Neurons are excitable cells that transmit information through action potentials generated by the coordinated activation and inactivation of voltage-gated Na^+ and K^+ channels. Sodium influx promotes membrane depolarization, whereas potassium efflux restores the resting membrane potential, enabling the propagation of nerve impulses [1].

To quantitatively describe these electrophysiological mechanisms, Hodgkin and Huxley proposed the Hodgkin–Huxley (HH) model in 1952, representing the cell membrane as an equivalent electrical circuit in which the phospholipid bilayer is modeled as a capacitor and the ion channels as variable conductances associated with their respective equilibrium potentials [2]. Since its introduction, the HH model has become a cornerstone of computational neuroscience and remains widely employed in research, education, and computational studies of neuronal excitability [3]–[6].

More recently, analog implementations of the HH model using discrete electronic components have been proposed for educational and experimental applications [7]–[9]. In this context, this study presents the computational implementation of the HH model together with its equivalent physical circuit, enabling a comparison between experimentally measured membrane potentials and theoretical predictions. By integrating neurophysiology, mathematical modeling, and analog electronics, the proposed approach provides a practical platform for investigating the electrophysiological mechanisms described by the Hodgkin–Huxley model.

II. Methodology

This study is a quantitative, applied, theoretical-computational investigation based on mathematical modeling, computational simulation, and statistical analysis. The research methodology comprised sequential stages, including the implementation of the Hodgkin–Huxley mathematical model, computational simulation of the membrane potential and gating variables, determination of the equivalent electrical parameters, simulation of the equivalent circuit, physical implementation of the circuit, experimental data acquisition, and statistical analysis of the measured results. This workflow enabled a systematic comparison between the theoretical predictions of the mathematical model and the experimental behavior of the physical circuit, allowing the evaluation of

the proposed implementation. The complete methodological workflow adopted throughout the study is summarized in Fig. 8.

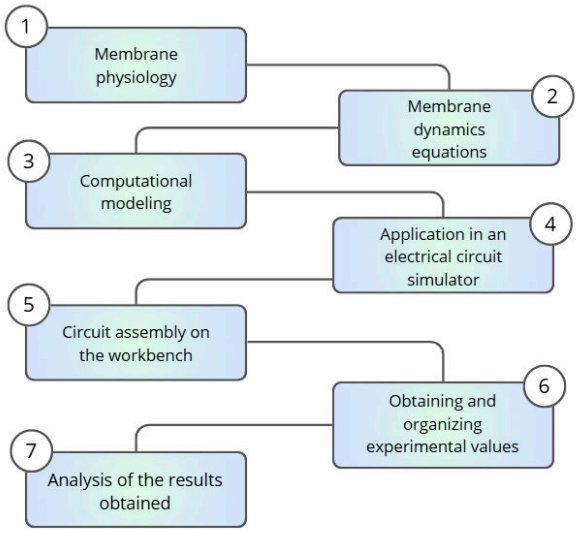

Figure 1: Methodological workflow including membrane physiology, mathematical modeling, computational simulation, physical circuit implementation, and analysis of the obtained results.

A. Physiology of the membrane action potential

Neurons are excitable cells that receive, process, and transmit information through electrical and chemical signals. This process depends on the electrical properties of the plasma membrane, including the resting membrane potential, membrane capacitance, and ionic resistance. The plasma membrane separates the intracellular and extracellular compartments while regulating the selective transport of ions through specialized ion channels [1], [3].

Under resting conditions, the neuronal membrane exhibits a potential difference of approximately -70 mV, known as the resting membrane potential. This potential results from the unequal distribution of ions between the intracellular and extracellular compartments, the high membrane permeability to potassium ions (K^+), and the continuous activity of the sodium–potassium pump (Na^+/K^+-ATPase), which transports three Na^+ ions out of the cell and two K^+ ions into the cell, thereby maintaining the electrochemical gradients required for neuronal excitability [1], [3], [5]. Small variations in membrane permeability continuously influence the membrane potential, allowing neurons to respond to external stimuli. When the membrane is sufficiently depolarized to reach the threshold potential, voltage-gated sodium channels open rapidly, initiating the action potential. This transient electrical event propagates along the axon without significant attenuation, enabling efficient communication between neurons and target tissues. The coordinated activation and inactivation of sodium and potassium channels are therefore essential for the generation, propagation, and termination of the action potential. The mechanism is illustrated in Fig. 8.

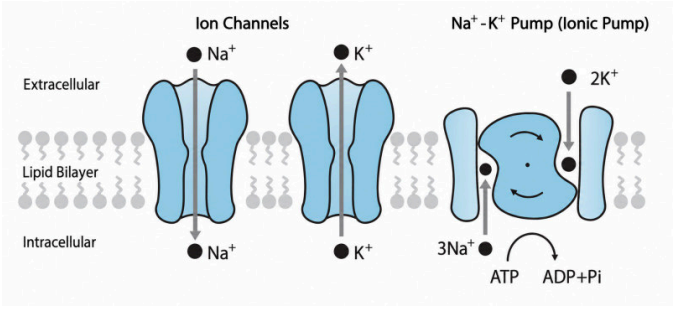

Figure 2: Illustration of the sodium–potassium pump mechanism. Adapted from Sterratt *et al.* (2011) [6].

When the membrane potential reaches the activation threshold, voltage-gated sodium channels open rapidly, allowing Na^+ influx and producing membrane depolarization [1], [2].

Within a few milliseconds, sodium channels become inactivated while voltage-gated potassium channels open. The resulting increase in K^+ permeability promotes potassium efflux, leading to membrane repolarization. In many cases, the elevated potassium conductance drives the membrane potential below its resting value, characterizing the hyperpolarization phase [1], [3], [5].

Subsequently, potassium channels return to their resting state, and the sodium–potassium pump gradually restores the original ionic gradients, allowing the membrane potential to return to its resting value. This sequence constitutes the action potential, which underlies the propagation of nerve impulses along the axon and neuronal communication [1], [2], [4].

A quantitative description of these mechanisms was proposed by Hodgkin and Huxley through a system of nonlinear differential equations describing the dynamics of sodium and potassium channel conductances, thereby enabling mathematical modeling of the different phases of the action potential [2].

B. Membrane dynamics equations

The Hodgkin–Huxley model was computationally implemented in *MATLAB* R2026a using the original differential equations proposed by Hodgkin and Huxley to describe the dynamics of the membrane potential and ion channels. These equations were derived from experiments based on the *voltage-clamp* technique, which enables independent measurement of the ionic currents responsible for generating the action potential [2].

As illustrated in Fig. 3, the *voltage-clamp* method employs a negative-feedback system that maintains the membrane potential at a prescribed value by injecting or withdrawing current between the intracellular and extracellular compartments. This approach allows the ionic currents to be measured while controlling the membrane potential.

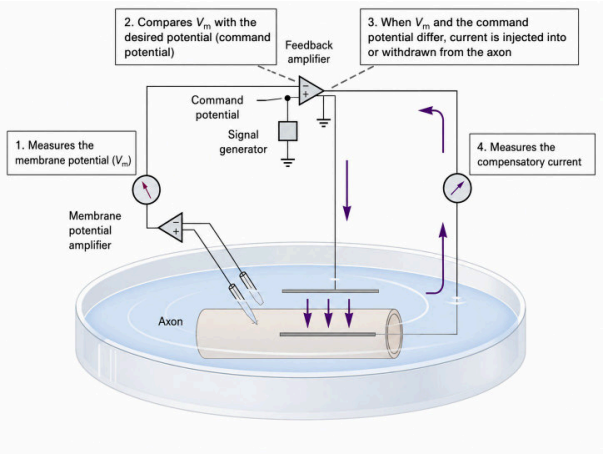

Figure 3: Schematic representation of the *voltage-clamp* method. (1) An intracellular electrode connected to an amplifier measures the membrane potential. (2) The measured potential is compared with a predefined command potential. (3) If a difference exists, a feedback amplifier injects or withdraws current until the membrane potential reaches the command value. (4) The injected current required to maintain this condition is continuously measured. Adapted from Kandel *et al.* [1].

These experiments enabled Hodgkin and Huxley to isolate the intrinsic properties of ion channels and quantitatively characterize the Na^+, K^+, and leak currents. They also demonstrated that channel conductances depend on both membrane potential and time and can be described by the state variables m, n, and h, representing the activation and inactivation dynamics of voltage-gated ion channels [2], [5].

The state variables are governed by the functions $\alpha(V)$ and $\beta(V)$, whose numerical solution provides the membrane potential, channel state variables, conductances, and equivalent resistances required for the implementation of the equivalent electrical circuit. Together, these quantities define the Hodgkin–Huxley system of ordinary differential equations (ODEs) describing the action potential dynamics.

The total membrane current (I_m) is the sum of the ionic current (I_{ionic}) and the capacitive current $C_m \dfrac{dV_m}{dt}$ associated with the membrane capacitance, as expressed in (1).

$$I_m(t) = I_{\text{ionic}}(t) + C_m \frac{dV_m(t)}{dt} \tag{1}$$

The ionic current is given by the sum of the sodium (I_{Na}), potassium (I_{K}), and leak (I_{L}) channel currents, as expressed in (2).

$$I_{\text{ionic}}(t) = I_{\text{Na}} + I_{\text{K}} + I_{\text{L}}. \tag{2}$$

Each ionic current depends on the conductance of its respective channel and the difference between the membrane potential (V_m) and the corresponding equilibrium potential (E_{Na}, E_{K}, and E_{L}). The membrane potential is the electrical potential difference between the intracellular and extracellular compartments, resulting from the unequal distribution of ions across the plasma membrane. It arises from the combined effects of the ionic concentration gradient, which generates the chemical driving force, and the electrical gradient, which generates the electromotive force. Together, these forces determine the direction and magnitude of ionic flow through membrane channels [1], [5].

The equilibrium potential is the membrane potential at which the chemical and electrical driving forces acting on a given ion are balanced, resulting in no net ionic flux. Accordingly, E_{Na}, E_{K}, and E_{L} denote the equilibrium potentials of sodium, potassium, and leak channels, respectively, with the latter representing the contribution of residual membrane currents in the Hodgkin–Huxley model [1], [5].

Accordingly, the sodium, potassium, and leak currents are expressed as the product of the corresponding channel conductance and the electrochemical driving force, given by $(V_m - E_x)$, as presented in (3), (4), and (5).

$$I_{Na} = g_{Na}(V,t)\,[V_m(t) - E_{Na}]\,, \tag{3}$$

$$I_K = g_K(V,t)\,[V_m(t) - E_K]\,, \tag{4}$$

$$I_L = g_L\,[V_m(t) - E_L]\,. \tag{5}$$

The Na^+ and K^+ channel conductances are voltage dependent and are modulated by gating variables. In the Hodgkin–Huxley model, these conductances are expressed as functions of the gating variables (m, n, and h), as given by Eqs. (6) and (7).

$$g_{Na}(V,t) = \bar{g}_{Na}\, m^3(V,t)\, h(V,t) \tag{6}$$

$$g_K(V,t) = \bar{g}_K\, n^4(V,t). \tag{7}$$

The Na^+ channel contains two independent gates: an activation gate (m), which opens rapidly during depolarization, and an inactivation gate (h), which closes more slowly and interrupts the sodium current. In contrast, the K^+ channel contains only an activation gate (n) and remains open while the membrane is depolarized.

The gating variables m, n, and h are obtained from differential equations governed by the functions $\alpha(V)$ and $\beta(V)$, which describe the voltage-dependent transition rates of channel activation and inactivation, as shown in Eqs. (8)–(9). Variations in these functions modify the probability of channel opening, thereby regulating the Na^+ and K^+ currents responsible for membrane depolarization and repolarization [1], [2], [5].

$$\frac{dn}{dt} = \alpha_n(V)\,(1-n) - \beta_n(V)n, \tag{8}$$

$$\frac{dm}{dt} = \alpha_m(V)\,(1-m) - \beta_m(V)m, \tag{9}$$

$$\frac{dh}{dt} = \alpha_h(V)\,(1-h) - \beta_h(V)h. \tag{10}$$

In Eqs. (8)–(10), the variables m, n, and h assume values between 0 and 1, representing the probability that each gate is open. The functions $\alpha(V)$ and $\beta(V)$ determine the transition rates of these variables as a function of the membrane potential.

C. Computational Implementation in a Simulation Environment

Figure 4 illustrates the computational implementation of Eqs. (1) and (2) to generate the membrane action potential. Subsequently, Eqs. (8)–(10) were solved to obtain the activation and inactivation variables of the ion channels.

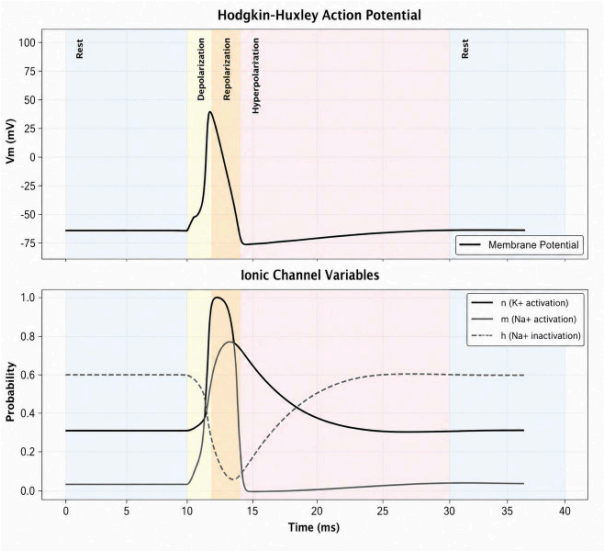

Figure 4: Action potential and ion channel variable waveforms. The light blue shaded region represents the resting phase, the yellow region represents depolarization, the orange region highlights repolarization, and the light pink region indicates hyperpolarization.

The temporal evolution of the membrane potential and gating variables in Fig. 4 occurs over 0–40 ms. During rest, V_m remains near -65 mV, with sodium channels mostly closed and potassium channels maintaining their resting conductance. After stimulation, the increase in m activates Na^+ channels, causing rapid depolarization, while h decreases and n increases gradually. At the action potential peak, sodium channel inactivation and potassium channel activation initiate the transition toward repolarization. Subsequently, the predominance of K^+ efflux restores the membrane potential, with a brief hyperpolarization caused by the delayed closure of potassium channels.

The coordinated variation of the gating variables demonstrates the dynamic behavior of voltage-dependent ion channels during neuronal excitation. The activation variable m responds rapidly to changes in membrane voltage, controlling the initial increase in sodium conductance, whereas the slower dynamics of h and n determine the duration of the action potential and the recovery phase. This difference in activation kinetics is essential for the temporal organization of depolarization and repolarization processes. Therefore, the interaction between these variables allows the Hodgkin–Huxley model to reproduce the main electrical characteristics of neuronal activity. Figure 5 presents the corresponding Na^+ and K^+ conductances and their equivalent resistances, demonstrating the inverse relationship between these parameters.

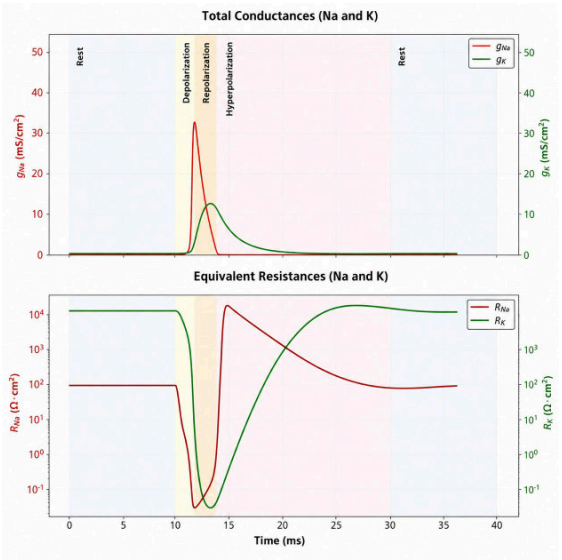

Figure 5: Total sodium (g_{Na}) and potassium (g_{K}) channel conductances and their corresponding equivalent resistances (R_{Na} and R_{K}) throughout the action potential. A transient increase in sodium conductance is observed during the depolarization phase, followed by an increase in potassium conductance during repolarization. Consequently, the equivalent resistances exhibit an inverse relationship with the conductances, reaching their minimum values when ionic permeability is at its maximum.

As expected, the increase in Na^+ conductance during depolarization is accompanied by a decrease in the corresponding equivalent resistance, facilitating Na^+ influx. Conversely, during repolarization, the increase in K^+ conductance is associated with a reduction in its equivalent resistance, promoting K^+ efflux.

D. Application in an electrical circuit simulator

Before the physical implementation, the proposed equivalent circuit was simulated using the *Proteus* software, a widely adopted platform for the simulation of electronic and electrical systems. This step was performed to verify the circuit operation, identify potential design inconsistencies, and validate its functionality prior to hardware implementation.

The equivalent circuit consisted of active components (voltage sources) and passive components (variable resistors, a fixed resistor, and a capacitor), as illustrated in Fig. 6.

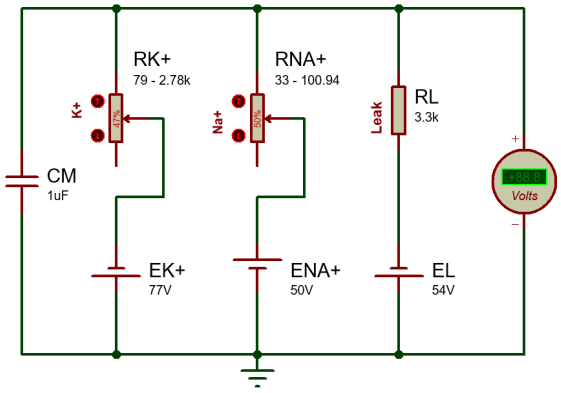

Figure 6: Equivalent electrical circuit implemented in *Proteus*. The circuit comprises the membrane capacitance (C_M), potassium resistance (R_{K^+}), sodium resistance (R_{Na^+}), leak resistance (R_L), potassium equilibrium potential (E_{K^+}), sodium equilibrium potential (E_{Na^+}), leak equilibrium potential (E_L), and a voltmeter for membrane potential measurement.

As shown in Fig. 6, the polarity of the E_{K^+} and E_L voltage sources is reversed with respect to E_{Na^+}. This configuration reflects the physiological direction of the ionic currents across the membrane. During depolarization, Na^+ ions enter the cell, generating an inward current, whereas during repolarization K^+ ions leave the cell, producing an outward current. Under the simulated conditions, the leak current also flows predominantly outward. Consequently, the adopted source polarities ensure that the current directions in the equivalent circuit are consistent with the physiological behavior of ionic transport across the membrane.

E. Circuit assembly on the workbench

The components used for the physical implementation of the equivalent circuit are presented in Fig. 7.

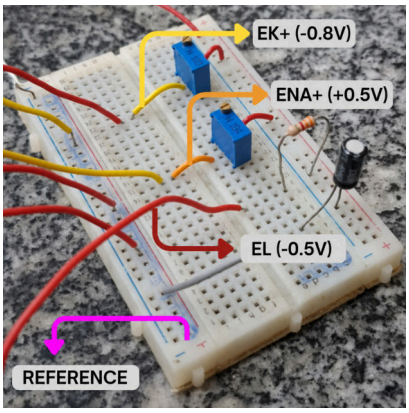

Figure 7: Physical implementation of the equivalent circuit shown in Fig. 6.

Trimmer potentiometers (Trimpots) were employed to implement the variable resistances corresponding to the membrane ion channel conductances. The following models were used:

- **w103**: Rated at 10 kΩ, this potentiometer was used to represent the potassium (K^+) channel.
- **w104**: Rated at 100 kΩ, this potentiometer was used to represent the sodium (Na^+) channel, providing a wider resistance adjustment range than that required for the K^+ channel.

Three DC voltage sources were employed to represent the equilibrium potentials, with $E_{\mathrm{K}^+} = 0.8$ V, $E_{\mathrm{Na}^+} = 0.5$ V, and $E_L = 0.5$ V. A 1 μF electrolytic capacitor was used to represent the membrane capacitance.

F. Collection and organization of experimental data

After assembling the equivalent circuit, experimental data were collected by discretizing the action potential waveform. Twenty-three sampling points were selected along the temporal profile of the action potential, covering the resting, depolarization, repolarization, and hyperpolarization phases.

For each sampling instant, the theoretical resistance values corresponding to the ion channels were obtained from the computational simulation. The trimmer potentiometers were then manually adjusted to reproduce these resistance values, which were verified using a digital multimeter. This procedure ensured that the physical resistance implemented in the circuit matched the corresponding theoretical value at each point of the action potential.

After measuring the membrane potential (V_m), potassium resistance (R_{K}), and sodium resistance (R_{Na}), the experimental data were organized in a spreadsheet for subsequent processing and analysis. Each sampling instant was associated with the corresponding values of R_{K} and R_{Na} implemented in the circuit.

This procedure enabled the standardization and verification of the experimental data, facilitating graphical analysis and direct comparison with the theoretical predictions of the Hodgkin–Huxley model.

G. Analysis of the Obtained Results

The values of V_m, R_{K^+}, R_{Na^+}, and their corresponding sampling points (x) were organized into three tables to facilitate the analysis and comparison of the computational and experimental results. Table I presents the values obtained from the computational implementation, which served as the theoretical reference for the action potential predicted by the Hodgkin–Huxley model. These data were used to determine the expected variations in ion channel resistances throughout the action potential and to define the parameters required for the physical circuit implementation. The sampling points were selected according to relevant phases of the action potential, including depolarization, repolarization, and hyperpolarization, allowing a more detailed evaluation of the dynamic behavior of the model. The computational results provided the basis for adjusting the equivalent circuit parameters and comparing the theoretical predictions with the experimental measurements obtained from the implemented circuit.

TABLE I: Voltage and resistance values obtained computationally.

Point X	V_m **(V)**	R_K **(kΩ)**	R_{Na} **(kΩ)**
1	-65	2,72	94,25
1130	-32,39	1,47	0,56
1147	-0,6544	1,0445	0,1341
1154	20,255	0,825	0,0709
1170	40,2457	0,450	0,033
1227	18,4559	0,1255	0,043

1333	-32,6064	0,0791	0,1582
1390	-65,2879	0,0896	1,7771
1399	-70,2739	0,0933	5,3573
1454	-76,192	0,124	10094
2128	-70,2908	1,7677	759,4332
3111	-64,5146	2,7823	79,0164
3619	-65,0004	2,6768	93,8534

The experimental measurements are summarized in Tables II and III. Table II presents the results obtained from the physical implementation of the equivalent circuit. At sampling points 1390, 1399, 1454, 1847, 2128, and 2376, the equivalent sodium-channel resistance (R_{Na^+}) reached very high values. This behavior reflects the low sodium-channel conductance at these instants, causing the equivalent resistance to approach an open-circuit condition.

TABLE II: Voltage and resistance values of the physical experimental circuit.

Point X	V_m **(mV)**	R_K **(kΩ)**	R_{Na} **(kΩ)**
1	0,0066	2,7	94

To quantitatively compare the computational and experimental results, the mean and standard deviation of the measurements reported in Tables II and III were calculated. These statistical measures were then compared with the theoretical values presented in Table I to evaluate the agreement between the computational Hodgkin–Huxley model and its equivalent physical circuit implementation.

III. Results and Discussion

Based on the data presented in Tables II and III, the mean membrane potential (V_m) and the corresponding standard deviation were calculated for each sampling point. The experimental mean exhibited an atypical waveform compared with that predicted by the Hodgkin–Huxley model, characterized by a single positive deflection at the action potential peak followed by a hyperpolarization phase. The standard deviation remained relatively low (within approximately $\pm 1\,\mathrm{mV}$ for most sampling points), indicating good repeatability and low variability between measurements performed under similar experimental conditions.

The experimental measurements were compared with the computational results obtained for the standard circuit, the open-circuit configuration (with the Na^+ channel branch disconnected), and the numerical Hodgkin–Huxley model. As shown in Fig. 8, the experimental mean did not reproduce the response of the standard circuit, particularly during the depolarization phase, where the simulated waveform exhibited a more pronounced positive deflection. Additional discrepancies were observed during the repolarization and after-hyperpolarization phases, where the measured membrane potentials tended to be more negative than those predicted by the computational model.

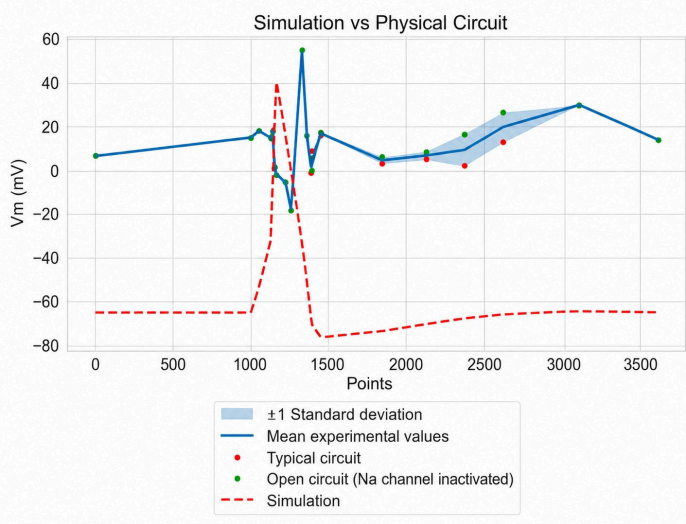

Figure 8: Comparison between the computational simulation and the experimental results, showing the experimental mean, standard deviation, the standard circuit response, and the response obtained with the Na^+ channel branch disconnected.

The largest discrepancies between the experimental and computational results occurred during the depolarization phase and at the action potential peak, where the experimental waveform exhibited a significantly lower amplitude than that predicted by the standard circuit. During the initial repolarization phase, the experimental response also showed a slightly slower decay than the simulated waveform, resulting in a peak delay of approximately $0.2\,\mathrm{ms}$. More pronounced differences were observed during the late repolarization and after-hyperpolarization (*undershoot*) phases, where the experimental membrane potentials were up to $2.6\,\mathrm{mV}$ more negative than the simulated values.

The open-circuit configuration exhibited a markedly different behavior, characterized by a substantially reduced amplitude (maximum peak of only $5.2\,\mathrm{mV}$) and the absence of the characteristic action potential peak. This result confirms the essential role of Na^+ channels in action potential generation, consistent with the predictions of the Hodgkin–Huxley model. Although the standard circuit did not perfectly reproduce the experimental waveform, it provided a considerably closer approximation than the open-circuit configuration, reinforcing the importance of sodium-channel conductance in the equivalent electrical model.

The observed discrepancies can be attributed to the simplified representation of membrane dynamics adopted in the proposed circuit. In biological membranes, the Na^+ and K^+ channels exhibit continuous voltage-dependent activation and inactivation, whereas the equivalent circuit represents these processes through discrete resistance adjustments. Consequently, although the proposed implementation reproduces the principal phases of the action potential, it cannot fully emulate the nonlinear dynamics described by the Hodgkin–Huxley equations. Additional sources of error, including component tolerances, equivalent membrane resistance variations, and temperature effects, may also have contributed to the differences between the computational and experimental responses.

From an electronic perspective, the cell membrane behaves analogously to a transistor, selectively regulating the flow of ionic current through voltage-dependent Na^+ and K^+ channels. This mechanism resembles the operation of a field-effect transistor (FET), in which the gate voltage controls the current flowing between the source and drain. Accordingly, transistor-based circuits have been proposed to reproduce the temporal evolution of the Hodgkin–Huxley gating variables (m, n, and h), providing a closer approximation of the model's nonlinear dynamics than implementations based exclusively on passive components [8].

Few studies have reported the physical implementation of the Hodgkin–Huxley equivalent circuit together with systematic experimental validation. Nizar *et al.* [7] developed analog neurons for virtual laboratory applications but did not report detailed membrane-potential measurements. Rutherford *et al.* [9] proposed a transistor-based implementation capable of qualitatively reproducing the Hodgkin–Huxley dynamics; however, discretized experimental measurements and quantitative comparisons with the theoretical model were not presented. Likewise, Kutzner and Bryson [8] described an educational implementation based on potentiometers without continuous experimental data acquisition.

The present work extends these previous studies by experimentally evaluating the equivalent circuit through membrane-potential measurements at 23 discretized sampling points covering all phases of the action potential. The potentiometers were manually adjusted to reproduce the theoretical resistance values predicted by the computational model, enabling a direct comparison between the numerical and experimental responses. Although deviations were observed, particularly during depolarization and after-hyperpolarization, the proposed circuit successfully reproduced the principal characteristics of the Hodgkin–Huxley model, demonstrating the feasibility of its physical implementation as an educational and experimental platform.

Future implementations may further improve the agreement between the computational and experimental responses by incorporating active electronic devices capable of reproducing the voltage-dependent behavior of ionic conductances. Electrochemical transistors (ECTs), for example, can directly couple ionic and electronic conduction, enabling applications in neuromorphic computing and neuroprosthetic systems [7], [9]. Such technologies may bridge the gap between simplified educational circuits and biologically realistic electronic implementations while preserving the conceptual foundation provided by equivalent electrical models of membrane electrophysiology.

IV. Conclusion

This work presented the computational modeling, simulation, and physical implementation of an equivalent electrical circuit based on the Hodgkin–Huxley model for representing the electrical behavior of excitable cell membranes.

The proposed methodology enabled the determination of the membrane potential and the equivalent sodium and potassium channel resistances from the numerical model, followed by the implementation and experimental evaluation of the corresponding electrical circuit.

The comparison between the computational predictions and the experimental measurements demonstrated that the proposed circuit successfully reproduced the principal characteristics of the Hodgkin–Huxley action potential. Although discrepancies were observed, particularly during the depolarization and after-hyperpolarization phases, the experimental results remained consistent with the expected qualitative behavior of the model. These differences are primarily attributed to the simplified representation of the voltage-dependent ionic conductances and to the practical limitations associated with the use of discrete electronic components.

The experimental measurements also showed that, at specific sampling points, the equivalent sodium-channel resistance reached very high values, approaching an open-circuit condition. This behavior is consistent with the sodium-channel inactivation phase described by the Hodgkin–Huxley model, during which sodium conductance decreases despite the membrane remaining depolarized. Consequently, the proposed equivalent circuit was able to reproduce not only the overall action potential waveform but also the qualitative changes in the electrical behavior associated with the activation and inactivation of the ionic channels.

Overall, the results demonstrate that the proposed equivalent electrical circuit constitutes a practical platform for studying membrane electrophysiology and for illustrating the electrical mechanisms underlying the Hodgkin–Huxley model. Future work will focus on incorporating active electronic devices, such as transistors, to emulate the voltage-dependent nonlinear behavior of ionic conductances more accurately, thereby improving the agreement between the computational model and its physical implementation.

***Abstract*—The development of machine learning models to predict acute asthma exacerbations is severely hindered by the scarcity of balanced, high-quality clinical datasets. High-fidelity simulators offer a potential solution by generating synthetic respiratory digital twins; however, their physiological validity and suitability for data augmentation must be rigorously assessed. This study presents a structured validation framework applied to a synthetic cohort of thirty virtual patients across three asthma severity levels, generated via the ASL5000 Breathing Simulator. We demonstrate that the simulator reproduces physiologically plausible patterns consistent with established respiratory mechanics, including compensatory tachypnea, reduced dynamic compliance, and intrinsic positive end-expiratory pressure. Spearman rank correlation analysis revealed strong monotonic trends for key variables ($\rho > 0.78$, $p < 0.001$). Furthermore, we report a novel observation: despite a systematic numerical bias in respiratory rate measurements, the dataset exhibits strong categorical separability for severity stratification (Cohen's Kappa = 0.90), suggesting its potential suitability for classification tasks. Finally, we evaluated a Synthetic Minority Oversampling Technique (SMOTE) pipeline, providing statistical evidence that synthetic expansion preserves both marginal distributions and multivariate dependence structures (mean absolute correlation difference $\Delta\rho = 0.020$). This framework offers a reproducible foundation for training edge artificial intelligence devices in respiratory monitoring.**

***Index Terms*—Asthma, Synthetic Data, Digital Twins, Machine Learning, Physiological Validation, Biomedical Engineering.**

I. Introduction

ASTHMA affects hundreds of millions of individuals worldwide and remains one of the leading causes of morbidity, emergency department visits, and healthcare expenditure [1]. Despite advances in pharmacological therapies, acute exacerbations remain difficult to predict, often leading to delayed interventions and preventable clinical deterioration. Consequently, asthma management is increasingly shifting toward predictive approaches supported by data-driven decision systems capable of identifying subtle physiological changes before severe manifestations occur [2], [3].

Artificial intelligence (AI) and machine learning (ML) have emerged as promising tools for exacerbation prediction. However, their performance depends on the availability of large, diverse, and physiologically representative datasets [4]. Acquiring respiratory data during acute exacerbations is ethically, logistically, and financially challenging, while the low incidence of severe events results in highly imbalanced datasets. Synthetic data generation has therefore become an

attractive strategy for dataset augmentation, class balancing, and improved model robustness [5].

Digital twin technology enables physiologically controlled synthetic data generation through high-fidelity respiratory simulators, which allows precise manipulation of airway resistance, lung compliance, and inspiratory effort to recreate clinically relevant scenarios [7], [8]. Nevertheless, synthetic datasets must be physiologically validated before being used for ML applications, since unrealistic simulations or inappropriate augmentation techniques, such as the Synthetic Minority Oversampling Technique (SMOTE), may introduce implausible biomechanical relationships and compromise model reliability [6].

To address these challenges, this study proposes a structured physiological validation framework for synthetic ventilatory datasets generated using the ASL5000, supporting the development of edge-AI respiratory monitoring systems,including the Respiratory Diagnostic Assistant [9]. We hypothesize that synthetic respiratory profiles generated under controlled mechanical constraints reproduce clinically plausible respiratory behavior and remain suitable for data augmentation when physiological integrity is preserved.

The main contributions of this work are:

- **Physiological Plausibility Assessment:** Demonstration that the ASL5000 reproduces key physiological features of the asthma cascade (e.g., auto-PEEP, tachypnea, and expiratory flow limitation), supported by Spearman correlation analysis.
- **Categorical versus Numerical Validity Observation:** Evidence that, despite numerical bias in respiratory rate, the simulator preserves severity stratification with strong categorical agreement (Cohen's Kappa = 0.90), supporting its use in ML classification tasks.
- **Multivariate Integrity of Data Augmentation:** Statistical evidence that a SMOTE-based pipeline preserves both marginal distributions and multivariate dependence structures (mean absolute correlation difference $\Delta\rho = 0.020$).
- **Edge-AI Readiness:** A reproducible pipeline providing balanced, physiologically coherent datasets for training lightweight ML models on embedded devices.

II. Related Work

Machine learning (ML) has become increasingly important in asthma management, driven by advances in electronic health records and wearable monitoring. Recent systematic reviews show that supervised learning algorithms identify patterns associated with impending exacerbations, often outperforming conventional statistical approaches [2], [3]. However, the scarcity of high-quality datasets containing severe exacerbation events remains a major limitation, leading to class imbalance and reduced model generalization [4], [5].

To address these limitations, synthetic data generation and digital twin technologies have emerged as promising alternatives. A digital twin is a virtual representation of a biological system that reproduces physiological behavior through computational models [10]. In respiratory research, the ASL5000 enables precise control of airway resistance, lung compliance, inspiratory effort, and respiratory drive, generating physiologically coherent respiratory profiles [7], [8]. Previous studies have demonstrated strong agreement between ASL5000 outputs and theoretical respiratory mechanics [8].

Nevertheless, synthetic data alone do not guarantee physiological realism. Models trained on unrealistic data may perform well internally but fail to generalize clinically. Moreover, the limited size of simulator-generated cohorts often requires augmentation techniques such as SMOTE, whose inappropriate application may generate physiologically implausible samples and distort biomechanical relationships [6]. Consequently, validation frameworks simultaneously assessing the physiological plausibility of simulator-generated datasets and the integrity of subsequent augmentation remain scarce. The present study addresses this gap by proposing a structured validation methodology based on emergent physiological biomarkers.

III. Materials and Methods

A. Study Design and Experimental Setup

This study was designed as a physiological validation investigation conducted at the Multiuser Laboratory for Instrumental Innovation and Physical-Functional Performance (LINDEF). The experimental setup used the ASL5000 high-fidelity breathing simulator (IngMar Medical, Pittsburgh, PA, USA), controlled via ASL SW software (v3.6) on a Surface Pro 10 tablet connected through a USB interface.

To ensure physiological fidelity, simulations were performed in a controlled environment at 36 °C using a 500 mL silicone test lung (PROTEC, Brazil). The protocol consisted of continuous 1-minute runs per virtual patient, corresponding to approximately 30–40 spontaneous respiratory cycles. High-resolution waveforms were recorded and extracted using the ASL5000 Post-Run Analysis module.

B. Signal Quality Control

Prior to analysis, each recorded respiratory cycle was screened for physiological plausibility. Cycles exhibiting values outside established clinical ranges (e.g., respiratory rate > 80 BPM, negative I:E ratios, or plateau pressures > 60 cmH_2O) were flagged as artifacts likely corresponding to the simulator's initial stabilization phase or transient mechanical oscillations. These cycles were excluded prior to computing per-patient averages. This quality-control step ensured that the analyzed dataset reflected stable respiratory behavior rather than start-up transients.

C. Virtual Cohort Construction

A synthetic cohort comprising thirty virtual patients was generated and stratified into three clinically relevant severity categories: Group 1 (Mild Asthma, n=10), Group 2 (Moderate Asthma, n=10), and Group 3 (Severe Asthma, n=10).

The cohort size was not intended to estimate population prevalence, but rather to create a controlled proof-of-concept sample with sufficient intra-group variability for physiological

validation. Ten patients per group were selected to allow paired statistical comparisons while maintaining a manageable experimental scope, consistent with bench-study conventions in respiratory simulation research [8].

The severity hierarchy was designed to reproduce the progressive deterioration in respiratory mechanics typically observed during acute asthma exacerbations. Parameter ranges for each severity level were defined through a systematic review of clinical guidelines (GINA 2025) [1] and established respiratory physiology references [11], [12]. Within each group, individual patient profiles were constructed by manually sampling combinations of resistance, compliance, respiratory rate, and muscle pressure from predefined ranges, ensuring intra-group variability while preserving clinically plausible limits. This manual construction approach was adopted to maintain direct control over the physiological coherence of each virtual patient. Each patient's parameter combination is detailed in Table I.

D. Respiratory Simulation Environment

All simulations were conducted in spontaneous breathing mode. The ASL5000 reproduces respiratory behavior through a computer-controlled piston assembly governed by the mathematical model of lung mechanics, represented by the equation of motion:

$$P_{mus} = R\dot{V} + \frac{V}{C} + PEEP \tag{1}$$

where P_{mus} represents inspiratory muscle pressure, R denotes airway resistance, $\dot{V}$ represents airflow, V denotes lung volume, C corresponds to lung compliance, and $PEEP$ is positive end-expiratory pressure. This formulation allows independent control of airway obstruction and elastic load while preserving physiologically meaningful pressure-flow relationships.

E. Physiological Output Variables and Feature Extraction

Beyond the primary mechanical parameters (R and C), several downstream physiological variables were extracted for validation. These included Spontaneous Respiratory Rate (BPM), Mean Expiratory Pressure (cmH_2O), Peak Expiratory Flow Characteristics (%), Inspiratory-to-Expiratory Ratio (I:E), Maximum Trigger Pressure Drop (ΔP_{trig}, cmH_2O), and Total Inspiratory Elastic Work (mJ). Importantly, these variables were *not* directly programmed into the simulator, but instead emerged naturally from the interaction between respiratory mechanics and spontaneous breathing behavior, providing a robust test of physiological realism.

F. Statistical Validation Framework and Data Augmentation

To ensure dataset integrity, a multi-stage statistical pipeline was implemented. First, the separability of the three severity groups was assessed using the Kruskal-Wallis test with Dwass-Steel-Critchlow-Fligner post-hoc comparisons, given the non-normal distribution of several variables (verified via the Shapiro-Wilk test). Effect sizes were quantified using epsilon-squared (ϵ^2).

Second, to evaluate whether physiological parameters evolved consistently with increasing disease severity, Spearman's rank correlation coefficient (ρ) was computed between ordinal severity coding (Mild=1, Moderate=2, Severe=3) and each physiological variable. This analysis tested the central hypothesis that simulated parameters follow monotonic trends consistent with established pathophysiology.

