response during this specific period (diastole was identified visually). Waveforms with less than two peaks were considered overdamped, and their parameters were not estimated.

Based on the estimated parameters, the system's dynamic response was classified as adequate or inadequate following Gardner's [5] criteria.

IV. Results

Real-time hemodynamic data were initially collected from 29 patients. Following preliminary data quality assessment, 18 patients were excluded from the study. The reasons for exclusion were: missing data due to system acquisition errors ($n = 4$); invalid signal identification variables, which precluded IBP file extraction ($n = 5$); and fast-flush test plateau duration of less than 1 second ($n = 9$), consistent with the criteria defined in Section III-D to exclude spurious noise rather than genuine flush maneuvers (Fig. 1). Consequently, data from 11 patients were considered adequate for further analysis.

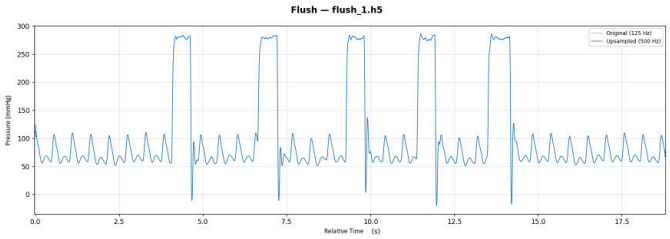

Fig. 1. Inadequate fast-flush test. The plateaus of the flush tests do not have a duration greater than 1 second. The X axis represents the time in seconds and the Y axis represents the blood pressure in mmHg.

Among the 11 analyzed patients, the catheter-transducer system was successfully classified and plotted on Gardner's reference graph in 8 cases. Three cases could not be plotted because they did not present measurable oscillations after the fast-flush test (indicating an overdamped or critically damped response, as shown in Fig. 2), precluding the calculation of the damping ratio and the natural frequency via Gardner's method.

The remaining 8 systems met the criteria and were individually analyzed (Fig. 3). For each flush test, the local peaks and valleys of the oscillation signal were detected to calculate the system's parameters, as illustrated in Fig. 4. Evaluation of these systems, according to Gardner's plot (Fig. 5), revealed that 5 systems presented an adequate dynamic response, whereas 3 were considered inadequate. The calculated parameters are detailed in Table I.

TABLE I
CHARACTERIZATION AND CLASSIFICATION OF THE 8 CATHETER-TRANSDUCER SYSTEMS ANALYZED.

Catheter	**Average parameters**				
	f_n ***(Hz)***	ω_n ***(rad/s)***	ω_d ***(rad/s)***	ζ	***Classification***
1	23.68	148.76	143.10	0.27	Adequate
2	23.62	148.43	142.80	0.27	Adequate
3	28.12	176.69	169.94	0.26	Adequate
4	22.45	141.04	136.39	0.25	Adequate
5	14.88	93.50	90.42	0.25	Inadequate
6	18.33	115.14	112.20	0.22	Inadequate
7	27.19	170.84	169.94	0.08	Inadequate
8	17.43	109.51	101.34	0.38	Adequate

V. Discussion

A methodological enhancement in the approach described in this paper pertains to the calculation of the undamped natural frequency. In classic assessments, such as Gardner's early works, the damped frequency was often utilized as a direct approximation for the undamped natural frequency. This simplification was historically justified because the mathematical divergence between the two values was negligible

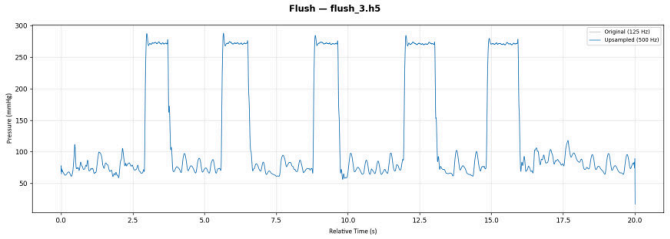

Fig. 2. Overdamped system. There is no oscillation after any of the flush tests. The X axis represents the time in seconds and the Y axis represents the blood pressure in mmHg.

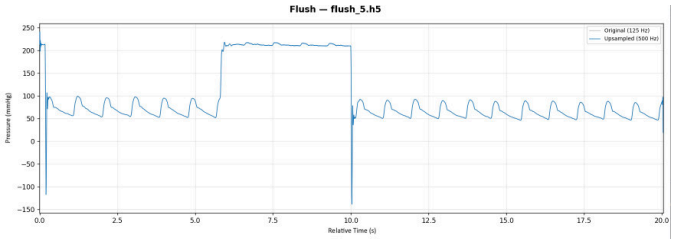

Fig. 3. Adequate fast-flush test for analysis. All the criteria defined are met. The X axis represents the time in seconds and the Y axis represents the blood pressure in mmHg.

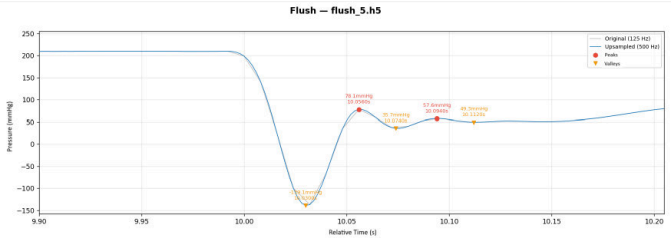

Fig. 4. This graph shows the valleys (in yellow) and peaks (in red) of an oscillation caused by a flush test. The X axis represents the time in seconds and the Y axis represents the blood pressure in mmHg.

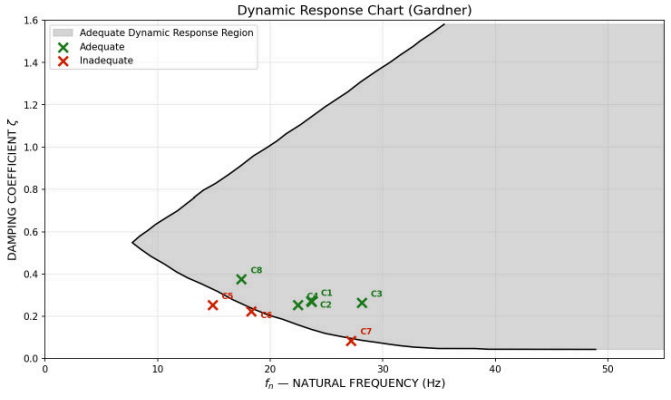

Fig. 5. Gardner's graph (light gray area) with HU's ICU catheter-transducer systems plotted (represented by "x") based on their damping coefficient and the natural frequency. The numbers refer to the catheters on Table I. The X axis represents the damping coefficient and the Y axis represents the natural frequency in Hertz.

when compared to the visual measurement errors inherent to analog paper-strip recordings. Leveraging contemporary digital data acquisition, it is possible to extract the damped frequency and the damping ratio more precisely, allowing for the direct computation of the exact natural frequency. This mitigates historical approximation errors and provides a more mathematically robust database for algorithm validation.

A challenge faced that merits future research is the classification of damped systems that exhibit fewer than two discernible oscillations following the fast-flush test. In such cases, the traditional amplitude ratio method (logarithmic decrement) for determining the damping coefficient becomes mathematically unfeasible. To address these scenarios, feature extraction applied directly to the continuous arterial waveform emerges as a viable solution. Rinehart et al. (2022) bypassed the need for fast-flush tests by extracting 124 morphological features per cardiac beat, demonstrating that machine learning algorithms could accurately detect damped transducer states [6]. This reinforces the potential utility of the database generated in this study for morphology-based AI training.

It is also important to highlight that the classification of the catheter-transducer systems as "adequate" or "inadequate" in this study relies exclusively on Gardner's established criteria, considered the gold standard procedure. These boundaries were originally formulated based on the minimum frequency response required to faithfully reproduce what he considered the average arterial pressure waveform. However, these criteria do not necessarily remain optimal across diverse physiological states, extreme hemodynamic profiles, and modern digital filtering techniques. This limitation aligns with the findings of Devasahayam et al. (2022), who demonstrated through numerical simulations that Gardner's fixed boundaries do not account for dynamic physiological variations [9]. They showed that systolic measurement errors are heavily dependent on heart rate and the systolic rise-rate, reporting that systems technically classified as adequate under static criteria could generate systolic errors exceeding 18 mmHg during tachycardic or hyperdynamic states.

Additionally, it is imperative to acknowledge the limitations imposed by using a single monitor brand and the restricted number of patients, the fact that data were collected at a single ICU, and that a single person performed the manual flush test and peak identification. Also, patient demographic and clinical variables (e.g., age, sex, comorbidities) were not systematically recorded in this pilot phase, precluding analysis of their association with dynamic response classification.

Although the constructed database provides a diversity of arterial waveform morphologies and artifact profiles suitable for preliminary algorithmic validation, the small sample size compromises its statistical generalizability. Consequently, it is not feasible to accurately characterize the overall quality of IBP monitoring within the ICU of the HU. While the current database fulfills its primary engineering objective (serving as an initial testing ground for failure-detection performance), determining the true prevalence of adequate or inadequate catheter-transducer systems in this clinical setting would re-

quire a broader, longitudinal study with a significantly larger sample size. Nevertheless, broader clinical screenings in the literature justify the clinical relevance of the present engineering objective. Devasahayam et al. (2022) evaluated 121 fast-flush tests in a surgical ICU and found that a significant proportion of active patient lines fell into unacceptably underdamped or overdamped regions [9]. This high prevalence of undetected monitoring errors reinforces the critical need for automated failure-detection algorithms such as the one our database aims to validate in the future. As this study focuses on database construction rather than algorithm evaluation, no sensitivity, specificity, or ROC analysis is presented; these will be addressed in the planned validation phase.

VI. Conclusion

This study established an initial framework for creating a clinical database of invasive blood pressure waveforms. Although the current sample size is limited, the characterized real-world data effectively captures common dynamic response distortions, bridging the translational gap required for the upcoming clinical validation of AI-based detection algorithms within the Brazilian Sistema Único de Saúde (SUS) context.

Moving forward, the goal is to expand data acquisition with an automated annotation pipeline across broader clinical samples (targeting a wider range of natural frequencies, damping coefficients, and artifacts) to enhance statistical generalizability and incorporate diverse patient demographics, evaluating the impact of variables such as age distribution and biological sex. This expansion is essential to ensure a comprehensive, unbiased, and robust future validation of the AI model across heterogeneous ICU populations.

VII. Acknowledgment

This study was financed in part by the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) (136156/2025-8 to AMKC and 309464/2022-6 to HTM). The authors are deeply grateful to the healthcare professionals and staff at HU for their hospitality, essential support in the ICU environment, and for making the clinical data collection possible.

Abstract*—This study presents a three-stage experimental investigation of deep learning approaches for pulmonary disease detection in chest radiographs. The first stage, based on experiments with the NIH ChestX-ray14 dataset, included a direct multiclass classifier with a maximum accuracy of 41%, a cascaded architecture with binary screening whose AUC remained approximately 0.76 across multiple architectures (DenseNet-121, VGG-16, ResNet-50, and EfficientNet-B3), and a multilabel sweep using high-capacity architectures (EfficientNetV2-L, ConvNeXt-XL, SwinV2-B, and MaxViT-L), which did not exceed a mean AUROC of 0.774. The second stage incorporated a TorchXRayVision DenseNet-121 model pretrained specifically on radiographic data and applied it to pathology-specific classification within the NIH-based cascade. For pneumothorax, recall reached 0.92 after reducing the decision threshold to 0.37, accompanied by a substantial increase in false-positive predictions. The third stage evaluated a different experimental setting: a compact CNN trained from scratch on the curated Kermany pediatric pneumonia dataset, combined with a six-step OpenCV preprocessing pipeline, achieved an AUROC of 0.959 and recall of 0.997 for binary NORMAL versus PNEUMONIA classification. These stages do not constitute a controlled comparison, since they differ in patient population, task definition, label-generation procedure, preprocessing, and model configuration. Therefore, the observed performance differences cannot be attributed to data quality alone. Nevertheless, when considered together with previous evidence regarding inconsistencies in NIH ChestX-ray14 labels, the experiments highlight label consistency, dataset curation, and task definition as important factors that should be considered alongside model capacity when developing chest-radiograph classifiers.

***Index Terms*—chest radiography, deep learning, convolutional neural networks, label noise, NIH ChestX-ray14, pneumonia detection, TorchXRayVision**

I. Introduction

Chest radiography is among the most widely performed and accessible medical imaging examinations worldwide, making it a central modality for screening and diagnosis of thoracic diseases [1], [2]; however, its interpretation remains challenging and subject to interobserver variability. Findings such as pulmonary nodules may measure only a few millimeters and can be obscured by dense anatomical structures. The shortage of radiologists and the increasing volume of imaging examinations motivate the development of automatic decision-support systems.

Convolutional Neural Networks (CNNs) have substantially advanced medical image analysis [3], and several studies have applied them to chest radiography [1], [2]. A recurring but often underemphasized obstacle is the quality of training labels. Our experimental trajectory illustrates this issue in a concrete manner.

We investigated three experimental stages in chronological order: (i) **previous approaches** using the NIH ChestX-ray14 dataset [1], including direct multiclass classification, a cascaded architecture, and a multilabel formulation; (ii) an **intermediate approach** incorporating TorchXRayVision [4], pretrained on chest radiographs while retaining NIH data; and (iii) a **new approach** based on the Kermany dataset [5], in which a six-step OpenCV preprocessing pipeline was combined with a compact CNN trained from scratch for binary pneumonia classification.

Importantly, these stages should not be interpreted as a controlled comparison in which only data quality changes. The NIH and Kermany experiments differ in several dimensions, including patient population, label-generation procedure, task definition, number and heterogeneity of target conditions, preprocessing, image resolution, and model configuration. The Kermany experiment therefore represents a contrasting experimental setting rather than an isolated test of the effect of label quality.

The main contributions of this paper are: (i) an empirical characterization of the performance obtained by several architecture families under the evaluated NIH ChestX-ray14 formulations; (ii) an analysis showing that radiography-specific pretraining with TorchXRayVision did not substantially resolve the difficulties observed in the NIH experiments; (iii) the evaluation of a compact CNN combined with a six-step preprocessing pipeline on a curated binary pneumonia dataset; and (iv) a comparative discussion, supported by previous analyses of ChestX-ray14, of how label consistency, task formulation, population, preprocessing, and model selection may jointly influence observed performance. Rather than establishing a causal advantage of one dataset over another, the study emphasizes the importance of considering these factors together when interpreting cross-dataset results.

II. Background and Related Work

A. Deep learning in chest radiography

The release of large datasets such as ChestX-ray14 [1] enabled the training of deep models for thoracic disease classification. CheXNet [2] popularized DenseNet-121 [6] for this task. Architectures such as VGG [7], ResNet [8], EfficientNet [9], and more recent models such as ConvNeXt [10] and EfficientNetV2 [11] have also been widely evaluated. The TorchXRayVision library [4] provides models pretrained specifically on chest radiographs from multiple sources, offering domain-specific representations.

B. Inconsistencies in NIH ChestX-ray14

The labels in ChestX-ray14 were *not* produced through direct image review. Instead, they were automatically extracted from associated radiology reports using natural language processing (NLP) [1]. Because radiology reports reflect the broader clinical context rather than only the visual findings present in the image, they constitute an imperfect proxy for what is actually visible in the radiograph [12].

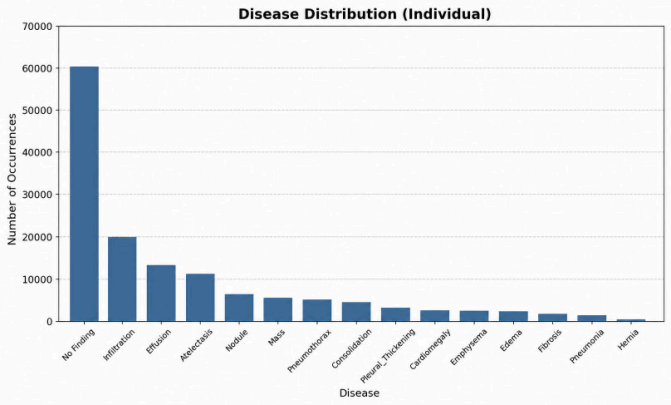

Figure 1. Distribution of NIH ChestX-ray14. The dominance of *No Finding* and the underrepresentation of pneumonia highlight the class imbalance.

An independent visual audit found substantially lower agreement with the pathology actually present in the image than the accuracy reported in the original paper (85–99%, validated only against report text). For instance, the agreement was approximately 36% for atelectasis and approximately 10% for fibrosis [12]. Peer-reviewed studies explicitly assume approximately 10% label noise and state that this makes it difficult to assess the true performance of any network [13].

A second issue is the presence of inconsistent and overlapping class definitions. Conditions such as infiltration, consolidation, and pneumonia are radiologically difficult to differentiate even for specialists [12]. The case of pneumothorax is particularly illustrative: the label often marks already treated cases in which a chest drain is visible in the image; gradient-based analyses show that the network learns to detect the drain rather than the acute condition [13]. Crucially, this means that a respectable AUC can coexist with clinically meaningless predictions: the model is not robust to structured label noise [12].

III. Materials and Methods

A. Datasets

NIH ChestX-ray14 [1]: a repository containing more than 112,000 chest radiographs annotated with 14 categories of radiological findings. In addition to these pathological labels, the dataset includes the *No Finding* label, which denotes examinations without any of the annotated findings. In the full dataset, *No Finding* exceeds 60,000 images, whereas pathologies such as pneumonia contain fewer than 1,000 samples. This severe imbalance makes direct training highly challenging (Fig. 1).

For the previous approaches, we extracted a subset of 9,419 images focused on five pathologies (Consolidation,

Mass, Nodule, Pneumothorax, and Pneumonia), reorganized for binary screening: 4,000 healthy images (42.5%) and 5,419 diseased images (57.5%). Within the "diseased" class, internal imbalance was substantial: Nodule (1,924, 34.3%) versus Pneumonia (300, 5.4%), a ratio of nearly 6:1 (Fig. 2).

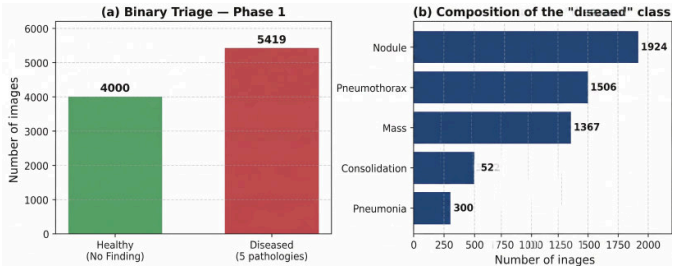

Figure 2. Distribution of the NIH subset used in the previous approaches: (a) binary healthy/diseased screening; (b) internal composition of the "diseased" class by pathology, showing marked imbalance.