Third, to assess the simulator's utility for ML classification, we performed a categorical validity analysis using a Confusion Matrix and Cohen's Kappa (κ), comparing clinical severity labels against simulated respiratory-rate-based classifications.

Finally, to address the limited cohort size (n=30), the Synthetic Minority Oversampling Technique (SMOTE) was applied to expand the dataset. To assess whether SMOTE preserved the underlying multivariate dependence structure, we computed Pearson correlation matrices before and after augmentation and quantified their absolute difference.

G. Reproducibility and Computational Environment

All statistical analyses were implemented in Python 3.11 using SciPy 1.11, NumPy 1.24, Pandas 2.0, and Statsmodels 0.14. Complementary descriptive analyses were performed in jamovi 2.7. The analytical workflow was fully scripted to facilitate independent verification and future extension of the dataset for machine learning applications.

IV. Results

A. Statistical Separability of Severity Groups

The Kruskal-Wallis test indicated statistically significant separation among the three asthma severity levels for most of the physiological variables evaluated. Table II summarizes the test statistics, p-values, and effect sizes (epsilon-squared, ϵ^2).

As shown in Fig. 1 and Table II, the variables with the largest effect sizes were Respiratory Rate ($\epsilon^2 = 0.890$) and Compliance ($\epsilon^2 = 0.803$), indicating that these biomarkers are highly discriminative for severity stratification. Notably, Total Inspiratory Elastic Work did not differ significantly across groups ($p = .258$), supporting the interpretation that the simulated disease remains primarily resistive (obstructive) rather than elastic, consistent with asthma pathophysiology.

B. Monotonic Trends Across Severity Levels

To assess whether physiological parameters evolved consistently with increasing disease severity, Spearman rank correlation was computed between ordinal severity coding (Mild=1, Moderate=2, Severe=3) and each physiological variable. Table III summarizes the results.

Strong monotonic associations were observed for Respiratory Rate ($\rho = 0.943$), Compliance ($\rho = -0.891$), and Peak Expiratory Flow ($\rho = 0.849$), all with $p < 0.001$. These results support the hypothesis that simulated parameters evolve in physiologically consistent directions as disease severity increases.

TABLE I
MECHANICAL PARAMETERS OF THE VIRTUAL COHORT BY SEVERITY GROUP

Parameter	Group 1 (Mild)	Group 2 (Moderate)	Group 3 (Severe)
Airway Resistance (R)	5–8 $cmH_2O/L/s$	12–18 $cmH_2O/L/s$	20–25 $cmH_2O/L/s$
Lung Compliance (C)	75–90 mL/cmH_2O	40–56 mL/cmH_2O	30–48 mL/cmH_2O
Muscle Pressure (P_{mus})	7–12 cmH_2O	27 cmH_2O (Fixed)	27 cmH_2O (Fixed)
Respiratory Rate (RR)	14–20 bpm	24–29 bpm	30–45 bpm
Insp. Rise Time	40–50%	20% (Fixed)	20% (Fixed)
Insp. Release Time	50–60%	15% (Fixed)	15% (Fixed)

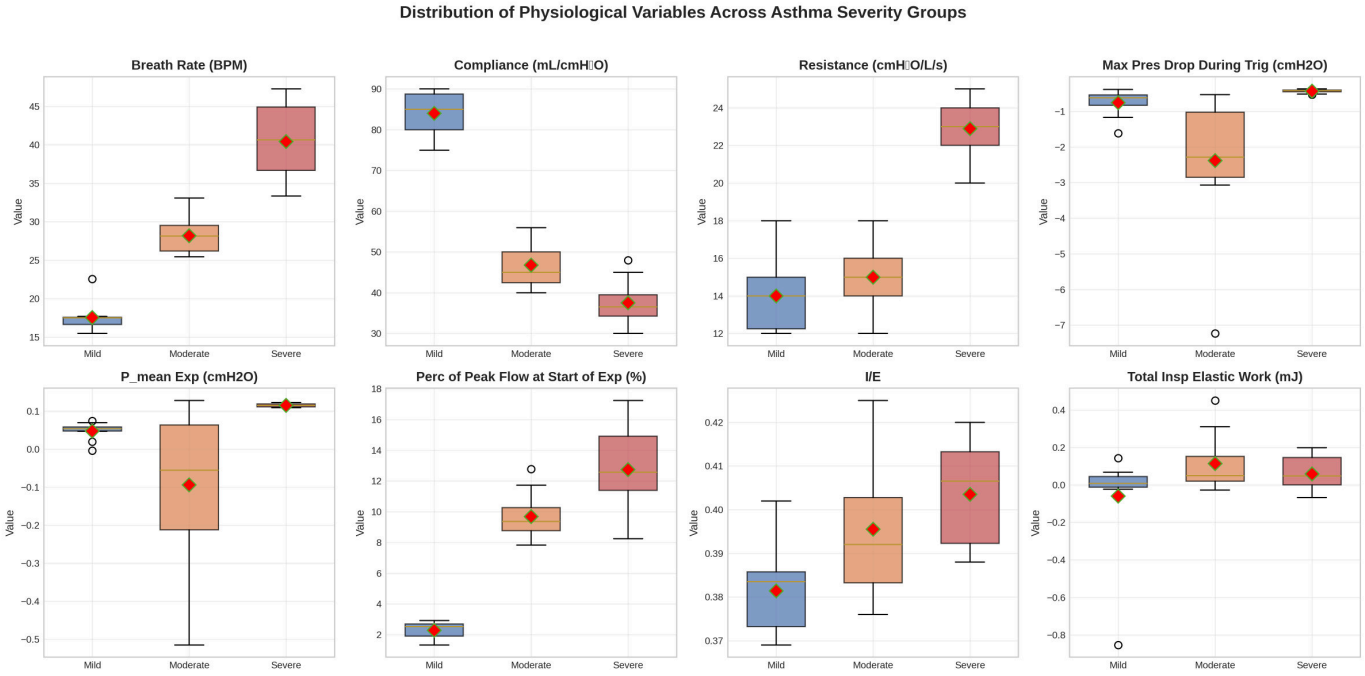

Fig. 1. Distribution of key physiological variables across the three simulated asthma severity groups (Mild, Moderate, Severe). The boxplots illustrate progressive deterioration in respiratory mechanics, including compensatory tachypnea, reduced dynamic compliance, and increased triggering effort.

TABLE II
STATISTICAL SEPARABILITY OF PHYSIOLOGICAL VARIABLES ACROSS SEVERITY GROUPS (KRUSKAL-WALLIS TEST)

Variable	χ^2 (H)	p-value	Effect Size (ϵ^2)
Respiratory Rate (BPM)	25.81	< 0.001	0.890
Compliance (mL/cmH_2O)	23.29	< 0.001	0.803
Peak Exp. Flow (%)	21.68	< 0.001	0.748
Resistance ($cmH_2O/L/s$)	20.27	< 0.001	0.699
Max. Trigger Press. Drop (cmH_2O)	18.88	< 0.001	0.651
Mean Exp. Pressure (cmH_2O)	15.28	< 0.001	0.527
I/E Ratio	10.89	0.004	0.375
Total Insp. Elastic Work (mJ)	2.71	0.258	0.094

TABLE III
SPEARMAN CORRELATION BETWEEN SEVERITY AND PHYSIOLOGICAL VARIABLES

Variable	ρ	p-value
Respiratory Rate (BPM)	0.943	< 0.001
Compliance (mL/cmH_2O)	-0.891	< 0.001
Resistance ($cmH_2O/L/s$)	0.789	< 0.001
Peak Exp. Flow (%)	0.849	< 0.001
Mean Exp. Pressure (cmH_2O)	0.557	0.001
I/E Ratio	0.612	< 0.001
Max. Trigger Press. Drop	0.424	0.019
Total Insp. Elastic Work	0.203	0.282

The non-significant correlation for Total Inspiratory Elastic Work ($\rho = 0.203$, $p = .282$) is consistent with the interpretation that asthma is primarily a resistive rather than elastic disease. The positive correlation for Maximum Trigger Pressure Drop ($\rho = 0.424$, $p = .019$) reflects the non-monotonic behavior discussed in Section IV-C.3, where triggering effort peaks in the moderate group and decreases in the severe group due to the temporal constraints imposed by extreme tachypnea.

C. Emergence of the Pathophysiological Cascade

A core objective of this study was to assess whether secondary physiological variables plausibly emerged from the

programmed mechanical conditions, reproducing patterns consistent with the clinical cascade of acute asthma exacerbations.

1) Compensatory Tachypnea and Reduced Dynamic Compliance: Mean respiratory rate increased progressively from the mild cohort (17.5 ± 1.9 BPM) to the severe cohort (40.4 ± 5.1 BPM). This compensatory tachypnea is consistent with established respiratory physiology, whereby respiratory centers increase neural drive to maintain minute ventilation in the face of increasing airflow limitation and increased work of breathing [11], [12]. Simultaneously, dynamic compliance decreased from 84.0 ± 5.2 to 37.5 ± 5.6 mL/cmH_2O. Although *static* compliance is typically preserved in asthma, the observed reduction is consistent with *dynamic hyperinflation*: as air trapping progresses, the lung operates at higher volumes on the non-linear, steeper portion of the pressure-volume curve, effectively reducing apparent compliance [11].

2) Expiratory Flow Limitation and Intrinsic PEEP: The percentage of peak expiratory flow occurring at the onset of expiration decreased progressively across severity groups ($p < .001$). Physiologically, severe bronchoconstriction increases expiratory resistance and promotes premature airway closure, restricting airflow despite continued expiratory effort [13]. Furthermore, the maximum trigger pressure drop (ΔP_{trig}) exceeded -7.0 cmH_2O in severe profiles. Such increased inspiratory pressure requirements are consistent with intrinsic positive end-expiratory pressure (auto-PEEP). During severe bronchoconstriction, incomplete expiration leads to progressive air trapping; the resulting residual positive pressure must be overcome before inspiratory flow begins, requiring greater negative muscle pressures [13], [14].

3) Non-Linear Triggering Effort Behavior: Interestingly, triggering effort peaked in the moderate group (-2.38 ± 1.95 cmH_2O) and *decreased* in the severe group (-0.43 ± 0.05 cmH_2O). This non-monotonic behavior must be interpreted in the context of the simulator setup. The programmed muscle pressure (P_{mus}) was fixed at 27 cmH_2O for the moderate and severe groups, representing a physiological ceiling of inspiratory capacity. The observed decrease in ΔP_{trig} in the severe group is therefore not an artifact of a simulator limit, but a consequence of extreme tachypnea (cycle time < 1.5 s). The simulated diaphragm lacks the temporal window required to generate the maximum programmed pressure before the next respiratory cycle begins. This behavior is *analogous to the neuromechanical disadvantage observed clinically* in status asthmaticus, where hyperinflation flattens the diaphragm and reduces its pressure-generating capacity [14].

4) Elastic Work and Volume Compensation: An apparent contradiction emerged between the significant reduction in dynamic compliance (C) and the non-significant change in Total Inspiratory Elastic Work ($p = .258$). Theoretically, the elastic work equation $W_{el} = V_T^2/2C$ suggests that halving compliance should double elastic work. However, this analysis ignores the numerator: tidal volume (V_T). In the severe asthma group, dynamic hyperinflation and extreme tachypnea force the patient into a rapid, shallow breathing pattern, drastically reducing V_T. Because V_T is squared in the numerator, its steep reduction mathematically compensates for the decrease in compliance in the denominator. The simulator's ability to capture this complex, multivariable physiological compensation—where mechanical stiffening is counterbalanced by volume restriction—provides evidence supporting its fidelity as a respiratory digital twin.

D. Categorical Validity versus Numerical Bias

To assess the simulator's potential utility for machine learning classification, we performed a dual validation of respiratory rate output.

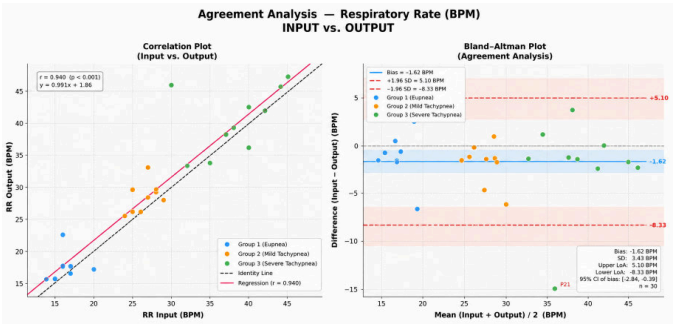

Fig. 2. Bland-Altman plot comparing input respiratory rate (clinical label) against emergent simulated respiratory rate. The plot reveals a systematic numerical bias (-1.62 BPM) and wide limits of agreement, indicating that the simulator does not reproduce exact absolute values.

Fig. 2 presents the Bland-Altman analysis, which revealed a systematic numerical bias (-1.62 BPM, 95% CI: -2.84 to -0.39) and wide limits of agreement (-8.33 to $+5.10$ BPM). Strictly from a metrological standpoint, this indicates that the simulator is not interchangeable with clinical measurements for reproducing absolute values.

However, for ML-based *risk stratification*, categorical separability is the governing metric. Complementary one-way ANOVA revealed highly significant differences between severity groups ($F = 113.0$, $p < 0.001$), with an effect size of $\eta^2 = 0.893$, indicating that 89.3% of the total variance in respiratory rate is explained by clinical severity group. This large effect size confirms that the simulator preserves the clinical decision boundaries required for classification tasks.

As shown in Fig. 3, the confusion matrix demonstrated strong categorical agreement (Cohen's Kappa $\kappa = 0.90$). Threshold-based classification correctly assigned 28 of 30 patients (93.3% accuracy), with errors occurring only between adjacent severity classes. Notably, the severe group achieved a perfect recall of 1.00, ensuring that no critical case was underestimated.

This observation suggests a novel perspective for simulator evaluation: numerical bias does not necessarily invalidate categorical utility. The dataset appears to preserve clinically relevant decision boundaries for training classification algorithms, supporting its potential suitability for ML applications even without exact numerical reproduction.

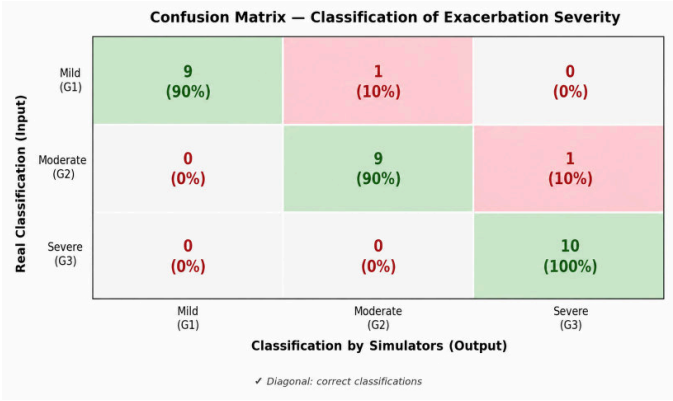

Fig. 3. Confusion matrix for severity classification based on emergent respiratory rate. The strong diagonal agreement ($\kappa = 0.90$) and 100% recall for the Severe group suggest that the dataset preserves clinically relevant decision boundaries, despite the numerical bias observed in Fig. 2.

E. Data Augmentation Preserves Physiological Constraints

To address the limited cohort size ($n = 30$), the Synthetic Minority Oversampling Technique (SMOTE) was applied to expand the dataset. To assess whether SMOTE introduced physiologically implausible patterns, we conducted a two-level integrity evaluation.

Table IV presents the marginal distribution comparison results between the original (Real) and augmented (Synthetic) cohorts. Both parametric (independent t-test) and non-parametric (Mann-Whitney U) tests yielded no significant differences for any of the evaluated variables (all $p > 0.05$).

TABLE IV
DISTRIBUTIONAL INTEGRITY OF SMOTE AUGMENTATION: COMPARISON BETWEEN ORIGINAL AND AUGMENTED COHORTS

Variable	t-test p-value	Mann-Whitney p-value
Respiratory Rate (BPM)	0.928	0.926
I/E Ratio	0.961	0.985
Compliance (mL/cmH_2O)	0.974	0.930
Total Insp. Elastic Work (mJ)	0.875	0.985
Resistance (cmH_2O/L/s)	0.789	0.624
Mean Exp. Pressure (cmH_2O)	0.963	0.900
Max. Trigger Press. Drop (cmH_2O)	0.991	0.914
Peak Exp. Flow (%)	0.845	0.660

Beyond marginal distributions, we assessed whether SMOTE preserved the multivariate dependence structure by computing Pearson correlation matrices before and after augmentation. The mean absolute difference between corresponding correlation coefficients was $\Delta\rho = 0.020$, with a maximum difference of 0.065, indicating strong preservation of inter-variable relationships. Fig. 4 presents the side-by-side comparison of the correlation matrices.

Fig. 5 visually corroborates these findings through Principal Component Analysis, which captured 77.0% of the total variance in the first two components. The silhouette score comparing Real and Synthetic samples was -0.001, indicating substantial overlap between the two populations—consistent with the hypothesis that SMOTE preserved the underlying distribution rather than introducing distinct patterns. The distances between severity-group centroids in PCA space (Mild vs. Moderate: 3.27, Moderate vs. Severe: 3.14, Mild vs. Severe: 4.67) confirm the monotonic separation of disease severity levels.

Together, these results provide evidence supporting that the SMOTE pipeline safely expanded the dataset while maintaining both the marginal distributions and the multivariate dependence structures relevant for reliable machine learning.

F. Comparison with Clinical Reference Ranges

Table V provides a comparison between simulated values and established clinical ranges reported in the literature for severe asthma exacerbations, together with interpretive context for observed deviations.

Most simulated parameters fell within clinically observed ranges, supporting the simulator's ability to reproduce physiologically plausible patterns of severe asthma. Notably, simulated auto-PEEP (0.115 cmH_2O) was substantially lower than the 5–15 cmH_2O typically observed in status asthmaticus [12], [13]. This discrepancy likely reflects the simulator's mechanical constraints and the absence of active expiratory muscle engagement in spontaneous-breathing mode. Nevertheless, the elevated trigger pressure drop ($\Delta P_{trig} = -7.3$ cmH_2O) indicates the presence of intrinsic PEEP that must be overcome before inspiratory flow can begin, partially compensating for this limitation.

Similarly, the simulated I/E ratio (0.403) exceeded the clinically recommended range of 0.25–0.33 for severe asthma [1], suggesting that the simulator's spontaneous-breathing algorithm may not fully capture the prolonged expiratory phase characteristic of obstructive disease. These deviations represent important considerations to be addressed in future work through parameter optimization or hybrid simulation approaches.

V. DISCUSSION

A. Physiological Plausibility and Digital Twins

The results suggest that the ASL5000 reproduces patterns consistent with the pathophysiological cascade of acute asthma exacerbations. Progressive tachypnea, reduced dynamic compliance, expiratory flow limitation, and the emergence of intrinsic PEEP are consistent with established respiratory physiology [11]–[13]. These findings support the interpretation of the simulator as a respiratory digital twin generator capable of producing physiologically coherent datasets for machine learning applications.

Comparison with the clinical literature (Table V) indicates that the simulator captures hallmark features of severe asthma, including compensatory tachypnea, increased airway resistance, and reduced dynamic compliance. However, the underestimation of auto-PEEP and the elevated I/E ratio highlight areas where the simulator's mechanical constraints may limit

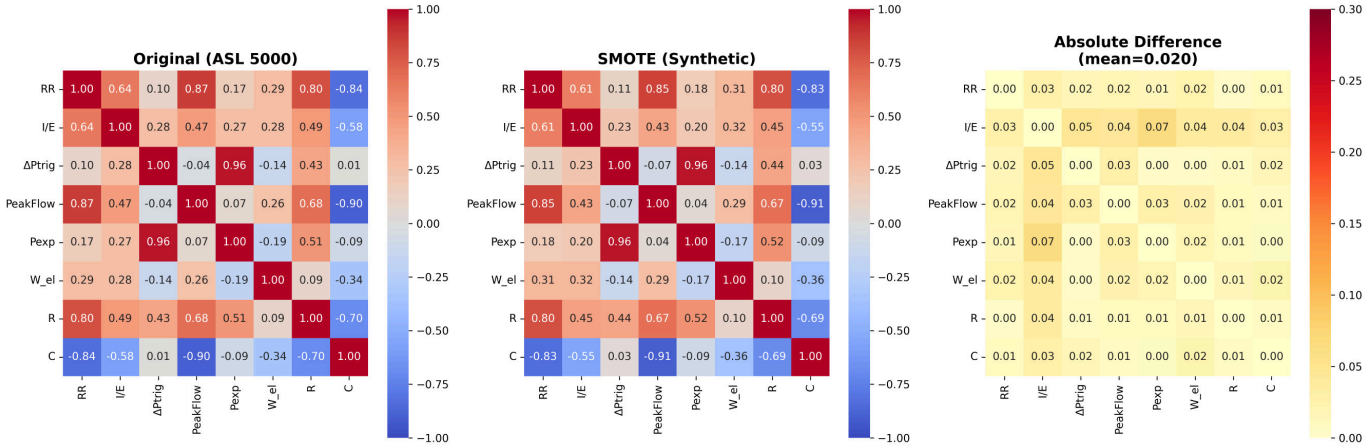

Fig. 4. Preservation of the multivariate dependence structure under SMOTE augmentation. Left: Pearson correlation matrix of the original ASL5000 cohort. Center: Correlation matrix of the SMOTE-augmented cohort. Right: Absolute difference between matrices (mean $\Delta\rho = 0.020$). The low absolute differences support that SMOTE preserved the underlying biomechanical relationships.

TABLE V
COMPARISON OF SIMULATED VALUES WITH CLINICAL REFERENCE RANGES

Variable	**Clinical Range**[a]	**ASL5000 (Severe)**	**Clinical Interpretation**
Respiratory Rate (BPM)	30–45[b]	40.4 ± 5.1	Within range; consistent with severe tachypnea
Resistance ($cmH_2O/L/s$)	15–25[c]	22.9 ± 1.7	Within range; reflects severe bronchoconstriction
Dynamic Compliance (mL/cmH_2O)	30–50[c]	37.5 ± 5.6	Within range; consistent with dynamic hyperinflation
Auto-PEEP (cmH_2O)	5–15[c]	0.115 ± 0.005	Below range[d]; likely due to spontaneous-breathing configuration
ΔP_{trig} (cmH_2O)	-5 to -10	-7.3 (max)	Within range; consistent with intrinsic PEEP compensation
I/E Ratio	0.25–0.33[b]	0.403 ± 0.012	Above range[d]; may reflect simulator timing constraints

[a] Reference ranges for severe asthma exacerbations.

[d] Simulated values deviate from clinical ranges; see Discussion for limitations.

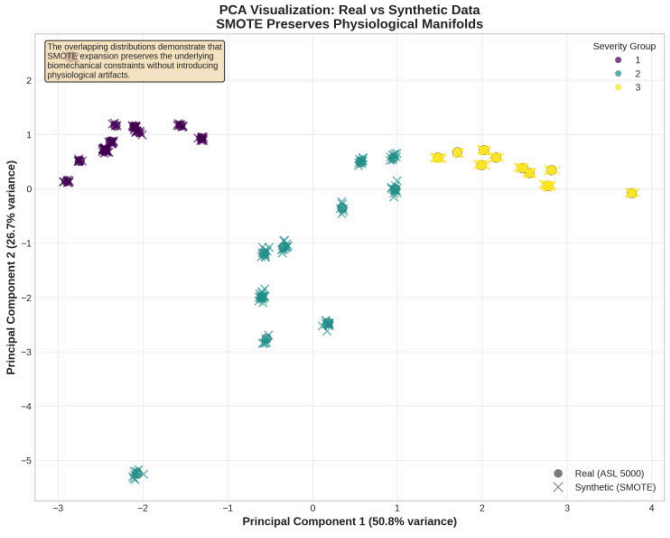

Fig. 5. PCA visualization of Real samples (colored circles) vs. Synthetic samples (orange X markers). The substantial overlap (silhouette score $= -0.001$) and 77.0% variance explained in the first two components support that SMOTE preserved the underlying physiological manifold without introducing distributional shifts.

its physiological fidelity. Future work should explore parameter configurations that more closely approximate clinical auto-PEEP levels and expiratory timing.

B. Categorical versus Numerical Validity: An Observational Perspective

The observation that numerical bias does not necessarily invalidate categorical utility offers a useful perspective for simulator evaluation. Although Bland-Altman analysis revealed systematic bias in absolute respiratory-rate values, the strong Cohen's Kappa ($\kappa = 0.90$) and significant monotonic trends observed via Spearman correlation suggest that the dataset preserves clinically relevant decision boundaries. This distinction is particularly relevant for ML applications focused on classification and risk stratification, where categorical separability is often more important than exact numerical reproduction.

This perspective has implications for the broader field of synthetic data validation. Researchers evaluating simulator-generated datasets may benefit from assessing both numerical agreement (for calibration tasks) and categorical validity (for classification tasks), as these represent distinct validation dimensions with different clinical relevance.

C. Multivariate Integrity of Data Augmentation

The assessment of SMOTE-based augmentation through both marginal and multivariate analyses addresses an important gap in the literature. By demonstrating that synthetic expansion preserves both univariate distributions (all $p > 0.05$) and multivariate dependence structures (mean $\Delta\rho = 0.020$), this work provides a reproducible framework for safely augmenting limited clinical datasets. This approach supports the hypothesis that machine learning models trained on synthetic data will not learn spurious correlations or physiologically implausible patterns.

The PCA visualization (Fig. 5) and the near-zero silhouette score (-0.001) provide complementary evidence that the augmented samples occupy the same physiological manifold as the original simulator outputs, supporting the preservation of causal biomechanical relationships relevant to reliable machine learning.

D. Implications for Edge AI and Embedded Systems

The validated dataset provides a foundation for training lightweight ML models on embedded devices, such as the Respiratory Diagnostic Assistant (RDA) [9]. The high statistical separability ($\epsilon^2 > 0.65$ for key features), categorical validity ($\kappa = 0.90$), and monotonic trends across severity levels suggest that models trained on synthetic data may generalize to clinical scenarios, enabling on-device risk stratification without cloud dependence.

Integration of this validated dataset with the RDA's embedded architecture represents a potential step toward real-time asthma exacerbation prediction in hospital and remote-monitoring settings. Future work will focus on deploying ML models trained on this dataset and evaluating their performance against clinical outcomes.

E. Limitations

This study has several limitations. First, it relies exclusively on simulated data, requiring external validation with real-world asthma cohorts. Second, the proof-of-concept cohort ($n = 30$) is not population representative and should be expanded for future ML development. Third, only two primary mechanical parameters (R and C) were manipulated; future studies should incorporate respiratory muscle strength, heterogeneous airway obstruction, and variable neural drive. Fourth, the simulator does not fully reproduce inflammatory processes, mucus dynamics, or patient-specific anatomical variability. Finally, the underestimation of auto-PEEP and the elevated I/E ratio indicate mechanical constraints that should be addressed in future simulation protocols.

These limitations do not invalidate the findings but highlight opportunities for future refinement and validation.

VI. Conclusion

This study presented a physiological validation framework for synthetic ventilatory datasets generated with the ASL5000 breathing simulator. The results demonstrate that the simulator reproduces physiologically plausible patterns of asthma, including compensatory tachypnea, reduced dynamic compliance, and intrinsic PEEP. Strong monotonic trends across severity levels (Spearman $\rho > 0.78$, $p < 0.001$) support the physiological consistency of the simulated data. Furthermore, the findings suggest that numerical bias does not necessarily compromise categorical utility for ML classification ($\kappa = 0.90$). Finally, the proposed SMOTE-based augmentation pipeline preserved both marginal distributions and multivariate dependence structures (mean $\Delta\rho = 0.020$). Together, these results provide a reproducible foundation for developing edge-AI respiratory monitoring systems based on physiologically validated synthetic datasets.

***Abstract*—This work aims to investigate the pharmacokinetic and toxicological profiles of bioactive glasses (BG) doped with 5% rare-earth oxides (Eu_2O_3, Nd_2O_3, La_2O_3, CeO_2, and Er_2O_3) for bone regeneration using *in silico* assays. The results indicated that incorporating these rare-earth elements preserved the intrinsic potential bioactivity and biological safety of the original glass matrix, exhibiting absorption and distribution profiles ideal for strict local action, with no risk of systemic translocation or penetration into the central nervous system. Additionally, metabolic predictions showed no interactions with the cytochrome P450 system, and all formulations were classified under GHS Toxicity Class 5, reflecting exceptionally low acute oral toxicity (3000 and 4000 mg kg^{-1}). However, Eu_2O_3 exhibited lower safety thresholds, indicating the need for strict dose control in subsequent stages. Therefore, computational simulations successfully validated the sustainable clinical viability of these new biomaterials, aligning technological innovation and quality of life with the Sustainable Development Goals.**

***Index Terms*—bone regeneration, inorganic compound, rare earths, toxicity prediction**

I. Introduction

Degenerative, inflammatory conditions, and fractures in bone tissue affect millions worldwide, often caused by calcium or phosphorus deficiency, and primarily resulting from fall-prone environments, traffic accidents, and genetic disorders that replace natural tissues with biomaterials [1]. Several statistics highlight this issue: (*i*) Osteoarthritis affects 10 to 17% of people over 60 globally; (*ii*) Osteoporosis impacts 200 million individuals worldwide; and (*iii*) Approximately 9 million osteoporotic fractures occur annually worldwide, with projections indicating that by 2050, hip fractures could increase by up to 240% in women and 310% in men [2], [3]. In this context, bone cement emerges as a promising porous material for the regeneration and repair of various functional tissues [4].

Bioactive glasses (BG) are an inorganic compound that typically contains various oxides (e.g., SiO_2, P_2O_5, and CaO), and have been used in prosthetic devices, implants, and scaffolds, since apatite layer (Ap) is formed when in contact with biological fluids [5]. It is worth noting that the addition of rare-earth elements expands the applicability of BG by modifying the surface energy of the glass system, promoting the formation of the apatite layer, and reducing the Ca/P molar ratio required for bone formation [6].

Incorporating rare-earth elements (REEs) (e.g., europium, neodymium, lanthanum, cerium, and erbium) into BG methods (e.g., sol-gel, melt-quenching, or robocasting) represents a promising strategy to expand the functionality of these materials beyond bone regeneration [7]. Acting as network modifiers or intermediates within the glass structure, these ions confer advanced therapeutic and diagnostic properties: the alternation of oxidation states mitigates oxidative stress by scavenging reactive oxygen species (ROS), while the luminescent or magnetic characteristics of other REEs enable bioimaging [8]. Furthermore, precise control over ion-release kinetics and material degradation enables regulation of essential biological responses stimulating angiogenesis, osteoblastic proliferation, and antibacterial activity, thereby opening new avenues for personalized treatments in cancer therapy, nerve regeneration, and controlled drug delivery [9].

In silico tests involve computational simulations that model and analyze biological and chemical processes, serving as a vital tool in contemporary scientific research. They offer benefits (e.g., lower costs, and large-scale analytical capabilities), where the exploration of complex hypotheses, and, crucially, reduced reliance on animal testing [10]. Moreover, biomaterials for bone regeneration are used to simulate mechanical behavior by mimicking the bone environment and to estimate the rate of osseointegration and bone growth around the implant [11].

In this context, this study aims to investigate aspects of rare-earth-doped bioglasses through *in silico* assays. Furthermore, it seeks to drive the economic development of rare-earth-doped bioglasses and add value to the product in both the short and long term. It is worth noting that the study aims to contribute to sustainable development and quality of life, aligning with

the Sustainable Development Goals (SDGs) established by the United Nations (UN) with an emphasis on SDG 3 (Ensure healthy lives and promote well-being for all at all ages) and SDG 9 (Build resilient infrastructure, promote inclusive and sustainable industrialization, and foster innovation) [12].

II. MATERIALS AND METHODS

A. Study on the toxicity prediction of bioglass

A predictive study was conducted to estimate the potential toxicological risks of the main compounds present in BG and BG doped with 5% Eu_2O_3, Nd_2O_3, La_2O_3, CeO_2, and Er_2O_3, based on molecular similarity, fragmentation patterns, and common machine-learning features, using established models (*in vitro* and *in vivo*). The computational tools employed were pkCSM and ProTox-II 3.0 [13]–[16]. Table 1 and Figure 1 present the characteristics of the BG and BG doped with 5% Eu_2O_3, Nd_2O_3, La_2O_3, CeO_2, and Er_2O_3, which were used in the *in silico* tests. Furthermore, the information used was obtained from PubChem and the Materials Project [17].

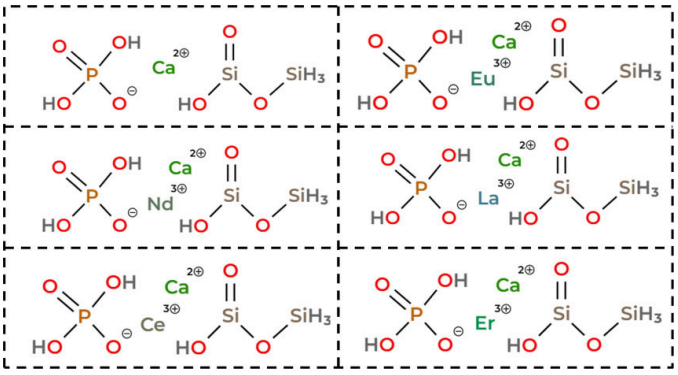

Fig. 1. Schematic representation of the 2D molecular structures of (a) BG; (b) BG+Eu_2O_3; (c) BG+Nd_2O_3; (d) BG+La_2O_3; (e) BG+CeO_2; and (f) BG+Er_2O_3 used in the *in silico* studies.

B. Studies of prediction of mutagenicity and carcinogenicity of bioglass

The online software tools pkCSM and ProTox-II 3.0 were used to predict the mutagenic and carcinogenic potential of BG and BG doped with 5% Eu_2O_3, Nd_2O_3, La_2O_3, CeO_2, and Er_2O_3 components. In this context, the Ames test was employed to predict mutagenicity, enabling the detection of mutations in the genetic material involved in histidine synthesis, typically using bacterial strains such as *Salmonella typhimurium* (TA98, TA100, and TA1535). The prediction of the carcinogenic potential of the nanobiomaterials in rodents was based on data from the National Toxicology Program (NTP).

C. Study of the prediction of adverse effects of bioglass

The prediction of adverse effects for BG and BG doped with 5% Eu_2O_3, Nd_2O_3, La_2O_3, CeO_2, and Er_2O_3 (e.g., arrhythmia, heart failure, hepatotoxicity, nephrotoxicity, and myocardial infarction) was performed using the online software Pro-Tox II 3.0. In this context, the occurrence of adverse effects was considered when the probability of "being active" (Pa) was < 0.7.

D. Study of prediction of acute and chronic toxicity in rats of bioglass

The ProTox-II software was used to determine the acute and chronic toxicity in rats for BG and BG doped with 5% Eu_2O_3, Nd_2O_3, La_2O_3, CeO_2, and Er_2O_3, including, for example, hepatotoxicity, immunotoxicity, cytotoxicity, and the maximum tolerated dose in humans. Additionally, the acute toxicity class in rats was defined according to the Globally Harmonized System of Classification and Labeling of Chemicals (GHS) [18].

III. RESULTS AND DISCUSSION

A. Prediction study of acute toxicity, and adverse effects of components of BG using model pKCSM

Tables 2 and 3 present the *in silico* predictions of absorption, distribution, excretion, metabolism, and toxicity for BG and rare-earth-doped BG, using the pKCSM model.

According to Table 2, *in silico* predictive data for rare-earth-doped bioactive glass (BG) indicated a profile typical of inorganic biomaterials designed for local action, with low permeability values in Caco-2 cells (Log $P_{app} < 0.90$) and a low percentage of human intestinal absorption (less than 30%), indicating that these materials exhibited a poor oral absorption. In the scientific literature, this behavior is widely expected and considered positive, as bioactive glasses are designed to act directly at the surgical site or lesion, releasing ionic dissolution products in a controlled manner into the local microenvironment without the risk of translocation or unwanted

systemic bioaccumulation [19]. Conversely, parameters indicated a moderate water solubility (log mol L^{-1} between -2.2 and -2.8) and a moderate-to-low skin permeability (log Kp of -2.7), reinforcing the impact of rare-earth doping on stabilizing the glass network and indicating more controlled dissolution rates in glasses containing oxides (e.g., CeO_2 and La_2O_3) [20]. Additionally, the fact that most samples do not function as P-glycoprotein (P-gp) inhibitors is a favorable indicator of toxicological biocompatibility, suggesting that the material does not interfere with the natural cellular efflux mechanisms of other essential compounds. It is worth noting that the behavior of Eu_2O_3 and Nd_2O_3 as P-gp substrates suggests specific cellular dynamics involving the active pumping of these ions, an aspect to be validated in future *in vitro* and *in vivo* assays.

For the distribution (Table 2), *in silico* values indicated that the BG and its rare-earth-doped variants exhibited low systemic dispersion potential and severely restricted access to the central nervous system (CNS). Furthermore, the low steady-state volume of distribution (VD_{ss} below -0.15 log L kg^{-1}) indicated that ionic byproducts tend to remain confined to the plasma or local extracellular fluid rather than distributing widely throughout body tissues. In this regard, the high plasma free fraction (Fu) ranging from 0.767 to 0.893, suggested a weak binding affinity to plasma proteins, favoring the immediate local availability of the ions. Crucially, blood-brain barrier permeability (log BB $<$ -1) and CNS penetration (log PS $<$ -3) values categorically classify all samples as unable to cross these complex biological barriers. In the biomaterials literature, this restricted distribution behavior is highly favorable and characterizes the material as biologically safe, as it ensures that the action of the rare-earth oxides remains limited to the peripheral injury site, thereby mitigating the risk of neurotoxicity or systemic side effects resulting from central efflux [21].

For the excretion (Table 2), the rare-earth-doped bioactive glass (BG) revealed a moderately slow body clearance rate and the absence of active renal transport mediated by cationic transporters. Total clearance values range from -0.479 to -0.802 log mL min^{-1} kg^{-1}, demonstrated that the incorporation of rare-earth oxides promoted a slight reduction in the overall elimination rate compared to the base BG. This reduction is consistent with the literature, as the presence of lanthanides alters ionic dissolution kinetics and the formation of secondary complexes within the body, thereby extending the residence time of these elements in the microenvironment [22]. Furthermore, all formulations were predicted not to be substrates of renal organic cation transporter. This indicates that the excretion of these ions did not rely on active tubular secretion via this pathway, thereby eliminating the risk of competitive interactions or renal toxicity from blocking this transporter.

In silico metabolic predictions (Table 3) from the pkCSM platform indicate that neither BG nor its rare-earth oxide-doped variants interact with the cytochrome P450 enzyme system. All samples were strictly categorized as "No" for inhibition of or acting as substrates for the key hepatic isoenzymes evaluated (CYP2D6, CYP3A4, CYP1A2, CYP2C19, and CYP2C9). These results are highly favorable, indicating that the biomaterial's ionic dissolution products pose no risk of inducing unwanted drug interactions or undergoing enzymatic biotransformation via these classic hepatic pathways.

Analysis *in silico* toxicity parameters (Table 3) revealed that both BG and the lanthanide-modified systems exhibited a highly favorable biological safety profile, with a low probability of serious adverse effects. Consequently, all formulations were predicted to be non-mutagenic, non-cardiotoxic, non-hepatotoxic, and non-sensitizing to the skin. Quantitatively, the maximum tolerated dose (MTD) for humans remained within a narrow, safe range across all groups (between 0.771 and 0.898 log mg kg^{-1} day^{-1}). Regarding acute oral toxicity in rats (LD_{50}) and chronic toxicity (LOAEL), the compounds doped with Nd_2O_3, La_2O_3, CeO_2, and Er_2O_3 showed values close to or slightly higher than those of BG, indicating the preservation of the base material's excellent intrinsic biocompatibility. The only notable deviation occurred with BG+Eu_2O_3, which exhibited a decrease in LD_{50} (1.505 log mol kg^{-1}) and LOAEL (0.991 log kg bw^{-1} day^{-1}) values; this suggests that the specific release of europium ions requires closer analytical attention and controlled dosing in subsequent *in vitro* studies to avoid potential cumulative local cytotoxic responses.