For the multilabel formulation, we used a different subset comprising 20,025 images distributed across 13 pathological finding classes. Thus, the *No Finding* label was not included in this setting, and among the 14 original pathological findings of NIH ChestX-ray14, the *Hernia* class was excluded due to its limited sample size. Each retained class had approximately 1,200 training samples.

Curated pneumonia dataset [5]: a binary NORMAL vs. PNEUMONIA collection with *expert-validated labels*. The partition used in our experiments contains 5,216 training images, 16 validation images, and 624 test images (Fig. 3). In contrast to the heterogeneous thoracic findings considered in the NIH experiments, this dataset defines a narrower binary pneumonia classification task and consists of a different patient population. Therefore, performance values obtained across the NIH and Kermany settings should not be interpreted as a controlled comparison of label quality alone.

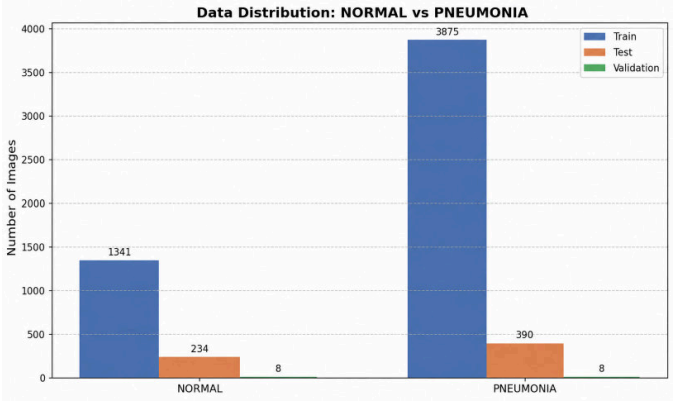

Figure 3. Class distribution of the curated pneumonia dataset in the training, test, and validation partitions. Labels were generated by radiologists rather than by NLP.

Table I summarizes the main differences among the experimental settings. These differences are treated as potential confounding factors when interpreting cross-stage performance.

B. Previous approaches: cascade and multilabel formulation on NIH

The initial approach attempted to classify the five pathologies directly using a single five-class classifier, reaching only 41% accuracy. This result motivated a cascaded architecture: a binary screening stage (Phase 1, "healthy vs. diseased") followed by pathology-specific binary verifiers (Phase 2).

For the initial NIH-based experiments, the selected image subsets were randomly partitioned at the image level, using approximately 80% of the samples for training and 20% for evaluation, with stratification according to the target classes. No patient-level grouping was enforced during this partitioning. Because ChestX-ray14 contains anonymized patient identifiers that may link multiple examinations to the same patient, the absence of patient-level separation is considered a limitation of these experiments.

In **Phase 1**, we evaluated four ImageNet-pretrained architectures—DenseNet-121, VGG-16, ResNet-50, and EfficientNet-B3—at a resolution of 384×384, using class-weighted `BCEWithLogitsLoss`, stratified sampling, and threshold calibration. During the preliminary experiments, an inversion in the class weighting assigned to the `pos_weight` parameter produced opposite collapse modes across three consecutive runs (v1–v3). This configuration issue was corrected in v4.

In the initial **Phase 2** experiments, prior to TorchXRayVision, we evaluated EfficientNet-B2 and DenseNet-121 variants fine-tuned for each disease, where the negative class consisted of diseased images from other pathologies rather than healthy images.

As an additional countercheck, we formulated the problem as a **13-class multilabel** task using the subset of 20,025 images, sweeping modern architectures: EfficientNetV2-L [11], ConvNeXt-Large/XL [10], SwinV2-B, and MaxViT-L, under three training regimes: *head-only*, *full fine-tuning*, and last-block unfreezing.

C. Intermediate approach: TorchXRayVision on NIH

For Phase 2 of the cascade, we incorporated the TorchXRayVision [4] DenseNet-121 model pretrained on multiple radiographic datasets (`densenet121-res224-all`), replacing the classifiers trained from scratch in the previous experiments. The hypothesis was that representations pretrained on domain-specific data would outperform ImageNet weights for radiological pathologies.

The model was adapted for each disease using *partial fine-tuning*: only the final block (`denseblock4`) and the classification head (2 outputs) were trained, while the remaining layers were kept frozen. We used `CrossEntropyLoss` with class weights, the AdamW optimizer, a CosineAnnealingLR scheduler, and early stopping based on `val_f1_binary`. The training set was balanced through *SAMPLE_MODE*, with

Table I
COMPARISON OF THE MAIN EXPERIMENTAL SETTINGS CONSIDERED IN THIS STUDY.

Characteristic	Previous NIH experiments	NIH + TorchXRayVision	Kermany experiment
Population	Predominantly adult chest radiographs	Predominantly adult chest radiographs	Pediatric chest radiographs
Label generation	Automatically derived from radiology reports using NLP	Same NIH label-generation procedure	Expert-validated labels
Main task	Multiclass, binary healthy/diseased, and multilabel classification	Binary pathology-specific classification; pneumothorax reported here	Binary NORMAL vs. PNEUMONIA classification
Disease scope	Multiple heterogeneous thoracic findings	Single pathology within the NIH dataset	Pneumonia
Model configuration	Multiple ImageNet-pretrained and high-capacity architectures	Radiography-pretrained DenseNet-121	Compact CNN trained from scratch
Image resolution	384×384 in Phase 1; configuration-dependent in other experiments	224×224	224×224
Preprocessing	NIH experiment-specific processing	TorchXRayVision-compatible processing	Six-step OpenCV pipeline
Controlled cross-dataset comparison	No	No	No

1,000 positive and 1,000 negative samples for training and 200 positive and 200 negative samples for validation.

The results reported here refer to **Pneumothorax**, selected because of its clinical relevance and its direct connection to the literature on noisy labels (Section II-B). In addition to the default decision threshold of 0.50, a threshold search was performed to maximize binary F1, identifying an adjusted operating point of 0.37. Both operating points are reported to characterize the trade-off between positive-class sensitivity and false-positive predictions.

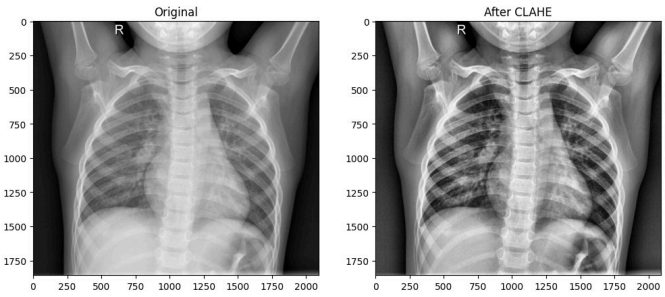

Figure 4. Effect of CLAHE on a chest radiograph: original image (left) and contrast-enhanced image (right). CLAHE makes local lung textures more visible.

D. New approach: OpenCV pipeline and CNN on the Kermany dataset

Given the limitations observed across the NIH experiments, we evaluated a distinct experimental setting using the curated Kermany dataset [5]. This dataset provides a well-defined binary NORMAL vs. PNEUMONIA task with expert-validated labels. The experiment should be interpreted as a separate configuration rather than as a controlled comparison with NIH, since the two settings differ in population, task definition, labeling procedure, preprocessing, and model configuration.

We designed a **six-step OpenCV preprocessing pipeline** applied to each grayscale radiograph: (1) scaling to $[0, 1]$; (2) normalization using training-set statistics (mean 0.477; standard deviation 0.233); (3) contrast enhancement with CLAHE [14] (`clipLimit`$= 2.0$; 8×8 tiles), which increases the salience of local image structures (Fig. 4); (4) validation and removal of corrupted or nearly black images; (5) resizing to 224×224 with padding to preserve aspect ratio; and (6) mild denoising using a 3×3 median filter.

The classifier is a **compact CNN trained from scratch**: three convolutional blocks (Conv–ReLU–MaxPool, with $16/32/64$ filters) followed by a fully connected layer with 128 units, *dropout* (0.5), and a two-class output. It was trained using the RAdam optimizer (learning rate 10^{-3}), cross-entropy loss, and early stopping with a patience of 3, which stopped training at epoch 6.

The validation partition contains only 16 images, which limits the stability of validation-based model selection. Normalization statistics (mean 0.477 and standard deviation 0.233) were derived from the training partition. Because no preprocessing ablation was performed, the reported performance should be attributed to the combined OpenCV pipeline and compact CNN rather than to any individual preprocessing step.

E. Evaluation protocol

We report accuracy, precision, recall, macro-F1, AUROC/AUC, and confusion matrices. For the initial NIH experiments, image subsets were randomly partitioned using an approximately $80/20$ training/evaluation split, with stratification according to the target classes and without patient-level grouping. Per-class recall was additionally monitored

in the binary screening experiments to identify class-specific prediction collapse.

For threshold-dependent analyses, classifier performance was examined at specific operating points. In the TorchXRayVision pneumothorax experiment, the default threshold of 0.50 was compared with an adjusted threshold of 0.37, identified by maximizing binary F1. For the multilabel experiment, the class-wise confusion matrices were generated using Youden's J thresholds.

For the Kermany experiment, accuracy, AUROC, precision, recall, F1-score, specificity, and negative predictive value (NPV) were evaluated on the 624-image test partition. Because the experimental stages differ in dataset, task definition, population, preprocessing, and model configuration, their metrics characterize each setting rather than constitute a controlled cross-dataset comparison.

IV. Results

A. Previous approaches on NIH: cascade and multilabel

Table II summarizes the experimental progression on NIH.

Table II
EXPERIMENTAL PROGRESSION ON NIH CHESTX-RAY14. PHASE 0: DIRECT MULTICLASS CLASSIFICATION. PHASE 1: BINARY SCREENING (HEALTHY VS. DISEASED). R_d AND R_s: RECALL FOR DISEASED AND HEALTHY CLASSES.

Model	Acc	AUC	F1-m	R_d/R_s	Note
Phase 0 — direct 5-class classification					
DenseNet-121	0.41	—	0.39	—	overfitting
VGG-16	0.38	—	0.34	—	lower performance
Phase 1 — binary screening (healthy vs. diseased)					
DenseNet v1	0.65	—	0.61	0.86/0.38	diseased bias
DenseNet v2	0.56	0.762	0.52	0.24/0.97	pos_weight issue
DenseNet v3	0.58	0.745	0.38	1.00/0.01	opposite collapse
DenseNet v4	**0.70**	0.759	**0.69**	0.69/0.70	corrected setup
EfficientNet-B3	0.57	**0.765**	0.37	1.00/0.01	collapse
ResNet-50	0.69	0.756	0.68	0.68/0.70	mild overfitting

The direct multiclass baselines achieved 0.41 accuracy for DenseNet-121 and 0.38 for VGG-16, motivating the subsequent cascaded formulation. In Phase 1, the `pos_weight` inversion produced opposite failure modes in versions v2 and v3, with diseased recall of 0.24 in one configuration and healthy recall of 0.01 in another. After correcting this configuration in v4, DenseNet-121 produced the most balanced class-wise behavior among the evaluated Phase 1 models, with accuracy of 0.70, AUC of 0.759, macro-F1 of 0.69, diseased recall of 0.69, and healthy recall of 0.70. Across the evaluated configurations, AUC values remained approximately within the 0.75–0.76 range. EfficientNet-B3 achieved the highest AUC (0.765), but its healthy-class recall was only 0.01, illustrating that ranking performance alone does not guarantee balanced classification at a particular operating point.

Fig. 5 illustrates the limited variation in AUC across the evaluated Phase 1 configurations, with the valid models remaining approximately within the 0.75–0.76 range.

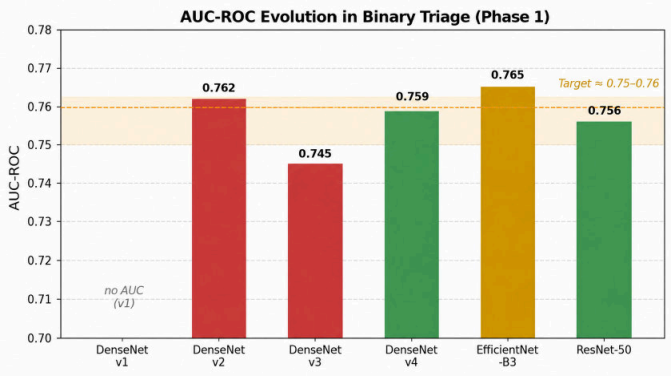

Figure 5. AUC-ROC evolution in binary screening (Phase 1). The evaluated valid configurations remained approximately within the 0.75–0.76 range.

To evaluate whether higher-capacity architectures produced substantial improvements under a different NIH formulation, we assessed the 13-class multilabel setting. The best mean AUROC was 0.774 with EfficientNetV2-L using *full fine-tuning*, while the five best models ranged from 0.759 to 0.774 (Table III).

Table III
MULTILABEL FORMULATION (13 CLASSES): MEAN AUROC ON THE TEST SET. *Full fine-tuning* UNLESS OTHERWISE INDICATED.

Model	Strategy	Mean AUROC
EfficientNetV2-L	full fine-tuning	**0.774**
ConvNeXt-XL	full fine-tuning	0.771
EfficientNet-B4	full fine-tuning	0.768
SwinV2-B	full fine-tuning	0.761
MaxViT-L	full fine-tuning	0.759
DenseNet-121	full fine-tuning	0.755
ConvNeXt-Large	last block	0.709

Even high-capacity architectures such as ConvNeXt-XL, SwinV2-B, and MaxViT-L did not substantially exceed this performance range in the evaluated multilabel setting. Class-wise performance was heterogeneous: findings such as emphysema, edema, and cardiomegaly reached AUROC values of 0.85–0.93, whereas pneumonia and fibrosis remained below 0.80 (Fig. 6). Within the NIH settings evaluated in this study, increasing model capacity or changing the architecture family therefore produced limited overall improvements. Because these experiments share the same underlying dataset and label-generation process, the results motivate examination of additional factors, including label consistency, task formulation, and class composition.

B. Intermediate approach: TorchXRayVision on NIH

The TorchXRayVision DenseNet-121 model (`densenet121-res224-all`), with *partial fine-tuning*, was applied to individual pneumothorax classification in Phase 2 of the cascade. The training curves (Fig. 7) show stable learning over 70 epochs, with decreasing training

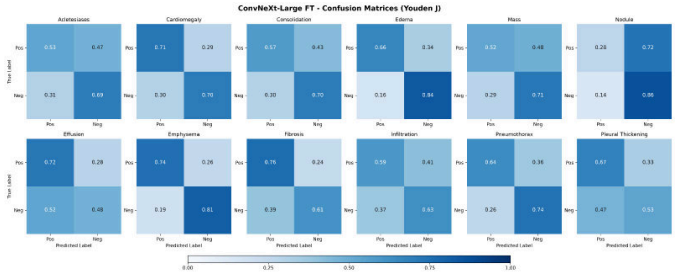

Figure 6. Class-wise confusion matrices using Youden's J threshold for the multilabel ConvNeXt-Large model. Pneumonia and infiltration show substantial classification errors among the evaluated findings.

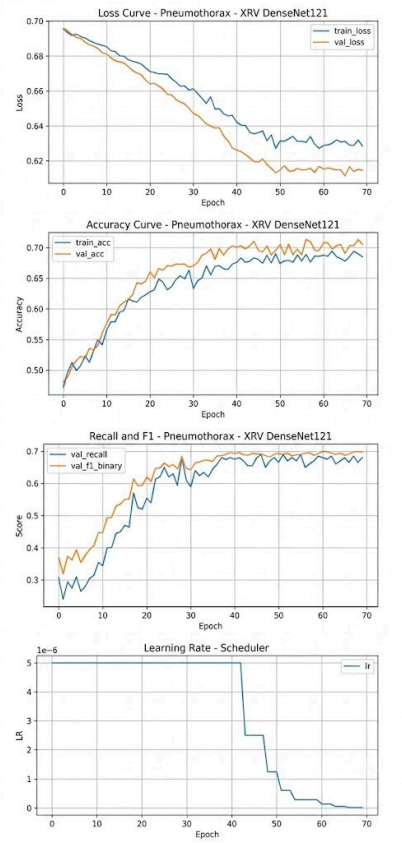

Figure 7. Training curves of TorchXRayVision DenseNet-121 for pneumothorax classification (Phase 2 of the cascade): loss, accuracy, recall/F1, and learning rate over 70 epochs.

and validation losses and validation accuracy converging to approximately 0.70.

With the default threshold of 0.50, the model achieved 0.71 accuracy, with a confusion matrix of 152/48/67/133 (TN/FP/FN/TP) and class-wise recall of 0.76/0.67 for the negative and positive classes, respectively (Fig. 8).

At the adjusted threshold of 0.37, identified by maximizing binary F1, positive-class recall increased to 0.92, while precision decreased to 0.58 and overall accuracy to 0.63. The increase in sensitivity was accompanied by a substantial rise in false-positive predictions and deterioration of negative-class performance (Fig. 9).

Table IV summarizes both operating points. Reducing the threshold from 0.50 to 0.37 increased recall from 0.67 to 0.92, but reduced precision from 0.74 to 0.58 and accuracy from

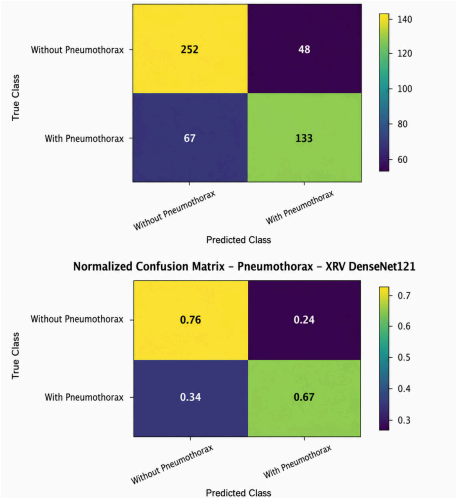

Figure 8. Confusion matrices of TorchXRayVision DenseNet-121 for pneumothorax at the default threshold of 0.50.