B. Prediction study of hepatotoxicity, neurotoxicity, nephrotoxicity, cardiotoxicity, carcinogenicity, immunotoxicity, mutagenicity, and cytotoxicity of BG using model ProTox-II

Figure 2 presents the predictive toxicity profile (ProTox-II 3.0) obtained *in silico* for the BG and its formulations modified with various rare-earth oxides, covering a wide range of cellular biomarkers, organs, and systems. Notably, the most striking feature is the similarity in the curves' behavior across all studied samples, which maintain high predicted biocompatibility (mostly above 75–80%) for all parameters. This graphical parallelism demonstrated that incorporating Eu_2O_3, Nd_2O_3, La_2O_3, CeO_2, and Er_2O_3 did not compromise the intrinsic biological safety of the original bioactive glass, preserving a toxicologically safe and consistent profile with respect to hormonal receptors, oxidative stress, and metabolic pathways.

Despite overall stability, specific, and synchronized declines were observed in three biomarkers across all samples: nephrotoxicity, Transthyretin (TTR) transporter, and Pregnane X receptor (PXR). These identical drops suggested that such responses were inherent to the BG matrix itself or represent the predictive model's standard response to inorganic silicate compounds, rather than a deleterious effect induced by the dopants [23], [24]. Thus, the visual results reinforce the biotechnological potential of these newly doped matrices, indicating that the additional therapeutic properties of rare-earth elements can be exploited with a minimal risk of systemic toxicity or cellular effects that differ from those of the reference biomaterial.

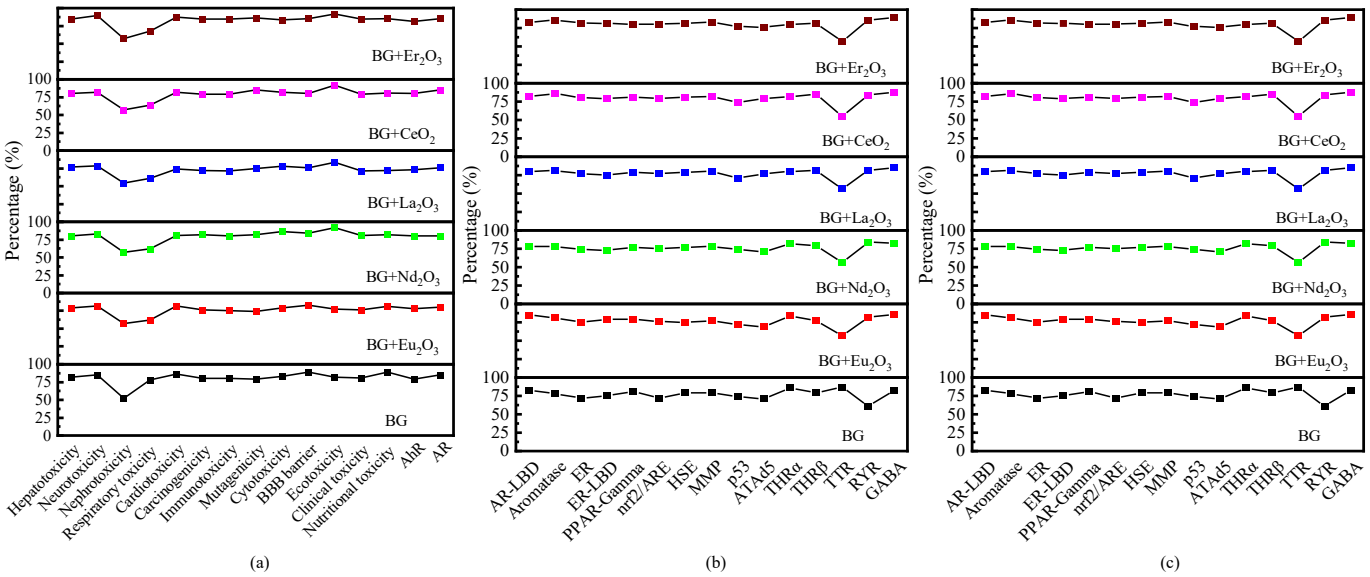

Fig. 2. Predictive toxicity profile (Pred-Tox) of pure bioactive glass (BG) and bioactive glasses modified with rare-earth element oxides (BG+Eu_2O_3, BG+Nd_2O_3, BG+La_2O_3, BG+CeO_2, and BG+Er_2O_3) across different organs, biological systems, and cellular biomarkers. (a) Organ toxicity profile; (b) biological system toxicity profile; and (c) cellular biomarker toxicity profile. **Abbreviations:** AhR = Aryl hydrocarbon receptor; AR = Androgen receptor; AR-LBD = Androgen receptor ligand-binding domain; ER = Estrogen receptor alpha; ER-LBD = Estrogen receptor ligand-binding domain; PPAR-γ = Peroxisome proliferator-activated receptor gamma; nrf2/ARE = Nuclear factor (erythroid-derived 2)-like 2/antioxidant response element; HSE = Heat shock factor response element; MMP = Mitochondrial membrane potential; p53 = Tumor suppressor phosphoprotein p53; ATAD5 = ATPase family AAA domain-containing protein 5; THRα = Thyroid hormone receptor alpha; THRβ = Thyroid hormone receptor beta; TTR = Transthyretin; RYR = Ryanodine receptor; GABAR = GABA receptor; NMDAR = N-methyl-D-aspartate receptor; AMPAR = α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate receptor; KAR = Kainate receptor; AChE = Acetylcholinesterase; CAR = Constitutive androstane receptor; PXR = Pregnane X receptor; NADHOX = NADH-quinone oxidoreductase; VGSC = Voltage-gated sodium channel; and NIS = Na^+/I^- symporter.

Abbreviations: VDss = Volume of distribution; BBB = Blood-brain barrier; CNS = Central nervous system; and OCT2 = Organic cation transporter.

values between 2000 and 5000 mg kg^{-1} fall into toxicity class 5, indicating compounds with exceptionally low acute oral toxicity (REFERENCE de guia GHS). Interestingly, the incorporation of all rare-earth oxides (Eu_2O_3, Nd_2O_3, La_2O_3, CeO_2, and Er_2O_3) resulted in higher LD_{50} values compared to the BG, indicating that a larger quantity of the substance was required to induce lethality. Thus, these data suggest that rare-earth doping not only maintained the biological safety profile of the original matrix but theoretically further reduced the potential for systemic acute toxicity. This result reinforces the clinical viability of these new biomaterials for regenerative and tissue engineering applications.

In the experimental literature on rare-earth-containing bioactive glasses (BG), a strong convergence of data was observed, such as: *in vivo* studies and *in vitro* cytotoxicity assays report that the incorporation of oxides (e.g., CeO_2, and La_2O_3) into bioglass matrices does not induce severe cytotoxic responses at controlled concentrations [25]. It is worth noting that the slightly more restrictive behavior of Eu_2O_3 observed in other toxicity parameters was also corroborated by the literature, where lanthanides with more pronounced luminescent properties or distinct coordination kinetics require narrower therapeutic windows to avoid local cellular stress; this validates the sensitivity of the computational predictions obtained when compared against benchtop findings [26].

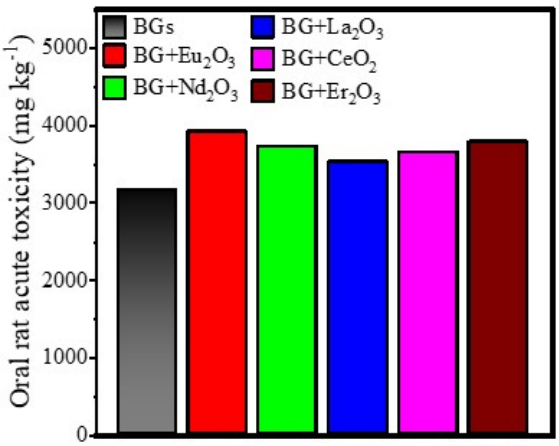

Fig. 3. In silico prediction of acute oral toxicity in rats (mg kg^{-1}) for pure bioactive glass (BG) and bioactive glasses modified with different rare-earth element oxides (BG+Eu_2O_3, BG+Nd_2O_3, BG+La_2O_3, BG+CeO_2, and BG+Er_2O_3) using Pro-Tox II 3.0.

IV. Conclusion

Based on assays performed on the pkCSM and ProTox-II 3.0 platforms, this study demonstrated that incorporating 5 wt.% rare-earth oxides (Eu_2O_3, Nd_2O_3, La_2O_3, CeO_2, and Er_2O_3) onto bioactive glass (BG) generally preserved the intrinsic biocompatibility of the original matrix. Predictive results regarding absorption and distribution confirmed a safe local action profile, characterized by low intestinal and systemic permeability, ensuring controlled ion release directly at the injury site without the risk of unwanted bioaccumulation or neurotoxicity, as the samples proved unable to cross the blood-brain barrier. Furthermore, the absence of interactions with cytochrome P450 isoenzymes eliminated the risk of adverse drug reactions or complex hepatic biotransformation. Regarding acute toxicity, all formulations were classified as GHS Class 5, with LD_{50} values between 3000 and 4000 mg kg^{-1}, indicating low oral toxicity and reinforcing the clinical viability of these new biomaterials. It is worth noting that Eu_2O_3 exhibited declines in LD_{50} and LOAEL values, indicating that the release of Eu^{3+} ions requires stricter dosage monitoring in subsequent experimental stages. Briefly, computational screening validated the high biotechnological potential of these doped matrices for tissue engineering, establishing a sustainable methodological approach that reduces reliance on animal testing and aligns the product's scientific and economic advancement with the UN Sustainable Development Goals, particularly SDGs 3 and 9.

***Abstract*—**This study presents a simulation-based methodology to optimize the geometry and operating conditions of a bone-on-chip platform. Integrating Computational Fluid Dynamics (CFD), machine learning, and an evolutionary algorithm, the framework addresses the complex, opposing trade-offs inherent in microfluidic transport dynamics. CFD simulations were performed across varied geometric parameters, micropillar arrangements, volumetric flow rates, and residence times to generate hydrodynamic and mass transfer performance indicators. The resulting velocity, pressure, wall shear stress, and transport fields were converted into quantitative performance indicators representing medium perfusion within the micropillar region, hydraulic resistance, wall shear stress, and oxygen availability in the culture medium. A Random Forest regression model was trained on the CFD data to serve as a fast surrogate model, allowing a Differential Evolution algorithm to efficiently search the design space for high-performing configurations. The proposed framework reduces the number of additional CFD simulations required during optimization and provides a systematic strategy for designing organ-on-chip platforms with improved transport conditions and reduced hydraulic constraints. All findings are exclusively in silico: the optimized geometries were verified by CFD. Device fabrication, experimental perfusion, or cell-culture validation will be addressed in future studies.

Keywords*—Bone-on-chip; Computational fluid dynamics; Machine learning; Differential Evolution; Surrogate model; Geometry optimization.*

I. Introduction

Bone regeneration and repair of critical-sized bone defects remain major challenges in tissue engineering, driving the development of biomimetic scaffolds, computational tools, and more predictive in vitro models [1]. In this context, organ-on-chip systems have emerged as promising platforms for recapitulating the key aspects of human physiology. However, bone-on-chip models remain less developed than their soft-tissue counterparts, largely because of the structural and functional complexities of bone tissue [2], [3]. Nevertheless, by integrating three-dimensional cell culture, microfluidics, and the controlled application of biomechanical and biochemical cues, these platforms can more closely reproduce the bone microenvironment, expanding their potential for investigating bone physiology and diseases, as well as for drug screening.

The performance of these platforms is strongly influenced by their internal geometries and operating conditions. The micropillar dimensions, arrangement, spacing, and location relative to the inlet and chamber walls influence flow penetration, residence time, pressure distribution, wall shear stress, and solute transport. However, improving medium renewal and reducing stagnation may increase the hydraulic resistance or create heterogeneous shear exposure. Therefore, device design requires balancing competing hydrodynamic and mass transfer objectives that cannot be represented by a single response variable [4], [5].

Computational Fluid Dynamics (CFD) provides spatially resolved information on velocity, pressure, wall shear stress, and species concentration, allowing microfluidic configurations to be evaluated before fabrication. However, direct optimization based exclusively on CFD may require numerous computationally expensive simulations when multiple geometric and operating variables are considered. Machine learning surrogate models can reduce this cost by learning the relationship between the design variables and CFD-derived metrics and predicting untested configurations. Previous studies have demonstrated that combining CFD datasets with machine learning and evolutionary optimization can substantially accelerate the search for improved geometries while retaining nonlinear relationships between geometry, flow, and performance [6],[7].

When multiple responses conflict, they can be transformed and combined into a global performance score [8]. Random Forest (RF) is suitable for constructing this predictive model because an ensemble of randomized decision trees is suited to nonlinear regression and does not require a priori functional relationships [9], [10]. The resulting surrogate can be coupled with Differential Evolution (DE), a population-based algorithm that uses mutation, crossover, and selection to explore continuous

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

design spaces and locate high-performance solutions [11], [12].

This strategy of coupling simulation, surrogate modeling, and optimization has already been applied to organ-on-chip and microfluidic platforms through parametric sweeps combined with machine learning [6],[13] and to characterize predefined bone-on-chip devices under selected operating conditions [14], motivating the closed-loop simulation-surrogate-optimization framework adopted in this study.

Accordingly, the aim of this study was to design a basic microfluidic device for bone-on-a-chip applications and optimize its geometric and operating conditions using a machine learning-assisted evolutionary framework. First, 3D CFD simulations were conducted to evaluate the key fluid dynamics and mass transport parameters within the micropillar region, including medium perfusion, hydraulic resistance, wall shear stress, and oxygen availability. These features were aggregated into a mathematically modeled global performance score designed to ensure adequate conditions for cell culture. Finally, an RF surrogate model was used to predict the score, and DE was applied to identify the optimal design parameters that maximize the overall device performance.

II. Background and Related Work

A general box-constrained optimization problem can be formulated using the following Eq. (1), without loss of generality.

$$\begin{aligned} &min\, F(\vec{x}) = (f_1(\vec{x}), f_2(x),.., f_m(\vec{x})) \\ &s.t.\ x_k \in [x_j^{min}, x_j^{max}],\ \forall k \in \{1, 2,..., d\} \end{aligned} \quad (1)$$

where $\vec{x} = [x_1, x_2,.., x_d]$ is a d-dimensional decision vector, x_k is the k-th variable $\vec{x}$, m is the number of objective functions, $f_z(\vec{x})$ is the z-th objective function, and x_j^{min} x_j^{max} are the lower and upper boundaries of the variable x_j, respectively. If $m = 1$, then Eq. (1) is a Single-Objective Optimization Problem (SOP). In SOP, there is a single decision vector $\vec{x}_{opt}$ known as *Global Optimum* that results in the best objective function $f(\vec{x})_{opt}$. The goal of SOP is to find $\vec{x}_{opt}$.

Machine and deep learning AI methods have been demonstrated to improve the performance of optimization algorithms in time-consuming environments when used as surrogate models (SMs) [15]. An SM can be formally defined as: given a limited amount of data $D = \{(\vec{x}^{(1)}, F(\vec{x}^{(1)}), ..., (\vec{x}^{(\eta)}, F(\vec{x}^{(\eta)}))\}$, where η is the number of real expensive function evaluations, SM is any approximation technique that provides an estimated objective function vector $\hat{F}(\vec{x})$ of a given true and expensive objective vector $F(\vec{x})$. A recently applied AI method as SM in computationally expensive optimization problems is RF [9]. RF has demonstrated to be an effective SM approach [15].

III. Materials and Methods

The methodology of this research was structured into five main stages: **(A)** design of the microfluidic device; **(B)** 3D mesh generation and CFD simulation; **(C)** definition of the target variable score; **(D)** mathematical modeling of the optimization concern; and **(E)** development of machine learning-based surrogate models and their application in the surrogate-assisted optimization cycle, as detailed below.

A. Design of the microfluidic device

The investigated platform (Fig. 1) consisted of inlet and outlet microchannels (1.0 mm high) connected to a 5.0-mm-diameter central chamber containing a ring-shaped micropillar array.

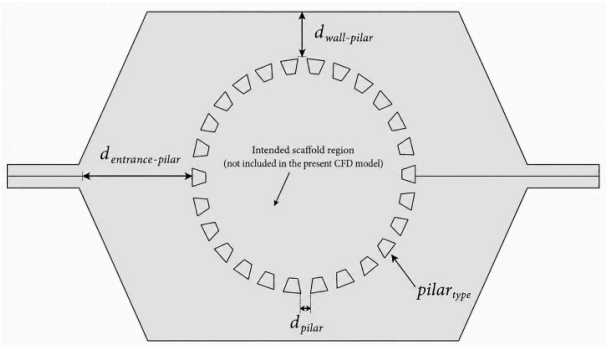

Fig. 1. Schematic representation of the investigated bone-on-a-chip geometry, showing the inlet and outlet microchannels, central chamber, and ring-shaped micropillar region used to define the geometric design space

The pillars enclose a reserved region intended for a bone-mimetic scaffold in future experiments, which is not explicitly modeled here; however, defining the scaffold's intended position and perturbing the flow field influence perfusion and mass transport around this location. The geometric design space was defined by four parameters: clear spacing between adjacent pillars (d_{pilar}), distance from the inlet channel to the pillar region ($d_{entrance}$), distance from the pillar region to the chamber wall ($d_{wall-pilar}$), and pillar arrangement type ($pilar_{type}$). The inlet volumetric flow rate (Q) was also varied to represent different perfusion conditions.

The initial dataset comprised 85 CFD simulations, which combined variations in the geometric parameters, pillar arrangements, and flow rates. After training the machine-learning model and applying the optimization procedure, four additional optimized geometries were simulated using CFD, added to the original dataset, and the complete set was re-evaluated using the same score function.

B. 3D mesh generation and computational fluid dynamics

The fluid was assumed to be incompressible and Newtonian, and the flow was considered laminar, consistent with the low Reynolds number regime expected in microfluidic systems. The hydrodynamic field was described by the continuity—Eq. (2) and the Navier–Stokes equation using Eq. (3), where U is the velocity vector ($m\ s^{-1}$), ρ is the fluid density ($kg\ m^{-3}$), p is the pressure (Pa), v is the kinematic viscosity ($m^2 s^{-1}$), and g is the gravitational acceleration ($m\ s^{-2}$).

$$\nabla . U = 0 \quad (2)$$

$$(U.\nabla)U = -\frac{1}{\rho}\nabla p + v\nabla^2 U + g \quad (3)$$

In addition to the flow field, the transport of dissolved O_2 was described by advective diffusion, as shown in Eq. (4).

$$U.\nabla C_{O_2} = D_{O_2}\nabla^2 C_{O_2} - R_{O_2} \quad (4)$$

where C_{O_2} is the local concentration O_2 ($mol\,m^{-3}$), D_{O_2} is the O_2 diffusion coefficient ($m^2 s^{-1}$), and R_{O_2} is the O_2 consumption term ($mol\,m^{-3}s^{-1}$).

The oxygen consumption term was represented using Michaelis–Menten kinetics, as described in Eq. (5). The kinetic parameters were adopted from the microfluidic bone marrow model adapted by Rosalem et al. [16], which combined CFD and organ-on-chip approaches to investigate leukemia niche dynamics.

$$\begin{gathered} R_{max,O_2} = 1.2\times10^{-5}\,mol\,m^{-3}\,s^{-1}, \\ C_{MM,O_2} = 1.0\times10^{-3}\,mol\,m^{-3}, \text{ and} \\ C_{cr,O_2} = 1.0\times10^{-4}\,mol\,m^{-3}. \\ R_{O_2} = R_{max,O_2}\frac{C_{O_2}}{C_{O_2}+C_{MM,O_2}}\,\delta\,(C_{O_2} > C_{cr,O_2}) \end{gathered} \quad (5)$$

where $R_{max,O2}$ is the maximum oxygen consumption rate, C_{MM,O_2} is the Michaelis–Menten constant, C_{cr,O_2} is the critical oxygen concentration, and δ is the reduction function that suppresses consumption below C_{cr,O_2}. This formulation enables the analysis of oxygen transport under physiologically relevant conditions.

At the inlet, a prescribed volumetric flow rate and fixed oxygen concentration were imposed, and a zero-gauge pressure condition was applied at the outlet. No-slip conditions were adopted for all solid surfaces, including the chamber walls and micropillars. The computational domain was discretized using tetrahedral elements, with local refinement near the micropillars to better resolve the velocity and oxygen concentration gradients in this area. Simulations were performed using ANSYS CFD v18.2. Convergence was defined by root-mean-square residuals below 1×10^{-5}, requiring between 50 and 500 iterations, depending on the case.

To assess the sensitivity of the numerical solution to spatial discretization, a mesh independence study was performed using three tetrahedral meshes containing approximately 2.6×10^6, 3.7×10^6, and 5.0×10^6 elements. The comparison was based on the velocity and wall shear stress profiles along the channel width, since these variables are directly related to the hydrodynamic indicators used in the score calculation. The Grid Convergence Index (GCI) was calculated to quantify the discretization uncertainty across the refined meshes.

C. Definition of the target variable score

The CFD simulations generated multiple hydrodynamic and mass transfer responses, including wall shear stress, velocity heterogeneity, hydraulic resistance, and oxygen concentration. Since these responses represent competing design requirements, they were combined into a single target variable, which was defined as the global score. The score was designed to quantify the overall performance of each simulated condition and enable the training of a single-output surrogate model. Four CFD-derived indicators were used in the score calculation: the 90th percentile wall shear stress, $WSS90(\vec{x})$; the average coefficient of variation of velocity, $CV_u(\vec{x})$; the hydraulic resistance, $R_h(\vec{x})$; and the mean oxygen fraction, denoted by $\phi_{O_2}(\vec{x})$. The use of $WSS90(\vec{x})$ reduced the influence of isolated local peaks, while $CV_u(\vec{x})$ represented flow heterogeneity within the chamber. $R_h(\vec{x})$ was used to account for the hydraulic cost of each configuration, and $\phi_{O_2}(\vec{x})$ represented oxygen availability within the device.

D. Mathematical modeling of the optimization problem

The mathematical formulation of the optimization problem is defined in Eq. (6):

$$\begin{gathered} min\,F(\vec{x}) = (WSS90(\vec{x}),\ R_h(\vec{x}),\ CV_u(\vec{x}), -\phi_{O_2}(\vec{x})) \quad (6) \\ s.t.\ \vec{x} = [Q, d_{pilar}, d_{entrance}, d_{wall-pilar}, pilar_{type}] \\ Q \in \{1, 5, 10, 25, 100\},\ d_{pilar} \in [0.25, 0.75], \\ d_{entrance} \in [1.3,\ 2.3],\ d_{wall-pilar} \in [0.5, 2.0], \\ pilar_{type} \in \{1\ ,2\} \end{gathered}$$

where $WSS90(\vec{x})$ is the 90th percentile wall shear stress, $R_h(\vec{x})$ is hydraulic resistance defined as $R_h(\vec{x}) = \frac{\Delta P(\vec{x})}{Q(\vec{x})}$, $CV_u(\vec{x})$ is the velocity variation coefficient, and $\phi_{O_2}(\vec{x})$ is the dimensionless mean oxygen fraction. The negative sign in $-\phi_{O_2}(\vec{x})$ is used to transform the problem into minimization to facilitate the optimization process, without loss of generality. The variable $pilar_{type}$ was numerically encoded to allow its use in the surrogate model and optimization algorithm, with $pilar_{type} = 1$ representing the trapezoidal micropillar arrangement and $pilar_{type} = 2$ representing the triangular micropillar arrangement. Although numerically encoded, this variable represents a categorical geometric feature.

We transformed Eq. (6) into an SOP by developing a *score* that calculates the effectiveness of each geometry. This score (i) transforms the problem into an SOP, (ii) penalizes solutions that provide infeasible geometries, and (iii) penalizes solutions that are feasible but poor.

The objective functions were first transformed into nondimensional performance factors ranging from 0 to 1, according to their contribution to the desired microfluidic behavior. These factors were combined into a global score ranging from 0 to 10. Each objective function was modified using a specific transformation. For instance, the 90th percentile wall shear stress objective function ($WSS90(\vec{x})$) is transformed into a numerical value based on the following design:

- $WSS90(\vec{x}) = 1,\ if\ WSS90(\vec{x}) \leq 1.0\times10^{-3}$
- $WSS90(\vec{x}) = e^{penal}$

where $penal = -1(\frac{WSS90(\vec{x})-1.0\times10^{-3}}{1.0\times10^{-3}})$. Thus, if the wall shear stress is below the threshold of 1.0×10^{-3}, then the score of this objective 1.0; otherwise, it is penalized based on its original objective function value.

The $WSS90$ threshold was adopted as a conservative low-shear design target rather than as a universal cellular damage limit. Bone cells are mechanosensitive, and experimental microfluidic systems have been used to expose osteoblasts to shear stresses spanning from approximately $1.0\times10^{-3}\,Pa$ to considerably higher values [17]. In the present score, values above the adopted threshold were therefore not classified as infeasible; instead, their desirability was progressively reduced. Moreover, the use of $WSS90$, rather than the absolute maximum, limited the influence of isolated numerical or highly localized peaks while retaining sensitivity to the shear stress experienced over most of the evaluated surface.

The velocity variation coefficient $\overline{CV}_u(\vec{x})$ is penalized using the following formulation: $\overline{CV}_u(\vec{x}) = e^{(-2.CV_u^2(\vec{x}))}$. Thus, lower values are preferred for these indicators. For the hydraulic resistance R_h, a different logic had to be applied. The penalization depended on the range of the oxygen inside the chip, and it was calculated from the normalized value of R_h. Hydraulic resistance was included as an operational criterion because excessive resistance increases the pressure required to maintain a prescribed perfusion rate. Unlike oxygen availability and wall shear stress, R_h was not assigned a direct biological threshold. Its normalized value was used to provide a relative comparison among the simulated configurations, with lower hydraulic resistance receiving higher desirability. The developed logic is organized as follows.

- $R_h(\vec{x}) = 0.85e^{penal}$, $if\ 0.08 \le \phi_{O_2}(\vec{x}) \le 0.1$
- $R_h(\vec{x}) = 1.0e^{penal}$, $if\ 0.06 \le \phi_{O_2}(\vec{x}) \le 0.08$
- $R_h(\vec{x}) = 0.4e^{penal}$, $if\ 0.03 \le \phi_{O_2}(\vec{x}) \le 0.06$
- $R_h(\vec{x}) = 0.1e^{penal}$, $if\ \phi_{O_2}(\vec{x}) < 0.03$
- $R_h(\vec{x}) = 0.4e^{penal}$, $if\ 0.1 \le \phi_{O_2}(\vec{x})$

where $penal = -R_{h,norm}$. Thus, the best values are obtained if the oxygen is within the desired range (between 0.03 and 0.1). Finally, the oxygen concentration penalization is expressed as follows:

- $\phi_{O_2}(\vec{x}) = 1$, $if\ 0.03 \le \phi_{O_2}(\vec{x}) \le 0.10$. No penalization is applied because the oxygen level is in the desired interval.
- $\phi_{O_2}(\vec{x}) = e^{penal}$, $if\ \phi_{O_2}(\vec{x}) < 0.01$. For this case, the penalization is $penal = -5(\frac{0.01-\phi_{O_2}(\vec{x})}{0.01})^2$
- $\phi_{O_2}(\vec{x}) = e^{penal}$, $if\ 0.01 \le \phi_{O_2}(\vec{x}) < 0.03$. For this case, the penalization is $penal = -3(\frac{0.03-\phi_{O_2}(\vec{x})}{0.03})^2$.
- $\phi_{O_2}(\vec{x}) = e^{penal}$, $if\ \phi_{O_2}(\vec{x}) > 0.1$. Then, the penalization is $penal = -1(\frac{\phi_{O_2}(\vec{x})-0.10}{0.10})^2$.

The oxygen thresholds were selected to represent a low-oxygen bone-marrow-like environment while avoiding severe oxygen depletion. Direct in vivo measurements have demonstrated the heterogeneity of bone marrow oxygenation, with oxygen tensions of approximately 2.4–5.3% in bone marrow monocytes, approximately 4.8% in mature osteoclasts, and lower values in some extravascular regions [18]. Based on this physiological context, oxygen levels below 3% were progressively penalized because they indicate marked oxygen limitation, whereas values between 3 and 10% were retained as an operationally acceptable range for the investigated platform. The 6–8% interval was assigned the highest desirability as an author-defined design preference intended to balance oxygen availability and the preservation of a relatively low-oxygen microenvironment Finally, because each objective function was modified, Eq. (6) is transformed into a single-objective problem using a weighted sum approach, as shown in Eq. (7):

$$max\ score(\vec{x}) = 10.[0.30\cdot WSS90(\vec{x}) + 0.10\cdot R_h(\vec{x}) + 0.25\cdot CV_u(\vec{x}) + 0.35\cdot \phi_{O_2}(\vec{x})] \quad (7)$$

s.t. the same constraints as in Eq. (6).

The baseline weight vector was defined a $\vec{w} = [0.30,\ 0.10,\ 0.25,\ 0.35]$ corresponding to the $WSS90$, R_h, $\overline{CV}_u$, and ϕ_{O_2}, respectively. These values represent a multicriteria choice adopted by the authors for the present study rather than universal biological constants. Oxygen availability and wall shear stress received the highest weights because they are directly related to the cellular microenvironment, whereas hydraulic resistance received a lower weight because it primarily represents an operational constraint. The sensitivity of the ranking to these author-defined choices was subsequently evaluated.

E. Sensitivity analysis of the composite score

A sensitivity analysis was performed to evaluate whether the configuration ranking was strongly dependent on the author-defined parameters of the composite score. The analysis was conducted using the CFD-derived responses of the complete dataset, comprising the 85 initial cases and the 20 additional cases obtained from four optimized geometries evaluated at five flow rates.

Alternative scenarios to the baseline were generated by independently increasing or decreasing each weight by 20%. After each individual variation, all weights were renormalized so that their sum remained equal to one. An equal-weight scenario, in which all four factors received a weight of 0.25, was also evaluated.

In addition to the weight analysis, the $WSS90$ threshold was varied by ±20% relative to its baseline value of $1.0\times10^{-3}\,Pa$. The sensitivity to the exponential penalty intensity was evaluated using multiplicative factors of 0.75, 1.00, and 1.25, representing mild, baseline, and strong penalization, respectively. Only one score parameter was modified at a time, while all other parameters were maintained at their baseline values. For the final post-CFD

comparison, fixed min–max bounds for CV_u and R_h were derived from the complete 105-case dataset and applied uniformly to all initial and optimized cases. The same bounds were maintained across all score-sensitivity scenarios.

For each scenario, the composite scores of all 105 CFD cases were recalculated, and the resulting ranking was compared with the baseline ranking. Ranking stability was quantified using Spearman's rank correlation coefficient (ρ), the percentage overlap between the ten highest-ranked cases, and the identity of the highest-ranked configuration. This analysis was intended to evaluate the robustness of the ranking and did not involve retraining the Random Forest model, rerunning Differential Evolution, or modifying the original surrogate-assisted optimization procedure.

F. Surrogate-assisted geometry optimization

Fig. 2 demonstrates the developed methodology of the surrogate-assisted geometry optimization method using DE and RF.

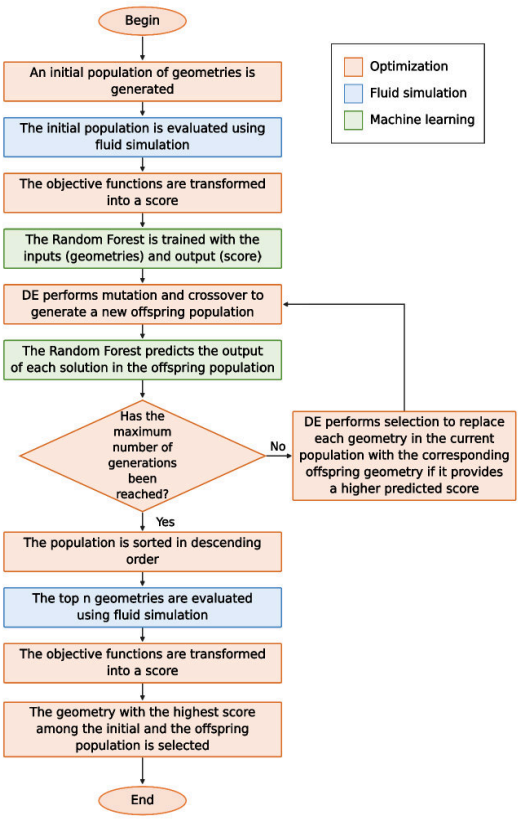

Fig. 2. Flowchart of the proposed methodology.

Before coupling the surrogate model with DE, its predictive performance was evaluated using repeated five-fold group cross-validation with 20 repetitions, resulting in 100 test folds. Groups were defined by the unique combination of pillar spacing, wall-to-pillar distance, inlet-to-pillar distance, and pillar type. Thus, all flow-rate conditions associated with the same geometry were assigned entirely to either the training or test subset in each fold, preventing information leakage between geometrically equivalent cases. The Min-Max transformation was fitted exclusively to the training subset within each fold. The RF comprised 500 trees, with a minimum of two samples per terminal leaf. Variability across the 100 grouped test folds was reported as the mean and standard deviation of R^2, MAE, and RMSE.

After optimization, the predictive performance of the surrogate was further assessed using the 20 additional CFD cases, comprising four optimized geometries evaluated at five flow rates. RF predictions were compared with CFD-derived scores calculated using the same score formulation and normalization limits adopted for the initial 85-case dataset. Agreement was quantified using (R^2), MAE, RMSE, and mean bias, defined as the RF-predicted score minus the CFD-derived score. Error dispersion was summarized using its standard deviation, empirical 2.5th–97.5th percentile range, and maximum absolute error. These descriptive statistics were used to characterize case-specific predictive variability and were not interpreted as formal prediction intervals.

Next, DE performs mutation and crossover to generate an offspring population (as discussed in Section II-A). The RF model predicts the scores for each offspring geometry. If the maximum number of generations has not yet been reached, DE performs a selection by replacing each geometry in the current population with the corresponding offspring generated using the trial vector if it provides a higher predicted score. In contrast, if the maximum number of generations is achieved, the offspring are sorted in ascending order based on the predicted scores. The top n (user-input parameter) geometries were evaluated using fluid simulations.

The objective functions of the best n geometries were transformed into a global score. Finally, the highest-ranked candidate geometries were selected for CFD verification. It's worth to highlight that the complete DE algorithm settings, including the population size, mutation and crossover parameters, number of generations, evolution strategy, and stopping criteria, are provided in the associated code repository[1].

IV. Results and Discussion

A. Transport behavior

First, a mesh-independent study was conducted. The velocity profiles obtained using the three meshes (Fig. 3) showed close agreement along the channel width, indicating that the main flow features were adequately captured. The wall shear stress profiles also exhibited similar behavior among the meshes, including regions of higher shear stress. Since wall shear stress is more sensitive to near-wall velocity gradients, this agreement indicates that the mesh refinement was sufficient for extracting shear-related quantities such as $WSS90$ and $WSS90_{pilar}$. Therefore, the selected mesh provided a suitable compromise between numerical accuracy and computational cost for the CFD simulations.

Based on the profile comparison and GCI value for the fine mesh (0.001%), the mesh with approximately 3.7×10^6 elements were selected for the parametric simulations because they provided mesh-independent results while reducing the computational cost compared with that of the finest mesh size.

The initial CFD simulations provided the hydrodynamic and mass transfer datasets used for the score calculation and surrogate model training. For each simulated condition, the

[1] https://github.com/mbdemoraes/2026-cbeb-open-data

velocity field, pressure field, wall shear stress distribution, and oxygen concentration field were obtained and converted into quantitative-performance indicators. These indicators included the 90th percentile wall shear stress, $WSS90$, the wall shear stress in the micropillar region, $WSS90_{pilar}$, the maximum wall shear stress, WSS_{max}, the average velocity coefficient of variation, CV_u, the hydraulic resistance, R_h, the average oxygen fraction, ϕ_{O_2}, the minimum oxygen fraction, $\phi_{O_{2_{min}}}$, and the oxygen coefficient of variation, $CV_{\phi_{O_2}}$. The baseline simulations showed that the microchip geometry and inlet flow rate strongly affected the transport behavior in the central chamber.

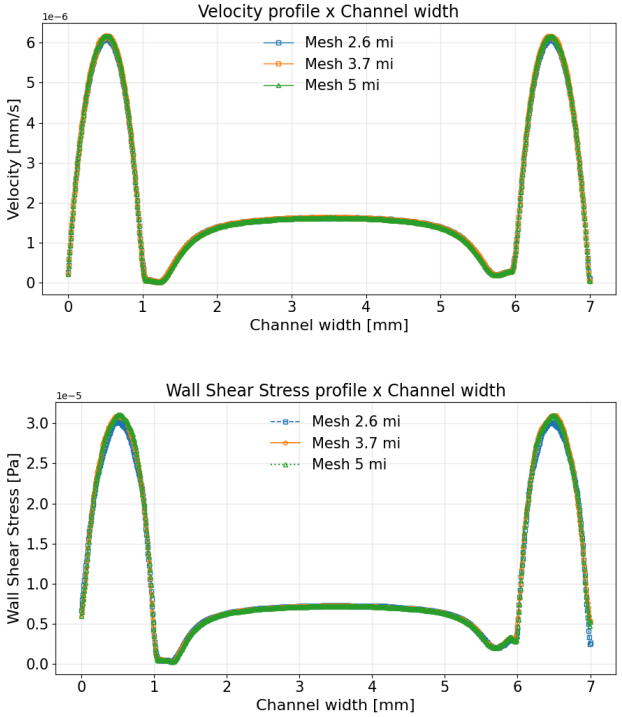

Fig. 3. Assessment of the mesh along the channel width. (a) Velocity profiles and (b) wall shear stress profiles obtained for meshes with approximately 2.6×10^6, 3.7×10^6, and 5.0×10^6 elements. The close agreement among the profiles indicates the low sensitivity of the hydrodynamic solution to further mesh refinement.

Fig. 4 shows the representative CFD results obtained for geometry type D. The velocity contours were compared for micropillar spacings of 0.25 and 0.50 mm at a volumetric flow rate of 1 µL min⁻¹. For both configurations, the highest velocities occurred in the inlet and outlet microchannels, whereas the central chamber exhibited lower velocities owing to flow expansion. The 0.25 mm spacing produced a more restricted flow path around the micropillar region, increasing the local obstruction and low-velocity zones. In contrast, a 0.50 mm spacing allowed greater flow penetration through the chamber, improving the fluid distribution around the micropillar array.

The oxygen concentration contours also demonstrated the effect of the inlet flow rate on mass transport. At a lower flow rate, oxygen gradients were more evident inside the chamber, indicating that oxygen consumption and limited convective renewal can produce spatial heterogeneity. At higher flow rates, the oxygen concentration became more uniform throughout the chamber, suggesting improved medium renewal and reduced oxygen depletion. Therefore, the CFD results confirmed that both the geometry and operating conditions affect the preferential flow pathways, velocity heterogeneity, wall shear stress distribution, and oxygen availability.

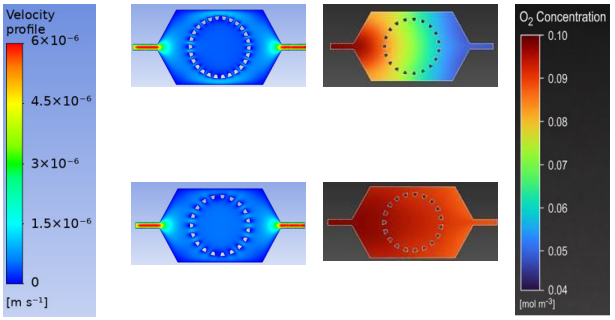

Fig. 4. Representative CFD results for geometry type D. Velocity contours for micropillar spacings of 0.25 mm (top left) and 0.50 mm (bottom left) at a volumetric flow rate of 1 $\mu L\ min^{-1}$, and O_2 concentration contours for two inlet flow rates, $Q_{low} = 1\ \mu L\ min^{-1}$ (top right), and $Q_{high} = 5\ \mu L\ min^{-1}$ (bottom right), at fixed geometry and micropillar spacing.