Search mode: #1
Best threshold: 0.37
Metrics with best threshold:
{'accuracy': 0.6325, 'precision': 0.5841269841269842, 'recall': 0.92, 'f1_binary': 0.7145631067961165, 'f1_macro': 0.5993868165559529}

Classification report with adjusted threshold:

	precision	recall	f1-score	support
Without Pneumothorax	0.81	0.34	0.48	200
With Pneumothorax	0.58	0.92	0.71	200
accuracy			0.63	400
macro avg	0.70	0.63	0.60	400
weighted avg	0.70	0.63	0.60	400

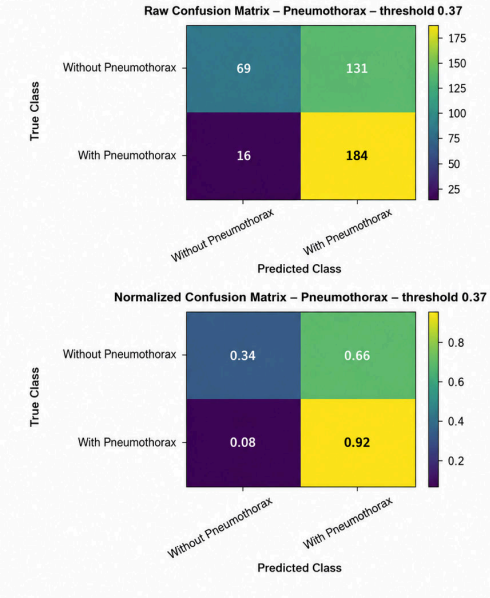

Figure 9. Classification report and confusion matrices at the adjusted threshold of 0.37. Positive-class recall increases to 0.92, while precision and negative-class performance decrease.

0.71 to 0.63, while binary F1 remained approximately stable.

Table IV
TORCHXRAYVISION DENSENET-121 RESULTS FOR PNEUMOTHORAX IN PHASE 2.

Threshold	Acc	Prec	Rec	F1	Macro-F1
0.50	0.71	0.74	0.67	0.70	0.71
0.37	0.63	0.58	**0.92**	0.71	0.60

These results illustrate the trade-off associated with decision-threshold adjustment. The 0.37 operating point should therefore be interpreted as a high-recall configuration within this experiment rather than as a clinically validated threshold. This behavior is also consistent with concerns documented in the literature regarding NIH pneumothorax labels [13]. Previous studies have reported that some labeled pneumothorax images correspond to already treated cases containing visible chest drains, creating the possibility that classifiers associate treatment-related artifacts with the target label. The present experiments do not directly determine which visual features were used by the TorchXRayVision model; however, radiography-specific pretraining alone was insufficient to eliminate the observed classification difficulties.

C. New approach: compact CNN on the Kermany dataset

The compact CNN combined with the six-step OpenCV preprocessing pipeline achieved an AUROC of 0.959, accuracy of 79.7%, precision of 0.755, recall of 0.997, and F1-score of 0.860 on the Kermany test set (Fig. 10). These values characterize the complete preprocessing-and-classification configuration, since the contribution of each preprocessing step was not evaluated separately.

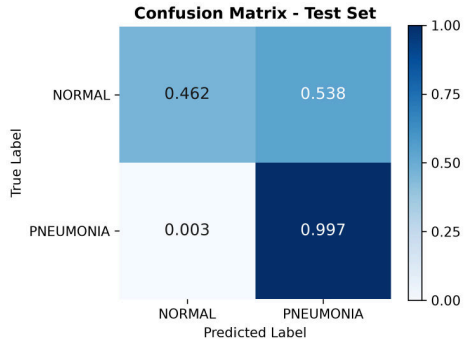

Figure 10. Normalized confusion matrix on the Kermany test set (NORMAL vs. PNEUMONIA). The evaluated operating point achieves very high pneumonia sensitivity while producing a substantial proportion of false-positive predictions among NORMAL images.

Table V summarizes the test-set results. The model achieved AUROC 0.959 and recall 0.997, but specificity was only approximately 0.46, revealing a sensitivity-oriented operating point with a substantial false-positive rate.

Table V
TEST-SET RESULTS (624 IMAGES) FOR THE COMPACT CNN WITH THE SIX-STEP OPENCV PIPELINE ON KERMANY.

Acc	AUROC	Prec	Rec	Spec	NPV	F1
0.797	**0.959**	0.755	**0.997**	≈0.462	≈0.991	0.860

Early stopping halted training at epoch 6. Because the validation partition contains only 16 images, the selected stopping point is sensitive to individual predictions and should be interpreted cautiously. Although the final test-set recall indicates that the evaluated configuration rarely missed pneumonia cases within this dataset, this occurred together with limited specificity.

V. DISCUSSION

Across the evaluated NIH settings, increasing model capacity or changing the architecture family produced limited gains. Binary screening remained around AUC 0.75–0.76, the multilabel experiments reached a maximum mean AUROC of 0.774, and the TorchXRayVision pneumothorax experiment reached recall 0.92 at the adjusted operating point of 0.37, at the cost of substantially more false positives. These findings indicate that architecture or radiography-specific pretraining alone was insufficient to resolve the difficulties observed under the evaluated NIH formulations.

Previous analyses have documented limitations in ChestX-ray14 labels, which were extracted from radiology reports rather than generated through direct image annotation [12], [13]. Our results are consistent with concerns regarding ambiguous or indirect labels, but they do not establish label quality as the sole cause of the NIH performance profile. In particular, the Kermany experiment represents a different setting: a curated pediatric binary NORMAL vs. PNEUMONIA task, with different population, preprocessing, architecture, and training procedure. Therefore, its AUROC of 0.959 cannot be directly interpreted as evidence that label quality alone explains the improvement.

The Kermany results should also be interpreted as the performance of the combined six-step preprocessing pipeline and compact CNN because no preprocessing ablation was performed. The distinction between discrimination and operating-point performance is important: an AUROC of 0.959 indicates strong ranking ability across possible thresholds, but it does not imply balanced classification at the evaluated operating point. Recall reached 0.997, whereas specificity was approximately 0.462, indicating that the high sensitivity was accompanied by a substantial false-positive rate. The validation partition contains only 16 images, further limiting the stability of early stopping and model-selection decisions.

The NIH experiments also have limitations related to data partitioning and threshold-dependent evaluation. The initial NIH subsets were randomly partitioned at the image level using an approximately 80/20 split, without grouping examinations by patient identifier. Consequently, images from the same patient may occur in different partitions, potentially

increasing similarity between training and evaluation samples. In addition, the improvement in pneumothorax recall obtained by reducing the decision threshold from 0.50 to 0.37 illustrates the strong dependence of sensitivity and specificity on the selected operating point. These threshold-dependent results should therefore be interpreted together with threshold-independent metrics such as AUROC rather than in isolation.

Overall, the experiments suggest that dataset curation, label consistency, task definition, population, preprocessing, partitioning strategy, and model design should be considered jointly. The NIH–Kermany comparison is observational rather than a controlled ablation; isolating the effect of label quality would require the same pneumonia task, architecture, preprocessing, resolution, patient-aware partitioning strategy, and evaluation protocol on both datasets. External validation would also be required before conclusions regarding clinical applicability.

VI. Conclusion

This paper presented a three-stage experimental investigation of deep learning approaches for pulmonary disease detection in chest radiographs. Across the evaluated NIH ChestX-ray14 settings, including direct multiclass classification, binary screening, multilabel classification, and radiography-specific TorchXRayVision pretraining, changing or increasing model capacity produced relatively limited performance gains. In the pneumothorax experiment, recall increased to 0.92 at the adjusted threshold of 0.37, but this improvement was accompanied by a substantial increase in false-positive predictions.

In a separate experimental setting, a compact CNN combined with a six-step OpenCV preprocessing pipeline achieved an AUROC of 0.959 and recall of 0.997 for binary pneumonia classification on the curated Kermany dataset. However, this operating point also showed limited specificity, and the Kermany setting differs from the NIH experiments in patient population, task definition, labeling procedure, preprocessing, and model configuration. The observed cross-setting performance difference therefore cannot be attributed exclusively to data quality or label consistency.

Overall, the results show that increasing architecture complexity alone did not substantially improve performance within the evaluated NIH settings, whereas a simpler model achieved stronger discriminative performance under a narrower and differently curated experimental configuration. Together with previous evidence regarding inconsistencies in ChestX-ray14 labels [12], [13], these findings reinforce the importance of considering label reliability, dataset curation, task definition, population, preprocessing, and model design jointly rather than interpreting model capacity in isolation.

Future work should include a controlled pneumonia-versus-normal comparison between NIH ChestX-ray14 and Kermany using the same architecture, preprocessing, input resolution, data-partitioning strategy, and evaluation protocol. Additional experiments should also investigate the individual contribution of the OpenCV preprocessing stages through ablation studies and assess model generalization on independent external cohorts before conclusions regarding clinical applicability are drawn.

***Abstract*—Stroke is the leading cause of disability worldwide and often leads to speech impairments such as aphasia and dysarthria. Recent advances in Artificial Intelligence have enabled the development of automated methods to support speech assessment in people after stroke. This study presents a literature review of Artificial Intelligence techniques applied to the automatic analysis of post-stroke speech. Twelve studies published between 2020 and 2026 were analyzed with respect to datasets, preprocessing methods, computational architectures, evaluation metrics, and reported results. Most studies employed deep learning approaches, particularly convolutional neural networks and hybrid models, achieving promising performance in speech assessment. However, common limitations included small datasets, methodological heterogeneity, limited external validation, and the scarcity of publicly available databases. These findings highlight the potential of Artificial Intelligence to support clinical assessment after stroke while emphasizing the need for more robust and standardized research.**

***Index Terms*—Stroke, Speech Analysis, Artificial Intelligence, Deep Learning, Aphasia, Dysarthria.**

I. Introduction

Stroke is a neurological emergency characterized by the interruption of cerebral blood flow due to the occlusion or rupture of a blood vessel, leading to brain tissue damage and neurological impairment. It is one of the leading causes of mortality and long-term disability worldwide. In 2021, an estimated 11.9 million new stroke cases and 93.8 million stroke survivors living with long-term sequelae were reported, making stroke the third leading cause of death and disability globally. Furthermore, approximately one in four individuals is expected to experience a stroke during their lifetime, highlighting its increasing burden on healthcare systems and quality of life worldwide [1]. Among the most common sequelae are motor, cognitive, and communication impairments which substantially affect social participation, functional independence, and the rehabilitation process. In this context, early multidisciplinary rehabilitation, including speech-language therapy, plays a fundamental role in functional recovery and improving patients' quality of life [1], [2].

Among the most disabling consequences of stroke are communication disorders, particularly aphasia and dysarthria. Aphasia affects language comprehension and/or production as a result of brain lesions, whereas dysarthria arises from impairments in the neuromuscular control of speech, impacting respiration, phonation, articulation, and resonance. Aphasia is estimated to affect approximately one-third of stroke survivors, while dysarthria is present in about 30–40% of patients in the acute phase and may persist for months after the event, significantly affecting speech intelligibility, social interaction, functional independence, and quality of life [3], [4]. In this context, speech-language assessment is essential to characterize impairments, monitor clinical evolution, and guide therapeutic planning. However, clinical practice is still characterized by heterogeneity in assessment methods, reliance on perceptual-auditory evaluation, and limitations related to the availability of specialized services, which hinder standardization of protocols and longitudinal patient monitoring [3], [4].

In light of these limitations, computational methods for automatic speech analysis have gained increasing attention as supportive tools in clinical practice. The advancement of Artificial Intelligence (AI), particularly techniques based on machine learning, deep learning, automatic speech recognition, and natural language processing, has enabled the development of systems capable of identifying acoustic and linguistic patterns associated with communication disorders, contributing to objective evaluation, monitoring of clinical progression, and decision-making support in therapeutic planning [5]. Beyond improving analytical precision, these approaches also offer potential to support remote monitoring and expand access to

This paper was produced with the assistance of artificial intelligence tools (OpenAI - ChatGPT) for text review, and English translation. The scientific content, literature analysis, article selection, interpretation of findings, and conclusions are the sole responsibility of the authors.

specialized care, especially in settings with limited availability of healthcare professionals.

Although the number of studies investigating automatic speech analysis in post-stroke individuals has increased substantially in recent years, considerable heterogeneity remains regarding the study populations, languages, speech tasks, datasets, pre-processing strategies, AI architectures, and performance metrics employed. This variability hinders direct comparison of the reported findings, limits the reproducibility of the proposed methods, and makes it difficult to identify the approaches with the greatest potential for clinical application. Therefore, a critical synthesis of the available evidence is needed to provide a comprehensive overview of the current state of the field, identify methodological trends, and highlight research gaps that may guide future investigations.

In this context, this study presents a narrative literature review on the application of AI techniques to automatic speech analysis in individuals affected by stroke. The objective was to critically analyze studies published between 2020 and 2026, comparing the datasets used, the investigated populations, speech acquisition protocols, preprocessing strategies, Artificial Intelligence architectures, evaluation metrics, and the main reported results. In addition, the study discusses the recurring limitations in the literature and the prospects for the development of more robust methods with greater potential for clinical application.

II. Methodology

This study presents a narrative literature review on the application of AI and deep learning techniques to automatic speech analysis in stroke-affected individuals, with a particular focus on communication disorders associated with aphasia and dysarthria.

A. Search Strategy and Data Sources

The literature search was conducted using the Scopus, Web of Science, PubMed, and Virtual Health Library (VHL) databases, selected for their broad coverage of publications in the fields of biomedical engineering, health sciences, and applied computing.

The search strategy was developed by combining four groups of keywords. The first group included terms related to stroke, namely “stroke”, “cerebrovascular accident”, and “post-stroke”. The second group included terms related to speech and language disorders, such as “dysarthria”, “aphasia”, “speech impairment”, and “speech disorder”. The third group comprised terms related to automatic speech analysis and processing, including “speech recognition”, “automatic speech analysis”, “acoustic analysis”, “voice-based”, “audio-based”, “speech analysis”, and “automatic speech recognition”. Finally, the fourth group consisted of terms related to deep learning techniques, namely “CNN”, “deep learning”, and “convolutional network”. The searches were conducted between April 25, 2026, and July 12, 2026, with the final search performed on July 12, 2026. This search was conducted by two reviewers, who obtained the same result.

For Scopus, the complete search strategy was: “(TITLE-ABS-KEY (stroke OR “cerebrovascular accident” OR “post-stroke”) AND TITLE-ABS-KEY (dysarthria OR aphasia OR “speech impairment” OR “speech disorder”) AND TITLE-ABS-KEY (“speech recognition” OR “automatic speech analysis” OR “acoustic analysis” OR “voice-based” OR “audio-based” OR “speech analysis” OR “automatic speech recognition”) AND TITLE-ABS-KEY (“CNN” OR “deep learning” OR “convolutional network”)) AND PUBYEAR $>$ 2019 AND PUBYEAR $<$ 2027 AND (LIMIT-TO (SRCTYPE , “j”)) AND (LIMIT-TO (DOCTYPE , “ar”)) AND (LIMIT-TO (LANGUAGE , “English”))”.

For Web of Science, the search was conducted in the Core Collection using the query builder with the following strategy: “TS=(“stroke” OR “cerebrovascular accident” OR “post-stroke”) AND TS=(“dysarthria” OR “aphasia” OR “speech impairment” OR “speech disorder”) AND TS=(“speech recognition” OR “automatic speech analysis” OR “acoustic analysis” OR “voice-based” OR “audio-based” OR “speech analysis” OR “automatic speech recognition”) AND TS=(“CNN” OR “deep learning” OR “convolutional network”) AND PY=(2020-2026) AND DT=(Article) AND LA=(English)”.

For PubMed, the following search strategy was used: “((”stroke”[Title/Abstract] OR “cerebrovascular accident”[Title/Abstract] OR “post-stroke”[Title/Abstract]) AND (“dysarthria”[Title/Abstract] OR “aphasia”[Title/Abstract] OR “speech impairment”[Title/Abstract] OR “speech disorder”[Title/Abstract]) AND (”speech recognition”[Title/Abstract] OR “automatic speech analysis”[Title/Abstract] OR “acoustic analysis”[Title/Abstract] OR “voice-based”[Title/Abstract] OR “audio-based”[Title/Abstract] OR “speech analysis”[Title/Abstract] OR “automatic speech recognition”[Title/Abstract]) AND (“CNN”[Title/Abstract] OR “deep learning”[Title/Abstract] OR “convolutional network”[Title/Abstract])) AND (“2020/01/01”[Date - Publication] : “2026/12/31”[Date - Publication]) AND english[Language] AND journal article[Publication Type]”.

For the Virtual Health Library (VHL), the following search strategy was used: “(ti:(stroke OR ”cerebrovascular accident” OR “post-stroke”) OR ab:(stroke OR ”cerebrovascular accident” OR “post-stroke”)) AND (ti:(dysarthria OR aphasia OR “speech impairment” OR “speech disorder”) OR ab:(dysarthria OR aphasia OR “speech impairment” OR “speech disorder”)) AND (ti:(“speech recognition” OR “automatic speech analysis” OR “acoustic analysis” OR “voice-based” OR “audio-based” OR “speech analysis” OR “automatic speech recognition”) OR ab:(“speech recognition” OR “automatic speech analysis” OR “acoustic analysis” OR “voice-based” OR “audio-based” OR “speech analysis” OR “automatic speech recognition”)) AND (ti:(“CNN” OR “deep learning” OR “convolutional network”) OR ab:(“CNN” OR “deep learning” OR ”convolutional network”))”.

In the VHL, the publication year (2020–2026), study type (journal article), and language (English) filters were applied through the platform settings.

Initially, studies were screened based on their titles and abstracts to determine whether they addressed voice, speech, or language analysis in individuals affected by stroke and used artificial intelligence techniques. Studies focused on classification, recognition, diagnosis, or automated speech analysis were considered eligible.

Studies were excluded if they were not directly related to stroke or communication disorders, relied exclusively on non-speech signals such as electroencephalography (EEG), medical imaging, or motor signals, or were review articles, editorials, book chapters, or publications without full-text availability that prevented adequate extraction of methodological data.

B. Study Selection Process

Titles and abstracts were initially screened, followed by full-text assessment of potentially eligible studies. For each database, a manual search was conducted for duplicate articles already identified in previous databases. This deduplication was performed manually by comparing the titles, DOIs, and authors of potentially duplicate articles. All this screening and selection process was conducted by two independent reviewers, and there were no disagreements between them.

The search of Scopus retrieved 13 records, of which 10 studies were included in the final analysis. Two potentially relevant articles could not be fully assessed because their full texts were unavailable, while one study was excluded because it relied exclusively on brain signals without performing voice or speech analysis. Thus, 10 articles were selected from Scopus.

The Web of Science search identified seven records. Of these, two additional articles were included in the review, whereas the five remaining records corresponded to studies previously identified in Scopus, and this correspondence was manually checked by comparing the titles and authors. These studies were therefore considered duplicates. Thus, two additional articles were included from the Web of Science search.

The PubMed search yielded six records, four of which had already been identified in the other databases and were therefore considered duplicates, again based on a manual comparison of titles and authors. Of the remaining two records, one was a review article and the other was excluded because it relied exclusively on brain signals rather than speech analysis and therefore did not meet the predefined eligibility criteria. No additional studies were included from PubMed.

The search conducted in the Virtual Health Library (VHL) identified six records. All of these records corresponded to articles previously retrieved from the other databases and were therefore considered duplicates, based on a manual check of titles and authors. Thus, no additional studies were included from the VHL search.

After screening and application of the eligibility criteria, 12 studies were included in the qualitative synthesis. Figure 1 presents the PRISMA flow diagram of the identification, screening, eligibility assessment, and inclusion process.

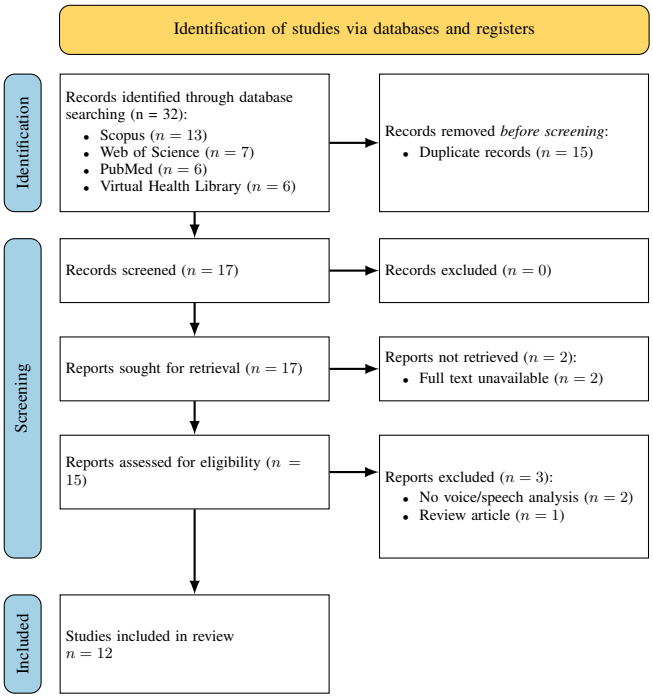

Figure 1. PRISMA flow diagram summarizing the study selection process.

C. Data Extraction and Analysis

For each included study, information was extracted on the year of publication, study objective, characteristics of the dataset, study population, speech tasks, preprocessing procedures, computational techniques and architectures, speech acquisition methods, extracted acoustic features, performance metrics, main findings, and the limitations reported by the authors. This stage was conducted by a reviewer.

The extracted data were summarized in comparative tables, enabling the systematic synthesis of the methodological characteristics and principal findings of the selected studies.

Data analysis was performed using a descriptive qualitative approach to identify trends in the application of AI and deep learning techniques to speech analysis in post-stroke individuals. Furthermore, research gaps and opportunities for the development of novel approaches to the automated assessment of speech impairments associated with aphasia and dysarthria were identified.

III. Results and Discussion

A. Overview of the Included Studies

Twelve studies published between 2020 and 2026 were included. The studies present different applications of artificial intelligence and deep learning for automatic speech analysis in the post-stroke context, ranging from diagnosis and screening to aphasia assessment, speech recognition, therapy, and assistive communication. This diversity of applications makes direct comparison between studies challenging, as the objectives, populations, speech tasks, and evaluation protocols differ across studies. Tables I and II provide an overview of the

datasets, population and stroke stage, language and speech task categories, application types, recording devices and conditions, extracted features, split and segmentation units, techniques, and primary outcomes reported by the included studies.

Overall, the identified studies can be grouped into four main application areas. The first comprises systems designed for stroke diagnosis or screening through automatic speech analysis. Within this category, the multimodal DeepStroke framework stands out for integrating speech and facial expression features to assist in the identification of stroke patients in emergency settings [10]. Similarly, [16] proposed an early diagnosis system based on sustained vowels and spontaneous speech, incorporating a speech enhancement module prior to the classification stage. Their findings suggest that reducing background noise can improve the performance of speech-based classification models.

A second research direction focuses on automatic speech recognition systems primarily targeting dysarthria, the most frequently addressed communication disorder among the included studies. Rather than merely detecting the presence of the disorder, these approaches aim to improve speech intelligibility or enhance the performance of automatic systems when applied to pathological speech. While some authors proposed hybrid architectures for dysarthric speech classification [9], [14], others investigated communication support strategies by comparing different speech processing approaches [11] or developing TinyML-based embedded devices for speech rehabilitation [13].

The third research direction encompasses studies focused on automated language assessment in individuals with aphasia. Unlike dysarthria-focused studies, which primarily emphasize speech intelligibility, these works aim to objectively reproduce tasks traditionally performed by speech-language pathologists during clinical assessment and follow-up. Within this context, researchers have developed models for the automatic assessment of aphasic speech [7], systems for verifying picture-naming tasks during speech therapy [8], and comparative evaluations of architectures specifically trained for pathological speech against commercial automatic speech recognition platforms, highlighting the potential advantages of specialized models for post-stroke populations [12]. Complementing this line of research, [17] presented a case study involving a patient with global aphasia associated with dysarthria, demonstrating the potential use of personalized models to support communication in individuals with severe speech impairment.

In addition to these specific applications, broader approaches aimed at developing more generalizable speech analysis models were also identified. [15] proposed a multitask architecture capable of integrating phonetic recognition, temporal alignment, and articulatory trajectory prediction into a single deep learning model using publicly available datasets comprising both healthy speakers and individuals with dysarthria. In contrast, [6] investigated different acoustic representations for detecting speech impairments associated with various neurological disorders, including stroke, providing a methodological reference for subsequent studies.

Although dysarthria represents the predominant clinical focus among the analyzed studies, the included literature addresses different clinical objectives, ranging from screening and classification to language assessment, speech recognition, and therapeutic support. Therefore, the reported results should be interpreted according to the specific objective and protocol of each study, rather than being considered directly comparable solely on the basis of the reported performance metrics. This heterogeneity is particularly relevant when interpreting differences in model performance, as variations in datasets, speech tasks, recording conditions, preprocessing procedures, and evaluation strategies may influence the reported outcomes.

B. Datasets

The analyzed studies showed substantial variability in the datasets employed, reflecting one of the main challenges currently faced by this research field: the limited availability of large, standardized public datasets for automatic speech analysis in post-stroke populations. As a result, most studies relied on proprietary datasets. Of the 12 studies included, eight were based exclusively on proprietary datasets [6], [7], [9]–[12], [16], [17], two combined proprietary and public datasets [8], [13], and only two relied exclusively on publicly available datasets widely used in the literature [14], [15].

This predominance of proprietary datasets indicates that many research groups still need to conduct dedicated data collection campaigns to obtain datasets suitable for training deep learning models. In contrast, studies relying on public datasets were primarily based on resources originally developed for speech recognition or articulatory analysis, such as TORGO, UASpeech, CommonPhone, HPRC, Nemours, and Speech Commands v2 [13]–[15]. Although these datasets are widely used in the literature, they differ in terms of language, speech tasks, number of participants, and clinical characteristics, making direct comparisons between the proposed models more challenging.

Considerable variability was also observed in the composition of the study populations. While some studies included relatively large cohorts, such as the DeepStroke framework, which was developed using data from 221 individuals evaluated in emergency settings [10], others relied on much smaller samples, including eight individuals with aphasia [8], a single patient with global aphasia and dysarthria [17], or even healthy volunteers simulating dysarthric speech to evaluate rehabilitation devices [13]. Between these extremes, most studies enrolled groups comprising individuals affected by stroke and healthy controls, typically involving a few dozen participants [7], [9], [11], [16]. Such variability complicates direct comparisons across studies and limits the generalizability of the proposed models.

Regarding language, English and Mandarin were the most frequently represented in the analyzed datasets. English predominated in the public datasets used for automatic speech recognition, including TORGO, UASpeech, CommonPhone, and Nemours [14], [15], whereas Mandarin was adopted in studies that collected proprietary datasets for the assessment

of post-stroke aphasia and dysarthria [7], [9], [16]. Studies involving Italian [17], Indonesian [13], and Lithuanian [6] were also identified. Despite this linguistic diversity, no studies using publicly available datasets composed of Brazilian Portuguese speakers were identified, highlighting an important gap for the development and validation of tools intended for the Brazilian clinical setting.

Speech tasks also varied considerably across the analyzed studies. Sustained vowels were primarily employed in studies focused on early stroke diagnosis or dysarthria classification, as they provide more controlled speech samples and facilitate the extraction of acoustic features [9], [16]. Other studies relied on syllables, isolated words, or picture-naming tasks for aphasia assessment [7], [8], [12], [17], whereas standardized sentences and voice commands were adopted in automatic speech recognition systems and rehabilitation devices [11], [13], [14]. Only a few studies incorporated spontaneous speech into their data collection protocols, typically in combination with structured tasks, as reported by [16] and in the multimodal DeepStroke framework [10]. Taken together, these findings indicate that there is still no consensus regarding speech acquisition protocols for AI-based applications in the post-stroke context. This lack of standardization hampers both direct comparisons across studies and the development of publicly available shared datasets for training and validating AI models.

C. Preprocessing and Speech Signal Representation

Initial preprocessing steps were primarily intended to reduce the effects of noise and standardize the audio signals. Procedures such as amplitude normalization, recording segmentation, and removal of silent segments were reported across different studies [7], [8], [17]. In applications focused on early stroke diagnosis, [16] adopted a more elaborate strategy by incorporating a dedicated Speech Enhancement module based on the SEWUNet architecture prior to the classification stage, demonstrating that improvements in signal quality led to performance gains of approximately 10% in the trained models. Similarly, [17] applied voice activity detection (VAD), normalization, and noise reduction using spectral gating, whereas [13] implemented embedded processing compatible with TinyML devices, prioritizing computationally efficient operations.

Another strategy adopted by some studies was data augmentation, mainly employed when the number of available samples was limited. Among the analyzed studies, this approach was explicitly reported by [16], who applied different augmentation techniques to expand the spontaneous speech dataset prior to neural network training. In contrast, several studies did not report the use of data augmentation, relying instead on cross-validation strategies or on architectures specifically designed for small patient datasets [8], [9], [17].

Following preprocessing, feature extraction and signal representation constituted the predominant intermediate step between the raw speech signal and the AI models. Mel-Frequency Cepstral Coefficients (MFCCs) were the most frequently used representation, being employed in studies addressing both aphasia and dysarthria [6]–[10], [16], [17]. Their widespread use can be attributed to their ability to capture perceptually relevant characteristics of speech while maintaining low computational cost, making them particularly suitable for clinical applications and embedded devices.

More recent studies, however, have increasingly adopted two-dimensional feature representations capable of simultaneously preserving temporal and spectral information. Mel-spectrograms were used as input for convolutional and hybrid models in several studies [14], [16], whereas conventional spectrograms were also employed for comparison with MFCC-based representations [9]. These findings suggest that models based on MFCCs outperformed those trained directly on spectrograms, indicating that the choice of speech representation still depends on the characteristics of the task and the available dataset.

Beyond the representations traditionally employed in speech analysis, several studies explored more specialized descriptors. [6] compared three different feature representations, cepstrum, auditory spectrogram, and Wavelet Time Scattering (WTS), demonstrating that these descriptors capture complementary aspects of the speech signal. In turn, [11] employed Phonetic Posteriorgrams (PPGs) to encode phonetic information while comparing assistive systems based on automatic speech recognition. Meanwhile, [15] integrated articulatory information acquired from Electromagnetic Articulography (EMA) sensors with conventional acoustic features, thereby bringing computational models closer to the physiological mechanisms underlying speech production.

Overall, the analyzed studies reveal a gradual evolution in speech signal representation strategies. Earlier studies relied primarily on manually engineered acoustic features, such as MFCCs and cepstral representations [6], [7], whereas more recent work has increasingly adopted richer feature representations, including Mel-spectrograms, articulatory information, and models capable of learning discriminative patterns directly from these representations [14]–[16]. This evolution suggests that the performance of deep learning models depends not only on the model architecture but also on the quality of preprocessing and the representativeness of the features extracted from the speech signal.

D. Artificial Intelligence Architectures and Strategies

The AI architectures employed varied considerably across the analyzed studies. Rather than following a uniform progression toward increasingly complex models, the literature includes convolutional neural networks, hybrid CNN-LSTM architectures, Transformer-based models, transfer learning strategies, multimodal approaches, TinyML implementations, and personalized models. This heterogeneity reflects the different clinical objectives and speech analysis tasks addressed by the included studies.

CNNs were used in several of the included studies, covering applications such as automated aphasia assessment, dysarthric speech recognition, rehabilitation, and early stroke diagnosis [7], [9], [10], [13], [14], [16]. However, their use should not be

Table I
SUMMARY OF DATASETS, POPULATION, SPEECH TASKS, APPLICATION TYPES, AND RECORDING CONDITIONS.

Ref.	Dataset Type	Population & Stroke Stage	Language / Speech Task Category	Application Type	Recording Device & Condition
[6]	Own	15 (7 CNSD [1 acute stroke] + 8 HC); N=339	English, Lithuanian / Poem reading	Screening / Clinical Support	Android (NITS app); Presential (Supervised)
[7]	Own	46 (12 PWA [stroke 8–1096d] + 34 HC); N=402	Mandarin / 6 vowels, 20 words (CRRCAE)	Severity / In-Home Therapy	Lenovo Recorder Pen (48 kHz); Soundproof/Ward
[8]	Own/Public	8 PWA (chronic, 14–109m) + 140 HC; N=1,760	British English / Picture naming (220 words)	Anomia Support / In-Home Verification	Galaxy Tab S3 + Headset (16 kHz); Presential
[9]	Own	116 (71 PSD + 45 HC); N=7,318	Mandarin / 81 single syllables (vowels/digits)	Screening / Clinical Support	Prof. Recording Setup; Hospital (Supervised)
[10]	Own	221 (159 acute stroke/TIA + 62 ER ctrl); N=221	English / Sentences + Picture description	Emergency Triage Support	iPhone X (video+audio); Unconstrained ER
[11]	Own	14 (10 CVA + 4 CP; 4 mild, 9 mod, 1 sev)	Mandarin / Sentence reading (320 TMHINT)	SE / Communication Assist	Audio Setup; Soundproof (Supervised)
[12]	Own	46 (12 PWA + 34 HC)	Mandarin / Naming & Repetition (CRRCAE)	Screening / Aphasia Support	Lenovo Recorder Pen (48 kHz); Presential
[13]	Own/Public	2 sim. dysarthria + TORGO/SpeechCmds; N=106k	Bahasa Indonesia, English / Voice commands + Vowels	Assistive Robotic Control	INMP441 Mic + ESP-32; Lab (24–62 dB noise)
[14]	Public	11 dysarthria (Nemours) + 4 HC; 15 dys + 13 HC; N=3,700	English / Nonsense sentences + Words	Screening / Pathological ASR	Studio Mics; Soundproof/Controlled
[15]	Public	8 HC (HPRC) + CommonPhone + TORGO + UA (28 spk)	English / Sentences (IEEE) + Words	Multitask Articulation & Intelligibility	EMA + Array Mics; Lab + Crowdsourced
[16]	Own	64 (32 stroke + 32 HC); Test: 34 (24 stroke + 10 HC); N=1.9k	Mandarin / 6 SVs (/a,o,e,i,u,ü/) + 1 SS sentence	Early Diagnosis / Real-time Triage	USB Mic + Laptop C/S + WeChat; Quiet Ward
[17]	Own	1 female (chronic, 15y post-stroke; sev. dysarthria); N=2,056	Italian / 13 words (5 prompt types)	Assistive VIVOCA / AAC Support	Headset Mic + CapisciAMe App (16 kHz); Quiet Room

Abbreviations: HC = Healthy Controls; PWA = People with Aphasia; PSD = Post-Stroke Dysarthria; CNSD = Central Nervous System Disorders; TIA = Transient Ischemic Attack; ER = Emergency Room; CVA = Cerebrovascular Accident; CP = Cerebral Palsy; SVs = Sustained Vowels; SS = Spontaneous Speech; SE = Speech Enhancement; ASR = Automatic Speech Recognition; AAC = Augmentative and Alternative Communication; NITS = Neural Impairment Test Suite; CRRCAE = Chinese Rehabilitation Research Center Aphasia Examination; TMHINT = Taiwan Mandarin Hearing-in-Noise Test; N = Total audio samples; d = days; m = months; y = years; spk = speakers.

Table II
SUMMARY OF AI MODELS AND VALIDATION PROTOCOLS.