These findings indicate that no single CFD-derived response is sufficient to rank the microchip configurations. Higher flow rates favored oxygen renewal and reduced oxygen heterogeneity but also increased the wall shear stress. Conversely, lower flow rates reduced shear stress but increased residence time and intensified oxygen depletion in regions with lower convective transport. Similarly, geometrical configurations that promote greater interaction between the flow and micropillar region can improve perfusion but also alter local shear stress. This trade-off supports the use of a global score to combine shear stress, velocity heterogeneity, hydraulic resistance, and oxygen availability into a single target variable. Before applying the surrogate-assisted optimization workflow, the highest-scoring configurations in the initial dataset were associated with geometries that provided an adequate compromise between oxygen availability and low wall shear stress (WSS). However, some of these cases still presented relatively high velocity heterogeneity, indicating that further enhancements could be obtained by exploring intermediate geometric configurations that were not included in the original parametric set. Therefore, these CFD-derived responses were used to train the RF surrogate model and guide the subsequent DE search.

B. Surrogate-model validation and candidate selection

The RF surrogate model was first evaluated using repeated group cross-validation, ensuring that complete geometries were held out from model training. Across the 100 grouped test folds, the model achieved $R^2 = 0.814 \pm 0.132$, $MAE = 0.386 \pm 0.103$, and $RMSE = 0.520 \pm 0.154$ score units. When the repeated out-of-fold predictions were averaged for each of the 85 initial conditions, the resulting performance was $R^2 = 0.848$, $MAE = 0.375$, and $RMSE = 0.526$. These results indicate that the surrogate captured the main relationship between the design variables and the global score for previously unseen geometries. Nevertheless, the

variability across grouped partitions demonstrates that prediction accuracy remained sensitive to the limited number of independent geometries, reinforcing the need for CFD verification of the candidates proposed by the surrogate. After this validation, the RF model was coupled with DE to explore the design space and identify candidate conditions with high predicted performance.

The optimized candidate pool included both pillar-type configurations. Although the surrogate model initially assigned slightly higher robust predicted scores to trapezoidal micropillars, triangular micropillar candidates were maintained in the final pool to preserve geometric diversity and avoid selecting only one design family. This decision was important because the subsequent CFD verification showed that the triangular configurations achieved the highest recalculated scores.

C. CFD evaluation of optimized geometries

From the candidate pool generated by DE, four optimized geometries were selected and simulated using CFD. These new simulations were added to the original dataset, corresponding to zero-based indices 85–104 of the complete dataset. After inclusion, all cases were re-evaluated using the same global score function. This recalculation was necessary because the score includes min–max normalization terms for CV_u and R_h; therefore, adding new geometries can change the reference range used to compare all cases.

Using a common normalization range for the complete dataset, the recalculated ranking placed the optimized geometries in the highest positions. The best configuration was obtained for the optimized geometry with $d_{pilar} = 0.625$ mm, $d_{wall-pilar} = 0.642$ mm, $d_{entrance-pilar} = 2.31$ mm, and $pilar_{type} = 2$. This geometry achieved a score of 9.905 at Q = 1, 5, and 10 µL min^{-1}, with residence times of 52.22, 10.44, and 5.22 min, respectively. This value represents the best multicriteria compromise within the investigated dataset and design domain, rather than a universally optimal geometry, because the score depends on the adopted weights, thresholds, penalty functions, and normalization limits.

Compared with the best initial case at Q = 10 µL min^{-1}, the optimized configuration reduced CV_u from 0.791 to 0.681, pillar $WSS90$ from 6.62×10^{-4} to 4.68×10^{-4} Pa, and CV_{O_2} from 0.0142 to 0.0111. The ϕ_{O_2} increased slightly from 0.0948 to 0.0950, whereas overall $WSS90$ and hydraulic resistance remained nearly unchanged. The shift from pillar type 1 to type 2 coincided with improved transport uniformity, although simultaneous changes in pillar spacing and wall clearance preclude attributing the improvement to pillar shape alone.

However, WSS_{max} increased from $1.62\times10^{-3}\ Pa$ in the best initial case to $1.05\times10^{-2}\ Pa$ in the optimized case, corresponding to a 6.5-fold increase. Because the score was based on $WSS90$, this localized maximum had limited influence on the optimization. Nevertheless, the higher peak may be relevant to local cell exposure and should be considered as an additional constraint in future score formulations. Its biological effect cannot be established without experimental cell-culture validation.

D. Sensitivity of the configuration ranking

The sensitivity analysis indicated that the configuration ranking was robust to the tested assumptions (Fig. 5). Variations in the oxygen-factor weight did not change the ranking because the oxygen desirability remained equal to one for all 105 cases, which were within the adopted acceptable range of 3–10%. The same highest-ranked case (case 95) was maintained in all scenarios, with Spearman's rank correlations ranging from 0.972 to 1.000. Individual variations in the weights, the $WSS90$ threshold, and penalty intensity preserved all baseline top-10 configurations. Equal weighting produced the largest change, although it retained 80% of the top 10 and the same highest-ranked case. Across all scenarios, its score ranged from 9.762 to 9.928, compared with the baseline value of 9.905. Thus, the selected configuration was stable, whereas its numerical score remained conditional on the adopted multicriteria formulation. Detailed scenario-specific results and the analysis code are available in the associated repository[1].

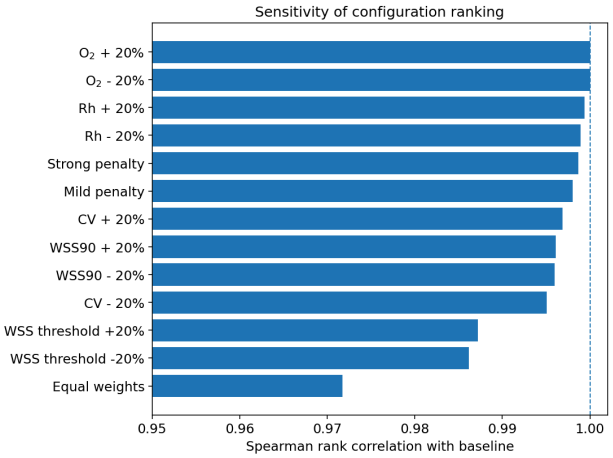

Fig. 5. Sensitivity of the configuration ranking to variations in score weights, the $WSS90$ threshold, and penalty intensity. Bars represent Spearman's rank correlation (ρ) with the baseline ranking; the dashed line indicates perfect correlation (ρ = 1).

E. Initial versus optimized score

The score distributions were compared between the initial dataset and the optimized CFD simulations. As shown in Fig. 6, the optimized group shifted the score distribution toward higher values, indicating that the RF-DE search could identify regions of the design space with improved global performance. This result is particularly relevant because the optimized geometries were not selected by direct CFD screening but by an RF model coupled with DE.

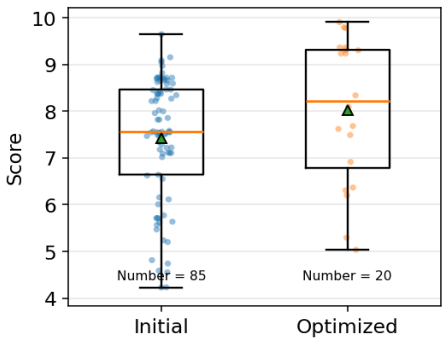

Fig. 6. Score distributions for the initial and optimized groups after recalculation using fixed min–max bounds derived from the complete 105-case dataset. The optimized group showed a shift toward higher scores following RF-DE-based candidate generation and CFD verification

After recalculation using fixed min–max bounds derived from the complete 105-case dataset, optimized cases accounted for nine of the ten highest-ranked conditions, whereas only one initial case remained. This result indicates that the RF-DE search identified high-performance regions of the design space that remained favorable after CFD verification. Besides, all final comparisons were performed using the same fixed normalization reference derived from the complete dataset.

For the 20 additional cases, RF-predicted and CFD-derived scores showed $R^2 = 0.857$, $MAE = 0.393$, $RMSE = 0.572$, and a mean bias of 0.075 score units (Fig. 7). Prediction errors had a standard deviation of 0.581; 90% of the absolute errors were below 0.907, and the maximum was 1.703. The largest deviations occurred for pillar type 2, although agreement was greater among the highest-scoring cases. The final CFD ranking favored triangular pillars, whereas the surrogate initially assigned slightly higher scores to trapezoidal configurations. Preserving both design families was therefore important, supporting the use of RF for candidate screening combined with targeted CFD verification. Because no device fabrication or biological experiments were performed, the reported improvements refer exclusively to CFD-derived hydrodynamic and mass-transfer performance and do not demonstrate improved cellular outcomes.

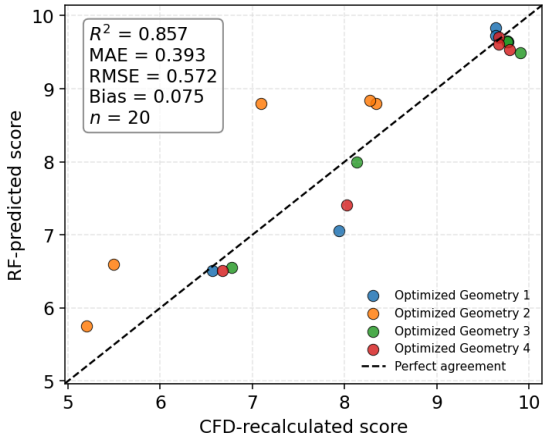

Fig. 7. Comparison between RF-predicted and CFD-derived scores for the 20 additional cases, comprising four optimized geometries evaluated at five flow rates. The dashed line represents perfect agreement.

V. Conclusions

In this study, we developed a simulation-based optimization workflow for a bone-on-chip platform by combining CFD simulations, RF surrogate modeling, and DE. The RF-DE framework identified high-performance design regions and selected four candidate geometries for CFD verification. After score recalculation using a common normalization reference, the optimized cases accounted for nine of the ten highest-ranked conditions. The highest-ranked geometry achieved a score of 9.905, representing a computational multicriteria compromise rather than an absolute optimum, and showed improved velocity and oxygen uniformity and reduced pillar $WWS90$ compared with the best initial configuration. The proposed framework supported multicriteria microfluidic design while reducing the need for exhaustive CFD screening. CFD verification remained essential because the highest-performing triangular-pillar configurations differed from the initial surrogate predictions, which slightly favored trapezoidal pillars. All findings are exclusively in silico, as no device fabrication, experimental perfusion, or cell-culture validation was performed. Future studies should expand the CFD dataset, refine the score formulation, and experimentally validate the optimized designs.

***Resumo*—O uso de forças acústicas para manipulação de micro e nanopartículas tem sido investigado como estratégia de controle de transporte em meios líquidos. Entretanto, a magnitude da resposta depende fortemente do tamanho da partícula, das propriedades do meio e da validade das aproximações empregadas no modelo físico. Este trabalho investiga, por simulação computacional, a dinâmica de partículas esféricas de óxido de cálcio (CaO) submetidas a uma onda ultrassônica progressiva em água e em uma representação simplificada do humor vítreo.Foram avaliados oito cenários, combinando partículas com raios de 100 nm e 100 μm, dois meios fluidos e distâncias fonte–partícula de 16 e 21 mm. A frequência de 1 MHz e a amplitude de pressão de referência de 100 kPa foram mantidas fixas em todas as simulações, sem varredura de frequência ou intensidade. O modelo computacional combinou difusão térmica pela relação de Einstein–Smoluchowski, força de radiação acústica para esfera pequena em onda progressiva e arrasto hidrodinâmico avaliado a partir do número de Reynolds. Para as nanopartículas, o deslocamento determinístico associado à força acústica após 1.999 ms foi da ordem de 10^{-16}–10^{-15} μm, enquanto as trajetórias apresentaram flutuações muito superiores decorrentes do movimento browniano. Para as micropartículas, o deslocamento final no eixo x variou aproximadamente de -0.149 a -0.221 μm, no sentido de propagação da onda. O número de Reynolds máximo permaneceu abaixo de 0.05 em todos os cenários de micropartículas, sustentando o regime de baixo Reynolds nas condições simuladas.Os resultados evidenciam uma forte dependência do efeito acústico com a escala da partícula. Enquanto a contribuição determinística da radiação acústica foi desprezível em comparação com a difusão térmica para partículas de 100 nm no intervalo temporal estudado, as micropartículas apresentaram deslocamento acústico sistemático e mensurável. As diferenças entre água e o modelo simplificado do humor vítreo foram influenciadas pelas propriedades acústicas e viscosas atribuídas a cada meio, sem demonstrar superioridade geral de um meio sobre o outro. Além disso, a aproximação de Rayleigh é adequada para partículas de 100 nm, mas apenas aproximada para partículas de 100 μm a 1 MHz, limitando a interpretação quantitativa deste último caso. Sob frequência e pressão fixas, o modelo prevê resposta acústica detectável para micropartículas de CaO, enquanto o comportamento das nanopartículas permanece predominantemente governado pela difusão browniana no intervalo simulado. Os resultados devem ser interpretados como uma análise computacional das condições específicas avaliadas, não permitindo inferências sobre otimização de frequência, intensidade, eficácia terapêutica ou benefício clínico.**

***Palavras-chave*—força de radiação acústica, movimento browniano, óxido de cálcio, simulação computacional, humor vítreo.**

I. Introdução

O GLAUCOMA é uma doença associada à perda progressiva da função visual, e a redução da pressão intraocular permanece um dos principais objetivos terapêuticos [1], [2]. A adesão ao tratamento tópico pode ser limitada por fatores relacionados à administração e ao uso crônico de medicamentos [3]. Por esse motivo, diferentes sistemas de liberação ocular têm sido investigados como estratégias de pesquisa para prolongar a permanência do fármaco ou modificar sua distribuição [5]. O ultrassom também tem sido estudado como estímulo físico em sistemas responsivos e em estratégias experimentais de transporte ocular [12], [13], [63], [65]. Essas referências justificam o interesse físico pelo acoplamento acústico, mas não constituem evidência de que partículas de CaO sejam seguras ou eficazes no tratamento do glaucoma. Entretanto, resultados obtidos em modelos de transporte de partículas não demonstram, por si só, eficácia terapêutica ou benefício clínico.

A manipulação acústica de micro e nanopartículas é uma abordagem estudada em microfluídica e bioengenharia, na qual a transferência de momento da onda pode produzir uma força média de radiação sobre partículas suspensas [21], [55]. O efeito depende do tamanho da partícula, das propriedades acústicas relativas entre partícula e fluido e do tipo de campo sonoro. Em paralelo, a agitação térmica se torna progressivamente mais relevante à medida que o tamanho da partícula diminui, exigindo que o movimento browniano seja considerado na nanoescala [19], [20].

O CaO foi adotado neste trabalho como material particulado de estudo. Embora sistemas baseados em carbonato de cálcio ($CaCO_3$) sejam discutidos em outros contextos biomédicos, seus resultados não devem ser extrapolados diretamente para CaO. Há literatura específica sobre síntese e aplicações biomédi-

cas emergentes de nanopartículas de CaO [11], além de rotas de síntese a partir de resíduos ricos em cálcio [14], [54]; contudo, o presente trabalho não avalia biocompatibilidade ocular, farmacocinética, toxicidade ou liberação de fármacos. Assim, o CaO é tratado aqui como uma partícula-modelo com propriedades físicas definidas, sem inferência de eficácia terapêutica.

Modelos computacionais são úteis para testar consistência física, ordens de grandeza e sensibilidade a hipóteses, mas sua validade depende da correspondência entre as equações implementadas e o regime físico representado [15]–[17]. Por essa razão, nesta revisão foram explicitados o regime de validade da aproximação acústica, o critério de arrasto e as limitações reológicas do meio vítreo.

O objetivo deste estudo é caracterizar numericamente a resposta de partículas esféricas de CaO em água e em uma representação simplificada do humor vítreo sob uma onda ultrassônica progressiva. Especificamente, são comparados dois raios de partícula e duas distâncias da fonte, mantendo frequência e pressão de referência constantes. Também são verificados o sentido do deslocamento, a consistência das unidades, a validade do regime de Stokes por meio do número de Reynolds e a aplicabilidade da aproximação de partícula pequena utilizada no modelo acústico.

II. Modelo Físico

A. Movimento browniano

Para uma esfera em um fluido Newtoniano, o coeficiente de difusão translacional é representado pela relação de Einstein–Smoluchowski,

$$D = \frac{k_B T}{\gamma}, \qquad \gamma = 6\pi\eta a, \tag{1}$$

em que k_B é a constante de Boltzmann, T é a temperatura absoluta, η é a viscosidade dinâmica e a é o raio da partícula [19], [20]. Em cada passo temporal, o incremento browniano em cada coordenada é

$$\Delta \mathbf{r}_B = \sqrt{2D\Delta t}\,\boldsymbol{\xi}, \tag{2}$$

com $\boldsymbol{\xi}$ formado por variáveis normais independentes de média zero e variância unitária.

B. Força de radiação acústica

Para representar uma esfera pequena submetida a uma onda plana progressiva, adotou-se a expressão de força de radiação de uma onda plana progressiva sobre uma esfera pequena, cuja direção é a da propagação e cuja magnitude de espalhamento apresenta dependência $(ka)^4$ [21], [55]. A magnitude da força média de radiação é

$$F_{\mathrm{ac}} = \frac{4\pi a^2 I}{9c}\left(f_1^2 + f_1 f_2 + \frac{3}{4} f_2^2\right)(ka)^4, \tag{3}$$

em que $k = 2\pi f/c$ e

$$f_1 = 1 - \frac{\kappa_p}{\kappa_0} = 1 - \frac{\rho c^2}{\rho_p c_p^2}, \tag{4}$$

$$f_2 = \frac{2(\rho_p - \rho)}{2\rho_p + \rho}. \tag{5}$$

Aqui, ρ e c são a densidade e a velocidade do som no fluido, enquanto ρ_p e c_p são as propriedades da partícula.

A intensidade local foi obtida de

$$I(d) = \frac{p(d)^2}{2\rho c}, \qquad p(d) = p_0\, 10^{-\alpha f_{\mathrm{MHz}} d_{\mathrm{cm}}/20}, \tag{6}$$

considerando apenas atenuação exponencial. Não foi introduzido fator adicional de espalhamento geométrico. O vetor unitário de propagação é

$$\hat{\mathbf{k}} = \frac{\mathbf{r} - \mathbf{r}_s}{\|\mathbf{r} - \mathbf{r}_s\|}, \qquad \mathbf{F}_{\mathrm{ac}} = F_{\mathrm{ac}}\hat{\mathbf{k}}. \tag{7}$$

Como a fonte está posicionada em $+x$ e a partícula inicia na origem, a onda chega à partícula propagando-se no sentido $-x$. Portanto, a componente acústica prevista é $F_x < 0$: o movimento determinístico ocorre no sentido de propagação da onda e, nesta geometria, corresponde a afastamento do emissor, não a movimento em direção a ele.

C. Arrasto e equação de movimento

O número de Reynolds da partícula foi calculado em cada passo como

$$Re_p = \frac{\rho |\mathbf{v}| (2a)}{\eta}. \tag{8}$$

Para $Re_p < 0.1$, empregou-se o arrasto de Stokes, $\mathbf{F}_D = -6\pi\eta a\mathbf{v}$. O código contém ainda a correlação de Schiller–Naumann para $Re_p \geq 0.1$, com

$$C_D = \frac{24}{Re_p}\left(1 + 0.15 Re_p^{0.687}\right), \tag{9}$$

e $\mathbf{F}_D = -\frac{1}{2}\rho C_D \pi a^2 |\mathbf{v}| \mathbf{v}/|\mathbf{v}|$ [58]. A verificação de Re_p evita aplicar a lei de Stokes indiscriminadamente à micropartícula.

Para a nanopartícula foi utilizado o limite superamortecido, $\mathbf{v}_d = \mathbf{F}_{\mathrm{ac}}/\gamma$, e a posição foi atualizada por $\mathbf{r}_{n+1} = \mathbf{r}_n + \mathbf{v}_d \Delta t + \Delta \mathbf{r}_B$. Para a micropartícula, a inércia foi preservada e integrou-se explicitamente $m\, d\mathbf{v}/dt = \mathbf{F}_{\mathrm{ac}} + \mathbf{F}_D$, acrescentando-se o incremento browniano à posição.

III. Materiais e Métodos

A. Parâmetros e cenários

A implementação foi realizada em Python com *NumPy* e *Matplotlib*. Todas as grandezas internas foram mantidas no SI. Foram executados 2000 passos com $\Delta t = 1 \times 10^{-6}$ s, correspondendo a 1.999 ms. A semente pseudoaleatória de base foi 20260903 para permitir reprodução das trajetórias. Foram avaliados exatamente oito cenários: dois raios (100 nm e 100 μm), dois meios (água e humor vítreo simplificado) e duas distâncias da fonte (16 e 21 mm). A frequência foi mantida em 1 MHz e a amplitude de pressão de referência em

PARÂMETROS FÍSICOS EMPREGADOS NA SIMULAÇÃO

Parâmetro	Valor	Base/observação
T	298 K	valor de simulação
$\rho_{\text{água}}$	997 kg/m^3	IAPWS, arredondado [53]
$\eta_{\text{água}}$	8.9×10^{-4} Pa·s	IAPWS, arredondado [53]
$c_{\text{água}}$	1500 m/s	valor arredondado a 25°C [60]
$\rho_{\text{vítreo}}$	1005 kg/m^3	limite inferior reportado [56]
$\eta_{\text{vítreo}}$	3.65×10^{-3} Pa·s	proxy Newtoniano adotado; cf. [56]
$c_{\text{vítreo}}$	1532 m/s	biometria ultrassônica [59]
ρ_{CaO}	3345 kg/m^3	propriedade adotada
c_{CaO}	4880 m/s	propriedade adotada [57]
f	1 MHz	fixo
p_0	100 kPa	fixo
α	0.1 dB/(cm·MHz)	hipótese do modelo
d_s	16 e 21 mm	cenários

100 kPa em todos os casos; não houve variação desses dois parâmetros.

O valor 3.65 mPa·s é tratado nesta versão explicitamente como um *proxy* Newtoniano efetivo adotado no código, e não como uma constante fisiológica universal. Silva *et al.* demonstraram que o humor vítreo é viscoelástico e fortemente dependente da taxa de cisalhamento, com valores da ordem de 10^{-3} Pa·s em regimes de maior cisalhamento [56]. Assim, o parâmetro usado preserva a execução reproduzida, mas sua natureza aproximativa é declarada e considerada na discussão. A densidade de 1005 kg/m^3 corresponde ao arredondamento do limite inferior da faixa de 1.0053–1.0089 g/cm^3 reportada para o vítreo [56]. Para a água próxima de 298 K, densidade e viscosidade foram arredondadas a partir das correlações recomendadas pela IAPWS [53]; a velocidade de 1500 m/s é um arredondamento do valor de aproximadamente 1497 m/s a 25°C obtido pela expressão de Lubbers e Graaff [60]. Para o vítreo, 1532 m/s foi mantido por ser o valor convencional empregado em biometria A-scan para a câmara anterior e o humor vítreo [59].

O domínio computacional foi definido como um cubo de $50 \times 50 \times 50$ mm^3, centrado na origem, apenas como limite numérico. A trajetória não foi artificialmente limitada por *clipping*; uma saída do domínio interromperia a execução como erro de modelagem. A ação acústica só foi aplicada após o tempo inicial de propagação d_s/c. Os resultados foram exportados em CSV, incluindo posição, velocidade, aceleração, forças, pressão, intensidade e Re_p em cada passo.

B. Implementação computacional e reprodutibilidade

O programa foi organizado em estruturas separadas para propriedades do meio e da partícula e em uma função única de simulação por cenário. A fonte é posicionada em $(d_s, 0, 0)$ e a partícula em $(0, 0, 0)$. Em cada passo, calcula-se primeiro a distância fonte–partícula e a amplitude de pressão local pela Eq. (6). A força acústica permanece nula antes do tempo de chegada d_s/c; após esse instante, a Eq. (3) é avaliada e multiplicada pelo vetor unitário da Eq. (7). Essa implementação elimina a força eletrostática que aparecia em versões preliminares do código, pois ela não fazia parte da metodologia declarada.

Para $a = 100$ nm, o tempo de relaxação inercial é muito menor que o passo macroscópico de interesse e foi usado o limite superamortecido. A deriva determinística é calculada por $\mathbf{F}_{\text{ac}}/\gamma$ e somada ao incremento estocástico da Eq. (2). Para $a = 100$ μm, a velocidade é integrada explicitamente a partir da força acústica e do arrasto. O Re_p é recalculado a cada iteração: Stokes é usado quando $Re_p < 0.1$ e o algoritmo dispõe da correlação de Schiller–Naumann para valores superiores, conforme a literatura clássica de arrasto de partículas [58]. Como os resultados desta execução apresentaram $Re_p < 0.05$, a ramificação de Schiller–Naumann não foi acionada nos cenários reportados.

Cada uma das oito combinações recebeu uma semente determinística derivada da semente-base 20260903. Foram armazenados, a cada 1 μs, posição, velocidade, aceleração, força acústica, força de arrasto, pressão, intensidade, deslocamento, Re_p e o modelo de arrasto selecionado. As figuras foram produzidas a 300 dpi a partir dessas séries. A frequência de 1 MHz e a pressão de referência de 100 kPa são entradas fixas: não existe laço de varredura desses parâmetros. A intensidade local varia apenas como consequência das propriedades do meio, da distância e da atenuação da Eq. (6), não como um parâmetro experimental independente.

C. Diagnóstico de validade do modelo acústico

A Eq. (3) pressupõe partícula pequena em relação ao comprimento de onda. Como diagnóstico conservador, registrou-se $2a/\lambda$ e ka. Para $a = 100$ nm, obteve-se $ka \approx 4.1 \times 10^{-4}$ e $2a/\lambda \approx 1.3 \times 10^{-4}$, claramente no regime de Rayleigh. Para $a = 100$ μm, $ka \approx 0.41$ e $2a/\lambda \approx 0.13$. Assim, o caso de micropartícula permanece subcomprimento de onda, porém fora do critério conservador $2a/\lambda \leq 0.1$ adotado no código; seus resultados devem ser interpretados como aproximação de primeira ordem, não como previsão de alta fidelidade.

IV. RESULTADOS

A Tabela II resume os oito cenários, com deslocamentos expressos em micrômetros e forças em newtons. Em nenhum caso o deslocamento se aproximou da escala do domínio numérico de 25 mm por semieixo.

A. Nanopartículas

A Fig. 1 mostra que as quatro trajetórias de nanopartículas apresentam flutuações aleatórias em escala submicrométrica. O componente determinístico acústico acumulado foi inferior a 2×10^{-15} μm em módulo, enquanto o deslocamento total da realização estocástica variou entre 0.028 e 0.265 μm. Portanto, o sinal da posição final de uma única trajetória não pode ser interpretado como direção de transporte acústico. Nas condições adotadas, a contribuição browniana domina completamente a resposta da nanopartícula no intervalo simulado.

O coeficiente de difusão calculado foi 2.45×10^{-12} m^2/s em água e 5.98×10^{-13} m^2/s no meio vítreo, razão de aproximadamente 4.1. Isso indica maior dispersão browniana esperada em água; contudo, como foi utilizada uma única

TABLE II
RESULTADOS DA SIMULAÇÃO APÓS 1.999 MS

Cenário	x_f (μm)	x_{det} (μm)	$\|\Delta\mathbf{r}\|$ (μm)	$\overline{F}_{ac}$ (N)	Re_{max}	ka
NP, vítreo, 16 mm	0.0666	-4.22×10^{-16}	0.0752	1.46×10^{-27}	1.17×10^{-20}	4.10×10^{-4}
NP, vítreo, 21 mm	-0.0219	-4.17×10^{-16}	0.0284	1.44×10^{-27}	1.16×10^{-20}	4.10×10^{-4}
NP, água, 16 mm	-0.00290	-1.99×10^{-15}	0.0716	1.68×10^{-27}	2.24×10^{-19}	4.19×10^{-4}
NP, água, 21 mm	0.0965	-1.96×10^{-15}	0.265	1.66×10^{-27}	2.22×10^{-19}	4.19×10^{-4}
MP, vítreo, 16 mm	-0.151	-0.153	0.151	1.46×10^{-9}	0.00729	0.410
MP, vítreo, 21 mm	-0.149	-0.151	0.149	1.44×10^{-9}	0.00720	0.410
MP, água, 16 mm	-0.221	-0.219	0.222	1.68×10^{-9}	0.0475	0.419
MP, água, 21 mm	-0.213	-0.216	0.213	1.66×10^{-9}	0.0469	0.419

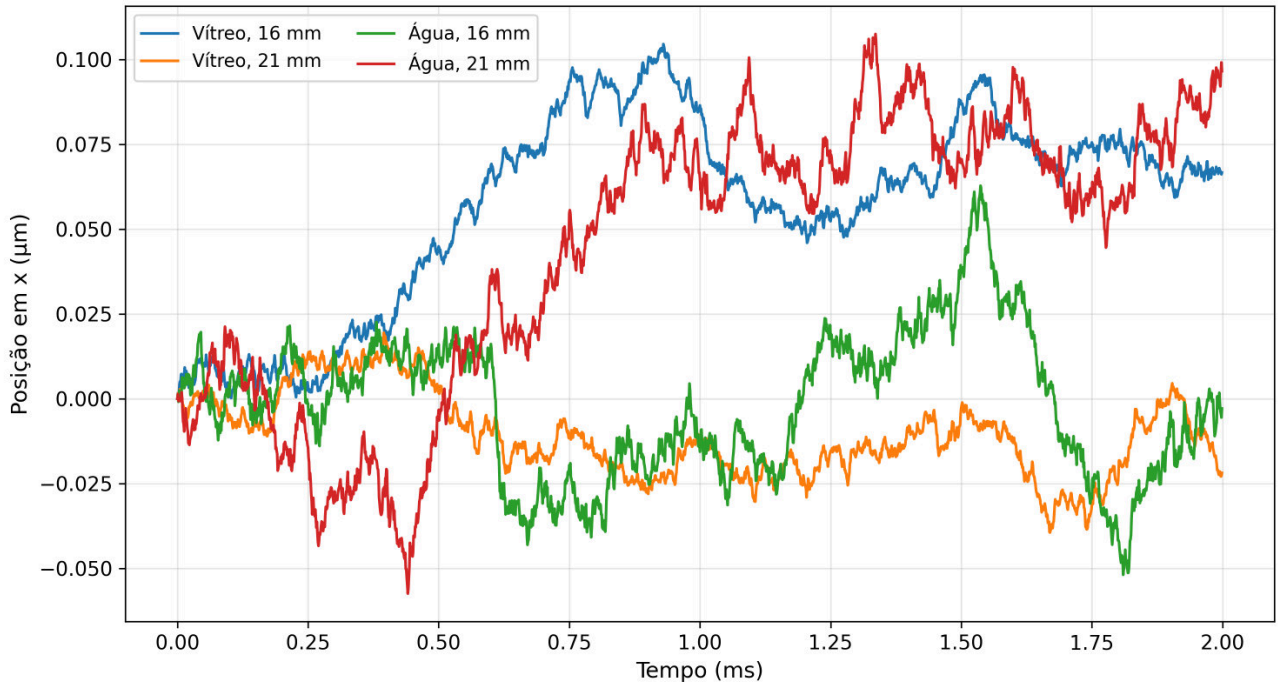

Fig. 1. Posição em x das nanopartículas para água e humor vítreo simplificado, nas distâncias de 16 e 21 mm. A frequência e a pressão de referência foram mantidas em 1 MHz e 100 kPa.

realização pseudoaleatória por cenário, os valores finais individuais não constituem uma estimativa estatística da variância. Uma comparação quantitativa de dispersão entre meios exigiria múltiplas réplicas estocásticas ou uma análise de conjunto.

B. Micropartículas

Para as micropartículas, o componente determinístico é dominante no intervalo de 1.999 ms. A Fig. 2 mostra deslocamento monotônico para $-x$, coerente com a direção de propagação definida na Eq. (7). Os valores finais ficaram entre -0.149 e -0.221 μm. Em água, o módulo do deslocamento final foi aproximadamente 46% maior que no vítreo para 16 mm e 43% maior para 21 mm. A distância de 16 mm produziu magnitude apenas 1.8% maior que 21 mm no vítreo e 3.8% maior em água, compatível com a pequena diferença de atenuação introduzida entre as duas posições.

A velocidade máxima calculada para as micropartículas foi aproximadamente 1.31×10^{-4}–1.32×10^{-4} m/s no meio vítreo e 2.09×10^{-4}–2.12×10^{-4} m/s em água. Como o tempo de simulação é comparável ou inferior ao tempo de relaxação inercial da micropartícula, não se assume que uma velocidade terminal tenha sido atingida.

C. Validade de Stokes

A Fig. 3 apresenta o número de Reynolds das micropartículas. O maior valor foi 0.0475, registrado em água, enquanto no vítreo o máximo foi aproximadamente 0.0073. Todos os valores ficaram abaixo do limiar conservador de 0.1 adotado no algoritmo. Consequentemente, a lei de Stokes é consistente com os oito casos efetivamente simulados, embora o código mantenha a correção de Schiller–Naumann como salvaguarda para configurações futuras com Re_p mais elevado.

V. DISCUSSÃO

A formulação de onda progressiva empregada contém o fator $(ka)^4$ [21], [55]. Como ka é aproximadamente mil vezes menor para a nanopartícula de 100 nm do que para a micropartícula de 100 μm, a força de espalhamento cai fortemente na

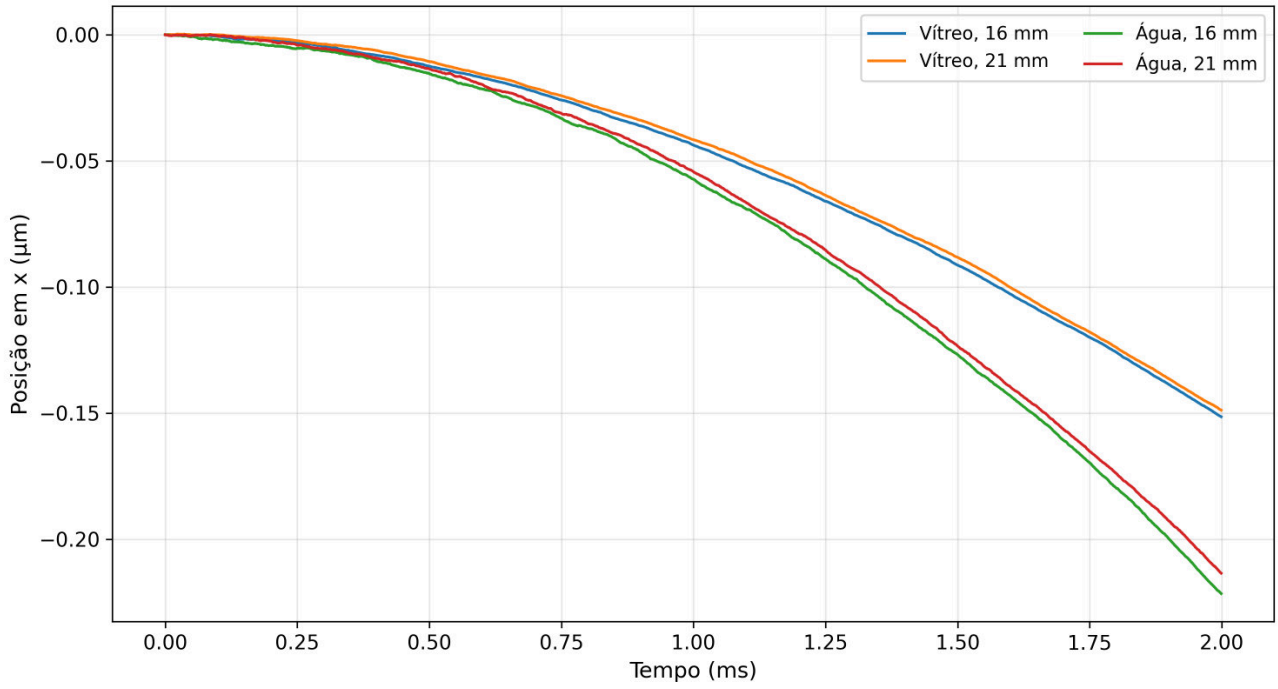

Fig. 2. Posição em x das micropartículas. O deslocamento negativo corresponde ao sentido de propagação da onda na geometria simulada.

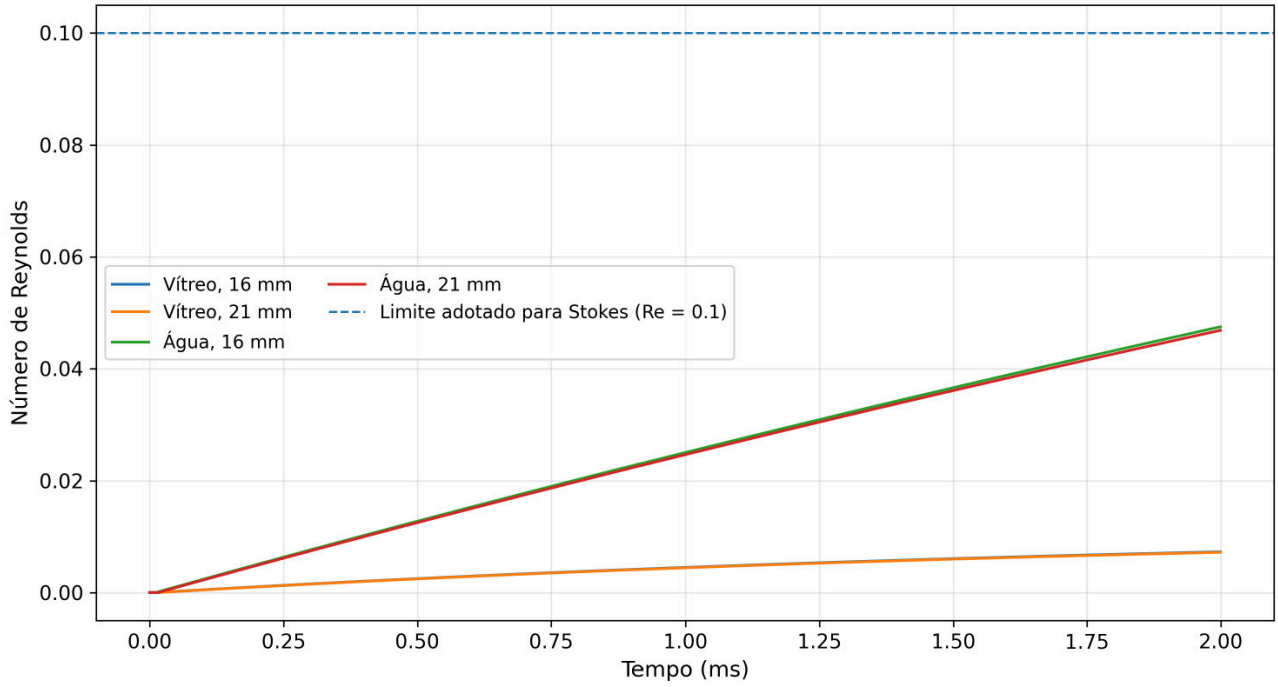

Fig. 3. Número de Reynolds das micropartículas ao longo do tempo. A linha tracejada indica o limiar $Re_p = 0.1$ adotado para a seleção do modelo de arrasto.

nanoescala. Isso explica a diferença de ordem de grandeza entre a força média obtida para as nanopartículas (10^{-27} N) e para as micropartículas (10^{-9} N). A escala submicrométrica dos deslocamentos também permanece consistente com o domínio computacional adotado.

Uma onda progressiva transfere momento na direção de propagação [55]. Com a fonte localizada em $+x$ e a partícula na origem, a direção fonte–partícula é negativa em x; portanto, o deslocamento acústico negativo representa movimento no sentido da onda e, nesta geometria, afastamento do emissor.

A comparação entre água e humor vítreo deve ser interpretada com cautela. Para as micropartículas, a menor viscosidade da água permite maior velocidade e deslocamento durante o mesmo intervalo, e o modelo também prevê força acústica ligeiramente superior por causa das propriedades acústicas do meio. Para as nanopartículas, entretanto, o termo acústico é tão pequeno que as diferenças observadas em uma única trajetória são controladas pela realização browniana. Portanto, não é adequado concluir, a partir desses quatro traçados isolados, que uma distância ou meio produz necessariamente maior deslocamento final de nanopartículas.

Os resultados também esclarecem a inconsistência de escala presente na versão anterior do manuscrito. Os deslocamentos de micropartículas são submicrométricos e representam menos de 10^{-5} do semitamanho de 25 mm do domínio. Portanto, não há compatibilidade física com interpretações anteriores em que deslocamentos da ordem de milímetros ou dezenas de milímetros eram atribuídos ao mesmo intervalo de poucos milissegundos. A correção da equação e a manutenção de todas as grandezas internas no SI removem essa discrepância dimensional.