Ref.	Features	Split / Segmentation Unit	Technique	Primary Outcome
[6]	Pitch, MFCC, GTCC, Auditory Spectrogram, WST	Segment-level (20–40 ms frames)	BiLSTM; WST + SVM	Acc.: 96.3% (WST+SVM), 94.5% (BiLSTM)
[7]	HTD (TFD RGB Images); 51 MFCC/Formants	Sample-level (Word/Vowel segments)	ResNet-34 (Transfer Learning) + LinReg	Acc.: 99.23% (words); Articulation r_s=0.71, Fluency r_s=0.60
[8]	26 Acoustic (12 MFCC, Energy, Deltas) $\rightarrow$ PPGs	Item-level (Single-word matrices)	7-layer BiGRU DNN + DTW Matching	10-fold CV: 89.5% acc.; Adapted: 91.3% vs Google STT (88.2%)
[9]	30 MFCC coefficients	Speaker-level split / Syllables	1DCNN + Double-LSTM + Soft-majority	Syllable Acc.: 75.5%; Speaker Acc.: 84.8%
[10]	Video frame diff. + Log-Mel Spectrogram	5-fold CV / Time-cutoff Holdout	Dual-branch ResNet (34+18) + Adv. Disc.	Case Acc.: 71.40%, Sens.: 81.13%, AUC: 0.7163 (vs 64.03% triage)
[11]	LPS (SE), WORLD Envelopes (VC), MFCC/PPG	Speaker-dependent split / Sentences	DNN-SE vs Gated-CNN VC vs ASR-TTS	ASR-TTS: 93.8% ASR acc., 95.5% Intelligibility, 4.56 MOS
[12]	Hyperbolic T-Distribution (HTD) RGB Images	5-fold CV / Word-level	CNN (ResNet-50 + HTD) vs ASR APIs	CNN Acc.: 99.64% (healthy), 67.78% (aphasic) vs Azure (88.09%)
[13]	STFT Log-Spectrogram (99 $\times$ 43 pixels)	80/10/10 Split / 1s audio frames	Lightweight 2DCNN + INT8 (TinyML)	Val. Acc.: 94.0%; Real-time ESP-32: 95% (24dB), 50% (62dB noise)
[14]	Mel-Spectrograms + Augmentation + Ensemble	80/20 Holdout Split / Utterances	Tran-DSR (Ensemble + ViT Encoder)	Acc.: 99.18% (Nemours/ASVSpoof), 98.98% (UASpeech)
[15]	Raw Audio (16kHz) $\rightarrow$ Wav2Vec2 (49Hz) + 9 TVs	LOSO / 70/15/15 Split / Utterances	f-APTAI (Wav2Vec2 + Cross-Attn + BiLSTM)	AAI: Mean PCC=0.71, RMSE=0.68mm; Intelligibility R=-0.96
[16]	88 Handcrafted (SVs); Mel-Spectrograms (SS)	5-Fold CV (Speaker-split) / Utterances	SEWUNet + AdaBoost (SVs) + CNN-Trans. (SS)	SVs Acc.: 92.31%; SS Acc.: 96.00%; Clinical 2-Stage Acc.: 100%
[17]	39 MFCCs (with Deltas) as 2D Representations	Session-based temporal / Word-level	Speaker-dependent Compact CNN	Tailored ASR Word Acc.: 72.65% vs Human Listeners: 56.75% ($p < 0.001$)

Abbreviations: MFCC = Mel-Frequency Cepstral Coefficients; GTCC = Gammatone Cepstral Coefficients; WST = Wavelet Scattering Transform; HTD = Hyperbolic T-distribution; TFD = Time-Frequency Distribution; PPG = Phonetic Posteriorgrams; LPS = Log-Power Spectrum; STFT = Short-Time Fourier Transform; TVs = Tract Variables; SVs = Sustained Vowels; SS = Spontaneous Speech; BiLSTM = Bidirectional LSTM; BiGRU = Bidirectional GRU; ViT = Vision Transformer; LOSO = Leave-One-Speaker-Out; CV = Cross-Validation; AAI = Acoustic-to-Articulatory Inversion; PCC = Pearson Correlation; RMSE = Root Mean Square Error; MOS = Mean Opinion Score; Acc = Accuracy; Sens = Sensitivity; AUC = Area Under Curve; r_s = Spearman correlation; R = Pearson correlation.

interpreted as evidence of a single dominant architecture across the literature, since the studies employed different datasets, speech tasks, input representations, and evaluation protocols.

Despite the frequent use of CNN-based approaches, several studies adopted alternative or hybrid architectures. In [9], a 1D CNN was combined with a Double-LSTM to capture local features and temporal dependencies within the speech signal. A similar strategy was adopted by [14], who developed the Tran-DSR model by integrating ensemble CNNs with a Transformer Encoder. These approaches illustrate how different architectures have been combined according to the characteristics of the speech analysis task rather than following a single architectural strategy.

Several studies also compared different AI strategies using the same dataset. [12] compared their CNN- and LDA-based models with the Microsoft Azure and Google Speech Recognition platforms, reporting superior performance for models specifically trained on pathological speech. Likewise, [11] evaluated three approaches aimed at improving speech intelligibility, Speech Enhancement, Voice Conversion, and Automatic Speech Recognition combined with Text-to-Speech, with the latter achieving the best overall performance. These comparisons indicate that performance depends not only on the model architecture but also on the specific task, speech representation, and system configuration.

Transfer learning was another strategy identified in the reviewed studies. In [16], a pretrained ResNet was employed for spontaneous speech recognition, whereas a separate SEWUNet-based model was first used to enhance the speech signal. The use of pretrained architectures may be particularly relevant in clinical speech applications, where datasets are often relatively small and difficult to collect. However, the potential advantages of transfer learning should be interpreted cautiously, as pretrained models may be affected by differences between their original training data and pathological speech datasets.

Other studies explored alternative architectural designs. DeepStroke integrated information from both speech and facial expressions into a multimodal model designed for triaging patients with suspected stroke [10]. In contrast, [13] explored the use of TinyML to implement a portable device for dysarthria rehabilitation, whereas [15] proposed a multitask architecture capable of performing phonetic recognition, temporal alignment, and articulatory trajectory prediction within a single model. These approaches demonstrate that architectural choices were also influenced by practical requirements, such as multimodal analysis, computational constraints, and the need to perform multiple speech-related tasks.

A different comparison was presented by [6], who evaluated a BiLSTM architecture alongside an SVM classifier based on the Wavelet Scattering Transform (WST) using different acoustic representations, including MFCCs, GTCCs, and auditory spectrograms. The best performance was achieved by the WST+SVM combination, suggesting that speech representation and feature extraction can influence model performance as much as, or potentially more than, the choice of learning architecture in some applications.

Taken together, the reviewed studies do not indicate a single dominant AI architecture across all applications. CNNs, hybrid models, Transformers, transfer learning, multimodal architectures, TinyML, and personalized models were employed according to the objectives and constraints of each study. Most of the included approaches remain based on CNNs, hybrid architectures, or task-specific models, while pretrained speech models, including self-supervised and large speech models, represent a more recent direction with potential relevance to clinical datasets with limited sample sizes. Nevertheless, their applicability to pathological speech should not be assumed from performance on other speech domains. Future studies should therefore evaluate these models using independent clinical datasets and reproducible protocols, with particular attention to external validation, data variability, and generalizability across speakers and recording conditions.

E. Evaluation Metrics

The evaluation metrics adopted across the analyzed studies were, for the most part, similar. Accuracy was reported in nearly all studies [6]–[10], [12]–[17], typically accompanied by precision, recall (or sensitivity), and F1-score [9], [12], [14]–[16]. Together, these metrics constitute the primary evaluation framework for pathological speech classification tasks in these studies.

ROC curves and the corresponding area under the curve (AUC) were also frequently reported, particularly in studies focused on diagnosis and patient classification [8]–[10], [14], [16]. In several studies, specificity was reported alongside sensitivity, providing a more balanced assessment of the discriminative ability of the models, an aspect that is particularly important in clinical applications [10], [16].

Although traditional classification metrics predominated, several studies adopted evaluation metrics tailored to the specific objectives of their applications. In the development of systems aimed at improving speech intelligibility, [11] employed intelligibility measures, Mean Opinion Score (MOS), and the recognition rate achieved by Google Speech Recognition, whereas [16] evaluated the speech enhancement module using objective speech quality metrics, including PESQ, STOI, SegSNR, CSIG, CBAK, and COVL. In contrast, [15] adopted task-specific metrics for phonetic recognition and articulatory trajectory prediction, including Phoneme Error Rate (PER), the Pearson Correlation Coefficient (PCC), Root Mean Square Error (RMSE), and segment overlap rate.

It is worth noting that high accuracy values should be interpreted with caution when obtained from small datasets, as limited sample sizes may increase the risk of bias and limit the generalization of the models to new speakers and clinical populations. Moreover, the results are not directly comparable across studies only based on the reported metrics, since the studies differ in clinical objectives, units of analysis, datasets, and validation protocols. For clinical use, evaluation with small samples alone is not sufficient; further testing with larger and independent datasets is needed to assess the robustness and generalizability of the models.

Overall, the reviewed literature still relies primarily on traditional classification metrics, particularly accuracy, precision, recall, and F1-score. However, as applications move closer to real-world clinical settings, evaluation has increasingly incorporated task-specific measures of speech intelligibility, speech quality, and agreement with expert assessments. Therefore, the reported performance metrics should be interpreted according to the specific objective and methodological protocol of each study rather than used for direct comparison of model performance.

F. Limitations of the Literature

Despite the advances achieved in recent years, the reviewed studies reveal recurring limitations that continue to hinder the consolidation of Artificial Intelligence systems for automatic post-stroke speech analysis. The most significant limitation concerns the availability of clinical data. Nearly all studies relied on relatively small numbers of participants, often comprising only a few dozen patients or, in extreme cases, a single patient [6]–[14], [16], [17]. However, a small number of participants does not necessarily correspond to a small number of samples, since several studies divided speech into words, syllables, segments, or analysis windows. When samples from the same participant are distributed across training and test sets, the reported performance may be influenced by speaker-specific characteristics and may not reflect generalization to new patients.

The limited number of participants also affects the generalizability of the proposed models. Several studies emphasized that their findings still require validation in larger populations, encompassing different levels of impairment, multiple data collection centers, and greater linguistic diversity [7], [9]–[11], [16], [17]. In some cases, the authors acknowledged that model performance was evaluated only in patients with specific levels of disease severity, under restricted speech tasks, or within proof-of-concept studies, limiting the applicability of the findings to broader clinical settings [8], [13], [17].

Another important limitation is the absence of external validation across the reviewed studies. Although cross-validation or internal train-test procedures were employed, none of the included studies evaluated model performance on an independent external dataset. Moreover, when partitioning is performed at the sample or item level rather than at the participant level, samples from the same individual may occur in both training and test sets, introducing potential data leakage and leading to optimistic performance estimates. Therefore, validation on independent patients and datasets is necessary

to assess model robustness and generalizability before clinical implementation.

Substantial methodological heterogeneity was also observed across the analyzed studies. These differences ranged from language and participant profiles to speech tasks employed, including sustained vowels, syllables, isolated words, picture naming, sentence reading, voice commands, and spontaneous speech [7]–[9], [11]–[13], [16], [17]. In addition, different preprocessing strategies, acoustic representations, AI architectures, and evaluation metrics were used, making direct comparisons between published results challenging.

The scarcity of public datasets specifically designed for post-stroke speech analysis represents another recurring limitation. As a consequence, many research groups have developed their own datasets [6]–[12], [16], limiting the reproducibility of experiments and hindering comparisons between models proposed by different research groups. Even studies that relied on publicly available datasets reported limitations related to the number of participants, linguistic diversity, or the availability of detailed clinical annotations [14], [15].

IV. Conclusion

This review shows that Artificial Intelligence has been applied to several tasks involving post-stroke speech, including dysarthria and aphasia assessment, screening, diagnosis, and rehabilitation support. However, the evidence remains limited by small numbers of participants, heterogeneous speech tasks and acquisition protocols, single-center datasets, and the absence of external validation. These limitations make reported performance difficult to compare and do not yet support conclusions about model generalizability to new patients.

The limited availability of datasets in languages other than English and Mandarin also represents an important gap. No publicly available dataset specifically designed for post-stroke speech in Brazilian Portuguese was identified in this review.

For future work, we propose prioritizing larger, multicenter datasets, participant-level data partitioning, external validation, standardized acquisition protocols, and publicly accessible datasets. A rigorous protocol should be established to collect and curate a speech dataset, incorporating evaluation in independent participants, that is, individuals not included in the training and validation sets. Such dataset characteristics can enhance quality and reliability, and make AI model performance metrics more robust regarding real-world scenarios, effectively contributing to the improvement of these systems. Furthermore, creating a Brazilian Portuguese dataset, containing samples from healthy participants and post-stroke individuals performing various speech tasks is important to support the development of a tool adapted to the Brazilian context.

***Resumo*—O câncer de pulmão é a principal causa de mortes por câncer no Brasil, especialmente no Nordeste. Atrasos no diagnóstico reduzem as taxas de sobrevivência e sobrecarregam os sistemas de saúde. A análise manual de imagens de Tomografia Computadorizada (TC) para a identificação de nódulos em estágios iniciais é uma tarefa complexa e suscetível a erros. Diante disso, este trabalho tem como objetivo principal realizar uma análise comparativa rigorosa entre duas arquiteturas de aprendizado profundo para a detecção precoce e segmentação de nódulos pulmonares: o modelo baseado em atenção DETR (Detection Transformer) e a arquitetura baseada em blocos convolucionais modernos ConvNeXt V2, acoplada ao framework multitarefa Mask R-CNN. A metodologia consistiu no uso de imagens de TC do banco de dados público LUNA16. Os exames foram pré-processados e filtrados para isolar nódulos com dimensão ($\leq$ 15 mm), divididos em subconjuntos categóricos. Ambos os modelos foram submetidos a 400 épocas de treinamento. A abordagem proposta com o ConvNeXt V2 foi configurada para operar simultaneamente a localização espacial geométrica (bounding boxes). Os resultados quantitativos demonstraram o bom desempenho do ConvNeXt V2 em relação ao baseline do DETR. Na tarefa de detecção, o ConvNeXt V2 obteve um mAP@0.50 de 0,7535 e um F1-Score de 0,7782, superando significativamente o DETR (0,5348 e 0,7030, respectivamente). Para os nódulos clinicamente desafiadores entre 10 e 15 mm de diâmetro, a avaliação por meio da curva FROC revelou um escore Λ de 0,6454, indicando um desempenho diagnóstico global, com baixa taxa de falsos positivos. Na análise de custo computacional, o ConvNeXt V2 reduziu o tempo de treinamento de 10 minutos (DETR) para apenas 2 minutos e 40 segundos por época, corroborando a literatura recente que atesta a eficiência dessas arquiteturas convolucionais modernas na mitigação do colapso de características, sem o peso computacional dos Transformers puros. Conclui-se que a integração do ConvNeXt V2 com a Mask R-CNN supera amplamente as limitações dos métodos de detecção tradicionais, garantindo não apenas a identificação precisa do tumor, mas também a sua fidelidade morfológica. Conclui-se que o modelo é promissor no uso de uma ferramenta de Auxílio ao Diagnóstico (CAD) viável, capaz de otimizar o fluxo de trabalho radiológico e elevar a eficácia clínica na identificação morfológica de tumores.**

***Palavras-chave*—Detecção de Objetos, VIsion Transformers, Nódulos Pulmonares, ConVneXt V2**

I. Introdução

O câncer de pulmão se destaca entre os tipos de câncer mais preocupantes no mundo, tanto pela alta prevalência quanto pela letalidade. Entre 2022 e 2025, foram registrados 2,5 milhões de novos casos, o que o torna o primeiro câncer mais comum globalmente, e 1,8 milhão de mortes, consolidando-o como a principal causa de morte por câncer (44). Esse panorama alarmante representa aproximadamente 12,4% dos diagnósticos de câncer e 18,7% das mortes por câncer em todo o mundo. No Brasil, o cenário reflete essa gravidade: conforme a estimativa oficial do Instituto Nacional de Câncer para o triênio 2025-2027, são esperados cerca de 36.160 novos casos anuais (15). O diagnóstico precoce do câncer de pulmão é essencial para aumentar as chances de sobrevivência do paciente, com uma taxa de sobrevivência de 5 anos que chega a 70% quando o câncer é diagnosticado em estágio inicial (16). Portanto, programas voltados à detecção precoce de nódulos pulmonares devem ser implementados para aumentar as chances de sobrevivência dos indivíduos afetados pelo câncer de pulmão.

A TC é a principal ferramenta utilizada pelos radiologistas para detectar nódulos pulmonares, pois fornece imagens em 3D de alta resolução, com contraste, que refletem as diferenças de intensidade, textura e forma dos tumores. No entanto, o diagnóstico de nódulos pulmonares, especialmente em estágios iniciais, é um desafio para radiologistas. Além do pequeno tamanho ($<$15 mm), os nódulos podem apresentar baixo contraste em relação ao tecido pulmonar e estar anexos a outras estruturas pulmonares complexas, o que aumenta as dificuldades (38).

Os sistemas CAD são ferramentas importantes que podem fornecer suporte à tomada de decisão dos radiologistas, atuando como uma segunda opinião (1). As ferramentas CAD podem automatizar o processo de diagnóstico, reduzindo o tempo e o esforço necessários à análise e melhorando a confiabilidade e a repetibilidade da tarefa (14). Os sistemas CAD envolvem tanto a localização de lesões em imagens médicas (CADe) quanto a classificação de lesões como malignas ou benignas (CADx), o que traz diversos desafios para o campo (22).

Atualmente, as técnicas de Aprendizado Profundo (AP) são consideradas o estado da arte em aplicações de CAD para nódulos pulmonares, e diversos estudos recentes têm demonstrado o potencial e a relação custo-benefício dessas abordagens em centros de saúde (41). Entre as arquiteturas, as redes neurais convolucionais (CNN) se destacam e têm apresentado resultados promissores na área da informática médica. Contudo, o grande desafio da literatura consiste em

otimizar simultaneamente duas métricas essenciais: a Sensibilidade (que mede a redução de Falsos Negativos - FN) e a Especificidade ou Precisão (relacionada à minimização de Falsos Positivos - FP). Apesar dos avanços algorítmicos, o desafio de manter alta sensibilidade sem inflar o número de FP ainda persiste, como corroborado por avaliações recentes no campo (14; 19).

A alta taxa de FP compromete a eficiência clínica ao exigir a revisão desnecessária de exames, constituindo um obstáculo severo à implementação de sistemas CAD em ambientes hospitalares. Uma revisão sistemática (11) apontou que o auxílio de IA no rastreio de câncer de pulmão aumenta a sensibilidade (de +5% a +20%) em relação à leitura não assistida, mas tipicamente leva a uma redução na especificidade (de -7% a -3%), o que se traduz em vigilância excessiva. Trabalhos específicos, baseados em arquiteturas modernas, ilustram com clareza essa dificuldade de equilíbrio. Por exemplo, a pesquisa de Zhao et al. (2024) (42), que utilizou a arquitetura Mask R-CNN acoplada ao ConvNeXt V2, alcançou alta sensibilidade e especificidade, porém, em um contexto macro de detecção de metástases ósseas. Por outro lado, o estudo de Mafra (2024) (24) demonstrou que, na detecção direta de micronódulos pulmonares, a CNN YOLOv8 sobressaía-se em precisão (minimizando FP), enquanto modelos baseados em atenção destacavam-se em sensibilidade (minimizando FN). Esses resultados indicam que a superação do trade-off entre FN e FP permanece uma área crucial de pesquisa.

O Transformer é uma arquitetura de codificador-decodificador que revolucionou o campo do Processamento de Linguagem Natural (do inglês, NLP) e inspirou o Vision Transformer (ViT) para tarefas de visão computacional, podendo atuar em conjunto ou em substituição às tradicionais CNNs. Na área médica, propostas baseadas em ViT demonstraram capacidade de manter alta sensibilidade com um número reduzido de parâmetros (4). Contudo, os modelos puramente baseados em atenção apresentam limitações importantes. Diferentemente das convoluções, eles carecem de vieses indutivos locais, o que exige volumes massivos de dados para evitar o sobreajuste (*overfitting*) em bases médicas mais restritas. Além disso, a sua complexidade computacional cresce de forma quadrática com o tamanho da imagem, o que eleva substancialmente o custo de processamento e a demanda de memória, dificultando a sua adoção em cenários clínicos rotineiros (8).

Para contornar as limitações computacionais dos Transformers sem abrir mão do seu alto desempenho em contextos globais, pesquisadores propuseram a arquitetura ConvNeXt, que moderniza as CNNs ao incorporar princípios de *design* dos Transformers hierárquicos (22). A sua evolução direta, o ConvNeXt V2 (39), introduziu aprimoramentos vitais, como o uso de autoencoders mascarados e a Normalização de Resposta Global (GRN), mitigando falhas na extração de características em redes muito profundas. Essa abordagem demonstrou que redes puramente convolucionais podem igualar ou superar os ViTs em termos de precisão, mantendo a eficiência computacional inerente às CNNs e despontando como uma solução robusta para contornar a alta taxa de FP em imagens radiológicas complexas.

Apesar da eficácia isolada do ConvNeXt V2 e de arquiteturas baseadas em atenção global pura, como o DETR (Detection Transformer), há uma notável lacuna na literatura quanto à comparação direta entre esses dois paradigmas na tarefa específica de detecção de nódulos pulmonares precoces (com diâmetro inferior a 15 mm). A maioria dos estudos foca em tumores de grandes dimensões e já consolidados, ou falha em documentar simultaneamente o comportamento de FP e FN em alvos morfológicos tão reduzidos (24). Para lidar com esse problema de maneira inovadora, este trabalho aplica e compara diretamente os modelos ConvNeXt V2 e DETR em um subconjunto de imagens estritamente filtrado para micronódulos, avaliando qual arquitetura oferece o equilíbrio mais favorável entre a identificação precoce da lesão e a redução de falsos alarmes clínicos.

II. Metodologia

A metodologia desenvolvida neste trabalho baseia-se em um *pipeline* estruturado de processamento e avaliação de arquiteturas de aprendizado profundo, conduzido conforme o fluxograma ilustrado na Figura 1. O fluxo metodológico segue os seguintes passos essenciais: inicia-se pela extração da base de dados original LUNA16 (LUng Nodule Analysis 2016) (A), avançando para o pré-processamento das imagens em 3D e a delimitação das caixas (B), processos detalhados na Seção 3.1. Na sequência, o *pipeline* estrutura as imagens em 2D e as anotações prontas para o algoritmo (C), abrangendo o refinamento e a divisão do conjunto de dados descritos na Seção 3.2. O processo segue para o bloco de detecção de objetos (D), que inclui a justificativa da escolha das arquiteturas (Seção 3.3) e culmina na configuração e no treinamento dos modelos DETR e ConvNeXt V2 (Seção 3.4). Por fim, a consolidação das predições e a análise comparativa das métricas (E) compõem o escopo de discussão a ser apresentado no Capítulo 4.

A base de dados escolhida para este estudo foi a LUNA16, uma base pública que reúne TCs de pacientes com nódulos pulmonares (33) e é uma extensão de outra base pública, a LIDC-IDRI (Lung Image Database Consortium) (37), com melhorias voltadas à detecção de nódulos. Para o desenvolvimento deste trabalho, utilizou-se o conjunto de dados já processado e organizado nos trabalhos de (24; 31). O objetivo de utilizar este conjunto de dados bidimensional (2D) pré-processado foi contornar o elevado custo computacional do processamento de volumes 3D e superar as restrições das arquiteturas de detecção, como o ConvNeXt V2 e o YOLOv8, que operam intrinsecamente com dados 2D. Visando conferir maior robustez à metodologia para futuras publicações e garantir a reprodutibilidade da pesquisa, descreve-se a seguir o *pipeline* detalhado de organização e pré-processamento estruturado pelos autores originais da base, cujas etapas viabilizaram o treinamento dos modelos propostos:

1) Seleção e Extração de Cortes 2D: Os exames de TC consistem, por padrão, em uma sequência de cortes axiais bidimensionais. Portanto, as imagens originais,

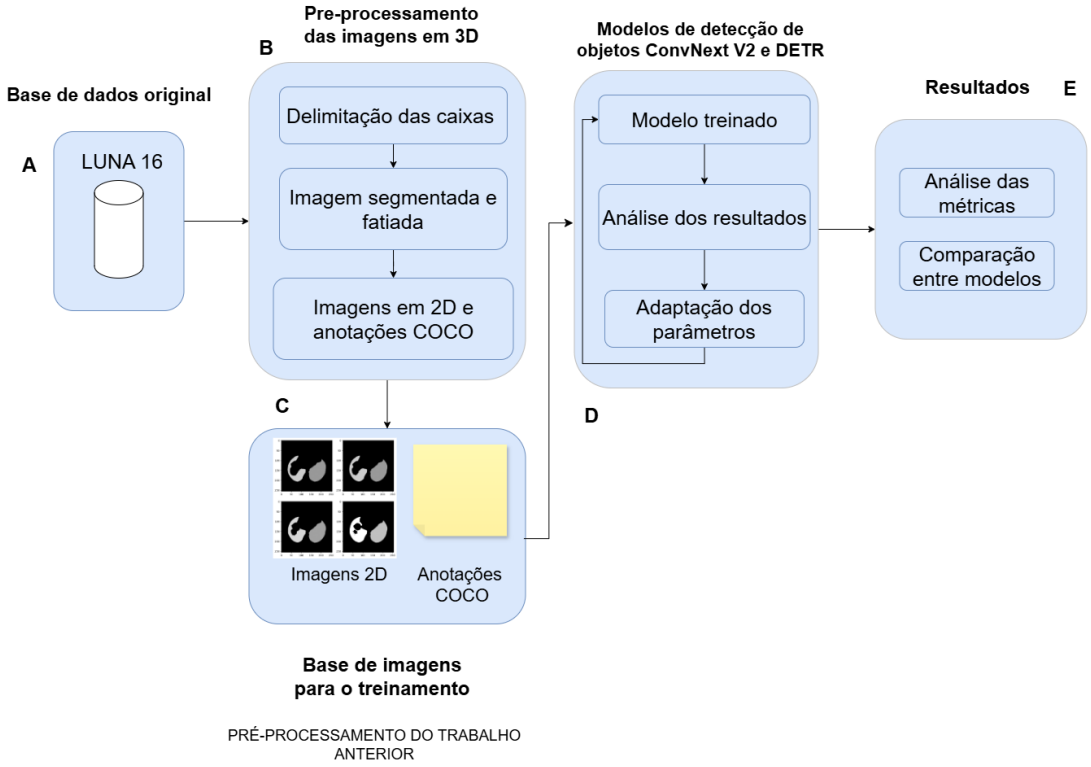

Figura 1. Diagrama ilustrativo da metodologia aplicada neste trabalho: (A) Base LUNA 16 para obtenção de imagens de TC de pacientes com nódulos pulmonares; (B) Etapa de pré-processamento das imagens em 3D; (C) Organização dos conjuntos de dados oriundos da etapa anterior; (D) Treinamento dos modelos; e (E) Análise dos resultados. Fonte: Autor(2026)

dispostas no padrão médico DICOM, e as anotações dos radiologistas (estruturadas em arquivos CSV contendo as coordenadas centrais X, Y, Z e o raio do nódulo) foram submetidas a um algoritmo de filtragem espacial. Foram incluídos no conjunto de dados apenas os cortes que continham o nódulo. Para garantir a riqueza geométrica e alimentar a rede neural com múltiplas perspectivas da lesão, extraíram-se múltiplos cortes do mesmo nódulo, sem se limitar à fatia central.

2) Pré-processamento (Atenuação de Ruídos): Aplicou-se um ajuste de brilho e contraste nas imagens geradas, configurando os valores de janela/nível (*Windowing*) para a escala Hounsfield de $-400/1200$. Este ajuste teve como objetivo eliminar ruídos e artefatos, atenuar sinais irrelevantes provenientes de outras estruturas torácicas e realçar exclusivamente a região do parênquima pulmonar.
3) Formatação das Anotações: As anotações espaciais dos nódulos foram convertidas para formatos padronizados da literatura de visão computacional, garantindo a compatibilidade de ingestão de dados para diferentes arquiteturas. Para este experimento foi adotado o padrão de formato COCO, mas no trabalho comparativo anterior também encontramos a padronização em YOLO.

   - Formato COCO (.json): É o formato adotado nativamente tanto pelo modelo DETR quanto pela arquitetura ConvNeXt V2 (acoplada à Mask R-CNN). Este formato estrutura os dados em um único arquivo, armazenando as coordenadas absolutas das caixas delimitadoras (x_{min}, y_{min}, largura, altura) e, fundamentalmente para este estudo, as coordenadas dos polígonos que permitem o treinamento da cabeça de segmentação semântica do ConvNeXt V2.
   - Formato YOLO (.txt): Formato gerado de forma complementar para manter a compatibilidade com a base de dados dos estudos prévios (24), que empregaram a arquitetura YOLOv8. Diferentemente do COCO, este padrão utiliza arquivos de texto descentralizados (um para cada imagem) contendo coordenadas espaciais normalizadas (x_{centro}, y_{centro}, largura, altura).

III. Organização dos conjuntos de dados

Para criar o conjunto de dados, a base pré-processada foi inicialmente dividida em conjuntos de treinamento (80%) e de teste (20%). Para permitir a otimização de hiperparâmetros e o uso de Early Stopping sem enviesar os resultados finais, o conjunto de treinamento foi subdividido internamente, extraindo-se um subconjunto de validação. Mitigamos o vazamento de dados (data leakage) garantindo que o particionamento, incluindo a validação, ocorresse estritamente ao nível do exame (paciente). O conjunto de teste refinado, composto por 587 imagens, foi mantido completamente isolado e intocado

até a etapa de avaliação final, garantindo uma validação justa das morfologias de nódulos.

As imagens foram mantidas em sua resolução original (512×512) com representação de 8 bits. No total, o conjunto de treinamento contém 3.255 imagens, enquanto o de teste contém 832, abrangendo nódulos com diâmetro d no intervalo $d \in [3, 32]$ mm.

1) Refinamento do Conjunto de Teste (Foco em Nódulos Pequenos): Para analisar a capacidade dos modelos de detectar nódulos pequenos, identificamos os nódulos do conjunto de testes com diâmetro inferior a 15 mm.

Este processo de refinamento envolveu a separação de todos os cortes de cada exame de TC no conjunto de teste. Em seguida, verificou-se a maior fatia nesse conjunto de seções tinha diâmetro inferior a $15\,\mathrm{mm}$. Caso essa condição fosse satisfeita, todas as fatias desse exame seriam mantidas. Aqueles exames que falharam nesta verificação (ou seja, continham um corte $\geq 15\,\mathrm{mm}$) foram removidos do conjunto de teste final.

Com isso, das 832 imagens originalmente no conjunto de teste, apenas 587 permaneceram, sendo utilizadas para a validação dos modelos de detecção.

Além disso, o conjunto de teste refinado foi subdividido em três intervalos (I1, I2 e I3) de diâmetros de nódulos, visando avaliar o desempenho dos modelos de forma categorizada, conforme demonstrado na Tabela I.

Tabela I
DISPOSIÇÃO DAS IMAGENS NO CONJUNTO DE TESTE REFINADO, CATEGORIZADAS POR FAIXA DE DIÂMETRO DOS NÓDULOS.

Diâmetro (d)	**N.º Cortes**	**Nódulos Únicos**	**Exames de TC**
I1: $15\,\mathrm{mm} \geq d > 10\,\mathrm{mm}$	172	31	27
I2: $10\,\mathrm{mm} \geq d > 5\,\mathrm{mm}$	385	127	77
I3: $5\,\mathrm{mm} \geq d$	30	5	5

IV. TREINANDO O MODELO

O treinamento de ambos os modelos foi conduzido em um servidor remoto, equipado com o sistema operacional Linux (Ubuntu 20.04 LTS) e uma placa gráfica NVIDIA Tesla T4 com 16 GB de memória. O procedimento de adaptação e treinamento dos modelos baseou-se na técnica de Aprendizado por Transferência, do inglês, TL, visando acelerar a convergência das redes.

A. Detection Transformer (DETR)

O treinamento do modelo DETR foi iniciado com a criação de um *fork* do repositório original no GitHub (4). Esse procedimento foi essencial para realizar as modificações no código-fonte e adaptar a arquitetura, que utiliza o ResNet-50 como *backbone* para extração de características, à tarefa de detecção de nódulos. Os hiperparâmetros da arquitetura (detalhados na Tabela II) foram definidos empiricamente, a partir das configurações padrão recomendadas pelos autores originais do modelo, e refinados com base em testes preliminares, não sendo necessários algoritmos de busca exaustiva (como *Grid Search*).

O procedimento inicial consistiu na adaptação da última camada da rede: o número de classes foi reduzido para 1 (apenas a classe "nódulo"). Consequentemente, o número de consultas de objeto (*object queries*), que determina a quantidade máxima de caixas delimitadoras previstas por imagem, foi drasticamente reduzido de 100 para 10, uma vez que a quantidade de nódulos em um único corte pulmonar é caracteristicamente baixa.

O modelo foi configurado para executar por 400 épocas, com um tamanho de lote (*batch size*) de 8. Para garantir que todos os tensores possuam dimennsões identicas, a arquitetura original do DETR aplica automaticamente a técnica de *padding* (preenchimento com zeros), uniformizando o tamanho final de todas as imagens submetidas ao treinamento em um mesmo *batch*.

Devido a limitações de memória na GPU, não se utilizou a versão estendida DETR-DC5, mantendo-se o ResNet-50 padrão. O modelo concluiu as 400 épocas sem acionar o mecanismo de parada antecipada (*Early Stopping*).

Tabela II
HIPERPARÂMETROS DE TREINAMENTO E ARQUITETURA DO MODELO DETR.

Parâmetro	**Valor**
Número de Camadas Encoder	6
Número de Camadas Decoder	6
Tamanho dos Embeddings	256
Slots para Detecção (*Object Queries*)	10
Dropout no Transformer	10^{-1}
Número de Attention Heads	8

B. ConvNeXt V2

Para a segunda arquitetura, utilizou-se o modelo Mask R-CNN acoplado ao *backbone* ConvNeXt V2 (na variante *Tiny*), implementado com a biblioteca Hugging Face. A abordagem de *Transfer Learning* aplicada consistiu na extração dos pesos de redes pré-treinadas sobre o amplo conjunto de imagens genéricas ImageNet-1k (42). A partir deste estado inicial, executou-se o *fine-tuning* (ajuste fino) de todo o modelo, treinando-o e ajustando os pesos exclusivamente com base na base de dados de nódulos pulmonares extraída da LUNA16. Os parâmetros resultantes desta configuração encontram-se na Tabela III.

A rede foi integrada a uma *Feature Pyramid Network* (FPN), permitindo a extração de mapas de características em múltiplas escalas. Para adequar o modelo à morfologia de micronódulos (diâmetros predominantemente inferiores a 15 mm), os geradores de *anchors* (caixas-âncora da rede) foram reconfigurados para as escalas reduzidas de 4, 8, 12 e 16 pixels. A camada *Global Response Normalization* (GRN), característica nativa do ConvNeXt V2, foi ativada para atuar diretamente na distinção visual entre as opacidades nodulares e as ramificações vasculares.

O processo de *fine-tuning* foi planejado com um limite máximo de 400 épocas, utilizando o otimizador AdamW com uma taxa de aprendizado inicial de 2×10^{-4} e um *batch size* de 16. Implementou-se um mecanismo de *Early Stopping* com tolerância de 50 épocas sem evolução na perda (*loss*) de validação. Para a otimização contínua dos hiperparâmetros em tempo de execução, foi incorporado o escalonador *ReduceLROnPlateau*, que aplica um fator de redução de 0,1 à taxa de aprendizado caso não haja melhoria na métrica de avaliação por 5 épocas consecutivas. O checkpoint final selecionado para a avaliação no conjunto de teste foi estritamente o que apresentou a menor função de perda (loss) no conjunto de validação durante o treinamento.

Tabela III
PARÂMETROS DA ARQUITETURA CONVNEXT V2 + MASK R-CNN.

Descrição do Parâmetro	**Valor**
Arquitetura de Detecção	Mask R-CNN
Backbone (Extrator de Features)	ConvNeXt V2 (Tiny)
Neck (Conexão Multinível)	FPN
Dimensão dos Canais (FPN)	256
Otimizador	AdamW
Taxa de Aprendizado Inicial (LR)	2×10^{-4}
Escalas das *Anchors*	(4, 8, 12, 16) pixels
Proporção das *Anchors*	(0.8, 1.0, 1.2)
Mecanismo de Atenção	GRN
Dropout / Stochastic Depth	10^{-1}

Fonte: Autor, 2026.

É importante ressaltar que, devido à limitação de memória da GPU, optou-se pela configuração padrão do DETR (ResNet-50 com estágio C5 convencional), em vez da variante DETR-DC5.

V. RESULTADOS E DISCUSSÃO

A Figura 2 apresenta os resultados do modelo DETR para erro de classe e mAP@0.50 obtidos após 400 épocas de treinamento. O modelo DETR (curva laranja) apresenta redução no erro de classe ao longo do treinamento, com a curva de mAP@0.50 exibindo leve tendência ascendente até as últimas épocas registradas, indicando que o modelo ainda possuía margem de aprendizado espacial.

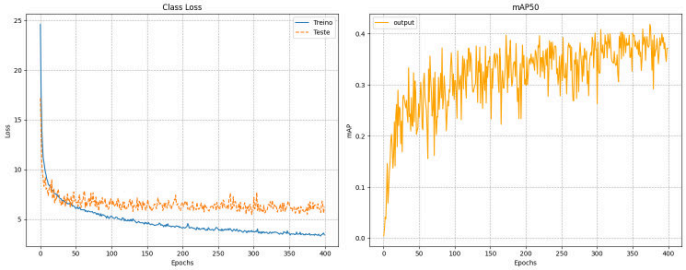

Figura 2. Plotagem dos logs de treinamento do modelo DETR. Fonte: Autor (2026).

Em contraste, a Figura 3 apresenta os logs de treinamento do modelo ConvNeXt V2. O treinamento demonstrou rápida convergência e excelente estabilidade em tarefas multitarefa. A adoção desta arquitetura corrobora achados recentes da literatura, que apontam o ConvNeXt V2 não apenas como um extrator de características altamente eficiente, mas também como superior em otimização computacional (5). A utilização de técnicas avançadas nativas da arquitetura ConvNeXt V2, como a Normalização de Resposta Global (GRN), mitiga problemas de colapso de características observados em redes mais profundas, garantindo uma competição eficaz entre os canais de características (5).