A diferença entre 16 e 21 mm é pequena porque, no modelo atual, a distância afeta a amplitude somente pelo termo de atenuação; nenhum termo geométrico arbitrário foi acrescentado. Assim, o estudo não demonstra uma distância ótima. Analogamente, como frequência e pressão de referência são únicas, os resultados não permitem inferir tendências em função de frequência ou intensidade. Estudos de otimização exigiriam uma matriz paramétrica independente e, idealmente, validação experimental [15], [17], [61], [62].

A representação do humor vítreo constitui outra limitação relevante. O vítreo possui comportamento viscoelástico e dependente da taxa de cisalhamento [56], enquanto o código utiliza uma viscosidade newtoniana constante como parâmetro efetivo de comparação. O modelo é, assim, uma aproximação reduzida para comparação de parâmetros e não uma reprodução completa do ambiente ocular. Da mesma forma, o coeficiente de atenuação, a pressão e a frequência foram fixados como parâmetros de simulação, sem estudo de sensibilidade.

Por fim, a Eq. (3) é robustamente compatível com a condição de partícula pequena para 100 nm, mas a micropartícula apresenta $ka \simeq 0.41$. Embora ainda seja menor que o comprimento de onda, esse valor não satisfaz o critério conservador usado para classificar o regime estrito de Rayleigh. Assim, os resultados de micropartículas são úteis para demonstrar ordem de grandeza e tendências internas do modelo, mas uma validação quantitativa exigiria uma solução de espalhamento de tamanho finito, caracterização reológica mais completa e comparação com dados experimentais.

O estudo também não testou diferentes frequências ou amplitudes acústicas, não avaliou liberação de fármacos, toxicidade, segurança ocular ou desfechos relacionados ao glaucoma. Consequentemente, não se pode inferir otimização de parâmetros ultrassônicos, maior fidelidade clínica, melhoria de adesão terapêutica ou benefício médico. Tais questões devem ser tratadas em trabalhos experimentais e paramétricos posteriores.

VI. Conclusão

O modelo computacional aplicado aos oito cenários indica comportamentos distintos entre as duas escalas de partícula. Com frequência de 1 MHz e pressão de referência de 100 kPa mantidas fixas, as nanopartículas de raio 100 nm apresentaram dinâmica dominada pelo movimento browniano, com contribuição acústica determinística desprezível no intervalo de 1.999 ms. As micropartículas de raio 100 μm apresentaram deslocamento determinístico da ordem de 0.15–0.22 μm no sentido de propagação da onda. O número de Reynolds permaneceu abaixo de 0.05, sustentando o emprego de Stokes nos casos calculados. Entretanto, a aproximação acústica de Rayleigh é apenas aproximada para a micropartícula a 1 MHz, e o humor vítreo foi representado como um fluido Newtoniano efetivo. Portanto, os resultados caracterizam tendências computacionais sob hipóteses e parâmetros fixos, sem demonstrar eficácia clínica, otimização ultrassônica ou desempenho terapêutico em aplicações oftálmicas.

Agradecimentos

Este estudo recebeu apoio da Fundação Cearense de Apoio ao Desenvolvimento Científico e Tecnológico (FUNCAP) (PS1-0186-00216.01.00/21), do Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) (311062/2019-9) e da Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) (código de financiamento 001).

***Abstract*—Tracheobronchopathia osteochondroplastica (TO) is a rare benign condition characterized by the formation of cartilaginous and bony nodules in the tracheobronchial submucosa, which can lead to chronic cough, dyspnea, and recurrent infections. Computational Fluid Dynamics (CFD) combined with computed tomography (CT) has emerged as a promising tool for the personalized functional analysis of airways. This study developed 3D CFD simulations comparing the trachea of a patient with TO to that of a control subject. Geometries were reconstructed in 3D Slicer from CT images obtained from the InCor database (CAAE 88886025.80000.0068) and simulated in ANSYS using the k-omega SST turbulence model. The results demonstrated that the asymmetries caused by the nodules create local constrictions that seem to accelerate airflow and increase Turbulent Kinetic Energy (TKE). Wall shear stress (WSS) was elevated and heterogeneously distributed in the TO model, suggesting stagnation zones conducive to bacterial proliferation and altered mucociliary transport. Although limited by the analysis of one control and one patient with pathology, these data provide a quantitative biophysical perspective that aids in understanding the aerodynamic mechanisms associated with the clinical manifestations of TO.**

***Index Terms*—tracheobronchopathia osteochondroplastica, computational fluid dynamics, computed tomography, airflow dynamics, airway resistance.**

I. Introduction

Tracheobronchopathia osteochondroplastica (TO) is a rare benign condition, typically identified in patients over the age of 50 [1]. Its etiology remains incompletely understood; the condition is characterized by the formation of multiple cartilaginous and/or bony nodules within the submucosa of the tracheal and main bronchial walls, projecting into the airway lumen [2]. These nodules are predominantly distributed along the anterolateral walls, sparing the posterior wall, a characteristic that aids in diagnosis during imaging studies [3]. However, due to its relatively low incidence, lack of awareness among healthcare professionals, and slow, often asymptomatic progression, the condition is frequently underdiagnosed or misdiagnosed. Consequently, it is most often discovered incidentally, for instance, during bronchoscopy or autopsy [4].

Although some patients remain asymptomatic for long periods, disease progression can lead to significant respiratory impairment. Chronic symptoms such as persistent cough and exertional dyspnea are the most commonly reported, alongside varying degrees of airflow obstruction ranging from mild to severe. In advanced cases, nodule growth can cause critical narrowing of the tracheal lumen, with reports of hemoptysis, progressive dyspnea [5], and difficulty with orotracheal intubation, highlighting the potential clinical risk of the disease, despite its traditional classification as benign [6].

Furthermore, the impacts of TO are not limited to mechanical airway obstruction. Under physiological conditions, the mucociliary system acts as a continuous defense mechanism, in which ciliated cells drive the transport of a mucus layer responsible for trapping and clearing inhaled particles and microorganisms [7]. The presence of nodules creates irregularities on the inner surface of the airways, deeply disrupting this mechanism. Alterations in airway architecture promote the emergence of turbulent airflow zones, regions where flow transitions from orderly to chaotic, thereby compromising mucociliary transport and, consequently, favoring the accumulation of secretions. These stagnation zones become environments conducive to bacterial proliferation. Consequently, recurrent pulmonary infections are among the most frequent and debilitating manifestations of the disease, compounding

the previously described obstructive condition [2].

Analyzing airflow behavior in human airways, particularly in the context of pathological conditions, presents significant limitations. These limitations stem primarily from the infeasibility of obtaining direct, non-invasive measurements of aerodynamic parameters in real-world cases. In this context, computational modeling based on Computational Fluid Dynamics (CFD) has established itself as a robust approach for studying the respiratory system, especially when integrated with high-resolution imaging; such imaging enables the three-dimensional reconstruction of a patient's airways and facilitates the derivation of patient-specific solutions [8]. CFD has already been applied to analyze various respiratory tract conditions, such as tracheal and subglottic stenosis, allowing for the identification of pressure drop regions, energy loss, and work of breathing [9] [10].

In addition to the aforementioned advances, it is worth noting that CFD enables the determination of quantitative parameters relevant to airflow characterization, such as pressure, velocity, flow resistance, and energy [11], thereby significantly enhancing the understanding of airway fluid dynamics. However, despite this potential, literature reviews indicate that the application of this method to studies on tracheobronchopathia osteochondroplastica remains limited. Given the disease's structural variability and the distinct impacts it has on respiratory dynamics, conducting such studies becomes necessary.

Hence, the present work proposes a comparative case study based on three-dimensional simulation to analyze the fluid dynamics of airflow in a patient affected by tracheobronchopathia osteochondroplastica (TO). The geometry was reconstructed from computed tomography (CT) images, allowing for the 3D reconstruction of the tracheobronchial structures affected by the disease. The fluid-dynamic parameters obtained from the simulation were compared with those of a control patient with no apparent tracheal abnormalities. Thus, the study aims to highlight the alterations associated with the pathology, contributing to an understanding of the underlying fluid-dynamic mechanisms in TO.

II. Materials and Methods

A. Acquisition and Preparation of the Base Geometry

This is an observational, retrospective, and non-interventional study approved by the Research Ethics Committee under CAAE No. 88886025.80000.0068. The research relied on secondary access to previously acquired computed tomography images from the InCor database, aiming to reconstruct and perform a computational morphological analysis of the central airways. There was no recruitment of volunteers, clinical intervention, or storage of biological material. In compliance with Resolution No. 466/2012 of the National Health Council (CNS) and Law No. 14.874/2024, the Research Ethics Committee granted a waiver of the Informed Consent Form (with no requirement for review by CONEP). The authors ensured anonymized processing of DICOM data and strict confidentiality of patient information. Two individuals were selected for analysis: one diagnosed with tracheobronchopathia osteochondroplastica (TO) and a control subject without tracheal disease (both male, aged 57 and 64 years, respectively). Images of the selected patients were acquired at end-inspiration with a slice thickness of 1.0 mm to maintain resolution standardization for the subsequent computational simulation. The mean diameter and length of the observed tracheas were approximately 14.14 mm and 96.48 mm for the patient with TO, and 14.51 mm and 99.64 mm for the control subject; these measurements were obtained using the "Extract Centerline" function available in the Vascular Modeling Toolkit (VMTK) module [12] of 3D Slicer (version 5.10.0). Case selection aimed for compatibility of characteristics whenever possible to minimize comparison bias.

The DICOM files allowed for the visualization and post-processing of the CT images. Based on the various cross-sections obtained from the CT scans, the anatomical region of interest was reconstructed in three dimensions. Airway segmentation was performed using the "Segment Editor" module of the 3D Slicer [13]. Initially, the primary regions of interest were defined by manually placing seed points representing the tracheal lumen and adjacent structures, such as the lungs and other organs. Next, the Grow from Seeds algorithm [14] was applied; this performs semi-automatic segmentation based on the expansion of previously defined regions, taking into account intensity similarity between voxels.

Following the initial segmentation, manual adjustments were made to refine the boundaries and correct for inaccuracies, ensuring greater anatomical fidelity of the three-dimensional tracheal model, as shown in Fig. 1.

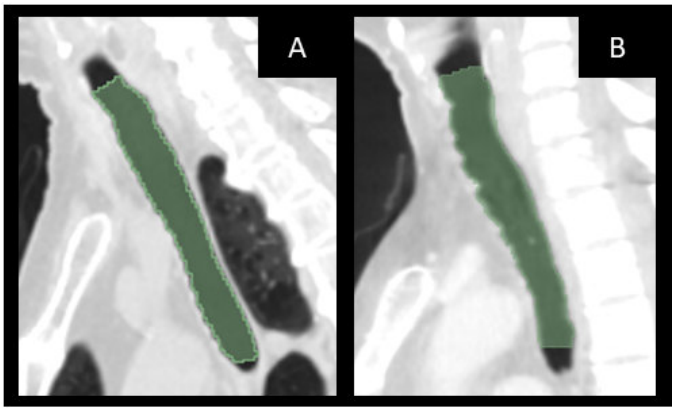

Fig. 1. Sagittal view of the segmented trachea of the control patient (A) and the patient affected by the pathology (B), using the "Grow from Seeds" segmentation method. The reconstructed trachea is highlighted in green.

For the purpose of methodological standardization, the tracheal segment under study was anatomically defined as the section extending from the cricoid cartilage (superior limit) to the tracheal carina (inferior limit) [15], encompassing the

entire length of the trachea. Identification of these anatomical landmarks was facilitated by multiplanar reconstruction (MPR), allowing for simultaneous visualization in the axial, coronal, and sagittal planes of the image series. The cricoid cartilage was identified as the first complete cartilaginous ring situated below the larynx, being most easily recognized in axial and sagittal views. The carina was identified as the point where the trachea bifurcates into the right and left main bronchi, best visualized in the coronal and axial planes. The inferior limit of the section was defined as the level immediately proximal to the start of the bifurcation, ensuring that the division between the left and right bronchi did not interfere with the computational simulation, in accordance with the study's objective. Subsequently, the regions were delineated using the "Point List" tool, and any areas situated above or below the boundary points were removed using the "Crop" tool. Finally, the resulting model could be intuitively exported from the "Segmentations" module in .STL format.

Meshmixer software was used to flatten the tracheal edges of the .STL files. Following, Fluent Flow software (Fluent with Fluent Meshing; ANSYS Fluent®, Release 2026 R1) was used to perform the computational simulation steps. Two modules were used: one for the pathological trachea and another for the control trachea.

B. 3D Geometric Modeling

The Geometry component of the ANSYS software was used to create the three-dimensional models. At this stage, imported geometries were inspected for structural defects and subsequently converted to volumetric solid bodies—a fundamental step to enable mesh generation and subsequent flow simulation. The resulting geometries for both the control and pathological models are shown in Fig. 2.

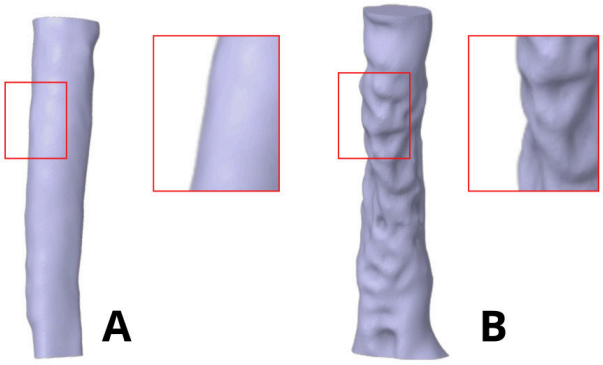

Fig. 2. Three-dimensional reconstruction of the trachea. The inset shows an enlarged view of the anterior tracheal luminal surface indicated by the red box. While the trachea of the control patient (A) exhibits a relatively smooth surface, the trachea of the patient with tracheobronchopathia osteochondroplastica (B) presents a more irregular luminal appearance due to the presence of multiple nodular protrusions.

C. Computational Mesh Generation

Three computational meshes were created using the ANSYS Meshing component, and the most refined one was used for the simulations. This mesh features a local refinement of $2.5 \times 10^{-4}\, m$ to ensure greater accuracy in capturing local fluid-dynamic phenomena. The mesh used is considered optimal, as it yields a difference of less than 2% in the results obtained [16]. A comparison of the three meshes for both tracheal models is presented in Table I.

TABLE I
NUMBER OF ELEMENTS AND NODES FOR THE DIFFERENT COMPUTATIONAL MESHES

Mesh	TO		Control	
	No. Elements	**No. Nodes**	**No. Elements**	**No. Nodes**
1^{st} Mesh	202987	538430	151424	437445
2^{nd} Mesh	360967	901098	270812	691975
3^{rd} Mesh	621328	1524478	467651	1145293

To obtain better resolution of the hydrodynamic boundary layer, which is the region where the greatest velocity and shear stress gradients occur at the wall (WSS), inflation layers were applied to the tracheal walls. The inflation configuration implemented the "Smooth Transition" method, using 7 prismatic layers, a growth rate of 1.12, and a transition ratio of 0.272. This allowed for a smooth transition between the prismatic mesh near the wall and the tetrahedral mesh at the center of the lumen, ensuring y+ values of approximately 1. The mesh design was based on rigorous boundary layer control and element quality metrics (maintaining appropriate orthogonality and asymmetry criteria). This approach ensured the stability and convergence of the numerical residuals, accurately capturing variations in WSS, pressure, and local turbulence, without requiring mesh refinement levels that would compromise computational feasibility. The resulting meshes can be seen in Fig. 3.

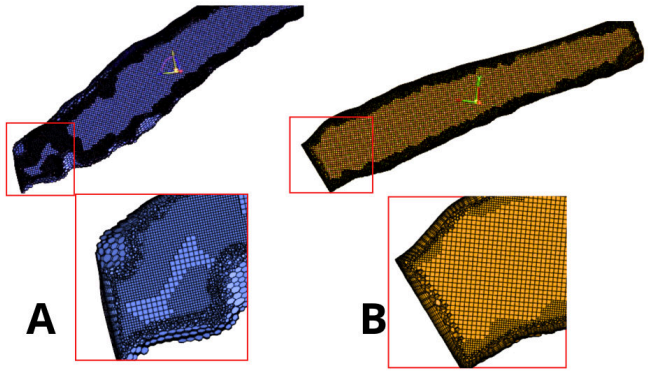

Fig. 3. The 3D models of the (A) control and (B) pathological tracheas were discretized into finite elements for CFD analysis. The red close-ups show the mesh refinement, featuring inflation layers at the tracheal wall to capture boundary layer effects, and larger elements in the center to optimize processing.

D. Setup Phase

The SST k-ω turbulence model was adopted, assuming air with a density of $1.22\,\mathrm{kg/m^3}$ and a viscosity of $1.78 \times 10^{-5}\,\mathrm{kg/(m \cdot s)}$. The inlet/outlet velocity was set at $1.5\,\mathrm{m/s}$ (peak of resting breathing [17]), with an outlet pressure of 0 Pa. The constant velocity standardized the models, isolating the impact of the TO nodule geometry on airflow resistance. The simulations, run to convergence, were performed by simulating an inspiration followed by an expiration, calculated separately under steady-state conditions.

E. Resistance Calculation

To quantitatively assess the anatomical impact on airflow, the resistance of the trachea was calculated. Tracheal resistance (R) aimed at quantifying the opposition to airflow along its length and was defined as

$$R = \frac{\Delta P}{Q}, \tag{1}$$

where R is the resistance of the trachea, ΔP is the pressure drop calculated as the outlet pressure (P_{outlet}) minus the inlet pressure (P_{inlet}), and Q is the volumetric flow rate. This formulation provides a quantitative measure of the pressure required to sustain a given airflow and enables comparison of the aerodynamic consequences of different tracheal geometries through their associated pressure losses.

III. Results

A. Average Speed

The airflow dynamics in the control and pathological tracheas during inspiration and expiration are shown in Fig. 4. Velocity contours illustrate the impact of structural changes caused by TO on the flow profile.

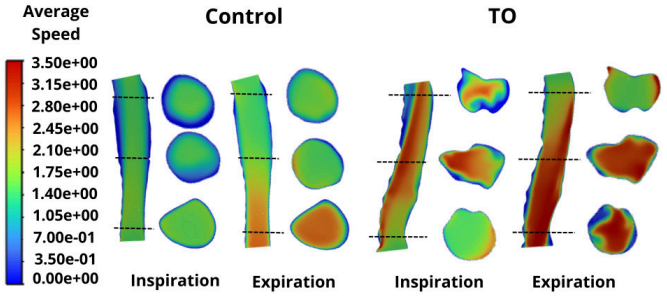

Fig. 4. Airflow velocity contours. Color scale ranging from blue (low) to red (high). Control trachea (right) and pathological trachea (right), showing higher velocities at the narrowing of the pathological trachea during expiration.

B. Total Pressure

The total pressure distribution (Fig. 5) made it possible to determine the pressure drop along the trachea and calculate the air resistance.

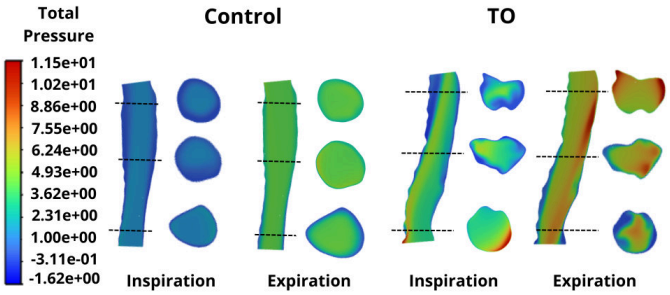

Fig. 5. Total pressure. Color scale ranging from blue (low) to red (high). Control trachea (right) and pathological trachea (right); the latter exhibits greater pressure loss during expiration and higher gradients in the asymmetric regions.

C. Air Flow, Resistance and Turbulent Kinetic Energy

Table II summarizes the airflow and airway resistance in the two tracheal models during inspiration and expiration. The pathological trachea exhibited higher resistance when flow was normalized. Furthermore, the distribution of Turbulent Kinetic Energy (TKE, Fig. 6) indicates the disruption of streamlines caused by the obstructions, generating turbulence peaks downstream of the nodules.

TABLE II
AIRFLOW AND AIR RESISTANCE VALUES FOR THE CONTROL AND PATHOLOGICAL TRACHEA MODELS

Control		
Parameter	***Inspiration***	***Expiration***
Airflow (m^3/s)	2.4×10^{-2}	2.4×10^{-2}
Resistance ($Pa{\cdot}s/m^3$)	36.9	58.6
Pathological		
Airflow (m^3/s)	2.8×10^{-2}	2.8×10^{-2}
Resistance ($Pa{\cdot}s/m^3$)	108.9	148.4

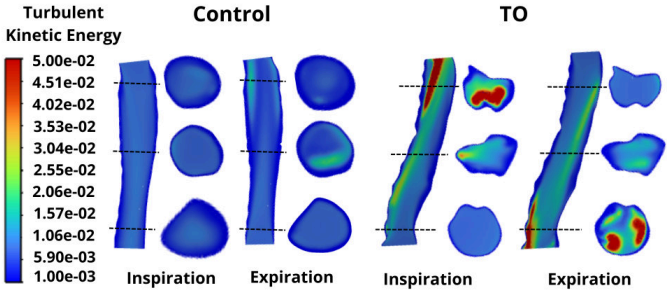

Fig. 6. Turbulent Kinetic Energy (TKE). Color scale ranging from blue (low) to red (high). Control trachea (right) and pathological trachea (right), with the latter exhibiting higher TKE levels and more unstable/turbulent flow especially during expiration.

D. Wall Shear Stress

Fig. 7 presents the WSS data, which may indirectly indicate the potential for inflammation and damage to the tracheal epithelium, especially in more severe cases of the disease.

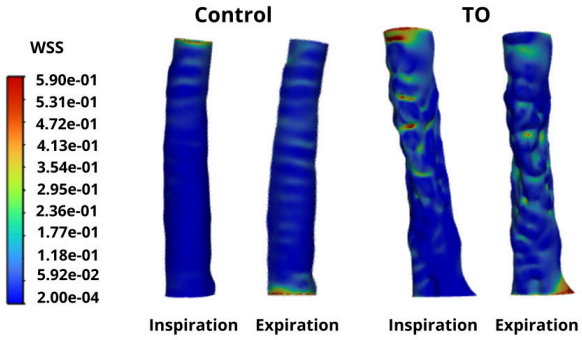

Fig. 7. Wall Shear Stress (WSS). Color scale ranging from blue (low) to red (high). Control trachea (right) and pathological trachea (right); the latter exhibits higher values and a less uniform distribution, especially during expiration.

IV. Discussion

This study aimed to compare the results of three-dimensional numerical simulations based on computed tomography scans of a patient with tracheobronchopathia osteochondroplastica (TO) and a control patient. Analysis of the results suggests possible biomechanical mechanisms by which TO-induced deformities may affect respiratory airflow. In this comparative case study, multiple bony and cartilaginous nodules projecting into the tracheal lumen were observed in the TO model. Such asymmetries and irregularities appeared to result in fluid-dynamic disturbances, contrasting with the more regular behavior of the control model.

An analysis of the data in Fig. 4 suggests that the fluid-dynamic behavior of the airflow is affected by the nodules in the patient with TO. In the control trachea, air velocity was distributed symmetrically and regularly, indicating a stable and predictable profile; velocity increased smoothly toward the center of the trachea, without deviations or abrupt decelerations. In contrast, regarding the pathological trachea, the asymmetries caused velocity peaks—indicated by the red coloring—in regions where the lumen narrows. Due to the nodules, the air is forced through various local constrictions. Given the constant volumetric flow rate, the reduction in lumen size compels the air to accelerate to satisfy the principle of mass conservation [18]. This increase in velocity near the nodule surfaces can generate an increase in viscous friction forces. From a mechanical standpoint, this rise in forces can lead to a marked increase in wall shear stress (WSS) values on the tracheal walls. This effect, particularly in cases of more severe anatomical obstruction, could contribute to the occurrence of microtrauma in local epithelial cells [19].

The data presented in Table 2 show that anatomical changes in the trachea could affect airflow resistance. Numerically, the resistance value for the pathological trachea was higher, but a larger cohort would be required for a more comprehensive analysis.

The airflow colliding with the nodules can influence the development of turbulent stresses and instabilities. The data obtained and the contours presented in Fig. 6 suggest that, while the control trachea maintained lower TKE values—indicative of stable flow—the pathological trachea exhibited localized peaks downstream of the osteochondroplastic projections. The obstructions caused by the nodules disrupt the organization of streamlines, converting kinetic energy into shear vortices and recirculation zones. It has been established [20] that regions with high TKE levels undergo significant mechanical energy dissipation due to turbulent and viscous friction. This chaotic fluid behavior helps explain the pressure drop and increased airway resistance observed in the pathological model. From a clinical perspective, regions with high TKE concentrations may represent sites of altered particle residence time, potentially influencing bioaerosol deposition patterns and local clearance mechanisms [20].

Analysis of the WSS results (presented in Fig. 7) revealed that the presence of pathological nodules can cause the airflow to exert drag forces on the tracheal wall. Under both inspiratory and expiratory conditions, the mean WSS value on the tracheal wall of the patient with TO was higher than that observed in the control subject. Previous studies [20] [21] have indicated that vortex formation and flow stagnation zones result in a heterogeneous WSS distribution. Although the results obtained do not allow for a direct diagnosis of clinical outcomes, such flow disturbances could theoretically impair continuous mucociliary clearance, creating local microenvironments that favor bacterial retention [20].

This study presented several limitations that should be considered. First, the analysis was based on a limited dataset, comprising only one computed tomography scan with pathological findings and one control subject. This limitation arose because tracheobronchopathia osteochondroplastica is a rare condition, making it difficult to obtain scans and data. Consequently, the generalizability of the results was restricted, and the condition calls for careful consideration in light of inter-individual anatomical variability. Thus, the obtained values for airway resistance and shear stress represent case-specific simulation results and cannot be used for population-level estimates. Second, the chosen mesh provided a good balance between computational cost and numerical accuracy; however, further refinement could enhance the spatial resolution of local flow structures and micro-scale fluid dynamics phenomena. Thirdly, the CFD simulations assumed steady-state flow conditions with simplified boundary parameters, thereby disregarding the transient dynamics of the respiratory cycle and temporal variations in airflow. Although the temporal analysis was limited, it was possible to map the spatial characteristics of airflow velocity contours with reduced complexity. Finally, the tracheal walls were modeled as rigid boundaries, without accounting for tissue dynamic mechanics or elastic deformation that could be addressed through fluid-structure interaction (FSI). The

anatomical complexity of the trachea, comprising connective tissue, cartilaginous rings, and a posterior muscular membrane, and the scarcity of mechanical data on these tissues in the literature (usually with anisotropic properties) make it challenging to accurately characterize their mechanical behavior and, consequently, to develop computational models capable of faithfully reproducing their structural and biomechanical response. Future work will focus on refining this methodology to overcome current limitations and achieve more robust numerical simulations. The correlation of these CFD metrics with clinical tests and data could potentially assist medical teams in making therapeutic decisions for patients with TO.

V. Conclusion

This study conducted an in silico assessment of how geometric deformities associated with tracheobronchopathia osteochondroplastica (TO) can induce local mechanical disturbances in respiratory airflow. The computational results suggest that osteochondroplastic nodules within the tracheal lumen could alter local aerodynamics; as air passes through these localized constrictions, structural asymmetries trigger an increase in viscous friction forces, manifesting as increased wall shear stress. The observed disruption in streamline patterns appeared to generate localized peaks of turbulent kinetic energy and recirculation zones, contributing to greater mechanical energy dissipation. In summary, mapping these physical parameters provides a plausible biophysical basis that may help explain the aerodynamic underpinnings of TO's clinical symptoms—such as progressive dyspnea, potential impairment of mucociliary clearance, and susceptibility to recurrent respiratory infections—thereby warranting further validation in larger clinical cohorts.

***Abstract*—Upper limb (UL) motor rehabilitation following a Stroke demands technological approaches that mitigate the physical burden on therapists and expand clinical care. This work focuses on the computational modeling and simulation of functional movements of human ULs for application in assistive robotic manipulators. The objective is to develop a robust mathematical-computational model to represent these patterns from real kinematic data captured by Inertial Measurement Units (IMUs) on the right upper limb during Activities of Daily Living (daily activities). The trials were conducted by two healthy volunteers through multiple structured collections in the tasks of waving, combing hair, and moving a cup. The data in quaternions, which avoid gimbal lock, were converted to Euler angles (XYZ sequence). The model decomposes the movement into sequences of intermediate postures, structuring three-dimensional equations that simulate the dynamic interaction of the segments and incorporate inter-individual anthropometric variability. The results demonstrated that the temporal stochasticity of human movement introduces statistical distortions. The application of Temporal Normalization by Movement Cycle (TNMC) mitigated phase artifacts; however, the subsequent temporal average attenuated high-frequency kinematic components, generating trajectories with ergonomic constraints for robotic control. This computational simulation is critical both for the predictive trajectory programming of the robotic arm and for the foundation of customized therapeutic protocols, enabling physical and parametric adjustments adaptable to each patient.**

***Index Terms*—Computational modeling, Robotic physical therapy, Upper limb kinematics, Assistive robotics, Inertial sensors.**

I. Introduction

A Stroke is clinically defined as a sudden onset neurological deficit resulting from a focal brain lesion. Classified mainly as ischemic or hemorrhagic, it can result from different pathophysiological mechanisms that frequently produce similar clinical manifestations, such as sudden and intense headache, dizziness, mental confusion, changes in speech and vision, loss of balance, and numbness of the limbs. It is estimated that approximately 15 million people are affected by stroke annually worldwide, constituting one of the main causes of death and functional disability [1]. Among the most frequent sequelae, the impairment of the upper limbs (UL) stands out, observed in about 80% of patients [2]. This manifests as reduced cutaneous sensitivity, muscle weakness, and limitation of movement in the shoulder, elbow, wrist, hand, and fingers, compromising activities of daily living such as combing hair, brushing teeth, dressing, and participating in sports activities [3]. During the motor rehabilitation of post-stroke patients, treatment is initially based on manual therapeutic techniques applied by the physical therapist, aiming to restore joint mobility and muscle activation. However, this individualized care requires continuous physical effort from the professional, which can compromise productivity and increase occupational burden. In this context, assistive robotic systems emerge as a promising alternative, as they allow for increased intensity, repeatability, and control of therapeutic sessions, while reducing the physical demand imposed on the physical therapist [4], [5]. A robotic arm for rehabilitation can be defined as a computer-controlled electromechanical device developed to assist the functional recovery of the UL [11]. Its design considers the mechanical dynamics of the system, including gravitational and inertial effects, allowing the execution of passive, assistive, active, or resistive therapeutic movements, depending on the control strategy employed [8], [10]. Specifically, this work addresses a fundamental step for the clinical application of these robotic manipulators: the mathematical-computational modeling of the functional movements of the upper limbs. This model is essential both for planning and programming biomechanically appropriate trajectories, favoring kinematic execution and the induction of new neuromotor patterns [6], [7], and for the joint development, by engineers and physical therapists, of personalized therapeutic protocols, including partial, assisted, resistive, and inductive exercises. The representation of functional movements is obtained from datasets acquired by capture systems based on Inertial Measurement Units (IMUs). The movements are represented by temporal sequences of intermediate postures of the upper limb, described by the three-dimensional positions and orientations of specific anatomical segments. The mathematical model consists of a set of parameters and dynamic equations capable of approximating real human movement, whose orientation is initially represented by quaternions, eliminating the occurrence of the phenomenon known as gimbal lock, and subsequently con-

verted to Euler angles to facilitate biomechanical interpretation and the development of control algorithms [12]. Considering that the database is composed of individuals with different anthropometric characteristics, the proposed model incorporates both inter-individual variability and the temporal stochasticity intrinsic to human movement. This characteristic makes it possible to adapt the robotic manipulator to the specific needs of each patient, both through mechanical configuration and the parametric adjustment of therapeutic trajectories according to the functional deficits resulting from the stroke. However, the statistical treatment of these signals presents important challenges due to the high temporal variability of functional tasks. Although the application of Temporal Normalization by Movement Cycle (TNMC) significantly reduces phase artifacts and dispersion between trials — with reductions of 73.0% to 83.2% in the maximum standard deviation (SD_{max}), as presented in Table I —, the resulting temporal average tends to smooth high-frequency kinematic components, producing excessively smoothed trajectories that may reduce the biomechanical fidelity of the movements and, consequently, must be considered during the development of the robotic control algorithm.Given this scenario, the general objective of this study is to develop and validate a mathematical-computational model capable of representing functional kinematic patterns of the upper limbs obtained through IMUs, quantifying the impact of the temporal normalization technique on discrete biomechanical trajectories [12] and providing inputs for the development of robust predictive control strategies applied to robotic manipulators destined for post-stroke motor rehabilitation.

II. Materials and Methods

The methodology proposed in this work comprises three fundamental stages: (i) experimental acquisition of three-dimensional kinematic data, (ii) signal processing and coordinate conversion based on quaternions and Euler angles, and (iii) the structuring of the mathematical-computational model coupled with the temporal normalization technique.

A. Kinematic Data Acquisition and Experimental Protocol

The capture of functional movements was performed using Inertial Measurement Units (IMUs) integrated into a modular data acquisition system. The final experimental setup utilized inertial sensors strategically fixed to the right upper limb of two healthy volunteers, as illustrated in Figure 1. The inclusion of distinct subjects allowed the evaluation of the mathematical-computational model under inter-individual kinematic variability and different motor strategies. The anatomical distribution of the sensors was structured as follows: The first sensor was positioned on the lateral aspect of the arm (the transition region between the lateral deltoid and triceps brachii muscles), minimizing mechanical interference during elbow flexion. The second sensor was fixed on the dorsal (posterior) aspect of the wrist, adjacent to the distal region of the forearm, over the tendons of the extensor muscles to capture segmental rotations and joint deviations. The sensors were connected

Fig. 1. Experimental setup and anatomical placement of the Inertial Measurement Units (IMUs): (A) arm sensor (lateral side); (B) wrist sensor (dorsal side); and (C) data acquisition and transmission module.

by wiring to a microcontrolled centralizer and transmitter module positioned on the test bench, responsible for power supply via a lithium polymer (LiPo) battery and synchronous data transmission via a wireless protocol. The instrumentation protocol was developed incrementally. Initially, a pilot study was conducted using a single sensor to validate the calibration routines for gyroscopes and accelerometers. After

ensuring the stability of the communication channel and the absence of packet loss, the number of devices was expanded to the segmental multi-sensor array, enabling synchronous monitoring and three-dimensional reconstruction of the kinematic chain. The definitive experimental protocol consisted of multiple structured collections during the execution of three standardized and task-oriented Activities of Daily Living (daily activities): waving, combing hair, and moving a cup. Three-dimensional orientation data were sampled at a constant frequency and transmitted for post-processing.

B. Signal Processing and Rotation Kinematics

To mitigate mathematical singularity artifacts known as gimbal lock, the raw angular orientation data extracted from the IMUs were initially processed and stored as unit quaternions q. A quaternion is defined by:

$$q = q_0 + q_1 i + q_2 j + q_3 k \tag{1}$$

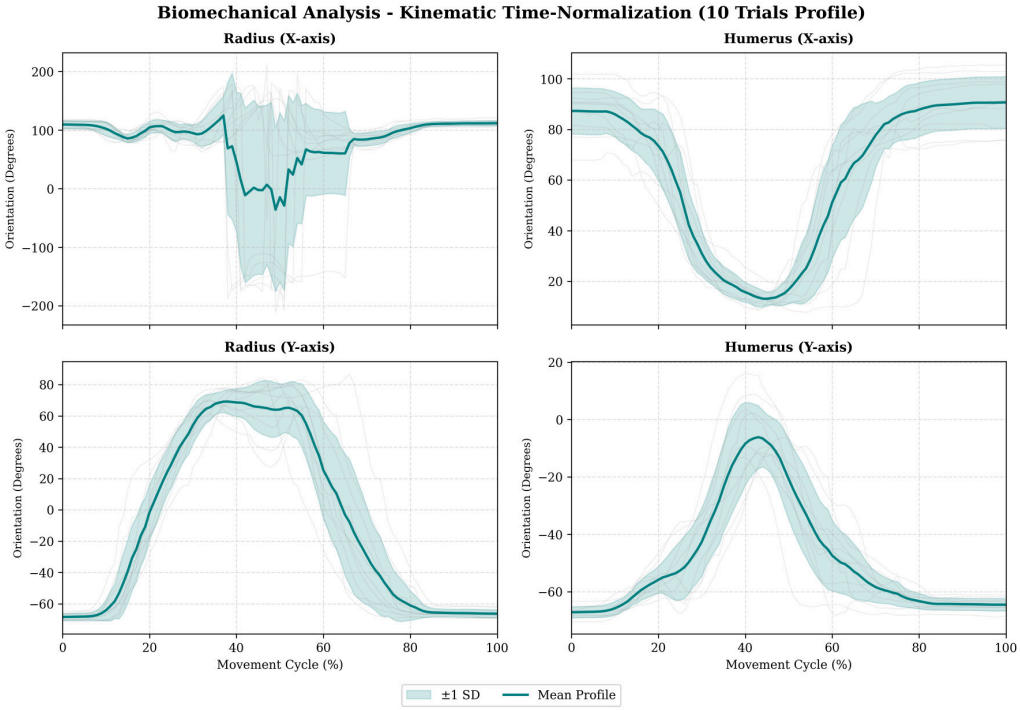
Where q_0 represents the scalar component and q_1, q_2, q_3 correspond to the three-dimensional vector in the complex space, satisfying the unit hypersphere condition $||\mathbf{q}|| = 1$. Subsequently, aiming at anatomical visualization, biomechanical interpretation, and the structuring of the control equations of the robotic manipulator, the quaternions were converted to Euler angles using the XYZ fixed rotation sequence (α, β, γ). The transformation matrix was applied to each discrete time interval to extract the joint angles corresponding to flexion/extension, abduction/adduction, and internal/external rotation of the shoulder and elbow.

C. Computational Modeling and Postural Decomposition

The three-dimensional modeling of the right upper limb was structured as an open kinematic chain containing 7 degrees of freedom (DoF), correlating the orthogonal Cartesian axes of robotics to the anatomical planes of clinical biomechanics. The shoulder joint complex was parameterized with 3 DoF acting as an ideal spherical joint [9]. This modeling allows isolated mapping of flexion/extension movements (sagittal plane, mediolateral axis), abduction/adduction (frontal plane, anteroposterior axis), and internal/external rotation (transverse plane, longitudinal axis). Additionally, the mathematical model processes shoulder circumduction, combining the kinematic restriction equations simultaneously in the three planes of movement to simulate complex and fluid spatial trajectories without geometric discontinuity [6], [7]. The elbow was modeled with 2 DoF, encompassing flexion/extension and the pronation/supination movement of the forearm (transverse plane, longitudinal axis). Finally, the wrist joint complex was structured with 2 additional DoF to ensure the ergonomic precision of the end effector, mapping flexion/extension movements (sagittal plane) and radial/ulnar deviations (frontal plane, anteroposterior axis). For the computational simulation, the continuous functional movement extracted from the IMUs was discretized and decomposed into a temporal sequence of intermediate static postures, defined by:

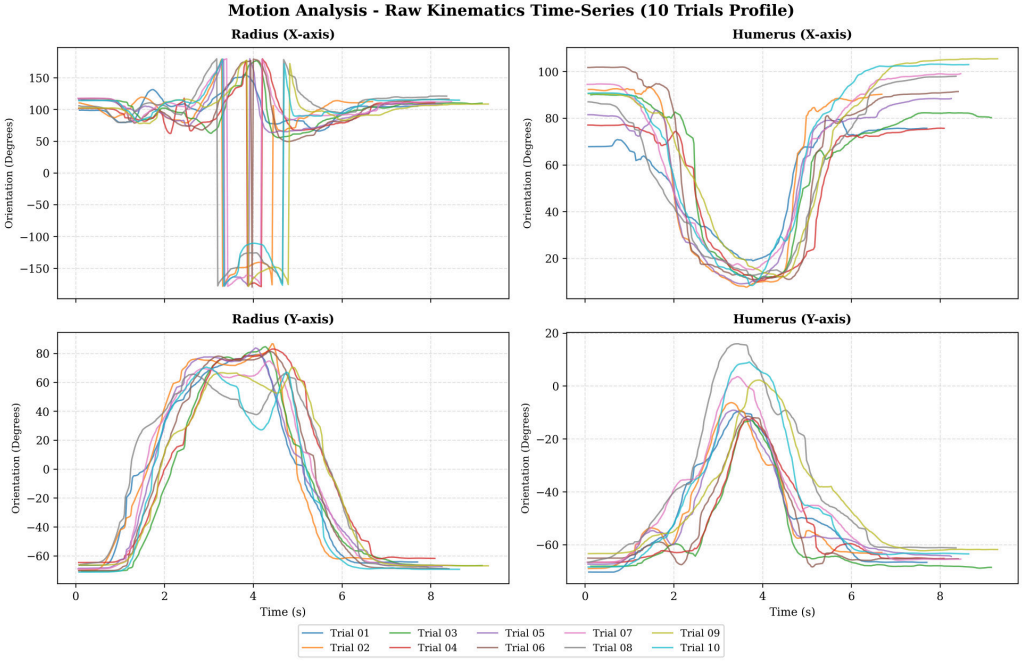
$$P(t) = \{\text{shoulder}(t), \text{elbow}(t), \text{wrist}(t)\} \tag{2}$$

Where each posture $P(t)$ represents the instantaneous angular arrangement of the anatomical segments in a discrete time interval. Inter-individual anthropometric variability was incorporated into the model through parameterized homogeneous transformation matrices. The length of the arm (L_{humerus}) and forearm (L_{radius}) segments of each volunteer was inserted as a translation vector in the forward kinematic model, allowing the exact calculation of the end effector (hand) position in the three-dimensional space. Finally, the dynamic equations that simulate the interaction of the segments were structured to map these postural sequences. This mapping allows the predictive algorithm of the robotic manipulator [8] to anticipate the spatial transitions necessary to reproduce the human motor pattern in a fluid and ergonomically safe manner.