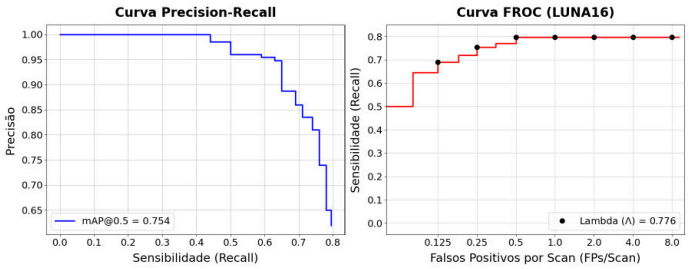

Figura 3. Plotagem dos logs de treinamento do modelo ConvNeXt V2 evidenciando a convergência das perdas. Fonte: Autor (2026).

A. Avaliação Quantitativa e Impacto do Tamanho do Nódulo

A avaliação quantitativa concentrou-se inicialmente na comparação direta de desempenho geral (Tabela IV). Para fins de análise, ressalta-se que a precisão indica a proporção de previsões positivas corretas, sendo valores mais altos associados a menos falsos positivos (FP). Já a revocação (sensibilidade) indica a capacidade do modelo de identificar corretamente os casos positivos, em que valores mais altos estão associados a menos falsos negativos (FN). Para garantir uma comparação rigorosa, as métricas foram calculadas exclusivamente com base nas bounding boxes geradas por ambos os modelos, sob os mesmos critérios de limiar de confiança e de Intersection over Union (IoU). Sob essas condições, o ConvNeXt V2 obteve um mAP@0.50 de 0,7535, uma precisão de 0,8106 e uma revocação de 0,7483. Esse índice tem relevância clínica direta, pois indica a redução de falsos alarmes na rede. O equilíbrio entre precisão e capacidade de detecção foi evidenciado por um F1-Score de 0,7782, superando significativamente o baseline do DETR. Para investigar a robustez arquitetural em função da morfologia dos tumores, o conjunto de teste foi subdividido em faixas de diâmetro (Tabela V). A avaliação clínica, validada por meio da análise FROC (Figura 4), revelou que, na classe de nódulos entre 10 e 15 mm (L1), o ConvNeXt V2 obteve um score Λ de 0,6454, mantendo uma taxa reduzida de falsos positivos na tarefa de detecção de nódulos.

Tabela IV
COMPARAÇÃO GERAL DAS MÉTRICAS DE DETECÇÃO ENTRE OS MODELOS AVALIADOS.

Modelo	**mAP@0.50**	**F1-Score**
DETR (Transformer)	0,703	0,772
ConvNeXt V2 (CNN)	**0,7535**	**0,7782**

B. Inferências e Avaliação Qualitativa

Durante a inferência, o modelo ConvNeXt V2 operou em multitarefa, realizando simultaneamente a detecção espacial por meio de *bounding boxes*, filtrando predições espúrias com base em um limiar de confiança de 0,8. As inferências geradas podem ser observadas visualmente por meio da sobreposição das predições em relação à verdade de referência (*ground truth*). A Figura 5 exibe os resultados do baseline DETR, enquanto a Figura 6 apresenta o painel qualitativo do ConvNeXt V2. Seguindo a ordem da esquerda para a direita e de cima para baixo, as imagens representam nódulos com $d > 15$ mm, seguidas de aproximações dos nódulos pertencentes aos intervalos L1 e L3, respectivamente.

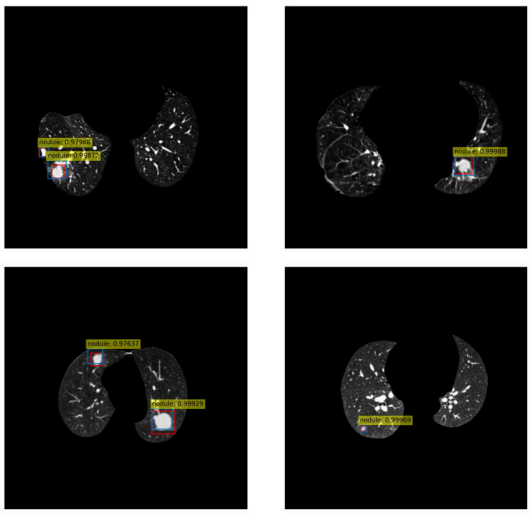

Figura 5. Inferências do modelo DETR (em azul) sobrepostas aos valores de *ground truth* (em vermelho). Fonte: (31).

Nas predições do ConvNeXt V2 (Figura 6), as caixas delimitadoras vermelhas representam a inferência do modelo, enquanto as tracejadas azuis confirmam a localização mapeada pelos radiologistas. O grande diferencial desta arquitetura reside na projeção simultânea da máscara de segmentação translúcida diretamente sobre os pixels anômalos. Essa dupla saída permite aos especialistas médicos avaliar não apenas a localização espacial, mas também a morfologia exata da lesão.

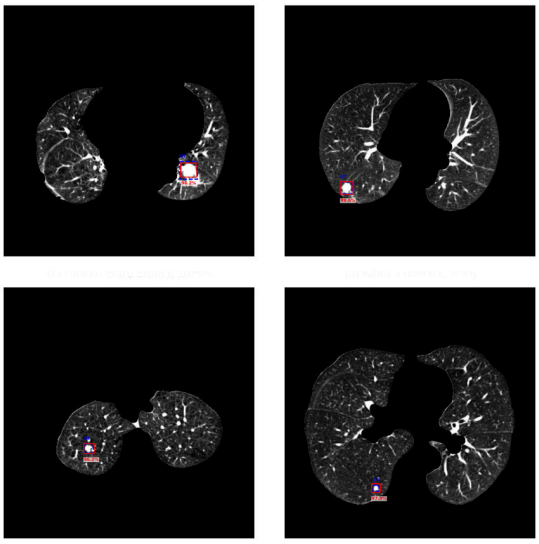

Figura 6. Inferências do modelo ConvNeXt V2 (predições e máscaras em vermelho) validadas contra as marcações de *ground truth* (caixas azuis tracejadas). Fonte: Autor (2026).

C. Análise de Custo Computacional

O pipeline customizado garantiu não apenas alta precisão, mas também eficiência operacional. O modelo foi treinado por 400 épocas. Conforme apresentado na Tabela VI, o treinamento do DETR exigiu 10 minutos por época, totalizando aproximadamente 66 horas. Em contrapartida, a eficiência dos blocos convolucionais modernos permitiu que o ConvNeXt V2 processasse cada época em apenas 2 minutos e 40 segundos.

Tabela VI
COMPARATIVO DE CUSTOS COMPUTACIONAIS ENTRE AS ARQUITETURAS.

Modelo	Treinamento (por época)	Inferência (por imagem)
DETR	10 minutos	600 ms
ConvNeXt V2	**2 min 40 s**	**120 ms**

Fonte: Autor, 2026.

Na inferência, o ConvNeXt V2 reduziu o tempo de processamento de 600 ms para apenas 120 ms por corte tomográfico. Esse ganho computacional reforça a viabilidade de implantação deste modelo como um CAD operável no fluxo de trabalho clínico padrão.

VI. CONCLUSÃO

Este trabalho apresentou uma comparação entre um algoritmo de detecção de nódulos pulmonares, baseado na arquitetura DETR, e um modelo proposto, baseado na arquitetura

ConvNeXt V2, acoplada ao *framework* Mask R-CNN. Exames de tórax obtidos do conjunto público de dados LUNA16 foram utilizados, e as imagens 2D foram adaptadas aos modelos de detecção escolhidos.

O modelo ConvNeXt V2 apresentou bons resultados, superando o baseline estabelecido por (31). Na avaliação quantitativa, o modelo obteve mAP@0.50 de 0,7535 e F1-Score de 0,7782, mantendo capacidade satisfatória de detecção de nódulos pequenos e baixa taxa de falsos positivos.

As caixas delimitadoras detectadas apresentaram um alinhamento preciso em relação aos valores de verdade absoluta (ground truth). Além da superioridade em precisão geométrica, o ConvNeXt V2 apresentou uma expressiva vantagem computacional, reduzindo o tempo de treinamento por época de 10 minutos (DETR) para 2 minutos e 40 segundos.

Conclui-se que o modelo demonstra excelente desempenho interno na base LUNA16, configurando-se como uma arquitetura promissora para futuras validações clínicas em cenários reais de Auxílio ao Diagnóstico (CAD).

VII. Trabalhos Futuros

Abaixo, algumas melhorias futuras:

- Exploração de Dados 3D: o uso de imagens 2D foi necessário para adaptar os exames aos modelos utilizados. No entanto, a utilização de modelos que operem diretamente em volumes 3D pode captar melhor as características espaciais dos nódulos pulmonares e, potencialmente, aumentar a acurácia da detecção.
- Aumento e Diversificação do Conjunto de Dados: ampliar o conjunto de dados, incluindo exames de diferentes populações e de diferentes equipamentos, pode tornar o modelo mais robusto e generalizável a diferentes cenários clínicos.
- Aprimoramento da etapa de Pós-Processamento: investigar técnicas mais avançadas de pós-processamento, como métodos de redução de falsos positivos e de refinamento das caixas delimitadoras, pode contribuir para um desempenho ainda melhor.
- Avaliação Clínica e Interpretabilidade: realizar avaliações em cenários clínicos reais e desenvolver mecanismos para tornar o modelo mais interpretável para profissionais da saúde são passos importantes para a adoção prática da tecnologia.
- Aplicação em algoritmos de classificação: utilizar o ConVNext aninhado com o DETR com tarefas que se complementam entre si, o primeiro avalia se existe nódulo ou não e o segundo detecta com precisão onde ele está e dá o diagnóstico
- Aplicações em outras áreas da saúde: investigar quais formas de arquitetura poderiam ser úteis na detecção de outras doenças no corpo humano.

***Abstract*—Remote photoplethysmography (rPPG) has emerged as a promising contactless technique for heart rate estimation by extracting pulse-related variations from facial video recordings. Several deep learning approaches have been proposed to improve the accuracy and robustness of heart rate measurement using rPPG. This technology represents a potential complementary alternative for physiological monitoring in Intensive Care Units (ICUs), as it is non-invasive, contactless and consequently reduces dependence on physical sensors and direct patient contact. This study presents a pilot comparative analysis of the inference time and heart rate estimation performance of six state-of-the-art deep learning models using remote photoplethysmography in a single intensive care unit patient. The evaluated models represent different deep learning architectures reported in the rPPG literature, including Convolutional Neural Networks, Transformers and State Space Models. For each model, two training configurations are considered using the PURE and RLAP datasets. Heart rate is estimated from a video recording for each 15-second interval in non-overlapping windows. The evaluated models are compared in terms of mean absolute error (MAE), Pearson correlation coefficient, and total inference time. The preliminary experimental results showed that TS-CAN presented the shortest total inference time of 5.66 seconds for the analyzed video, whereas EfficientPhys trained on RLAP achieved the lowest estimation error, with MAE of 2.74 $\pm$ 1.26 BPM and total inference time of 14.79 seconds.**

***Index Terms*—Remote photoplethysmography, heart rate measurement, deep learning models, intensive care units, real-time monitoring.**

I. Introduction

Heart rate monitoring is an important component of patient assessment, as variations in heart rate may provide early indications of physiological deterioration and changes in cardiovascular status [1]. In Intensive Care Units (ICUs), early detection of patient deterioration is essential to enable timely clinical intervention. Heart rate is one of the primary physiological parameters continuously monitored to assess a patient's clinical status and it is traditionally performed using contact-based devices and sensors, such as electrocardiography systems and pulse oximeters [2]. However, prolonged use of these devices may cause discomfort, skin irritation, and restrictions to patient mobility [3].

Remote photoplethysmography (rPPG) has emerged as a promising non-contact approach for heart rate measurement. This method uses video recordings acquired with conventional RGB cameras to capture subtle temporal variations in reflected light intensity caused by blood volume changes during the cardiac cycle [4]. When ambient light reaches the subject's skin, part of it is reflected directly from the skin surface, while another part penetrates the tissue, where it undergoes absorption and scattering before re-emerging at the skin surface. This latter contribution carries information about blood volume variations [5]. The camera captures a combination of both components, and rPPG algorithms seek to estimate cardiovascular signals from these subtle optical variations despite the presence of non-physiological light reflections, motion artifacts, and other sources of noise.

To address these challenges and motivated by the success of deep learning in other computer vision tasks, several deep learning models have been proposed for heart rate estimation from rPPG signals, incorporating mechanisms to improve robustness to different sources of noise. Among the proposed approaches, Convolutional Neural Networks (CNNs) were the earliest deep learning architectures explored for rPPG heart rate estimation. Liu et al. [6] proposed the Temporal Shift Attention Network (TS-CAN), a model using a 2D CNN architecture that incorporates a Temporal Shift Module (TSM)

This study was financed in part by Amigos da Poli endowment fund under CARE 4.0 project.

to enable temporal information exchange between consecutive frames. The TSM shifts feature maps along the temporal dimension, allowing the network to capture temporal information between multiple frames.

Standard 2D CNNs effectively extract spatial features from individual frames but do not explicitly model temporal dependencies. To capture temporal dynamics, 3D CNNs extend convolution operations to both spatial and temporal dimensions [7]. In the context of rPPG, Yu et al. [8] proposed PhysNet, a 3D CNN architecture with an encoder-decoder structure for rPPG signal estimation, and compared its performance with 2D CNN networks. The results demonstrated that the encoder-decoder 3D CNN architecture outperformed the evaluated architectures. However, 3D CNNs generally incur higher computational and memory costs because convolutions are performed jointly across spatial and temporal dimensions.

An alternative to CNNs is the Transformer architecture. Transformers were originally developed for sequence modeling using self-attention mechanisms [9]. Subsequent adaptations to computer vision and video analysis enabled these models to capture long-range spatial and temporal dependencies across video frames. Yu et al. [10] proposed PhysFormer, which employs temporal difference transformer to extract spatiotemporal physiological features and estimate rPPG signals from long video sequences. Additionally, the authors introduced a frequency-domain supervision strategy to encourage the extraction of pulse-related information and improve robustness to motion and illumination variations. Although Transformers are highly effective at modeling temporal dependencies, they generally incur high computational costs and often require larger training datasets than CNNs.

To address the computational limitations of Transformers, Mamba was proposed as a State Space Model (SSM) architecture capable of modeling long sequences with linear computational complexity [11]. Building on this architecture, Zou et al. [12] proposed RhythmMamba for rPPG signal estimation. The authors showed that the model achieves competitive accuracy compared with state-of-the-art methods while providing approximately three times higher throughput and reducing peak memory usage by about 30%. Several additional architectures have been proposed in the literature, most of which are variations or combinations of CNNs, Transformers and SSM approaches. Each architecture involves different trade-offs between computational training and inference costs, temporal and spatial feature representation capabilities, real-time suitability, and robustness to noise.

Despite the recent expansion of deep learning models for heart rate estimation using rPPG, systematic comparisons of these architectures and their suitability for clinical real-time applications remain limited, especially under challenging clinical conditions such as those found in ICUs. Models reported in the literature are commonly developed and evaluated using healthy subjects under controlled conditions, often with limited demographic diversity [13]. Unlike standard applications, such as fitness monitoring or online health assessment, ICUs require methods that combine accurate heart rate estimation with low inference latency and robust performance under challenging acquisition conditions.

As an initial investigation of these research gaps, this study presents a pilot comparative analysis of six deep learning models reported in the rPPG literature and evaluates their suitability for real-time inference using a single video acquired from an ICU patient. For each model, two training configurations are considered using the RLAP [14] and PURE [15] datasets, and performance is assessed in terms of inference time, mean absolute error (MAE), and Pearson correlation coefficient.

II. Methodology

A. Data Acquisition

The acquired data consisted of a facial video and a reference heart rate signal obtained from a single ICU patient admitted in the University Hospital of University of São Paulo (HU-USP)[1]. The video duration was 2 minutes and was recorded using a VCXU.2-57C camera (Baumer, Switzerland) positioned 190 cm from the patient's face and horizontally aligned with the patient's head. The recording was acquired at a resolution of 2000 × 2028 pixels, a frame rate of 25 fps, and an exposure time of 28 ms. Ambient illuminance at the acquisition site was 880 lux, measured using a Fluke 941 lux meter (Fluke Corporation, USA).

(a) (b)

Fig. 1: Sample frames from the recorded video. Figures (a) shows the patient sitting still without speaking, and (b) shows the patient speaking while displaying a concerned facial expression.

The patient was a woman with skin type classified as Fitzpatrick phototype IV [18]. Skin phototype was assessed using a skin phototype analyser (Skinup Beauty Devices, Brazil), with the measurement performed on the patient's forehead. The Fitzpatrick scale was adopted to facilitate the standardized characterization of skin phototype in future data acquisitions.

[1]All the data collected in this work was approved by the University of São Paulo Research Ethics Commitee under Ethics Review Certificate (CAAE) number 86650625.3.0000.0076. All data were collected with the explicit permission of the individuals involved or their representatives; data collection took place only after the participant or their legal representative had read and signed the Informed Consent Form.

TABLE I: Selected deep learning models and characteristics

Model name	Type	Number of frames per inference	Input size
ME-chunk [16]	SSM	160	36 x 36
ME-flow [16]	SSM	1	36 x 36
RhythmMamba [12]	Mamba	160	128 x 128
PhysFormer [10]	Transformer	160	128 x 128
TS-CAN [6]	2D CNN	160	36 x 36
EfficientPhys [17]	2D CNN	160	72 x 72
PhysNet [8]	3D CNN + Encoder-Decoder	128	32 x 32

The recording consists of the patient sitting still and speaking, exhibiting subtle head movements as well as occasional rapid head movements and facial expressions. Two sample frames from the recorded video is shown in Fig. 1.

The reference heart rate values were obtained from the photoplethysmography (PPG) signal acquired using a BSM-3000 Series bedside monitor (Nihon Kohden, Japan) at a sampling frequency of 62.5 Hz. The PPG signal was processed using the Python library HeartPy [19], which estimates heart rate from the detected pulse peaks. The resulting heart rate time series was used as the ground truth.

B. Deep Learning Models Selection

The deep learning models evaluated in this study were selected based on benchmark studies and recent literature in the rPPG field, with the objective of including representative architectures and implementations. The selected models have been reported to achieve high accuracy or competitive performance in previous researches.

All models were obtained from the publicly available rPPG toolkit *open-rppg* [20], which provides implementations and pretrained weights for multiple deep learning architectures. The toolkit includes pretrained models trained on the RLAP [14] and PURE [15] datasets. The model variants are denoted in this work as *ModelName-Dataset*, where the suffix indicates the weights used for model training (e.g., *PhysFormer-RLAP* and *PhysFormer-PURE*).

Table I presents the models evaluated in this work and their respective architectures, input size and number of frames used per inference. The models ME-chunk and ME-flow share the same underlying architecture but differ in the number of frames processed per inference.