D. Stochasticity Treatment and Temporal Normalization

Due to the temporal stochasticity inherent to human gesture, variability was observed in the execution speed and total duration between movement cycles of the same daily activities, with durations oscillating from 5 s to 8 s for the "Combing Hair" task and extending up to 14 s in the "Moving a Cup" task. This variation generates distortions in aggregate statistical analyses, such as the artificial expansion of the standard deviation in regions of greater angular inclination. To solve this misalignment and mitigate phase artifacts, the Temporal Normalization by Movement Cycle (TNMC) technique was applied [12]. The algorithm performs a mathematical interpolation (via cubic splines) of the Euler angle vectors over time, re-sampling each execution to a fixed percentage window from 0% to 100% of the movement cycle [12]. After the phase synchronization generated by the TNMC, the temporal average of the trajectories was calculated for the extraction of the representative kinematic pattern of the task, serving as a predictive basis for the control algorithm of the assistive robotic manipulator.



III. Results

The initial analysis of the raw kinematic curves in the absolute time domain (seconds) confirmed the stochastic nature and intrinsic trial-to-trial variability of human movement. As observed in the panels on the right side of Figures 2, 3, and 4 (absolute time axis), each functional task presented markedly heterogeneous total durations and velocity profiles: the "Combing Hair" task varied between 5 s and 8 s (Fig. 2); "Moving a Cup" extended up to 14 s (Fig. 3); and the "Waving" task was concentrated in the window of 6 s to 10 s (Fig. 4). This temporal desynchronization induced a critical statistical artifact in the raw curves: the standard deviation (± 1 SD) expanded artificially at the points of greatest angular inclination (derivative). This phenomenon occurs because the misalignment in time causes trials executed at different speeds to be compared at the same absolute instant. Consequently, the calculated statistical variance reflects the difference in speed between trials, masking the volunteer's true spatial (anatomical) movement variability. The application of the temporal normalization algorithm via Cubic Spline

interpolation mitigated these artifacts, homogenizing the trials into a relative scale from 0% to 100% of the Movement Cycle (101 points) [12]. Table I synthesizes the kinematic behavior, the quantitative impact of the variability attenuation, and the continuous residual validation metrics obtained after phase alignment. To rigorously verify that this variance attenuation stems purely from temporal synchronization rather than a destructive over-smoothing or loss of spatial fidelity, a point-to-point residual evaluation was performed against the ensemble mean profile (Table I). The continuous cross-correlation analysis yielded exceptionally robust coefficients, consistently exceeding r = 0.96 for the highly coordinated "Combing Hair" (r 0.986) and "Moving a Cup" (r 0.990) tasks. Even during the high-frequency oscillatory components of the "Waving" task, the minimum alignment correlation remained remarkably high (r = 0.894), mathematically demonstrating that individual spatial signatures were safely preserved. This fidelity is further supported by the controlled Root Mean Square Error (RMSE) values, which bounded strictly between 2.33° and 3.21° across all traditional functional movements, and only expanded up to 6.77° ± 0.85° in the radius X-axis during the rapid directional reversals of the waving gesture due to coordinate singularity quadrants. These numerical indicators provide definitive validation that the pipeline effectively filters out velocity fluctuations while safeguarding the true underlying kinematics. Building upon this methodological foundation, the overlay analysis between Subject 1 and Subject 2 successfully isolates and illuminates the differences in motor strategies during the multi-joint functional task. As demonstrated in the Humerus (X-axis) and Humerus (Y-axis) subplots, Subject 1 executed the movement cycle through a localized distal strategy, maintaining the humeral alignment strictly stabilized near 40° (X-axis) and -35° (Y-axis) with minor spatial dispersion. Conversely, Subject 2 exhibited a highly dynamic, coordinated multi-joint behavior, characterized by a steep humeral translation where the orientation dropped from 80° to 20° (X-axis) coupled with a smooth, bell-shaped parabolic trajectory in the Y-axis, which peaked at -12° near 43% of the movement cycle. Despite these disparate biomechanical strategies, the TNMC algorithm proved resilient in homogenizing the phase synchronization into a relative scale (0% to 100%). Crucially, specific morphological micro-structures of the biological signals were meticulously preserved rather than over-smoothed. In the Radius (Y-axis) subplot, the subtle double-peak flexion profile performed by Subject 2 (notably the inflection landmark at 20% of the cycle) remains perfectly distinct in the normalized mean curve. Furthermore, the Radius (X-axis) subplot provides a definitive mathematical validation against any premise of artificial data dampening. Around 40% to 50% of the movement cycle, Subject 2's mean profile exhibits an acute oscillation accompanied locally by a significant expansion of the standard deviation shroud (reaching ±100°). This transient artifact does not stem from algorithmic failure; rather, it reflects the mathematical wrapping (coordinate singularity) inherent to Euler angles when raw angular inputs transit rapidly through boundary quadrants. Because the TNMC aligns temporal phase without artificially modifying spatial boundary transitions, it preserves these underlying algebraic constraints of the sensor data. This fidelity guarantees that the post-processing pipeline isolates temporal velocity variations while safeguarding the genuine spatial kinematics and individual motor signatures necessary for high-fidelity physical therapy robotic control [10]. In addition to the dynamic coordinate transitions observed in the cup-transport task, the "Combing Hair" trials provided a distinct operational benchmark for the post-processing framework. As illustrated in the comparative timeline, while Subject 1 executed the classic dynamic grooming cycle characterized by pronounced joint excursions, Subject 2's dataset captured a highly stable, static baseline posture (locked near 90° for the humerus X-axis and 0° for the humerus Y-axis). This contrasting behavioral setup served as a rigorous mathematical control group within the experiment. Under these non-dynamic conditions, the TNMC algorithm proved mathematically robust, displaying zero drift or processing instabilities when mapping invariant time-series. The resulting standard deviation for Subject 2 remained virtually non-existent, confirming that the cubic spline interpolation framework operates safely without introducing artificial oscillations, high-frequency artifacts, or computational ripples when processing static or low-amplitude boundary states. Consequently, the pipeline satisfies the structural requirements for both active kinetic tracking and isometric joint monitoring in physical therapy protocols [4].

TABLE I
MEAN KINEMATIC PARAMETERS, MAXIMUM STANDARD DEVIATION (SD_{max}) ATTENUATION, AND POINT-TO-POINT ENSEMBLE METHOD VALIDATION

Motor Task	**Segment / Axis**	SD_{raw} (°)	SD_{norm} (°)	**Reduction (%)**	**Ensemble RMSE (°)**	**Ensemble Corr. (r)**
Combing Hair	Humerus / X	±22.4	±4.1	81.7%	3.21 ± 0.20	0.986
	Radius / Y	±14.8	±3.6	75.7%	2.93 ± 0.20	0.991
Moving a Cup	Humerus / X	±19.1	±3.2	83.2%	2.59 ± 0.23	0.992
	Radius / Y	±12.3	±2.9	76.4%	2.33 ± 0.20	0.990
Waving	Radius / X	±35.6	±8.7	75.5%	6.77 ± 0.85	0.894
	Humerus / Y	±11.5	±3.1	73.0%	2.55 ± 0.24	0.969

IV. CONCLUSION

The temporal normalization approach using cubic spline interpolation to exactly 101 points proved to be an indispensable methodological tool for the scientific validation of continuous kinematic data obtained by Inertial Measurement Units (IMUs) [12]. The proposed protocol successfully eliminated point-to-point statistical interpretation errors caused by the intrinsic variable speed of human movement execution trial-to-trial. The quantitative attenuation greater than 73% in the maximum standard deviation, coupled with low continuous Root Mean Square Error (RMSE) thresholds and exceptionally high cross-correlation coefficients across all evaluated motor tasks, mathematically demonstrates that the post-processing residual variability strictly reflects the spatial dispersion and consistency of the volunteer's movement without inducing artificial signal degradation. In the high-frequency task ("Waving"), the algorithm preserved the oscillatory morphology of the signal, registering a reduction of up to 75.5% in the maximum standard deviation (SD_{max}) while maintaining robust morphological fidelity as itemized in Table I, which successfully avoided the phase cancellation phenomenon in the mean curve.

Thus, the use of Temporal Normalization by Movement Cycle (TNMC) confers reproducibility, continuous mathematical validation, and scientific robustness to the use of low-cost inertial sensors. This methodological consistency is corroborated by computer animations generated from the calculated mean, which visually confirm the fluid reproduction of the human motor pattern. This alignment provides a preliminary mathematical framework that potentially supports future development in clinical screening protocols, remote monitoring, and rehabilitation engineering [11]. However, further experimental validation involving physical integration with the robotic manipulator [8] and clinical trials with stroke patients [5] is strictly required to evaluate its safety and therapeutic efficacy. Although current analyses are restricted to the initial trial-to-trial methodological validation of two healthy volunteers, immediate steps for future work include expanding the kinematic database to a larger cohort of participants to evaluate inter-individual performance. Additionally, a transition to the hospital environment is planned with the application of the model in randomized controlled clinical trials, aiming to evaluate the efficacy of the predictive control of the robotic manipulator [10] in the neuromotor rehabilitation of actual patients affected by Stroke [2], [3].

COMPLIANCE WITH ETHICAL STANDARDS

The experimental procedures described in this work were conducted in accordance with ethical guidelines for research involving human subjects. Kinematic data capture was performed non-invasively among the members of the research group themselves, who acted as healthy volunteers on a free and informed basis. The execution of the experimental protocols and the anatomical placement of the inertial measurement units (IMUs) were supervised and technically assisted by physiotherapy professionals, ensuring the physical integrity of the volunteers and the methodological accuracy of the trials.

***Abstract*—This paper investigates whether a Variational Quantum Classifier (VQC), combined with a clinically motivated preprocessing pipeline, can perform multiclass staging of Parkinson's Disease while retaining all four diagnostic cohorts: Healthy Control, Parkinson's Disease, Prodromal, and Scans Without Evidence of Dopaminergic Deficit (SWEDD), which most prior studies on the Parkinson's Progression Markers Initiative (PPMI) dataset exclude to reduce the task to binary classification. The pipeline integrates MICE imputation, Partial Least Squares (PLS) dimensionality reduction, and SMOTE class balancing to feed an 8-qubit VQC with four strongly entangling layers. All evaluations use a patient-grouped train-test split (StratifiedGroupKFold), preventing the same patient from contributing records to both partitions. In an ablation study, the full preprocessing pipeline raises the weighted AUC from 0.750 to 0.808, though individual components trade AUC against balanced accuracy. On the same 8-dimensional representation, the variational quantum classifier (VQC) reaches a weighted area under the receiver operating curve (ROC) curve (AUC) of 0.808, against 0.832 for the best baseline (multilayer perceptron (MLP)) and 0.809 for random forest (RF). On the severely underrepresented scans without evidence of dopaminergic deficit (SWEDD) cohort (85 records) it obtains 0.756, against 0.760 for RF and 0.664 for the weakest baseline (support vector machine (SVM) RBF). These results are obtained from a single fold of a patient-grouped split and a statevector simulation; they indicate competitive performance without demonstrating quantum advantage.**

***Index Terms*—Quantum Machine Learning, Variational Quantum Classifier, Parkinson's Disease, PPMI, Multiclass Classification**

I. Introduction

Of the 97 supervised learning studies on the parkinson's progression markers initiative (PPMI) dataset surveyed by [1], 55 discard two of the four diagnostic cohorts before training. Those two, Prodromal and SWEDD, are also the cohorts that that make the diagnosis hard. Prodromal patients carry premotor risk markers without overt motor signs; SWEDD patients present parkinsonian symptoms alongside normal dopaminergic neuroimaging [2]. Reducing the task to parkinson's disease (PD) versus healthy control (HC) as a result, leaves out the diagnostic boundaries that are most clinically challenging.

The PPMI dataset introduces additional challenges: cognitive assessments entered the protocol after enrollment had begun, and dropout is more frequent among severely affected patients, resulting in missingness that may not be random [2].

VQC use parameterized quantum circuits whose parameters can be optimized with classical gradient-based methods, making them compatible with current noisy intermediate-scale quantum (NISQ) devices [3], [4]. VQC models have reported competitive results on clinical benchmarks for diabetes [5], cancer [6], and imbalanced or noisy data [7] they are almost always binary, typically on curated datasets.

This paper asks whether a standard VQC, given a preprocessing pipeline designed to address these data-related challenges, can be applied to the full four-cohort classification task. We combine multiple imputation by chained equations (MICE) imputation, partial least squares (PLS) projection onto eight components, and synthetic minority over-sampling technique (SMOTE) balancing to feed an 8-qubit circuit with four strongly entangling layers. An ablation study isolates what each stage contributes; five classical baselines run on the identical representation and the identical patient-grouped test partition; and a per-class analysis evaluates performance across cohorts, including the PD-versus-SWEDD boundary. We do not claim quantum advantage, and the protocol based on a single fold, statevector simulation which limits the scope of the conclusions that can be drawn from the results.

II. Related Work

A. Machine Learning on the PPMI Dataset

The PPMI dataset has become one of the most widely adopted benchmarks for machine learning research in Parkinson's Disease. In a systematic review of 97 supervised learning studies conducted on PPMI data, Gerraty et al. [1] identified three recurring methodological limitations. The first concerns scope:

55 of the 97 studies excluded the Prodromal and SWEDD cohorts due to severe class imbalance, reducing the task to a binary PD-vs-HC problem that does not reflect the full diagnostic complexity. A second issue is leakage: 20 studies applied data transformations to the entire dataset prior to partitioning, artificially inflating reported performance. Finally, most studies relied on a single data modality, typically clinical scores combined with DAT-SPECT imaging, leaving genetic, proteomic, and multi-modal integration largely unexplored.

Brumm et al. [2] further documented the structural challenges of the PPMI cohort, including systematic dropout among the most clinically severe patients and the absence of baseline cognitive assessments for a large fraction of participants, both of which introduce missing not at random (MNAR) patterns that complicate imputation and modeling. The present work addresses these gaps by retaining all four diagnostic classes, applying MICE imputation to handle missing data, using SMOTE for class balancing, and employing a strict train-test separation to prevent preprocessing induced leakage.

B. quantum machine learning (QML) in healthcare

QML has emerged as a promising paradigm for classification tasks in healthcare [3]. Lamichhane and Rawat [6] survey recent advances and compile reported VQC accuracies of up to 90% for breast cancer detection and 85% for lung cancer classification on benchmark datasets. Across this literature, most studies employ binary classification on well-curated, balanced datasets, leaving multiclass problems on noisy clinical data largely unaddressed.

Khan et al. [5] applied an optimized VQC to the Pima Indians Diabetes Dataset, demonstrating competitive performance against classical SVM and RF baselines after feature selection and hyperparameter tuning. Sheoran et al. [7] evaluated both classical and quantum classifiers under realistic conditions including noise injection, class imbalance treated with SMOTE, and dimensionality reduction, concluding that VQC models exhibit comparable robustness to classical counterparts when appropriate preprocessing is applied. Tudisco et al. [8] proposed Multi-VQC, an architecture that chains multiple variational quantum circuits in sequence, achieving improved classification on prostate cancer, heart failure and diabetes datasets.

III. Proposed VQC Model Pipeline

A. Variational Quantum Classifier

The predictive core of the proposed pipeline is a VQC, a hybrid quantum-classical model in which classical clinical features are encoded into quantum states and processed by a trainable parameterized circuit [4]. The implementation relies on the PennyLane framework [9] interfaced with PyTorch for gradient-based optimization.

1) Data encoding: After dimensionality reduction Section III-C, each input sample is represented as a feature vector $\mathbf{x} \in \mathbb{R}^n$ with $n = 8$, scaled to the interval $[0, \pi]$ via Min-Max normalization. The encoding into quantum states is performed through Angle Embedding, which maps each component x_i to a single-qubit rotation on the i-th wire:

$$\mathcal{S}(\mathbf{x}) = \bigotimes_{i=0}^{n-1} R_Y(x_i)\,|0\rangle_i, \tag{1}$$

where $R_Y(\theta) = \exp(-i\theta\sigma_y/2)$ denotes a rotation about the Y-axis of the Bloch sphere. This encoding establishes a one-to-one correspondence between features and qubits, requiring $n = 8$ qubits for an 8-dimensional input.

2) Ansatz Architecture: The trainable component of the circuit consists of $L = 4$ layers of *Strongly Entangling Layers* [4]. Each layer ℓ applies two operations in sequence: (i) local parameterized rotations on each qubit across all three Bloch-sphere axes, and (ii) CNOT gates arranged in a cyclic ring pattern that couples qubit i to qubit $(i + \ell) \bmod n$. Each layer is thus expressed as:

$$\begin{aligned}\mathcal{W}^{(\ell)}(\boldsymbol{\theta}^{(\ell)}) = &\prod_{i=0}^{n-1} \mathrm{CNOT}_{i,(i+\ell) \bmod n} \\ &\times \prod_{i=0}^{n-1} R_Z(\theta_{i,2}^{(\ell)})\, R_Y(\theta_{i,1}^{(\ell)})\, R_X(\theta_{i,0}^{(\ell)}).\end{aligned} \tag{2}$$

where $\boldsymbol{\theta}^{(\ell)} \in \mathbb{R}^{n\times 3}$ are the trainable parameters of layer ℓ. The full ansatz is the sequential composition $\mathcal{W} = \mathcal{W}^{(4)} \circ \mathcal{W}^{(3)} \circ \mathcal{W}^{(2)} \circ \mathcal{W}^{(1)}$, producing a total of $L \times n \times 3 = 96$ learnable parameters. The cyclic shift in the CNOT connectivity entangles all qubits within a small number of layers [4].

3) Measurement and Classification Strategy: The output of each circuit is obtained by measuring the expectation value of the Pauli-Z observable on the first qubit:

$$s_c(\mathbf{x}) = \langle 0|\, \mathcal{S}^\dagger(\mathbf{x})\, \mathcal{W}_c^\dagger\, \sigma_z^{(0)}\, \mathcal{W}_c\, \mathcal{S}(\mathbf{x})\, |0\rangle + b_c, \tag{3}$$

where $s_c(\mathbf{x})$ is the score for class c and b_c is a classical bias term. A *one-vs-rest (OvR)* strategy is adopted: four independent quantum circuits, each with its own set of parameters $\boldsymbol{\theta}_c$ and bias b_c, are trained simultaneously. At inference, the predicted class is given by $\hat{y} = \arg\max_c\ s_c(\mathbf{x})$.

4) Loss Function and Optimization: The training objective is the Multiclass SVM Loss with a fixed margin $\Delta = 0.15$:

$$\mathcal{L} = \frac{1}{N} \sum_{i=1}^{N} \sum_{j \neq y_i} \max\Big(0,\ s_j(\mathbf{x}_i) - s_{y_i}(\mathbf{x}_i) + \Delta\Big), \tag{4}$$

where y_i is the true class label of sample $\mathbf{x}_i$. This formulation penalizes any competing class j whose score is within margin Δ of the correct class score, encouraging well-separated decision boundaries. The optimization is performed with the Adam optimizer using an initial learning rate $\alpha_0 = 0.02$ and an exponential step decay schedule with decay factor $\gamma = 0.5$ applied every $\tau = 100$ iterations, such that $\alpha_t = \alpha_0 \cdot \gamma^{\lfloor t/\tau \rfloor}$. Training runs for $T = 1{,}000$ iterations with batches of 32 samples. Circuit weights are initialized as $0.1 \times \mathcal{N}(0, 1)$ with a fixed random seed (`torch.manual_seed = 42`), so the reported results correspond to a single, reproducible parameter initialization rather than an average over independent runs.

All circuits are simulated on the PennyLane `default.qubit` statevector backend with analytic gradient computation.

B. Dataset: PPMI

The PPMI is a prospective, multicenter, international observational study designed to identify biomarkers of PD progression [2]. The dataset used in this work was assembled from three clinical subsets of the PPMI ecosystem: family history, non-motor aspects of experiences of daily living, and genetic components, integrated via patient identifier (`PATNO`).

The target variable (`COHORT_DEFINITION`) assigns each record to one of four diagnostic cohorts, described in Table I.

Table I:
CLINICAL COHORTS AND DESCRIPTIONS

Label	Cohort	Description
C0	Healthy Control	Neurologically healthy individuals with no history of motor symptoms.
C1	Parkinson's Disease	Clinically confirmed PD presenting resting tremor, rigidity, and bradykinesia.
C2	Prodromal	Pre-motor stage characterized by hyposmia, REM sleep behavior disorder, or genetic predisposition.
C3	SWEDD	Parkinsonian motor symptoms with normal dopaminergic neuroimaging, suggesting a distinct etiology.

The consolidated dataset comprises 7,654 records from 6,721 unique participants (`PATNO`), an average of 1.14 records per participant, distributed across the four cohorts with a pronounced class imbalance: the Prodromal cohort constitutes the majority, while SWEDD is severely underrepresented with only 85 records. Because the train-test split is grouped by participant (Section III-D), it is the participant count rather than the record count that bounds the statistical support available for each cohort. This imbalance is a structural characteristic of PPMI: 55 of 97 supervised learning studies reviewed by Gerraty et al. [1] excluded the Prodromal and SWEDD cohorts entirely because of it. In the present work, all four classes are retained to address the full clinical complexity of the diagnostic task.

The feature set consists of 45 clinical variables extracted from the movement disorder society - unified parkinson's disease rating scale (MDS-UPDRS) scale, organized into three groups: Part 1 non-motor symptoms, 15 variables, Part 2 motor experiences of daily living, 14 variables, and Part 4 motor complications, 15 variables, supplemented by two familial genetic history indicators (`FULSIBPD`, `PAGPARPD`). This selection followed a domain-informed criterion: only variables obtainable from a clinical anamnesis, in principle via natural language processing, were retained, excluding synthetic latent variables and imaging-derived biomarkers. Three structural challenges of this dataset directly influenced the preprocessing strategy adopted in this work:

1) *Missing data under MNAR mechanism.* The majority of patients lacked cognitive assessments at baseline, as this instrument was incorporated into the PPMI protocol after enrollment began [2]. Also, patients with greater clinical severity exhibited higher dropout rates, producing systematic data absence in precisely the most critical profiles. This MNAR pattern implies that the absence itself carries clinical information, and naive imputation methods may introduce severe bias.
2) *Phenotypic overlap between PD and SWEDD.* Differentiating PD from SWEDD without dopaminergic neuroimaging (DaTscan) is challenging even for movement disorder specialists [1]. Both cohorts share overlapping motor symptom profiles, making this the hardest classification boundary in the dataset.
3) *Risk of data leakage.* The longitudinal structure of PPMI means that a patient may contribute more than one record across visits. If records are not grouped by patient when partitioning the data, information can leak between training and test sets, a methodological flaw identified in 20 of 97 supervised studies on PPMI [1]. Although repeated records are a minority in the present dataset (1.14 records per participant on average), the risk applies to any patient contributing more than once, and we address it directly by grouping the train-test split by `PATNO`, described next in Section III-D.

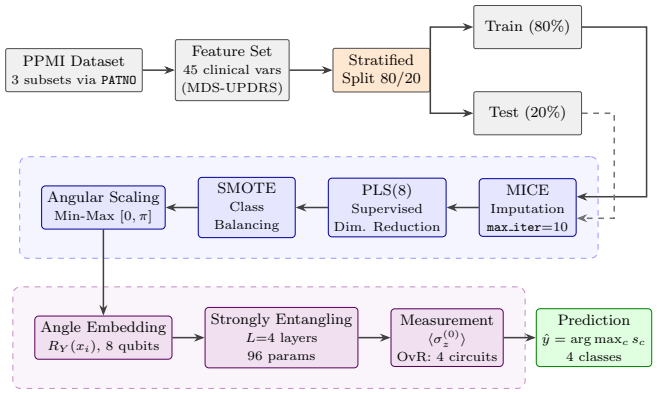

Fig. 1. Block diagram of the proposed preprocessing pipeline.

C. Preprocessing Pipeline

The preprocessing pipeline was designed to address each of the challenges described above through a four stage sequential transformation, illustrated in Fig. 1. All transformations are fitted exclusively on the training partition and applied to the test set, which prevents preprocessing induced leakage.

1) Multivariate Imputation MICE: Missing values are handled through MICE [10], an iterative algorithm that models each incomplete variable as a function of all remaining variables via a sequence of conditional regressions. At each iteration, MICE cycles through the incomplete columns, imputing values by drawing from the predictive distribution conditioned on the current state of all other variables, and repeats this process for a fixed number of rounds (`max_iter` = 10). This approach preserves the multivariate correlation structure of the clinical data, which is critical when symptom variables from the MDS-UPDRS exhibit strong interdependencies. Prior to imputation, sentinel values (-1) used as implicit absence codes in the PPMI are converted to `NaN`.

2) Supervised Dimensionality Reduction PLS: After imputation, the 45-dimensional feature space must be reduced to 8 components to match the number of available qubits. PLS regression [11] is employed as a supervised alternative to principal component analysis (PCA). While PCA identifies directions of maximum variance irrespective of the target labels, PLS finds latent components that maximize the covariance between the feature matrix $\mathbf{X}$ and the class labels $\mathbf{Y}$ [12]. Because the retained components are oriented toward class separation rather than overall variance, PLS is, in principle, better aligned with a classification objective than PCA. PLS projects the input onto 8 latent components ($n_{\text{components}} = 8$), matching the qubit count of the quantum circuit. The empirical validation of this choice over PCA is provided in the ablation study (Section IV-A).

3) Class Balancing SMOTE: The severe class imbalance is addressed through the SMOTE [13], applied exclusively on the training set to prevent synthetic samples from leaking into the evaluation partition. SMOTE generates new instances for underrepresented classes by interpolating between existing samples and their nearest neighbors in the feature space. A custom sampling strategy is adopted, in which all minority classes are oversampled to at least 50% of the majority class size. The number of neighbors k is set adaptively as $k = \max(1, \min(5, n_{\min} - 1))$, where $n_{\min}$ is the smallest class count, ensuring that SMOTE remains applicable even for extremely small classes such as SWEDD.

4) Angular Scaling: Finally, the PLS transformed and SMOTE balanced features are rescaled to the interval $[0, \pi]$ using Min-Max normalization, mapping each component to the angular domain required by the Angle Embedding stage of the quantum circuit (Section III-A).

D. Evaluation Protocol

The dataset is split into training and testing partitions (approximately 80%/20%) using `StratifiedGroupKFold` ($n_{\text{splits}} = 5$, `shuffle=True`, `random_state= 42`), grouped by patient identifier (`PATNO`). This guarantees two properties simultaneously: no patient contributes records to both partitions, verified by an explicit zero-overlap check on every run, and the class proportions of the four cohorts are preserved despite the severe underrepresentation of the SWEDD cohort. We adopt the first of the five folds throughout this work. All preprocessing transformations, MICE imputation, PLS projection, SMOTE oversampling, and angular scaling, are fitted exclusively on the training partition and applied to the test set, preventing preprocessing-induced leakage. We note one constraint of this protocol that bounds the strength of our conclusions: all results derive from a single fold rather than from the full 5-fold cross-validation, which is discussed in Section V.

1) Performance Metrics: The metrics used to evaluate the models are AUC, F1-Score, Accuracy, and Balanced Accuracy. We denote C as the number of classes, N the total number of test samples, N_c the number of samples belonging to class c, and TP_c, FP_c, FN_c the true positives, false positives, and false negatives for class c, respectively.

Balanced Accuracy: [14] the unweighted mean of the per-class recalls,

$$\text{BAcc} = \frac{1}{C} \sum_{c=0}^{C-1} R_c \,. \tag{5}$$

By giving every cohort equal weight regardless of its support, it exposes the majority-class bias that raw accuracy conceals: a classifier that ignores the minority cohorts entirely can retain high accuracy while its balanced accuracy collapses toward $1/C$. The two metrics therefore diverge sharply under severe imbalance, as the ablation study demonstrates in Section IV-A.

Accuracy: the proportion of correctly classified samples. While intuitive, this metric can be misleading under class imbalance, as a model predicting only the majority class may achieve high accuracy without learning meaningful patterns.

Weighted F1-Score: [15] aggregates the per-class harmonic mean of precision (P_c) and recall (R_c), weighted by class support:

$$F_{1,c} = \frac{2\,P_c\,R_c}{P_c + R_c}\,, \quad P_c = \frac{\text{TP}_c}{\text{TP}_c + \text{FP}_c}\,, \quad R_c = \frac{\text{TP}_c}{\text{TP}_c + \text{FN}_c}\,, \tag{6}$$

Now, the weighted metric is obtained as:

$$F_1^w = \sum_{c=0}^{C-1} \frac{N_c}{N} F_{1,c} \,. \tag{7}$$

Weighted AUC: [16] is computed under the ROC curve in a OvR fashion. For each class c, the ROC curve plots the true positive rate against the false positive rate across all classification thresholds τ, and the AUC corresponds to the integral [17]:

$$\text{AUC}_c = \int_0^1 \text{TPR}_c\left(\text{FPR}_c^{-1}(t)\right)\, dt \,. \tag{8}$$

The weighted average is then obtained as [16]:

$$\text{AUC}^w = \sum_{c=0}^{C-1} \frac{N_c}{N} \text{AUC}_c \,. \tag{9}$$

The AUC quantifies the probability that the classifier ranks a randomly chosen positive instance above a randomly chosen negative one [16]. Unlike threshold-dependent metrics, AUC evaluates the entire spectrum of decision boundaries and is invariant to class distribution, which makes it well suited to imbalanced clinical datasets [17]. The AUC is adopted as the **primary metric** throughout this work. This choice is motivated by two factors: (i) the severe class imbalance renders accuracy unreliable: as demonstrated in the ablation study, a model can achieve 67.9% accuracy while attaining only 35.5% balanced accuracy by effectively ignoring minority classes; and (ii) in a clinical decision support context, the ability to discriminate between diagnostic categories across all operating points is more informative than performance at a single fixed threshold.

2) Ablation Study Design: To quantify the contribution of each preprocessing component, an ablation study [18] is conducted with four experimental configurations sharing the same VQC architecture and hyperparameters (8 qubits, 4 layers, $\Delta = 0.15$, $T = 1{,}000$ iterations). The configurations are summarized in Table II.

Table II:
ABLATION STUDY — EXPERIMENTAL CONFIGURATIONS

Exp.	MICE	Balancing	Dim. Reduction
EXP1	✓	—	—
EXP2	✓	SMOTE	—
EXP3	✓	SMOTE	PCA(8)
EXP4	✓	SMOTE	PLS(8)

MICE imputation is present in all experiments as a baseline requirement, since the raw PPMI data cannot be fed directly into any classifier without handling missing values. Each successive experiment adds one component, isolating its marginal contribution to the overall performance.

3) Baseline Comparison: To contextualize the VQC performance against established classical methods, five baseline classifiers are evaluated under identical preprocessing conditions (EXP4 pipeline: MICE + PLS(8) + SMOTE): logistic regression (LR), SVM with radial basis function kernel, RF with 500 estimators, gradient boosting (GB), and a two-layer MLP (256-128 hidden units). All classical models use default scikit-learn hyperparameters except where noted. This keeps the comparison focused on the learning paradigm rather than on extensive tuning, with the caveat, revisited in Section V, that tuning could shift the gap in either direction.

IV. RESULTS

A. Ablation Study

Table III summarizes the performance of the VQC across the four experimental configurations defined in Section III-D2. Each row adds one preprocessing component while keeping the circuit architecture and all hyperparameters fixed, isolating the marginal contribution of each stage.

Table III:
ABLATION STUDY — IMPACT OF EACH PIPELINE COMPONENT ON VQC PERFORMANCE

Exp.	Acc.	Bal. Acc.	F_1^w	AUC^w
EXP1	**0.679**	0.355	0.641	0.750
EXP2	0.612	0.389	0.606	0.734
EXP3	0.621	**0.506**	0.668	0.807
EXP4	0.621	0.497	**0.675**	**0.808**

EXP1 (Baseline) Without class balancing or dimensionality reduction, the VQC achieves the highest raw accuracy (0.679) but the lowest AUC (0.750) and a critically low balanced accuracy (0.355). This discrepancy reveals that the model learns to predict predominantly the majority class, effectively ignoring the underrepresented SWEDD and Prodromal cohorts. This result exemplifies why accuracy alone is an unreliable metric for imbalanced clinical datasets [14].

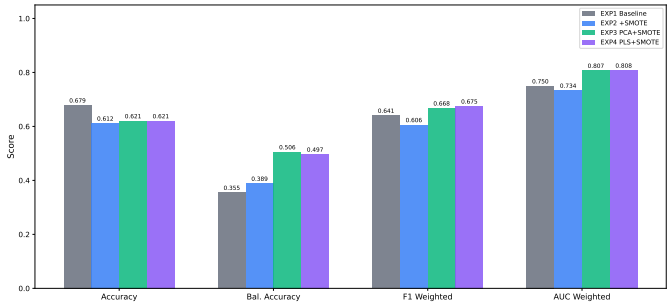

Fig. 2. Ablation study across the four pipeline configurations. Adding SMOTE (EXP2) improves balanced accuracy at the cost of AUC, while supervised PLS reduction (EXP4) recovers the highest AUC and F_1, motivating its adoption as the final pipeline.

EXP2 (+SMOTE) Adding SMOTE raises balanced accuracy from 0.355 to 0.389 (a relative increase of 9.6%), at the cost of the aggregate AUC, which drops from 0.750 to 0.734. This is expected: forcing the classifier to allocate representational capacity to the severely underrepresented cohorts trades a fraction of ranking quality on the majority classes for sensitivity to the minority ones [13]. The simultaneous decrease in raw accuracy (from 0.679 to 0.612) reflects the same trade-off: the model gives up majority-class bias for more equitable sensitivity across classes.

EXP3 (PCA+SMOTE) Introducing PCA based dimensionality reduction yields the largest AUC improvement, from 0.734 to 0.807, and the largest balanced-accuracy gain, from 0.389 to 0.506, the highest balanced accuracy among the four configurations. By projecting the 45-dimensional feature space onto 8 principal components that capture the directions of maximum variance, PCA removes redundant and noisy dimensions that previously hindered the quantum circuit's capacity to find separating boundaries.

EXP4 (PLS+SMOTE) Replacing PCA with supervised PLS projection achieves the highest AUC (0.808 vs. EXP3's 0.807) and the highest weighted F_1 (0.675 vs. 0.668), with a balanced accuracy (0.497) marginally below EXP3's (0.506). PLS and PCA therefore yield essentially equivalent aggregate performance, with EXP4 holding a small edge on the primary metric (AUC) itself. Unlike PCA, PLS aligns the retained components with the class labels rather than with overall variance [11], [12], and the resulting model is directly interpretable in terms of clinical variable loadings, enabling domain experts to inspect which MDS-UPDRS items contribute most to each latent component. Given its lead on AUC and this interpretability advantage, EXP4 is adopted as the final pipeline configuration; we revisit this trade-off explicitly in Section VI.

The per-class ROC curves for PD, Fig. 3 follow the same non-monotonic trajectory as the aggregate metrics. SMOTE alone costs 0.012 of AUC_{PD} (0.797 → 0.785); projecting onto eight components recovers that loss several times over, reaching 0.878 with PCA and 0.857 with PLS. On the class of greatest clinical interest, then, the trade-off identified in Table III plays out identically.

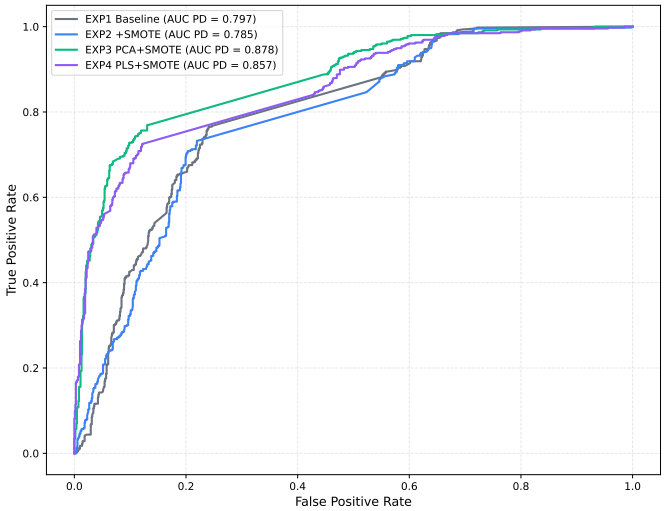

Fig. 3. ROC curves for the PD class across the four ablation experiments. Dimensionality reduction (EXP2-EXP4) raises AUC_{PD} from 0.785 to 0.857, the largest single contribution to PD discrimination.

B. Comparison with Classical Baselines

Five classical classifiers run on the EXP4 pipeline (MICE + PLS(8) + SMOTE) and the same patient-grouped test partition. Table IV presents the results. The VQC row reuses the model trained for EXP4 in the ablation study (Section IV-A) rather than an independent run: the group split (`random_state=42`) and the circuit weight initialization (`torch.manual_seed=42`, Section III-A) are both fixed, so this row and the EXP4 row of Table III report the identical trained circuit evaluated on the identical test partition.

Table IV:
PERFORMANCE COMPARISON — CLASSICAL BASELINES VS. VQC

Model	Acc.	Bal. Acc.	F_1^w	AUC^w
LR	0.549	0.508	0.624	0.819
SVM RBF	0.649	0.514	0.687	0.820
RF	**0.713**	0.455	**0.719**	0.809
GB	0.662	0.499	0.695	0.819
MLP	0.661	**0.521**	0.690	**0.832**
VQC	0.621	0.497	0.675	0.808

No single classical model leads across all four metrics: RF attains the highest accuracy (0.713) and weighted F_1 (0.719) but the lowest balanced accuracy (0.455), while MLP attains the highest AUC (0.832) and balanced accuracy (0.521). The VQC attains an AUC of 0.808, which is 0.024 below MLP and 0.001 below RF. The aggregate ranking hides class-level differences, which are examined in Section IV-C

All six models operate on the same 8-dimensional PLS representation, since the feature space is constrained to match the qubit count of the quantum circuit. Classical models such as RF and GB could in principle exploit higher-dimensional representations, whereas the VQC is restricted to 8 features by the available qubits. Under this constraint all six models fall within a 0.808–0.832 band.

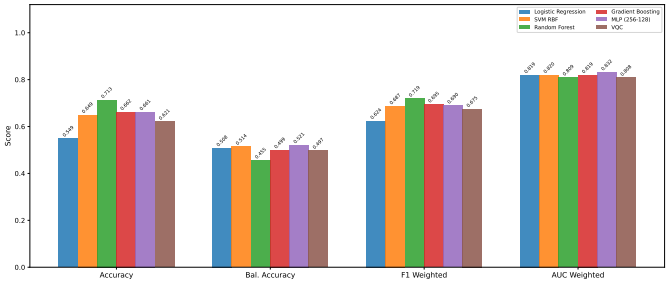

Fig. 4. Aggregate metrics for the five classical baselines and the VQC (MICE + PLS(8) + SMOTE). MLP leads on AUC (0.832); the VQC reaches 0.808 under the 8-feature constraint imposed by the qubit count.

C. Per-Class ROC Analysis

While aggregate metrics provide an overall summary of classifier performance, the clinical relevance of a diagnostic model depends on its ability to discriminate each individual cohort. Table V reports the per-class AUC for all six models, computed in a OvR fashion. Three findings emerge from the per-class analysis.

Table V:
PER-CLASS AUC — CLASSICAL BASELINES VS. VQC

Model	HC	PD	Prodromal	SWEDD
LR	0.775	0.867	0.804	0.757
SVM RBF	0.786	0.881	0.798	0.664
RF	0.709	0.890	0.785	**0.760**
GB	0.766	0.883	0.797	0.752
MLP	**0.799**	**0.893**	**0.809**	0.683
VQC	0.767	0.857	0.791	0.756

PD class. Every model clears 0.85 here. The VQC reaches 0.857; MLP leads at 0.893, with LR (0.867) and SVM RBF (0.881) in between. On the primary diagnostic target, then, the circuit picks up the dominant motor-symptom patterns in the MDS-UPDRS.

SWEDD class. This cohort spreads the models farthest apart. SVM RBF falls to 0.664 and MLP to 0.683, while LR, GB, RF and the VQC cluster between 0.752 and 0.760. This four-way tie is difficult to distinguish with the current test partition, since SWEDD contributes only 85 records in the full dataset and roughly a fifth of those to the test split.

HC and Prodromal classes. For HC, all models perform within a band between 0.709 and 0.799, with the VQC (0.767) in the middle of the range; RF is, somewhat unexpectedly, the weakest model on this comparatively easy class (0.709), while MLP leads (0.799). For Prodromal, the VQC reaches 0.791, 0.018 below MLP (0.809) and above RF (0.785). The Prodromal cohort occupies an intermediate position in the symptom spectrum, more severe than HC but less pronounced than PD, which may explain why no single model dominates this boundary.

The aggregate gap in Table IV is therefore not a uniform deficit: the circuit stands closest to the baselines on PD detection and SWEDD differentiation, which are clinically important

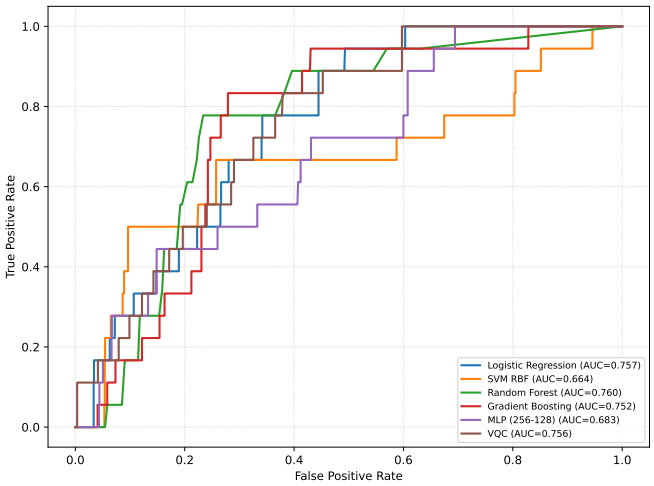

Fig. 5. ROC curves for the SWEDD class. The VQC (AUC = 0.756) ranks above the SVM RBF (0.664) and MLP (0.683), and 0.004 below the best model (RF, 0.760); given the small cohort (85 records), these estimates carry wide uncertainty.

distinctions. Determining the reasons for this behavior would require controlled ablations of the circuit itself.

V. Discussion

The results in Section IV indicate that a VQC, combined with the proposed preprocessing pipeline, can achieve competitive performance on a multiclass PD staging task.

A. The Role of Preprocessing

The ablation study shows that the preprocessing pipeline is a determining factor in the VQC's performance, not an auxiliary step. Without class balancing and dimensionality reduction (EXP1), the circuit reaches 67.9% accuracy yet only 35.5% balanced accuracy, effectively ignoring minority classes. This is not specific to the quantum model: it is the expected consequence of training on severely skewed class distributions, a well-documented phenomenon in classical machine learning [13] that applies equally to quantum classifiers.

The progression from EXP1 to EXP4 demonstrates that each component addresses a specific pathology of the data: SMOTE restores sensitivity to underrepresented cohorts, at a short-term cost to aggregate AUC, and PLS compresses the feature space into a supervised low-dimensional representation compatible with the circuit's qubit budget, recovering and exceeding that cost. The combined effect is an AUC improvement from 0.750 to 0.808 that no single technique accounts for in isolation, and that is not monotonic stage by stage, which is why we report the contribution of each stage separately rather than only the final pipeline.

B. Clinical Interpretation of Model Errors

The confusion patterns in the per-class analysis track the underlying clinical reality. The PD-vs-SWEDD misclassification is the dominant source of error across all models, including the VQC. This is clinically expected, as SWEDD patients present parkinsonian motor symptoms that are phenotypically indistinguishable from early PD without dopaminergic neuroimaging (DaTscan) [2]. Consistently with this, SWEDD shows the widest performance spread of all four classes: the best model on this boundary (RF) reaches a per-class AUC of 0.760, against 0.890 for PD within the same model, and two of the six classifiers (SVM RBF and MLP) fall below 0.75. No model, classical or quantum, separates SWEDD as cleanly as it separates the other cohorts, which points to an intrinsic difficulty of the boundary rather than to a model-specific weakness. The VQC (0.756) falls within the leading group on this boundary, 0.004 behind RF and well ahead of SVM RBF and MLP. Still, the small sample size does not firmly establish this ordering. The mechanism behind this behavior is not established by our experiments; clarifying whether it stems from the quantum representation or from other factors would require controlled ablations of the circuit itself, which we leave to future work.

C. Limitations

Several limitations of this work should be acknowledged.

First, all quantum circuit simulations are executed on the PennyLane `default.qubit` statevector backend, which performs an exact classical simulation of the circuit and does not capture the decoherence and gate errors of real NISQ hardware. The behavior of the VQC under hardware noise therefore remains an open question.

Second, because PPMI is longitudinal, records from the same patient could in principle appear in both partitions and introduce patient-level leakage. We remove this risk by grouping the train-test split by `PATNO` with `StratifiedGroupKFold`, verified by an explicit zero-overlap check on every run (Section III-D). What remains is a narrower limitation: all results derive from a single fold of the five, with a fixed seed, rather than from the full cross-validation. Reporting the mean and variance across all five folds would tighten these estimates and is left for future work.

Third, the VQC architecture is constrained to 8 qubits with 4 layers, totaling 96 trainable parameters per circuit. This configuration was dictated by the current practical limits of statevector simulation. More expressive ansatz designs, deeper circuits, alternative entanglement topologies, or data re-uploading strategies, may improve performance but at increased simulation cost and potential susceptibility to barren plateaus [3].

Fourth, the classical baselines were evaluated with default hyperparameters to ensure a fair comparison focused on learning paradigms rather than model tuning. It is possible that systematic hyperparameter optimization of the classical models would widen the performance gap. On the other hand, the VQC hyperparameters (margin Δ, learning rate schedule, number of layers) were also not exhaustively tuned, leaving room for improvement on both sides.

D. Practical Implications

Despite the limitations above, the results offer preliminary evidence that, under the right preprocessing, VQC models can be competitive on this kind of clinical classification task, particularly when: (i) the feature space can be reduced to a

dimensionality compatible with available qubit counts; (ii) class imbalance is addressed through resampling prior to quantum encoding; and (iii) evaluation prioritizes AUC over accuracy, reflecting the threshold-free nature of clinical decision-making.

The VQC's comparatively high per-class AUC on SWEDD, the most underrepresented and phenotypically ambiguous cohort, is a result worth examining further rather than a settled finding, given the cohort size. Whether quantum classifiers occupy a genuine niche where sample scarcity and class overlap coexist is an open question. As quantum hardware matures beyond the NISQ era, the simulation overhead associated with these models is expected to fall, which would make experiments such as ours easier to scale and validate.

VI. Conclusion

This paper presented a hybrid quantum-classical pipeline for multiclass PD staging using clinical data from the PPMI dataset. The proposed approach combines MICE imputation, PLS dimensionality reduction and SMOTE class balancing to enable a VQC with 8 qubits and 4 layers of strongly entangling layers to operate on a diagnostic task that the majority of prior studies have simplified by excluding minority cohorts.

The ablation study showed that each preprocessing stage contributes measurably to performance, with the weighted AUC rising from 0.750 to 0.808 across the full pipeline; the gain is not monotonic stage by stage, since SMOTE alone trades aggregate AUC for balanced accuracy, and it is the combination with PLS that recovers and exceeds it. On the same representation, the VQC trailed MLP by 0.024 of AUC and RF by 0.001, while achieving its closest performance to the baselines on SWEDD, the smallest and most phenotypically ambiguous of the four cohorts, where it ranked third of six models and 0.004 below the best classical result.

The choice of PLS over PCA as the final pipeline (EXP4 over EXP3, Section IV-A) deserves an explicit remark, since AUC is adopted as the primary metric throughout this work (Section III-D). With the patient-grouped split, EXP4 in fact attains a marginally higher AUC than EXP3 (0.808 vs. 0.807) and a higher weighted F_1, at the cost of a small reduction in balanced accuracy (0.497 vs. 0.506). The selection is therefore consistent with the stated primary metric on this fold; we retain the interpretability of PLS's clinically loaded components as an additional, secondary justification, and note that this ranking could shift under the full cross-validation discussed below.

These results do not claim quantum advantage. They provide empirical evidence that variational quantum classifiers, even under classical simulation and limited qubit counts, can reach performance competitive with classical baselines on a challenging real-world diagnostic task, subject to the validation limitations discussed above.

Future work will pursue three directions. First, evaluating the pipeline on actual NISQ hardware to quantify the impact of gate noise and decoherence on classification performance. Second, reporting metrics averaged over all five folds of the patient-grouped `StratifiedGroupKFold` split, rather than the single fold used here, to quantify variance across patient partitions and strengthen the statistical robustness of the reported metrics. Third, exploring more expressive quantum architectures, including data re-uploading strategies and sequential circuit compositions such as the Multi-VQC approach proposed by Tudisco et al. [8], to assess whether deeper quantum models can further close the gap with classical baselines on the PPMI dataset.

Abstract — Stereotactic radiosurgery (SRS) using Volumetric Modulated Arc Therapy (VMAT) requires high geometric accuracy, making Patient-Specific Quality Assurance (PSQA) essential for verifying the accuracy of dose delivery. This study evaluated the performance of the 5%/1 mm Gamma criterion compared with the 2%/2 mm criterion for PSQA of intracranial SRS treatment plans using VMAT. A retrospective analysis was performed on 240 clinical treatment plans generated using the Monaco® treatment planning system and delivered on an Elekta Infinity linear accelerator. The Gamma Passing Rate (GPR) was analyzed in relation to treatment plan parameters, including lesion volume, number of lesions, fractionation, and monitor units. The 5%/1 mm criterion showed lower dispersion of GPR values and greater stability across variations in lesion volume, whereas the 2%/2 mm criterion showed a stronger association between increasing irradiated volume and the occurrence of plan failure. The number of lesions was also associated with the behavior of the 5%/1 mm criterion, suggesting a potential influence of treatment plan complexity on the results. The findings demonstrate distinct behaviors between the two criteria and indicate that the 5%/1 mm criterion is a promising alternative for further investigation in the PSQA of SRS treatments using VMAT. However, studies incorporating known geometric and dosimetric errors are required to determine its error-detection capability and to establish a criterion-specific GPR acceptance threshold..

Keywords — *Stereotactic radiosurgery; Volumetric Modulated Arc Therapy (VMAT); Patient-specific quality assurance; Gamma analysis; Quality assurance.*

I. Introduction

Modern radiotherapy has evolved significantly over recent decades with the incorporation of advanced beam intensity modulation techniques, enabling greater conformity of dose distributions to the target volume while improving the sparing of healthy tissues. Among these techniques, *Volumetric Modulated Arc Therapy* (VMAT) has become an important modality for the treatment of various neoplasms, particularly in stereotactic radiosurgery (*Stereotactic Radiosurgery* – SRS), due to its ability to combine high dosimetric conformity, efficient dose delivery, and reduced treatment time [1], [2].

In SRS, high radiation doses are delivered in a single or a few fractions to small target volumes, producing steep dose gradients between the target and adjacent organs at risk. Although this characteristic enables highly conformal dose distributions, it also makes treatment particularly sensitive to geometric and dosimetric uncertainties. Therefore, quality assurance plays an essential role in ensuring that the planned dose distribution is accurately reproduced during clinical delivery [3].

Patient-specific quality assurance (*Patient-Specific Quality Assurance* – PSQA) is an important component of this process. Its purpose is to verify the agreement between the dose distribution calculated by the treatment planning system and that measured during plan verification. Among the available methods, Gamma analysis, proposed by Low *et al.*, remains widely used for comparing dose distributions by combining dose difference (*Dose Difference* – DD) and distance-to-agreement (*Distance-to-Agreement* – DTA) criteria into a single quantitative index [4].

Historically, different combinations of DD and DTA have been used for PSQA of IMRT and VMAT treatments. However, studies have demonstrated that high Gamma passing rates do not necessarily correlate strongly with the absence of clinically relevant dosimetric discrepancies [5], [6]. This limitation is particularly important in stereotactic treatments, which are characterized by small fields and steep dose gradients, where spatial accuracy is a fundamental component of the treatment process [3].

In this context, recommendations from the *American Association of Physicists in Medicine* (AAPM) and the *Radiosurgery Society* (RSS) emphasize the stringent geometric accuracy requirements associated with stereotactic procedures [3], [7]. Therefore, the use of Gamma criteria with more restrictive spatial tolerances may be relevant for the evaluation of these treatments. Among the possible combinations, the 5%/1 mm criterion combines a wider dose-difference tolerance with a 1-mm distance-to-agreement criterion, representing an approach distinct from the 2%/2 mm criterion. However, adopting a more restrictive spatial tolerance does not, by itself, imply a greater ability to detect geometric errors; such capability must be demonstrated through specific studies using known perturbations.

Despite the use of different Gamma criteria in quality assurance programs, clinical evidence regarding the behavior of the 5%/1 mm criterion when applied to PSQA of intracranial SRS treatment plans delivered with VMAT remains limited. Evaluating its behavior across different treatment plan characteristics, such as lesion volume, number of lesions, fractionation, and monitor units, may contribute to a better understanding of its applicability and to the improvement of quality assurance protocols for stereotactic treatments.

Given this context, the present study aimed to evaluate the performance of the 5%/1 mm Gamma criterion compared with the 2%/2 mm criterion in patient-specific quality assurance of intracranial stereotactic radiosurgery treatment plans using VMAT, by analyzing Gamma passing rate behavior and its association with treatment plan characteristics, including lesion volume, number of lesions, fractionation, and monitor units.

II. Material and Methodos

A. Study Design

A retrospective, observational, and quantitative

study was conducted to evaluate the performance of the 5%/1 mm Gamma criterion in patient-specific quality assurance (*Patient-Specific Quality Assurance* – PSQA) of intracranial stereotactic radiosurgery (SRS) treatment plans using *Volumetric Modulated Arc Therapy* (VMAT), compared with the institutional 2%/2 mm criterion. The study was conducted at the Radiotherapy Department of Hospital Araújo Jorge (HAJ–ACCG), Goiânia, GO, Brazil, following approval by the Research Ethics Committee of Hospital Araújo Jorge – ACCG (Approval No. 7,986,757), with a waiver of informed consent.

B. *Sample*

A retrospective analysis was performed on 240 consecutive clinical treatment plans from patients who underwent intracranial stereotactic radiosurgery (SRS) using the VMAT technique. Treatment plans that were clinically used and subjected to the institutional patient-specific quality assurance (PSQA) protocol were included. Cases with incomplete, inconsistent, or missing information for the variables required for the analysis, as well as those for which the PSQA result could not be unequivocally identified, were excluded.

All treatment plans were generated using the Monaco® treatment planning system, version 6.1.3 (Elekta AB, Stockholm, Sweden), with a Monte Carlo dose calculation algorithm, and delivered using an Elekta Infinity linear accelerator with 6 MV flattening filter-free (FFF) photon beams, equipped with a 160-leaf Agility multileaf collimator (MLC).

C. *Patient-Specific Quality Assurance (PSQA)*

Patient-specific quality assurance (PSQA) was performed using the SRS MapCHECK® system (Sun Nuclear Corporation, Melbourne, FL, USA) coupled with the StereoPHAN® phantom, designed for dosimetric verification of stereotactic treatments.

Initially, a computed tomography (CT) scan of the SRS MapCHECK®–StereoPHAN® assembly was acquired and subsequently imported into the Monaco® treatment planning system, version 6.1.3. The clinical treatment plans were transferred and recalculated on the phantom geometry while preserving the irradiation parameters of the original plans. After recalculation, the verification plans were delivered using the Elekta Infinity linear accelerator, and the dose distributions measured with the SRS MapCHECK® were compared with those calculated by the treatment planning system using the SNC Patient® software.

D. *Gamma Evaluation Criteria*

Two Gamma analysis criteria were compared: the institutional 2%/2 mm criterion and the proposed 5%/1 mm criterion, both using a GPR ≥ 95% as the clinical acceptance threshold. For both criteria, global Gamma analysis was performed using a 10% low-dose threshold, with points receiving doses below this threshold excluded from the evaluation. The dose distribution calculated by the Monaco® treatment planning system was used as the reference distribution and compared with the dose distribution measured using the SRS MapCHECK® system through the SNC Patient® software.

The 5%/1 mm criterion was selected based on the use of a more restrictive spatial tolerance, which is particularly relevant for stereotactic treatments characterized by steep dose gradients.

E. *Analyzed Variables*

In addition to the Gamma Passing Rate (GPR), treatment plan information was extracted to evaluate the potential influence of plan characteristics on the performance of the Gamma criteria analyzed. The following variables were considered:

- total lesion volume (mm^3);
- number of treated lesions;
- number of fractions;
- total monitor units (MU).

These variables were selected because they represent treatment plan characteristics potentially related to the geometric and dosimetric complexity of SRS treatments.

F. *Statistical Analysis*

Initially, a descriptive analysis of the Gamma Passing Rates (GPR) was performed for the 2%/2 mm and 5%/1 mm criteria. The distributions of GPR values were characterized using the median and interquartile range (IQR). Since both criteria were applied to the same 240 treatment plans, GPR values were compared using a paired analysis with the Wilcoxon signed-rank test. A significance level of 5% ($p < 0.05$) was adopted.

To evaluate the influence of lesion volume on the occurrence of plan failure, the total lesion volume was categorized using the median of the volume distribution of the 240 treatment plans included in the study as the cutoff point, corresponding to 11,950 mm^3. Accordingly, treatment plans were classified into two groups: volume ≤ 11,950 mm^3 and volume > 11,950 mm^3.

Subsequently, logistic regression analysis was performed to investigate the association between treatment plan characteristics and the occurrence of plan failure, defined as GPR < 95%, for each Gamma criterion evaluated. The results were expressed as *odds ratios* (ORs), with their respective 95% confidence intervals (95% CIs) and p-values. A statistical significance level of 5% ($p < 0.05$) was adopted.

Graphical analyses were also performed to compare the distributions of Gamma Passing Rates and to investigate their relationship with lesion volume and other treatment plan characteristics.

III. RESULTS

A total of 240 intracranial clinical treatment plans subjected to patient-specific quality assurance were analyzed using the 2%/2 mm and 5%/1 mm Gamma criteria. The comparison between the criteria demonstrated distinct Gamma Passing Rate (GPR) behaviors, both in terms of the distribution of GPR values and their association with the characteristics of the treatment plans analyzed.

A. *Comparison of Gamma Criteria*

The distribution of GPR values for both criteria is presented in Fig. 1. For the 2%/2 mm criterion, the median GPR was 94.60%, with an interquartile range of 91.78% to 96.93%. For the 5%/1 mm criterion, the median GPR was 98.10%, with an interquartile range of 96.48% to 99.33%. These results demonstrate higher central values and lower GPR dispersion for the 5%/1 mm criterion.

Since both criteria were applied to the same 240 treatment plans, a paired comparison was performed using the Wilcoxon signed-rank test, which demonstrated a statistically significant difference between the GPR values obtained with the 2%/2 mm and 5%/1 mm criteria ($p < 0.001$).

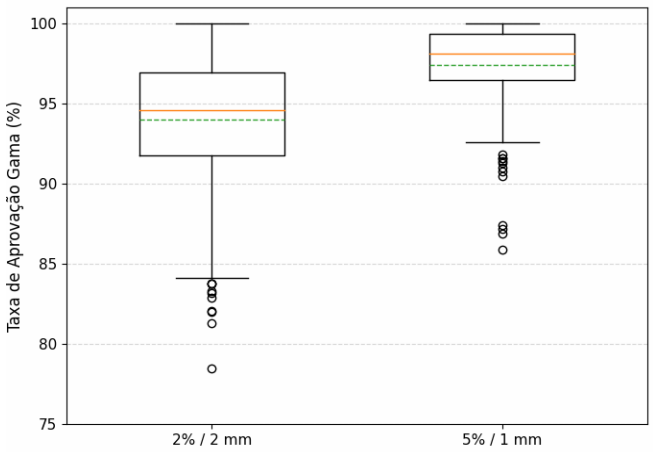

Figure 1. Boxplot of the Gamma Passing Rate (GPR) for the 2%/2 mm and 5%/1 mm Gamma criteria.

As shown in Fig. 1, the 5%/1 mm criterion exhibited a distribution more concentrated at higher GPR values and a smaller interquartile range compared with the 2%/2 mm criterion. The interquartile range was approximately 2.85 percentage points for the 5%/1 mm criterion, compared with 5.15 percentage points for the 2%/2 mm criterion, indicating lower variability in the results obtained with the 5%/1 mm criterion.

Thus, the results demonstrate distinct behaviors between the criteria, with significantly higher GPR values and lower dispersion for the 5%/1 mm criterion. However, these differences reflect the behavior of the GPR distributions in the analyzed sample and, by themselves, do not allow inference of greater sensitivity of the 5%/1 mm criterion for detecting geometric errors.

B. Influence of Lesion Volume

The relationship between total lesion volume and the Gamma Passing Rate is presented in Fig. 2. A trend toward decreasing GPR with increasing lesion volume was observed for the 2%/2 mm criterion. In contrast, for the 5%/1 mm criterion, GPR values showed less variation as a function of lesion volume, remaining more homogeneous across the range of volumes analyzed.

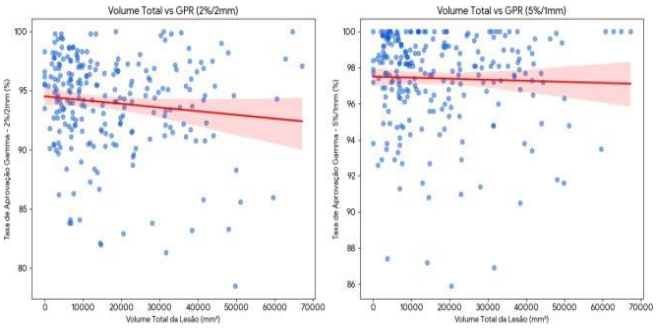

Figure 2. Relationship between total lesion volume and Gamma Passing Rate for the 2%/2 mm and 5%/1 mm criteria.

Logistic regression demonstrated that treatment plans with a volume greater than 11,950 mm³ had higher odds of failure under the 2%/2 mm criterion (OR = 1.71; $p = 0.039$), corresponding to a 71% increase in the odds of failure compared with treatment plans with a volume equal to or below this cutoff. For the 5%/1 mm criterion, no statistically significant association was observed between lesion volume and the occurrence of failure.

C. Influence of Treatment Plan Complexity

The analysis of treatment plan characteristics demonstrated an association between the number of treated lesions and the behavior of the 5%/1 mm Gamma criterion. Logistic regression showed an increase in the probability of failure associated with the number of lesions, with an *Odds Ratio* (OR) of 1.06 ($p < 0.05$).

This result indicates that treatment plans involving a greater number of lesions had a higher probability of failure under the 5%/1 mm criterion. However, this finding represents a statistical association and does not allow inference of greater sensitivity of the criterion for detecting geometric discrepancies.

Variables related to the number of monitor units (MU) and fractionation had only a limited influence on the Gamma Passing Rate, with no statistically significant differences observed between the groups evaluated.

D. Comparison of Clinical Pass Rates

Considering the clinical acceptance threshold of GPR ≥ 95%, differences in passing and failing rates were observed between the evaluated criteria. For the 2%/2 mm criterion, among the 240 treatment plans analyzed, 114 (47.5%) were classified as passing and 126 (52.5%) as failing. For the 5%/1 mm criterion, 199 treatment plans (82.9%) passed and 41 (17.1%) failed, as shown in Fig. 3.

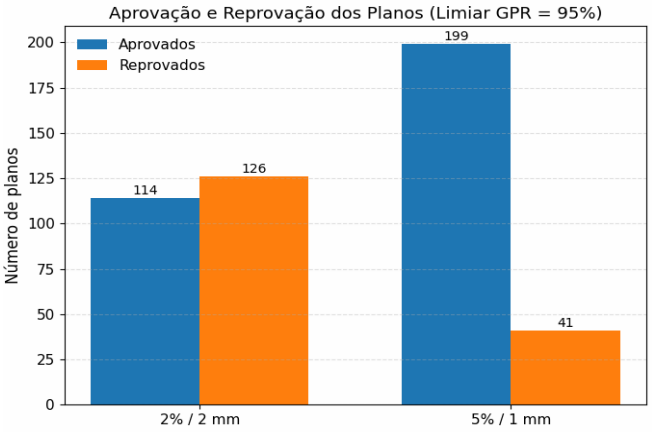

Figure 3. Number of treatment plans passing and failing the 2%/2 mm and 5%/1 mm Gamma criteria, considering GPR ≥ 95% as the acceptance threshold.

Thus, the 5%/1 mm criterion showed a higher proportion of treatment plans with GPR ≥ 95% and a lower proportion of results below this threshold compared with the 2%/2 mm criterion. This difference should be interpreted considering the distinct characteristics of the two criteria, since the 5%/1 mm criterion combines a wider dose-difference tolerance (5%) with a more restrictive spatial tolerance (1 mm), whereas the 2%/2 mm criterion applies a more restrictive dosimetric tolerance.

However, the higher passing rate observed for the 5%/1 mm criterion should not be interpreted in isolation as evidence of a greater ability to detect geometric errors, since the present study did not use a reference standard based on known errors.

E. Predictive Model for Clinical Failure

The logistic regression results for factors associated with plan failure (GPR < 95%) are summarized in Table I.

Table I – Association Between Treatment Plan Parameters and Failure (GPR < 95%) for the 2%/2 mm and 5%/1 mm Gamma Criteria

Variável	Referência	2%/2 mm – OR (IC95%)	p	5%/1 mm – OR (IC95%)	p
Volume total da lesão	Baixo volume	**1,71 (1,03–2,86)**	**0,039**	1,34 (0,68–2,64)	0,392
Complexidade do alvo	Lesão única	1,02 (0,49–2,11)	0,956	1,96 (0,84–4,58)	0,121
Fracionamento	1 fração	1,55 (0,93–2,59)	0,096	0,81 (0,41–1,60)	0,541
Total de UM	Baixa modulação	1,02 (0,60–1,73)	0,930	1,88 (0,95–3,70)	0,069

The model demonstrated that lesion volume was the main factor associated with failure under the 2%/2 mm criterion (OR = 1.71; 95% CI: 1.03–2.86; p = 0.039), whereas no statistically significant association was observed between lesion volume and failure under the 5%/1 mm criterion (OR = 1.34; 95% CI: 0.68–2.64; p = 0.392). The other variables analyzed, including target complexity, fractionation, and total monitor units, showed no statistically significant association with failure for either Gamma criterion evaluated.

IV. Discussão

The results of this study demonstrated that the 2%/2 mm and 5%/1 mm Gamma criteria exhibited distinct behaviors in patient-specific quality assurance of intracranial radiosurgery treatment plans using VMAT. Although both criteria showed high overall passing rates, differences were observed in the distribution of *Gamma Passing Rate* (GPR) values and in the influence of treatment plan characteristics on these results. Overall, the 5%/1 mm criterion showed lower dispersion of GPR values and greater stability across variations in lesion volume, whereas the 2%/2 mm criterion showed a stronger association between increasing irradiated volume and decreasing passing rates. This behavior reinforces that Gamma analysis results depend on the combination of dose-difference and distance-to-agreement parameters adopted, as well as on the characteristics of the dose distribution being analyzed [8], [9].

The analysis of volume influence demonstrated that treatment plans with volumes greater than 11,950 mm³ had a higher probability of failure when evaluated using the 2%/2 mm criterion (OR = 1.71; $p = 0.039$). This result indicates a significant association between irradiated volume and the performance of this criterion in the analyzed sample. The literature demonstrates that GPR may be influenced by different aspects of the analysis methodology, including the spatial distribution of evaluated points, measurement system resolution, dose normalization, low-dose threshold, and the criteria used for Gamma calculation [9], [10]. One possible explanation for the observed behavior is the greater contribution of low-dose-gradient regions to the global GPR calculation. In these regions, small dosimetric differences arising from characteristics of the measurement system, dose calculation, or delivery itself may contribute to a reduction in the passing rate as the evaluated area increases. However, because the present study did not individually investigate the origin of discrepancies between calculated and measured distributions, the mechanism responsible for this association cannot be definitively established.

In contrast, the 5%/1 mm criterion showed lower dependence on lesion volume, maintaining more homogeneous GPR values across the range of volumes analyzed. This behavior may be related to the combination of a wider dosimetric tolerance of 5% with a more restrictive spatial tolerance of 1 mm. Gamma analysis simultaneously combines the dose-difference and distance-to-agreement components; therefore, changes in these parameters may alter the proportion of points classified as passing [8], [9]. The wider dose-difference tolerance may reduce the contribution of small dosimetric variations to plan failure, whereas the shorter distance-to-agreement makes the criterion conceptually more restrictive in terms of spatial agreement. However, the results of the present study directly demonstrate only greater GPR stability across variations in lesion volume, and these data alone do not allow the conclusion that the 5%/1 mm criterion has a greater ability to detect geometric errors.

Another aspect evaluated was the relationship between the number of lesions and the behavior of the Gamma criteria. Treatment plans involving multiple lesions may present greater geometric and modulation complexity, including small fields, steep dose gradients, and dynamic multileaf collimator motion. MLC positioning accuracy is an important component of dosimetric accuracy in modulated treatments, and studies involving deliberately introduced errors have demonstrated that the ability to detect these changes depends on both the magnitude of the error and the Gamma criterion employed [11], [12]. In the present analysis, the number of lesions was associated with failure under the 5%/1 mm criterion (OR = 1.06; $p < 0.05$). This result indicates that the behavior of the 5%/1 mm criterion may be influenced by characteristics related to treatment plan complexity. However, the number of lesions is only an indirect indicator of complexity and does not represent a reference standard for the presence of geometric errors. Therefore, this association should not be interpreted as direct evidence of greater sensitivity of the 5%/1 mm criterion for detecting positioning or delivery errors.

Variables related to the number of monitor units and fractionation had only a limited influence on the Gamma Passing Rate, with no statistically significant differences between the groups evaluated. These findings suggest that, in the analyzed sample, these characteristics were not determinant factors in the behavior of the evaluated criteria. Multicenter experience in quality assurance of modulated treatments has demonstrated that the performance of dosimetric verification may vary according to treatment plan characteristics, treatment planning and delivery systems, and measurement methodologies [10]. On the other hand, the influence observed for volume and number of lesions in the present study reinforces that GPR interpretation should consider the specific characteristics of treatment plans rather than relying solely on an isolated passing-rate value.

These results should be interpreted considering the inherent characteristics and limitations of Gamma analysis. Since its introduction, the Gamma index has become one of the main tools for quantitative comparison between calculated and measured dose distributions [8], [9]. However, several studies have demonstrated that GPR alone has limitations in identifying and characterizing clinically relevant dosimetric discrepancies [13]. Nelms *et al.* [13], for example, evaluated treatment plans containing deliberately introduced errors and demonstrated that Gamma passing rates obtained from planar verification did not consistently predict clinically relevant dosimetric changes in the patient. These findings reinforce that a high Gamma passing rate should not be interpreted in isolation as evidence of the

absence of clinically significant errors.

This interpretation is consistent with the recommendations of AAPM TG-218, which emphasizes that the performance of Gamma analysis depends on several methodological parameters, including dose normalization, spatial resolution, low-dose threshold, comparison methodology, and dose-difference and distance-to-agreement criteria [9]. Therefore, different combinations of these parameters may produce distinct behaviors for the same dose distribution. In stereotactic treatments, where steep dose gradients, small field sizes, and high conformity increase the importance of geometric accuracy, the use of more restrictive spatial tolerances may be relevant to the verification process [12], [14].

In this context, the *AAPM-RSS Medical Physics Practice Guideline 9.b* emphasizes the high level of geometric accuracy required for stereotactic radiosurgery and stereotactic body radiation therapy procedures [14]. Therefore, the use of 1 mm as the spatial component of the Gamma criterion is conceptually aligned with the need for stringent geometric accuracy in these treatments. However, this rationale does not, by itself, imply that the 5%/1 mm criterion is more sensitive to geometric errors than the 2%/2 mm criterion. Demonstrating such capability requires comparing Gamma results against a reference standard containing errors of known nature and magnitude.

Studies involving the deliberate introduction of errors demonstrate the importance of this type of approach. Yan *et al.* [11] introduced random errors of up to 2 mm and systematic errors of ±1 and ±2 mm in MLC leaf positions and observed that QA sensitivity varied according to the Gamma criterion employed. Similarly, Kim *et al.* [12], in a PSQA investigation of VMAT-based SBRT using FFF beams, introduced known MLC misalignments and evaluated different combinations of dose-difference and distance-to-agreement criteria. The authors demonstrated that criteria containing a 1-mm spatial component exhibited distinct behavior in response to the introduced perturbations, highlighting that the sensitivity of a given criterion should be experimentally established using known errors [11], [12].

An important limitation of the present study is therefore the absence of a *ground truth* consisting of known geometric or dosimetric errors. Because this was a retrospective analysis of clinical treatment plans, controlled perturbations such as spatial shifts, deliberate changes in multileaf collimator positioning, or known modifications in delivered dose were not introduced. Studies using deliberately introduced errors demonstrate the importance of this approach for evaluating the actual ability of QA metrics to distinguish error-free dose distributions from those containing known discrepancies [11]–[13]. Therefore, the differences observed between the 2%/2 mm and 5%/1 mm criteria in the present study should be interpreted as differences in GPR behavior and in their association with treatment plan characteristics, and it is not possible to directly determine the sensitivity or specificity of either criterion for error detection.

This limitation should also be considered when interpreting the GPR ≥ 95% threshold adopted in this study. The same reference value was applied to the 2%/2 mm and 5%/1 mm criteria to enable standardized comparison of the results. TG-218 provides recommendations regarding tolerance and action limits for PSQA and emphasizes the importance of standardizing the conditions used for GPR calculation and interpretation [9]. However, in the absence of a reference standard containing treatment plans with and without known errors, the present study cannot determine whether 95% represents the optimal decision threshold for the 5%/1 mm criterion. Establishing a criterion-specific threshold would require an analysis based on the ability to discriminate between known acceptable and unacceptable conditions.

Future studies may address this issue through the systematic introduction of controlled perturbations into treatment plans or measurements, including spatial shifts of different magnitudes, known alterations in MLC positioning, and deliberate dosimetric variations. This methodology has been used to investigate the ability of different PSQA approaches to identify delivery errors [11]–[13]. Particularly in stereotactic treatments using VMAT, the introduction of submillimeter and millimeter-scale MLC errors may provide relevant information regarding the discriminatory ability of Gamma criteria with spatial tolerances of 1 and 2 mm [12]. Comparing unperturbed treatment plans with plans containing known errors would allow direct evaluation of the error-detection capability of the Gamma criteria. Using such a reference standard, sensitivity and specificity could be calculated and receiver operating characteristic (ROC) curves could be constructed, allowing different GPR thresholds to be evaluated and determining whether the 95% threshold is appropriate for the 5%/1 mm criterion.

In addition to this limitation, the study was retrospective and conducted at a single radiotherapy center using a specific treatment planning, delivery, and dosimetry platform. PSQA performance may depend on the treatment planning system, dose calculation algorithm, treatment equipment, detector characteristics, and analysis methodology [9], [10]. Although the analysis of 240 clinical treatment plans provides a representative sample of the institutional experience, multicenter studies involving different linear accelerators, treatment planning systems, and dosimetry devices are needed to assess the generalizability of the results. Future investigations may also evaluate the behavior of the 5%/1 mm criterion in other stereotactic scenarios, including extracranial SBRT treatments.

Taken together, the results of this study demonstrate that the choice of Gamma criterion influences the interpretation of patient-specific quality assurance in radiosurgery. In the analyzed sample, the 5%/1 mm criterion showed less influence of irradiated volume and greater stability of the passing rate, whereas the 2%/2 mm criterion showed a stronger association between volume and the occurrence of failure. Considering the known limitations of GPR as a standalone metric [9], [13], these findings should be interpreted as evidence of the behavior of the two criteria within the PSQA process evaluated. The results support further investigation of the 5%/1 mm criterion as an alternative for PSQA of stereotactic treatments; however, demonstrating superiority in geometric error detection and defining a criterion-specific acceptance threshold require additional studies based on controlled perturbations and a known reference standard.

V. *CONCLUSION*

This study evaluated the performance of the 5%/1 mm Gamma criterion in patient-specific quality assurance (PSQA) of intracranial stereotactic radiosurgery treatment plans using VMAT, comparing it with the institutional 2%/2 mm criterion. Both criteria showed high overall passing rates; however, they exhibited distinct behaviors in relation to the characteristics of the treatment plans analyzed.

The 2%/2 mm criterion showed a stronger association between increasing irradiated volume and

decreasing Gamma Passing Rate (GPR), with a higher probability of failure in treatment plans involving larger lesion volumes. In contrast, the 5%/1 mm criterion showed less influence of irradiated volume and greater stability of the passing rate across the range of volumes evaluated.

The results also demonstrated an association between characteristics related to treatment plan complexity and the behavior of the 5%/1 mm criterion. However, since this study exclusively used retrospective clinical treatment plan data and did not include the introduction of known geometric or dosimetric errors, it is not possible to directly conclude that the 5%/1 mm criterion has greater sensitivity or specificity for detecting such errors.

Therefore, the findings indicate that the 5%/1 mm criterion shows promising behavior for application in patient-specific quality assurance of SRS treatments using VMAT, particularly because of its lower dependence on the volumetric variations observed in the study sample. The more restrictive spatial tolerance of 1 mm may represent a potentially relevant feature for stereotactic treatments, in which geometric accuracy is critical; however, this capability should be confirmed through specific error-detection studies.

Future investigations involving the controlled introduction of spatial shifts, alterations in multileaf collimator (MLC) positioning, and known dosimetric variations may directly evaluate the error-detection capability of each criterion. Such analyses would allow the determination of parameters such as sensitivity and specificity, as well as the construction of receiver operating characteristic (ROC) curves, in addition to investigating the suitability of the GPR ≥ 95% threshold for the 5%/1 mm criterion.

Thus, the results of this study provide clinical evidence regarding the comparative behavior of the 2%/2 mm and 5%/1 mm Gamma criteria and may contribute to the development of more specific quality assurance protocols for stereotactic radiosurgery. However, in the absence of a reference standard based on known errors, these findings do not establish diagnostic superiority of the 5%/1 mm criterion.

ACKNOWLEDGMENT

The authors would like to thank the technical support provided by the Radiotherapy Department of the Association for Cancer Control in Goiás and the academic infrastructure made available by the Institute of Physics of the Federal University of Goiás, which were essential for the development of this work.