C. Real-Time Inference and Evaluation Protocol

In order to simulate a real-time monitoring environment, the recorded video was processed using consecutive 15-second windows. For each window with index i, the error E between the model estimated heart rate $\hat{HR}$ and the ground truth GT was calculated (1), and the inference time T for each window was measured. The complete video frames were directly used as model input, without any preprocessing.

$$E[i] = |\hat{HR}[i] - GT[i]| \tag{1}$$

The ground truth GT used for error calculation was obtained by averaging the heart rate values obtained from the processed PPG signal within each temporal window. As shown in (2), gt represents the ground truth heart rate temporal series, where N denotes the number of heart rate samples contained in each 15-second window, defined as $N = \lfloor f_s \times 15 \rfloor$, and f_s is the oximeter sampling frequency in Hz.

$$GT[i] = \frac{1}{N} \sum_{n=iN}^{(i+1)N-1} gt[n] \tag{2}$$

After processing all windows in the video, the mean absolute error MAE (3), its standard deviation σ_{MAE} (4), the total inference time T_{inf} (5), and the Pearson correlation coefficient r (6) were calculated. The Pearson correlation coefficient was computed between the heart rate values estimated by the model and the corresponding ground-truth heart rate values for each window. In the equations, M denotes the number of windows into which the video is divided, $\overline{GT}$ is the mean ground-truth heart rate, and $\overline{\hat{HR}}$ is the mean heart rate estimated by the model across all windows. Variables MAE, σ_{MAE}, $E[i]$, $\hat{HR}[i]$, $GT[i]$, $\overline{GT}$ and $\overline{\hat{HR}}$ are expressed in bpm (beats per minute), while $T[i]$ and T_{inf} are expressed in seconds.

$$MAE = \frac{1}{M} \sum_{i=0}^{M} E[i] \tag{3}$$

$$\sigma_{\mathrm{MAE}} = \sqrt{\frac{1}{M-1} \sum_{i=1}^{M} (E[i] - MAE)^2} \tag{4}$$

$$T_{inf} = \sum_{i=0}^{M} T[i] \tag{5}$$

$$r = \frac{\sum_{i=1}^{M} \left(\hat{HR}[i] - \overline{\hat{HR}}\right)\left(GT[i] - \overline{GT}\right)}{\sqrt{\sum_{i=1}^{M} \left(\hat{HR}[i] - \overline{\hat{HR}}\right)^2} \sqrt{\sum_{i=1}^{M} \left(GT[i] - \overline{GT}\right)^2}}, \tag{6}$$

$$\overline{\hat{HR}} = \frac{1}{M} \sum_{i=1}^{M} \hat{HR}[i], \qquad \overline{GT} = \frac{1}{M} \sum_{i=1}^{M} GT[i] \tag{7}$$

TABLE II: Performance metrics of evaluated deep learning models trained on RLAP and PURE datasets. Best results in **bold**, second best are underlined.

Model	Training dataset	MAE $\pm\sigma_{MAE}$ (BPM)	Error median (BPM)	T_{inf} (s)	T (s)	r
ME-chunk	RLAP	11,29 ± 8,08	8,95	24,42	3,05	0,528
	PURE	20,14 ± 12,16	21,68	24,18	3,02	0,025
ME-flow	RLAP	18,36 ± 9,80	16,92	75,53	9,44	0,480

	PURE	22,26 ± 18,47	16,37	8,40	1,05	-0,307

Processing was performed on a system equipped with a 12th Gen Intel® Core™ i5-1235U processor (12 logical cores), 12 GB of RAM, running Ubuntu 24.04 LTS. Each model was processed separately to avoid potential cache effects or residual system load from previous model inferences affecting the measured inference time. The source code used for the inference and evaluation procedures is publicly available on GitHub[2].

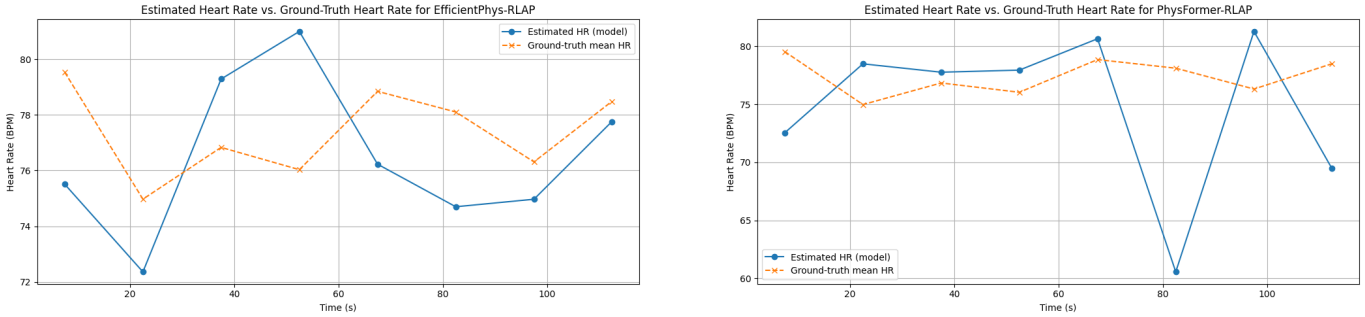
III. Results

Table II summarizes the performance of all evaluated models. Detailed experimental results for each model are reported in the GitHub repository, including the inference time for each window and the window-wise error for all models. The experiments showed negligible variation in inference time across windows for a fixed model and training dataset configuration. Therefore, Table II reports the average inference time per window T for each configuration.

The results show that EfficientPhys-RLAP achieved the lowest MAE, followed by PhysFormer-RLAP and PhysNet-RLAP. However, EfficientPhys-RLAP and PhysNet-RLAP provide a better trade-off between inference time and error. The model that achieved the lowest inference time was TS-CAN, followed by PhysNet and EfficientPhys. TS-CAN required a total inference time of 0.71 s for a 15-second window, while PhysNet required 1.00 s for the same window. The results also show that, for most architectures, models trained on the RLAP dataset achieved higher accuracy than the same models trained on the PURE dataset. The only exception was TS-CAN, which achieved higher accuracy when trained on PURE.

Most models exhibited a significant error ($MAE > 10$ BPM) and a large standard deviation of the absolute errors (σ_{MAE}), indicating high variability in the estimation error for each window. Therefore, the MAE alone does not fully characterize model performance. For this reason, the median absolute error was also included in Table II to provide additional information about the distribution of the absolute errors. Additionally, most models exhibited absolute Pearson correlation values between 0 and 0.5 ($0 < |r| < 0.5$), indicating a weak linear relationship between the estimated and reference heart rate values.

[2]https://github.com/larianog/icu-rppg



IV. Discussion

It is important to note that the results presented in this article constitute a preliminary study and that differences in model performance could have been influenced by the characteristics of the evaluated video. Additional data and further studies are required to assess the generalizability of these findings.

A. Analysis of Heart Rate Estimation Accuracy

The results show relatively high MAE values, large variability, and weak Pearson correlation coefficients. These findings are mainly attributed to the high variability of the heart rate estimates across inference windows. For a 2-minute video processed using 15-second windows, only eight inference windows are available; therefore, a small number of windows with large estimation errors can substantially increase the overall MAE. Similarly, the low Pearson correlation is related to fluctuations in the estimated heart rate temporal trend, which reduces the agreement between estimated and reference values.

In the processed videos, some windows contain faster head movements and more pronounced facial expressions, resulting in higher estimation errors compared with windows in which the patient remains still or speaks with limited facial movement. As examples of this behavior, Figure 2a presents the experimental results for EfficientPhys-RLAP, while Figure 2b presents the results for PhysFormer-RLAP. These figures illustrate the variability of the window-by-window heart rate estimates, with some windows showing overestimation and others underestimation, which contributes to the low Pearson

(a) (b)

Fig. 2: Comparison of the estimated and ground-truth heart rate for each window using (a) EfficientPhys-RLAP and (b) PhysFormer-RLAP. Although the absolute estimation error is the smallest presented, discrepancies in the temporal trend between successive windows result in a low Pearson correlation coefficient.

correlation. Additionally, some windows exhibit larger errors than others, increasing the overall MAE and its variance.

These results suggest that longer video recordings could potentially reduce fluctuations in the average estimation error and improve robustness to window-wise errors, as a larger number of inference windows would be available.

B. Impact of Model Architecture on Heart Rate Estimation Accuracy

Despite the overall high MAE values, EfficientPhys-RLAP, PhysFormer-RLAP, and PhysNet-RLAP achieved the lowest estimation errors among the evaluated models for this experiment. Although these results cannot be conclusively attributed to differences in model architectures, given the study's limitation to a single video from a single patient, these architectural differences may provide an initial basis for comparison and validation in further studies on this domain.

In this context, EfficientPhys uses frame differencing to capture temporal variations between adjacent frames and TSM to enable temporal information exchange between adjacent frames. PhysFormer applies a convolutional preprocessing stage to extract local spatio-temporal features and employs Temporal Difference Transformers to model temporal variations from frame differencing within the transformer architecture. PhysNet uses an encoder-decoder structure after the 3D convolutional layers to compact information into latent representations of physiological signals. These mechanisms, including frame differencing, spatio-temporal feature extraction, and latent representation learning, are designed to emphasize the subtle physiological variations associated with rPPG signals while improving robustness to motion and illumination artifacts.

However, it is important to note that the presence of individual architectural components does not necessarily determine performance. For example, TS-CAN also employs a 2D CNN backbone combined with TSM but achieved lower accuracy in this study. This difference may be related to the characteristics of the evaluated video, which can influence the generalization capability of each architecture.

Among the SSM-based models, RhythmMamba-RLAP and ME-chunk-RLAP achieved the best performance in terms of MAE. However, both models underperformed the evaluated CNN and Transformer models in this experiment. Although both networks incorporate mechanisms for frame differencing and extraction of subtle rPPG variations, differences on performance may be related to the mechanisms used to represent and encode information. Mamba architectures are designed for efficient long-range sequence modeling by maintaining hidden state representations of sequential information. However, this mechanism may introduce information compression, which could potentially reduce sensitivity to the subtle temporal variations associated with physiological signals.

As previously mentioned, the observed performance differences cannot be directly attributed to model architectures due to the data and demographic limitations of this study. Therefore, further evaluation on larger and more heterogeneous clinical populations is required to determine whether these performance patterns are consistent across model architectures, patients, and recording configurations.

C. Impact of Model Architecture on Computational Efficiency

Regarding total inference time, TS-CAN achieved the lowest inference time among the evaluated models, with a total inference time of 5.66 s. It was followed by PhysNet and EfficientPhys. The differences in inference time are influenced by the input size and computational complexity of each architecture. Additionally, the number of frames processed per inference affects the overall processing time.

TS-CAN uses a reduced input size of 36 × 36 pixels and is primarily composed of 2D convolutional layers combined with TSM. Since TSM does not increase computational complexity, the reduced input resolution and relatively simple architecture contribute to its lower inference time. PhysNet uses an input resolution of 32 × 32 pixels and relies mainly on 3D convolutional layers. Although 3D convolutions are computationally more demanding than 2D convolutions, the reduced spatial resolution decreases the computational cost of these operations, resulting in lower inference time.

In contrast, PhysFormer achieved the highest total inference time, requiring 83.80 s for inference when trained on RLAP. This result can be explained by its larger input resolution of 128 × 128 pixels and the combination of convolutional operations, self-attention mechanisms, and transformer layers, which increases the computational complexity of the model.

A similar trend was observed for RhythmMamba and ME-flow. RhythmMamba operates with 128 × 128 pixel inputs, increasing the computational cost of the Mamba layers. ME-flow uses a reduced input resolution of 36 × 36 pixels but processes one frame at a time to update its states. This sequential processing strategy increases the total inference time in this experimental setup due to the repeated state updates required for each frame. In contrast, ME-chunk uses the same input resolution as ME-flow but processes 160 frames per inference, reducing the number of sequential inference steps required and resulting in lower total inference time in this experiment.

Nevertheless, all evaluated models completed inference within the 15-second acquisition window, indicating that they are potentially suitable for the proposed real-time ICU monitoring framework. However, lower inference latency remains preferable, as longer inference times may increase system latency and reduce responsiveness.

D. Impact of Training Dataset on Model Generalization

Models trained on the RLAP dataset generally achieved lower MAE values than those trained on the PURE dataset. One possible explanation is the larger amount of training data and the greater variability in facial expressions present in RLAP compared with PURE. The RLAP [14] dataset is composed of 754 videos of Chinese students recorded under various scenarios, including problem-solving tasks, emotion-inducing videos, and hallucinatory image viewing. In contrast, PURE [15] consists of 60 videos of healthy subjects recorded under controlled conditions, including predefined head movements and sitting-still or speaking scenarios.

In the processed video, the patient displays frequent facial expressions while speaking and showing signs of concern or concentration. Therefore, the greater facial expression diversity in the RLAP dataset may have contributed to the improved performance of models trained on this dataset.

However, although facial expression variability may be better represented in the RLAP dataset, both training datasets have limited demographic diversity, with participants primarily from Asian and Caucasian populations. In addition, the datasets consist primarily of healthy subjects. As the patient evaluated in this study differs from these populations in both demographic and clinical characteristics, this mismatch represents an additional source of domain shift that may have affected model performance.

V. Conclusion

As the experimental results show, EfficientPhys-RLAP provided the best trade-off between heart rate estimation accuracy and inference time among the evaluated models, achieving a mean absolute error (MAE) of 2.74 ± 1.26 BPM and a total inference time of 14.79 s for the evaluated video. The next best trade-offs were obtained by PhysNet-RLAP and PhysFormer-RLAP. However, the estimation errors observed in this study may have been influenced by the characteristics of the single ICU patient video used for evaluation. Therefore, further studies are required to validate these findings using a larger dataset and longer video recordings, in order to enable a more reliable assessment of estimation error and correlation with the ground truth.

Regarding inference time, TS-CAN achieved the fastest inference, requiring 5.66 s to process the entire video when trained on RLAP, followed by PhysNet and EfficientPhys. Since inference time is primarily determined by the model architecture and implementation rather than the video content, these results can be used to guide the selection of models for future real-time rPPG monitoring studies in ICU environments.

Finally, further researches involving a larger and more diverse ICU dataset are required to investigate the impact of model architecture and training data on estimation accuracy and generalization under clinical conditions.

VI. Further Work

Future work will focus on acquiring additional data from ICU patients to evaluate the performance of different architectures and models on a larger and more diverse dataset. Furthermore, longer video recordings will be collected to assess model performance during continuous real-time monitoring. The expanded dataset will include variations in illumination conditions, patient characteristics, skin tones, and clinical scenarios, such as intubation, sleep, talking, and limited-motion conditions.

Following this initial assessment, the best-performing models will be selected for evaluation in a real-time video streaming environment to investigate their practical feasibility for ICU monitoring. This evaluation will consider different operational scenarios, including illumination variations, patient motion, and clinical conditions such as arrhythmias and intubation. Additionally, this work will aim to establish practical acquisition requirements for rPPG monitoring, including illumination levels, camera settings, distance from the patient's face, and relevant patient conditions.

***Abstract*—Deep learning has shown substantial potential for breast ultrasound analysis. However, most studies rely on a fixed decision threshold, limiting the ability of classifiers to adapt to different operating objectives. In this work, we present a transfer learning approach based on the InceptionV3 architecture combined with decision-threshold calibration for the classification of benign and malignant breast lesions in ultrasound images. Using the publicly available Breast-Lesions-USG dataset, we systematically investigated multiple operating points and evaluated different training strategies, including data augmentation and fine-tuning. Data augmentation improved the performance observed on the independent test set and increased malignant-lesion detection, whereas fine-tuning failed to provide consistent benefits because of overfitting. In contrast, threshold calibration proved to be the most effective strategy, enabling a single trained model to be adapted to different classification objectives without architectural modifications. For the model trained with data augmentation, decision-threshold calibration increased malignant-lesion sensitivity from 68.75% (11/16) at the default threshold to 87.5% (14/16) at the balanced operating point, while maintaining a specificity of 87.5% (21/24). In addition, the Safe Benign configuration achieved a benign-class precision of 91.3% (21/23). These results indicate that decision-threshold calibration is a simple and computationally efficient strategy for adjusting classifier behavior according to different operating requirements. However, the findings should be interpreted as preliminary because of the limited test-set size and require validation in larger and independent clinical datasets before conclusions regarding clinical applicability can be established.**

Keywords—Breast ultrasound, deep learning, decision threshold calibration, transfer learning, clinical decision support

I. INTRODUCTION

Breast cancer is the most frequently diagnosed cancer and the leading cause of cancer-related death among women worldwide [1]. In Brazil, breast cancer is also the most incident cancer among women, excluding non-melanoma skin cancer [2]. According to national estimates, approximately 78,610 new cases are expected annually during the 2026–2028 triennium, while 20,849 deaths from the disease were recorded in 2024, highlighting its significant public health impact. Early detection strategies have contributed substantially to improving survival rates among women diagnosed with breast cancer [3]. In this context, deep learning-based systems have emerged as promising tools for assisting in the analysis of medical images and the automatic classification of breast lesions as benign or malignant, with the potential to support diagnostic assessment and clinical decision-making.

The classification of breast lesions in both ultrasound and mammography is typically formulated as a binary classification problem (benign versus malignant), in which the decision threshold is the value used to convert the probability predicted by the model into a final class label [4]. The choice of this threshold directly affects the occurrence of false positives (benign lesions incorrectly classified as malignant) and false negatives (malignant lesions incorrectly classified as benign). Although several studies have reported promising results in breast lesion classification using deep learning techniques [5] - [7], the evaluation of these models remains largely restricted to performance metrics obtained at a single operating point, typically associated with the default decision threshold of 0.5, without discussing the impact of alternative threshold values. This approach limits the assessment of classifier behavior under different operating requirements, since different classification scenarios may require different trade-offs between sensitivity and specificity. Furthermore, depending on the intended application, the costs associated with false positives and false negatives are inherently asymmetric.

In potential clinical applications where the priority is to reduce unnecessary procedures, such as biopsies and additional diagnostic examinations, it may be desirable to operate the model at threshold values that increase confidence in benign classifications [8], [9]. Conversely, in screening and triage applications, the primary concern is the reduction of false negatives, favoring threshold values that increase

sensitivity for the detection of malignant lesions. In this direction, the study presented in [9] proposed a classifier capable of significantly reducing false negatives; however, its operating point was not adaptable to different operating objectives. Therefore, decision-threshold calibration emerges as a relevant strategy for tailoring model behavior to distinct classification requirements, potentially increasing its practical flexibility without requiring modifications to the neural network architecture.