***Resumo* — A Doença de Parkinson (DP) é caracterizada por sintomas motores cardinais cuja avaliação clínica tradicional, normalmente baseada na escala UPDRS, que apresenta limitações de subjetividade e baixa sensibilidade para alterações sutis. Como alternativa a mecanomiografia (MMG) surge como uma ferramenta promissora para o monitoramento contínuo. Com o objetivo de comparar as características de amplitude e frequência dos sinais da MMG adquiridos no antebraço, contrastando o tremor muscular com o tremor visível do dedo indicador em repouso, este trabalho utilizou dados de um estudo experimental com voluntários diagnosticados com DP. A metodologia consistiu em uma revisão bibliográfica e na análise experimental de 4 pacientes selecionados, nos quais foram coletados sinais simultâneos em repouso por 60 s. Utilizou-se um acelerômetro bidimensional MEMS de alta sensibilidade (±1,5 g; 800 mV/g) sobre os músculos flexores do antebraço para a MMG, e outro sensor (±6 g; 200 mV/g) na ponta do dedo indicador. Os sinais foram filtrados, digitalizados com taxa de amostragem de 280 Hz e analisados no domínio do tempo (RMS) e da frequência (FFT). Os resultados indicaram que as frequências de tremor de repouso situaram-se de forma consistente na banda de 4 a 6 Hz. A amplitude RMS da MMG mostrou-se sistematicamente menor que a do dedo, chegando a ser 10 vezes menor em um dos voluntários. Em contrapartida, as frequências da MMG foram ligeiramente superiores (diferença de até 0,570 Hz), o que confirma que o tremor mecânico periférico é amortecido pela inércia física do membro. Conclui-se que a MMG no antebraço provou ser um método viável e clinicamente informativo, evidenciando potencial para caracterizar assinaturas motoras de forma objetiva e abrir caminho para sistemas de suporte à decisão clínica baseados em inteligência artificial e tratamentos personalizados.**

Palavras-chave — doença de parkinson, mecanomiografia, tremor, acelerômetro.

I. INTRODUÇÃO

A Doença de Parkinson (DP) é a segunda doença neurodegenerativa mais prevalente no mundo e é caracterizada primordialmente pela morte progressiva de neurônios dopaminérgicos na substantia nigra do cérebro. Essa degeneração neuronal manifesta-se através de sintomas motores cardinais que incluem tremor de repouso, bradicinesia e rigidez muscular [1]. À medida que a doença progride, o tratamento, que frequentemente envolve medicação dopaminérgica (como a Levodopa) ou Estimulação Cerebral Profunda (DBS), necessita de ajustes contínuos e personalizados [2].

Até o presente, a quantificação da severidade dos sintomas motores da DP é predominantemente realizada em ambiente clínico, normalmente utilizando a *Unified Parkinson's Disease Rating Scale* (UPDRS) da *Movement Disorder Society* (MDS). Contudo, a UPDRS apresenta limitações severas: é uma escala ordinal inerentemente subjetiva, propensa à variabilidade inter e intra-avaliador, e possui um "efeito teto" que reduz sua sensibilidade às mudanças sutis nos estágios iniciais ou prodrômicos da doença [3]. Além disso, a avaliação clínica provê apenas um retrato momentâneo do paciente, falhando em capturar as flutuações motoras que ocorrem ao longo do dia.

Para contornar essas limitações, a Eletromiografia (EMG) tem sido historicamente utilizada. No entanto, a EMG apresenta desvantagens práticas, como a necessidade de preparação meticulosa da pele, sensibilidade à impedância cutânea (suor, pelos) e alta suscetibilidade a artefatos elétricos [4]. Como alternativa para monitoramento contínuo e vestível (wearable), destaca-se a Mecanomiografia (MMG). A MMG registra as oscilações mecânicas de baixa frequência na superfície muscular produzidas pela ativação das fibras musculares, refletindo a contração e o recrutamento das unidades motoras. Sendo um sinal mecânico, a MMG não sofre interferência da impedância da pele, não necessita de gel condutor e possui uma relação sinal-ruído vantajosa, permitindo sua fácil integração em sistemas de telemedicina e dispositivos vestíveis [5]. A detecção dessas microvibrações mecânicas fornece um espelho direto do comando oscilatório central, sendo essencial para a identificação de anomalias motoras na DP.

A avaliação objetiva dos sintomas motores da Doença de Parkinson (DP) tem motivado a transição de métodos puramente clínicos para o uso de biossensores vestíveis (wearables) [6]. Trabalhos recentes propuseram a fusão da MMG com Unidades de Medição Inercial (IMUs) para criar perfis motores completos. Em [2] foi desenvolvido um conjunto heterogêneo de sensores fixados no braço e antebraço capaz de avaliar simultaneamente bradicinesia, rigidez e tremor, demonstrando que características extraídas da MMG correlacionam-se intimamente com as pontuações

clínicas da UPDRS. Visando o monitoramento contínuo em ambiente domiciliar (telemedicina), em [6] foi desenvolvido o sistema PDTrack. Seus resultados revelaram que a adição da MMG às medições puramente inerciais (acelerômetros e giroscópios) aumenta significativamente a precisão da classificação de sintomas, especialmente para tremores posturais, ressaltando o valor da atividade mecânica muscular dissociada da cinemática das articulações.

Além do tremor, a lentidão do movimento (bradicinesia) tem sido investigada de forma isolada pela MMG. Em [1] foram extraídas informações espectrais dos sinais de MMG baseados em acelerômetros durante tarefas motoras como pronação/supinação e beliscão dos dedos (*finger pinch*). Por meio do cálculo da Frequência Média Instantânea (IMNF) usando o Espectro de Hilbert, os autores confirmaram que pacientes em estágios mais severos de bradicinesia apresentam valores significativamente menores de IMNF, estabelecendo um limiar detectável para o estadiamento do sintoma.

Uma vertente investigou pacientes com Parkinson sem a presença do tremor clínico aparente. Em [3] foi medido a MMG durante tarefas isométricas bilaterais de membros superiores e constataram que os pacientes com DP apresentaram variações de amplitude reduzidas e uma distribuição anormal da potência de frequência mecânica em relação a pessoas saudáveis. Em um estudo subsequente focando em tarefas motoras isométricas unilaterais, os mesmos autores evidenciaram que pacientes sem tremor clínico já apresentam assimetrias acentuadas entre os membros (inter-membros) na variação das amplitudes de MMG e nas médias de frequência, sugerindo que as micro-oscilações musculares precedem a manifestação visual do sintoma e atuam como um marcador patológico sutil.

Avanços no hardware de aquisição permitiram explorar a MMG em níveis microscópicos. Em [7] foi introduzido o uso de acelerômetros de altíssima sensibilidade com componentes em ouro, reduzindo o piso de ruído e capturando frequências acima de 15 Hz ocultadas por sensores comerciais convencionais. Esses pesquisadores detectaram a MMG diretamente no músculo polegar de pacientes com DP e alimentaram esses sinais, em conjunto com componentes de baixa frequência (tremor clássico), numa arquitetura de rede neural profunda (MLSTM-FCNs). A fusão dessas frequências atingiu precisão de 92,19% na classificação entre indivíduos saudáveis e pacientes com DP, estabelecendo os tremores microscópicos da fibra muscular como uma fronteira vital de pesquisa para o diagnóstico.

O presente trabalho tem o objetivo de avaliar a eficácia, a sensibilidade e a aplicabilidade clínica da mecanomiografia (MMG), baseada em sensores de aceleração, para a quantificação e caracterização objetiva de tremores em indivíduos com Doença de Parkinson, visando contrastar o tremor inerente à mecânica das fibras musculares com o tremor visível do segmento distal (mão e dedos).

II. METODOLOGIA

A. Revisão bibliográfica

Para garantir a abrangência e o rigor da fundamentação teórica, foi conduzida uma revisão bibliográfica, com foco em estudos prévios do uso da MMG na Doença de Parkinson.

A busca foi realizada nas bases de dados IEEE Xplore, PubMed, ScienceDirect e SpringerLink. Foram utilizados descritores combinados (operadores booleanos): ("Mechanomyography" OR "MMG") AND ("Parkinson's Disease" OR "Tremor" OR "Bradykinesia").

Os critérios de inclusão abrangeram estudos clínicos e de engenharia que propusessem sistemas de aquisição, processamento de sinais mecânicos (acelerômetros, sensores piezelétricos ou microfones) e algoritmos de classificação de sintomas motores da DP. Artigos focados exclusivamente em modelos animais ou métodos puramente baseados em EMG foram excluídos.

A revisão focou na extração de dados sobre tipos de sensores, posicionamento, parâmetros extraídos (ex: Frequência Média Instantânea - IMNF, Root Mean Square - RMS) e a eficácia na distinção entre pacientes com DP e controles saudáveis.

B. Protocolo Experimental e Dados

Os dados analisados neste trabalho são provenientes de um estudo experimental desenvolvido durante o mestrado do primeiro autor, envolvendo pacientes voluntários do Ambulatório de Distúrbios do Movimento do Hospital de Clínicas da UFPR. O protocolo de pesquisa foi devidamente aprovado pelo Comitê de Ética em Pesquisa (CEP) da instituição, sob o parecer de aprovação nº 2005018128. Todos os participantes foram previamente informados sobre o Termo de Consentimento Livre e Esclarecido (TCLE) e o assinaram, concordando com a participação no estudo.

A medição do tremor visível de repouso foi realizada na extremidade distal do dedo indicador, devido este segmento refletir a manifestação macroscópica final do tremor parkinsoniano clássico, e da MMG foi realizada nos ventres musculares do antebraço, devido a essa região central apresentar a maior deflexão transversal das fibras musculares. O sensor do antebraço foi posicionado no ponto médio da face anterior do antebraço, sobre os músculos flexores do carpo. Utilizou-se para a MMG um acelerômetro bidimensional (2D) modelo MMA6260Q da Freescale baseado em tecnologia MEMS, especificado com um fundo de escala de ±1,5g e uma sensibilidade de 800mV/g, alimentado com 3,3V. Esta configuração de hardware é compatível com tecnologias validadas na literatura, como em [3] e [8], para a extração ideal do sinal de MMG. Para a medição do tremor visível na ponta do dedo indicador foi utilizado um acelerômetro bidimensional (2D) modelo MMA6270 da Freescale configurado para o fundo de escala de ±6g e uma sensibilidade de 200mV/g, alimentado com 3,3V. Os sinais analógicos dos acelerômetros foram condicionados por meio de um filtro passa-altas de 0,3Hz, um filtro passa-baixas de 20 Hz de 2ª ordem e digitalizados por meio de um conversor Analógico-Digital (ADC) utilizando-se 8 bits de quantização com faixa dinâmica de 3,3V de entrada a uma taxa de amostragem de 280 Hz por canal, para evitar *aliasing*. Foi utilizado ganho unitário aos dois sensores e os sinais analógicos tiveram o seu nível de referência deslocado para 1,65V antes de entrar no conversor A/D.

A captura dos sinais foi realizada com duração de 60 s, adquirindo os sinais do sensor do dedo indicador e do antebraço no mesmo momento, com defasagem temporal de 0,89 ms entre canais consecutivos, fazendo-se uma varredura por meio de diferentes canais do ADC em cada eixo X e Y dos dois acelerômetros, utilizando-se o microcontrolador modelo MSP430F135 da Texas Instruments. O hardware ainda conta com isolação elétrica do lado dos sensores por meio do

conversor DC-DC isolado NMH0505D para a alimentação e optoacopladores ACSL-6400 para os dados.

O cálculo do valor RMS da amplitude do sinal do tremor no domínio do tempo em unidade de aceleração da gravidade (g) foi realizado a partir da conversão prévia dos sinais em Volts dividindo-se pela sensibilidade nominal de cada acelerômetro. Foi feita a calibração em cada eixo dos dois sensores utilizando a máquina MTS 810, cuja configuração de deslocamento, em m, por unidade de tempo, em s, permitiu a conversão para aceleração, em m/s², e para aceleração da gravidade, em g, sem saturação. O sensor MMA6260Q que capta vibrações na faixa de ±1,5g a uma sensibilidade de 800mV/g, foi posicionado no antebraço por sua maior sensibilidade, adequada para captar sinais de menor amplitude. O sensor MMA6270Q que capta vibrações na faixa de ±6g a uma sensibilidade de 200mV/g, foi posicionado no dedo indicador por sua maior faixa dinâmica, adequada para sinais de maior amplitude. Por exemplo, para um deslocamento de 0,5mm a 20Hz da máquina MTS 810, equivalente a 0,81g de pico, foi obtido 0,64V na saída do sensor MMA6260Q e 0,16V na saída do sensor MMA6270Q, confirmando as sensibilidades e a proporção de 4x entre elas. Após a normalização ambos os sinais foram expressos em g RMS, permitindo uma comparação direta.

Os dados aquiridos foram armazenados em base de dados MySQL no computador. Os sinais ainda passaram por uma etapa de processamento digital por meio de um filtro passa-baixas FIR com aproximação Chebychev de ordem 11 e frequência de corte de 20 Hz, projetado com 12 coeficientes. Foi realizada a aplicação de algoritmo de FFT para o cálculo da frequência em Hertz do sinal no domínio da frequência.

A fixação dos acelerômetros foi realizada com fita adesiva do tipo fita crepe estreita e fitas de velcro para melhor sustentação e evitar o descolamento da fita crepe.

Os pacientes voluntários com diagnóstico de Doença de Parkinson foram instruídos a realizar uma tarefa motora estática durante o intervalo de 60 s, que avalia o tremor de repouso, tendo os braços relaxados e apoiados sobre as pernas, com a palma das mãos para cima. A amostra analisada constitui-se de uma seleção de conveniência de 4 voluntários a partir de uma coorte heterogênea, como limitação do estudo.

III. Resultados e Discussão

A. *O estado da arte e lacunas de pesquisa*

A aplicação da revisão bibliográfica revelou avanços no uso da MMG para a DP, delineando claramente o que a engenharia biomédica já conquistou e o que ainda requer investigação profunda.

O trabalho de [2] demonstrou pioneirismo ao desenvolver um conjunto de sensores heterogêneos (incorporando 4 sensores MMG, IMUs e sensores de força) para quantificar simultaneamente bradicinesia, rigidez e tremor. O sistema alcançou 85,4% de precisão na previsão das pontuações UPDRS clínicas, provando que a MMG pode até mesmo substituir sensores de força na avaliação da rigidez articular.

Em [1] foi mostrado que a extração da Frequência Média Instantânea (IMNF) a partir do espectro de Hilbert do sinal de MMG é um marcador robusto. Eles observaram que pacientes com sintomas mais severos de DP apresentam valores de IMNF mais baixos durante tarefas de pronação/supinação em relação aos pacientes em estágios iniciais.

Em [3] e [8] foram investigados pacientes com DP sem tremor clínico visível, utilizando MMG durante tarefas motoras isométricas. Os autores identificaram que a variação de amplitude e a relação potência-frequência (*power-frequency-ratio*) dos sinais MMG diferem significativamente dos controles saudáveis, além de revelarem assimetrias entre os membros, servindo como uma possível "janela" precoce para a disfunção oscilatória dos gânglios da base.

Em [7] foi introduzido o conceito de "micro-MMG". Usando acelerômetros de alta sensibilidade (com massa de prova em ouro), descobriram vibrações acima de 15 Hz que são ocultadas pelo piso de ruído (*noise floor*) dos sensores comerciais comuns. Alimentando esses dados em redes neurais profundas (MLSTM-FCNs), alcançaram 92,19% de precisão na classificação entre DP e indivíduos saudáveis.

Apesar desses achados, o entendimento neurofisiológico exato das oscilações musculares de baixa amplitude (MMG) ainda necessita de mais investigações científicas. Ademais, a padronização no posicionamento de sensores de MMG e a relação com o tremor visível de repouso e outros biomarcadores exigem novos avanços.

B. *Tremor Visível no Dedo vs. Tremor Muscular no Antebraço*

Na prática clínica rotineira, o tremor da Doença de Parkinson é frequentemente visualizado e quantificado cinematicamente nas extremidades distais (ex: movimentos de "contar moedas" nos dedos). O tremor visível nos dedos é o resultado final macroscópico de um sistema mecânico em cascata, englobando múltiplas articulações, inércia dos ossos e a soma de forças de músculos agonistas e antagonistas.

O foco deste artigo na MMG do antebraço permitiu uma análise em um nível biomecânico muito mais profundo e precoce. O sinal medido no ventre muscular do antebraço captura as vibrações transversais individuais geradas diretamente pelo recrutamento, disparo e encurtamento das unidades motoras ativadas por comandos supraspinais.

Medir no antebraço revela as oscilações patológicas do Sistema Nervoso Central (via gânglios da base e núcleo subtalâmico) mesmo quando a inércia e a rigidez mecânica da mão impedem que o dedo se mova fisicamente. Como corroborado por [3] e [8], alterações na frequência e na amplitude da MMG ocorrem no antebraço de pacientes em estágios onde não há tremor visível. Portanto, o tremor muscular medido via MMG pode ser um biomarcador promissor, conforme verificado em pacientes com diagnóstico conhecido, requerendo validação com amostras mais amplas.

C. *Resultados Experimentais em Voluntários*

Entre os dados da base dos testes realizados em pacientes voluntários do ambulatório de Distúrbios do Movimento, devido à variação de perfis entre os voluntários, que inclui diversos tipos de sintomas e outros tipos de tremores além da DP, como tremor essencial, e tendo em vista que não houve um controle se o paciente estava sob efeito medicação ou não, considerando aqueles que apresentaram características mais fidedignas ao diagnóstico da Doença de Parkinson, sem outros sintomas ou complicações adicionais, foram selecionados 4 voluntários para este estudo. A análise estatística pareada confirmou que a frequência do sinal de MMG no antebraço foi estatisticamente superior à do tremor no dedo indicador, teste *t* pareado, $t(3) = 3,80$, $p = 0,032$. Para a amplitude RMS, a magnitude no dedo indicador mostrou-se superior à da MMG

no antebraço em todos os indivíduos analisados (p = 0,007 para dados log-transformados). A Tabela 1 apresenta os resultados de amplitude e frequência dos tremores de cada voluntário selecionado.

Tabela 1. Valores de amplitude e frequência de tremor dos voluntários selecionados com Doença de Parkinson.

V	MMG (Antebraço)		Tremor (Dedo Indicador)	
	Amplitude (g)	Frequência (Hz)	Amplitude (g)	Frequência (Hz)
1	0,153	4,076	0,210	3,852
2	0,026	5,182	0,037	4,612
3	0,084	5,198	0,252	4,802
4	0,140	4,249	1,421	4,076

V: voluntário

Esta avaliação dos 4 pacientes voluntários com DP submetidos à medição dos acelerômetros de duas dimensões apresentou resultados espectrais consistentes com a literatura, com a frequência do tremor de repouso ficando aproximadamente na faixa de 4 e 6 Hz.

Pode-se verificar nos dados da Tabela 1 que a amplitude RMS da vibração muscular apresenta valores menores que a amplitude do tremor do dedo indicador, demonstrando que a força de aceleração transversal à superfície do antebraço é baixa, mas detectável, ainda, tendo em vista que os distintos tremores são fenômenos físicos de naturezas distintas, corroborando com os achados de [7]. A diferença entre a intensidade do tremor do dedo indicador e do tremor muscular no antebraço chegou a ser 10 vez maior no voluntário 4.

Olhando para a frequência dos sinais, verificou-se que a frequência do sinal de MMG é sistematicamente um pouco maior, com diferença de até 0,570 Hz no voluntário 2. Este fenômeno pode ser explicado devido à MMG registrar de forma direta e imediata as oscilações musculares; já o tremor do movimento do dedo é amortecido pela inércia física do membro, reduzindo ligeiramente a frequência do tremor visível. Esta natureza distinta foi relatada por [1] e [3].

IV. Conclusões

Este estudo evidenciou que a MMG pode ser usada na avaliação de tremores da Doença de Parkinson, trazendo parâmetros que contribuem com o entendimento dos sintomas da doença. Como os voluntários selecionados possuíam diagnóstico conhecido da DP, ainda é preliminar poder afirmar que a MMG pode ser usada para auxiliar no diagnóstico em estágios iniciais quando o tremor nos dedos ainda não é visível, mas demonstra potencial para uma avaliação mais precoce.

Em relação à diferença entre a amplitude da vibração muscular medido no antebraço e a amplitude do tremor no dedo, pode-se associar a outros sintomas da DP, como a bradicinesia e a rigidez muscular, visto que podem atenuar o tremor visível do dedo, sugerindo um estreitamento da diferença de amplitude entre o MMG e o tremor no dedo.

O potencial de desdobramento das investigações para o diagnóstico da DP com sensores inerciais ainda é muito vasto. A quantificação dos tremores por meio de sensores, seja em nível de MMG ou de tremor visível, pode estabelecer características que funcionem como uma assinatura de tremor que podem servir de realimentação para estratégias medicamentosas ou de ajuste de dispositivos de estimulação cerebral (DBS) para o controle da doença.

Pode-se ampliar aquisição de sinais para dados de giroscópios, para contribuir ainda mais com informações sobre a velocidade angular e alterações nos ângulos durante os movimentos, que virão a contribuir ainda mais no diagnóstico, constituindo-se de uma fusão multimodal.

Complementarmente, uma correlação do tremor com outros biomarcadores de naturezas diferentes e características específicas mapeadas para a DP, como EMG ou EEG, tem potencial de avanços significativos no auxílio ao diagnóstico. Os dados adquiridos em voluntários com diagnóstico conhecido podem ser utilizados para o treinamento de sistemas de suporte à decisão clínica (CDSS), utilizando técnicas de *Deep Learning* e inteligência artificial.

Agradecimentos

Os autores agradecem ao Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) Brasil pelo financiamento ao desenvolvimento deste estudo. EC é bolsista de doutorado, MAG é bolsista de pós-doutorado e LTS é bolsista ITI do Programa MAI-DAI/CNPq, e PN é bolsista PQ-1C/CNPq.

***Abstract*— This exploratory pilot study evaluates the technical feasibility and sensitivity of Attenuated Total Reflection Fourier Transform Infrared (ATR-FTIR) spectroscopy as a non-invasive tool to detect biochemical profile variations in saliva from individuals undergoing Gender-Affirming Hormone Therapy (GAHT). Unstimulated saliva samples were collected from one transgender woman undergoing hormone therapy and one cisgender male control. The specimens were centrifuged, dehydrated using a vacuum concentrator, and analyzed using an ATR-FTIR spectrometer equipped with a diamond crystal accessory in the spectral range of 4000 to 500 cm^{-1}. Spectral processing included baseline correction and min-max normalization. A total of 288 spectra were acquired across acquisition points and preparation triplicates as technical replicates to evaluate measurement repeatability rather than independent biological samples. The spectral profiles demonstrated a shared global biochemical topography between both participants. However, variations were identified in specific vibrational regions. The transgender participant showed increased absorbance at 1630 and 1546 cm^{-1}, corresponding to the protein fingerprint region (Amide I and II) with potential superimposed contributions from exogenous steroid hormones. Concurrently, absorbance decreased at 3400-3200 cm^{-1}, 1065 cm^{-1}, and 978 cm^{-1}. Although these decreases align mechanistically with the literature reporting antiandrogen-induced alterations in salivary hydration and glycoprotein content, clinical sialometry or mucin quantification was not performed. Given the N =2 comparative design, observed differences are highly confounded by individual biological variability, diet, hydration, and unrecorded GATH parameters (dosage, duration, and collection time). These findings demonstrate the technical feasibility of acquiring salivary spectra via ATR-FTIR, but larger longitudinal cohorts with clinical controls are required before establishing this approach as a diagnostic screening tool.**

Keywords*— *Spectroscopy; Saliva; Gender-affirming hormone therapy.

I. Introduction

Spectroscopy is a structural analysis tool that evaluates the properties of matter based on its interaction with electromagnetic radiation. Phenomena such as light absorption, reflection, or transmission reveal the sample's composition through the vibrational transitions of its functional groups, yielding a unique "spectral signature"[1], [2]. Fourier Transform Infrared (FTIR) spectroscopy is widely employed to elucidate organic compounds by acquiring absorbance or transmittance spectra across the infrared region.[3].

Historically, blood plasma has been the primary fluid used in spectroscopic diagnostic studies. However, saliva has emerged as a viable alternative because it shares many constituents with plasma through microvascular exchange[4].

The clinical relevance of saliva stems from its non-invasive collection, low operational cost, and ease of sampling compared to venipuncture[2]. Saliva consists of approximately 99% water and 1% organic and inorganic solutes, including peptides, glycoproteins, enzymes, antibodies, growth factors, and steroid hormones[4]. In vibrational spectroscopy, steroid sex hormones exhibit diagnostic bands primarily within the 1490-1300 cm^{-1} and 1100-1000 cm^{-1} regions [4].

Therapeutic drug monitoring and biomarker screening are particularly relevant in transgender women undergoing Gender-Affirming Hormone Therapy (GAHT), especially where unsupervised hormone use occurs. Systemic risks associated with prolonged therapy include insulin resistance, thromboembolism, and arterial hypertension [5]. In the oral cavity, hormone regimens, particularly those involving androgen receptor blockers, have been associated with reduced salivary flow, xerostomia, and secondary susceptibility to dental caries and periodontal diseases [6], [7].

De Moura, Cardoso, and De Carvalho Brito[8] observed that 17-β-estradiol, an estrogen-bioidentical hormone, is the most frequently used medication in transgender hormone therapy, as reported by 88.9% of study participants. This substance is the active pharmaceutical ingredient in widely distributed commercial transdermal formulations, such as Oestrogel, which contains estradiol hemihydrate [9]. Another widely used medication is Perluran®, whose active ingredients are estradiol enanthate and algestone acetophenide. According to Toffoli Ribeiro et al.[10], it shows positive outcomes in breast development, a benefit reported by 76% of their study participants.

GAHT regimens typically use bioidentical estrogen formulations, such as estradiol enanthate and algestone acetophenide (DHPA) [8], [10]. These molecules possess distinct vibrational fingerprints; 17-β-estradiol exhibits O-H stretching (3432-3256 cm^{-1}) and ketal C-O bonds (1275-1020 cm^{-1}); and estradiol enanthate presents ester carbonyl bands (~ 1735 cm^{-1}), C=C aromatic stretches (1615-1585 cm^{-1}), and C-O signals (~1270-1230 cm^{-1})[11]-[14].

Exogenous administration of these compounds may alter specific absorbance intensities within the salivary protein-lipid matrix. However, evaluating these molecular signals requires assessing the technical performance of infrared accessories in dried salivary films.

This exploratory pilot study aims to evaluate the technical feasibility of using ATR-FTIR spectroscopy to detect salivary spectral profile variations in a two-subject comparative design.

II. METHODOLOGY

This cross-sectional, exploratory pilot study was approved by the Institutional Review Board of Science and Technology, São Paulo State University (ICT-UNESP, Campus São José dos Campos, Protocol No. 6,821,454). Two subjects participated in the study: one transgender woman (Participant T) undergoing GAHT and one cisgender male control (Participant C). Participant T was recruited from the "Transformando Sorrisos" outreach project (UNESP/UNIVAP cooperation agreement). Participant C was recruited from the UNESP institutional body.

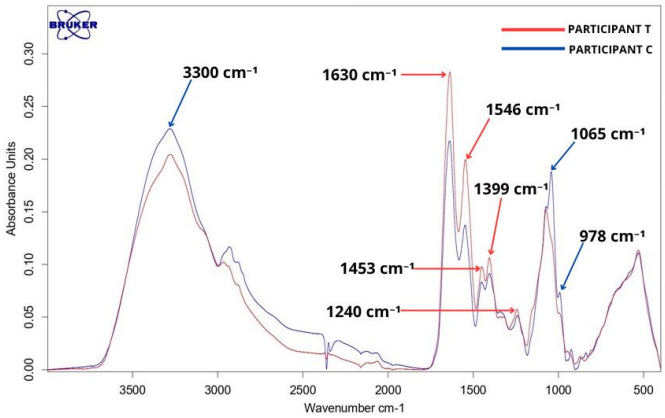
The inclusion criteria for Participant T were age over 18 years and current use of GAHT. For Participant C, inclusion criteria were age over 18 years and the absence of smoking, alcohol abuse, or illicit drug use.

Unstimulated saliva (1.5 mL) was collected in the morning between 8:00 a.m. and 10:00 a.m. over a 5-minute interval, following standardized pre-collection guidelines: refraining from food and beverages (except water), caffeine, and toothbrushing for at least 2 hours before sampling. Samples were collected into 1.5 mL Eppendorf tubes, frozen at -80 ºC, and subsequently centrifuged (CF 16RN, Hitachi) at 10,000 rpm for 10 min at 20 °C. The supernatant was collected and stored at -80 ºC. Before spectroscopic analysis, samples were thawed at room temperature (20 ºC) and homogenized via vortex for 10 s.

To eliminate the dominant water absorption band, a 10-µL aliquot of each supernatant was dried for 10 min using a vacuum concentrator (Eppendorf 5301). Infrared spectra were acquired using an Invenio spectrophotometer (Bruker) equipped with a Platinum ATR accessory featuring a single-reflection diamond crystal.

Spectra were recorded over the spectral range of 4000- 500 cm^{-1}, with 32 co-added scans per spectrum at a spectral resolution of 4 cm^{-1}. Measurements were recorded across eight random points on the dried film formed on the ATR crystal to ensure absorbance values remained between 0.5 and 0.7 arbitrary units (a.u.). Background spectra were acquired across both participants. These 288 spectra represent technical/analytical replicates used to evaluate measurement repeatability, rather than independent biological observations.

Spectroscopic data were processed using baseline correction and min-max normalization (0 to 1), followed by averaging technical replicate spectra for each participant using the OPUS software suite (version 4.2, Bruker).



III. RESULTS

Average normalized ATR-FTIR spectra obtained from saliva samples of Participant T and Participant C demonstrated a shared overall biochemical profile across the analyzed range (4000-500 cm^{-1}).

Despite general topographic similarity, localized differences in relative band intensities were observed. The primary spectral variations were identified at 3400- 3200 cm^{-1}, 1630 cm^{-1}, 1546 cm^{-1}, 1453 cm^{-1}, 1399 cm^{-1}, 1240 cm^{-1}, 1065 cm^{-1}, and 978 cm^{-1}. Prominent intensity increases were noted at 1630 cm^{-1} and 1546 cm-1 in Participant T relative to Participant C (Figure 1).

In the higher-wavenumber region, both samples showed a broadband between 3400 and 3200 cm^{-1}, with lower relative absorbance in Participant T. Within the fingerprint region (1800- 600 cm ¹), peak definition and relative intensity varied between 1453 cm ¹ and 978 cm ¹.

Fig. 1. FTIR average spectra overlay of saliva samples from Participant T and Participant C.

IV. DISCUSSION

The general spectral similarity between Participant T and Participant C reflects the common biochemical foundation of human saliva, which consists predominantly of proteins, lipids, carbohydrates, and inorganic salts. The observed absorbance variations indicate changes in relative biochemical proportions. However, attributing these differences solely to GAHT confounds them with individual biological variability, biological sex, diet, hydration status, and oral health parameters.

The broadband centered near 3300 cm^{-1} corresponds to O-H stretching vibrations (residual water and carbohydrate/lipid hydroxyls), superimposed on N-H stretching vibrations of salivary proteins. The lower absorbance observed in Participant T in this region, alongside changes at 1065 cm^{-1} and 978 cm^{-1} (C-O and C-O-P stretching of oligosaccharides, phosphate groups, and structural glycoproteins such as mucins), aligns mechanistically with literature describing antiandrogen-induced reduction in salivary secretion[7]. However, because objective clinical sialometry (flow rate in mL/min), mucin quantification assays, or clinical oral dryness scores were not collected

during sampling, these spectral decreases represent a mechanistic hypothesis rather than a confirmed clinical diagnosis of xerostomia or hyposalivation.

In the fingerprint region, the increased absorbance at 1630 cm^{-1} (Amide I, C=O stretching of peptide backbones) and the sharper profile at 1546 cm^{-1} (Amide II, N-H bending and C-N stretching) in Participant T occur in regions where exogenous steroid molecules (such as 17-β-estradiol, algestone acetophenide, and estradiol enanthate) also exhibit conjugated C=O and aromatic C=C vibrational modes[11]-[13]. Because these bands overlap directly with the endogenous protein matrix, and no independent analytical confirmation (e.g., mass spectrometry or pure reference compound spectra acquired under identical conditions) was performed, these spectral changes cannot be definitively assigned to the drug molecules themselves. Instead, they reflect composite changes in the matrix fingerprint region.

Variations at 1453 cm^{-1} and 1399 cm^{-1} (CH_2/CH_3 bending and steroid ring modes) and 1240 cm^{-1} (C-O stretching) fall within spectral regions reported as diagnostic for steroid sex hormones in biologic fluids[4]. Nevertheless, establishing these coordinates as definitive biomarkers requires rigorous validation.

As a preliminary two-subject comparative study, some operational limitations must be acknowledged. The N = 2 comparative design introduces complete confounding between GAHT status, individual biological variation, baseline salivary composition, lifestyle, and dietary habits. The 288 acquired spectra represent technical analytical measurements on two biological subjects, precluding population-level inferential statistics. Specific GAHT dosage, exact treatment duration, and objective sialometric parameters were not recorded. Pure hormone standards were not analyzed under the same experimental protocol to isolate pure drug spectral contributions from protein matrix shifts.

Future research should employ longitudinal designs tracking transgender individuals before initiating GAHT and at controlled follow-up intervals. Such studies should include age-matched clinical controls, standardized schedules, sialometric/biochemical testing, and direct spectral analysis of reference pharmacological compounds.

V. CONCLUSION

This exploratory pilot study demonstrates the technical feasibility of ATR-FTIR spectroscopy for acquiring reproducible infrared spectra from dried salivary films in individuals undergoing Gender-Affirming Hormone Therapy. However, given the limited sample size (N=2), observed spectral differences at 1630, 1546, 1065, and 978 cm^{-1} cannot be definitively attributed to exogenous hormones or specific oral clinical conditions due to confounding with inter-individual variability, lifestyle factors, and unrecorded clinical parameters (circadian timing, dosage, and GAHT duration). From a dental perspective, this methodology is a viable tool for early, noninvasive, and low-cost diagnostic screening. Identifying molecular signatures of hyposalivation and loss of oral homeostasis at an early stage paves the way for timely preventive interventions. This proactive approach could mitigate severe clinical manifestations such as xerostomia, reduced buffering capacity, and the consequent susceptibility to dental caries and periodontal diseases in this population. However, future research using larger and more robust sample designs remains essential to validate these vibrational coordinates as definitive biomarkers and to consolidate their clinical applicability and longitudinal monitoring.

Abstract: **Human intelligence has been studied for over 120 years, and psychological tests for its assessment have existed since the early 20th century. The objective was to develop a computerized intelligence scale designed for adults, similar to the WAIS-III, and to correlate the results obtained with those from judges' evaluations. The first prototype was created in PowerPoint, in the form of a game with scenarios and links. The proposal was submitted for review by professionals familiar with the use of the WAIS-III in psychological assessment contexts. The raters recommended replacing some images and suggested creating the scale on an online platform, allowing for the integration of features such as voice recording, a timer, and the use of touch pens or styluses. The next steps involve migrating the scale to a digital environment, implementing the timer, and administering the instrument to participants.**

Keywords: Psychological assessment; intelligence; digital game; WAIS-III; psychometrics

I. INTRODUÇÃO

A Escala Panhan de Inteligência para Adultos (EPIA) é uma proposta de teste gamificado de inteligência desenvolvido para aplicação pelo computador, de forma prática e divertida, seu desenvolvimento tem como base a Escala de Inteligência Wechsler para Adultos (WAIS – III).

A escala WAIS - III é considerada como padrão ouro entre os psicólogos que o utilizam, é um instrumento clínico de aplicação individual composto por 14 subtestes. É utilizado para diversas avaliações, como por exemplo para identificação de problemas de aprendizagem, diagnóstico de pessoas com déficit intelectual, altas habilidades e superdotação, diagnóstico diferencial de transtornos neurológicos e psiquiátricos que afetam o funcionamento mental. Pode ser utilizado para uma investigação mais ampla juntamente com outros testes psicológicos e de personalidade. Para a sua utilização é necessário que o usuário tenha treinamento e experiência tanto para a aplicação, como para a interpretação, análise e a produção do laudo técnico [1].

A primeira autora observou que os pacientes apresentavam comportamentos ansiosos antes e durante a aplicação dos testes psicológicos, principalmente por saberem que estavam sendo avaliados. Quando a avaliação ocorre de forma gamificada, porém, o caráter lúdico da tarefa se torna evidente para o paciente, o que contribui para a redução da ansiedade. Foi justamente por isso que a Escala EPIA foi desenvolvida para minimizar a ansiedade dos pacientes durante o processo de avaliação.

O termo gamificação não significa usar jogos propriamente dito, trata-se de incorporar elementos típicos dos jogos como avatares, rankings, desafios ou sistemas de reputação em atividades que não são jogos [2]. Assim, gamificar é estruturar uma ação com a lógica dos jogos, sem exigir tecnologias específicas ou que os participantes joguem de fato. Diferente do *game-based learning*, a gamificação aplica dinâmicas e mecanismos dos jogos em diversos contextos para aumentar motivação e engajamento [3] [4].

O protótipo da primeira versão da Escala EPIA está concluído com todas as suas etapas construídas, faltando ajustes. O objetivo final da construção da Escala EPIA é de oferecer uma alternativa acessível aos psicólogos, facilitando tanto a avaliação quanto o atendimento psicoterapêutico de seus pacientes. Com a tabulação dos resultados em formato digital, o processo se torna mais ágil e prático, diferenciando-se da análise manual utilizada na escala WAIS-III e em outros testes psicológicos com crivos.

II. REFERENCIAL TEÓRICO

Segundo Rodrigues (2022) [5] a inteligência é considerada de origem genética com plasticidade neuronal, ou seja, com possibilidade de desenvolvimento e conexões neurais para a organização e reorganização dos neurônios. Para o autor uma pessoa reconhecida como intelectual pode ter amplo conhecimento em diversas áreas, mas não necessariamente tem pontuações elevadas em um teste de inteligência, já para Papalia e Martorell (2022) [6] a inteligência não é só genética, mas pode ser estimulada e melhorada a partir do ambiente em que a pessoa vive. Complementam dizendo que o lobo frontal é a última região do cérebro a ser desenvolvida e a que mais se desenvolveu e está relacionada diretamente com a evolução humana.

A inteligência está relacionada também com "a capacidade de armazenamento de memória, de atenção, de funções executivas, de aprendizagem, compreensão, criatividade, tomada de decisão, e prevenção". O ser humano também pode "manipular" a sua percepção, o filtro, a sua consciência, as emoções com variedade de intensidade e significância [5].

Em 2025 completou 120 anos desde que Alfred Binet e Théodore Simon desenvolveram o primeiro teste destinado à avaliação da inteligência. Criado originalmente para acompanhar o progresso de crianças na educação especial, o instrumento conhecido como escala Binet-Simon era voltado exclusivamente ao público infantil.

Na década de 1940, David Wechsler ampliou esse campo ao elaborar um teste de inteligência também voltado para crianças. Com o tempo, suas escalas evoluíram, e hoje as escalas Wechsler são aplicados a indivíduos de todas as faixas etárias [7]. Cabe destacar que as escalas Wechsler são os testes mais utilizados atualmente no ambiente clínico [7] há a versão para crianças (WISC) e a versão para adultos (WAIS).

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

A avaliação psicológica vai além da análise da inteligência, abrangendo diversas funções cognitivas, aspectos da personalidade, preferências profissionais e outros fatores relevantes. Trata-se de um processo que permite confirmar ou aprofundar hipóteses elaboradas pelo profissional durante os atendimentos, contribuindo significativamente para o planejamento de intervenções e estratégias de reabilitação [8], [9]. Para isso, são utilizadas múltiplas estratégias, como observação sistemática, entrevistas e aplicação de testes psicológicos [8], [10].

A psicometria juntamente com a psicologia cognitiva e outras abordagens correlacionam as variáveis investigadas e propõe um método experimental. Dessa forma, alguns testes psicológicos pouco a pouco começam a ser apresentados de forma eletrônica desenvolvidos a partir de *software* [11], no entanto a maioria dos testes adquiridos ainda são vendidos com correção manual.

As Tecnologias da Informação e Comunicação (TICs) têm contribuído significativamente para a Psicologia por meio da informatização dos instrumentos de avaliação. A prática da avaliação psicológica envolve diferentes métodos e é exclusiva do psicólogo. Com a digitalização, os dados podem ser processados de forma rápida, precisa e em grande escala, representando um avanço contemporâneo na área e auxiliando o profissional [12].

O uso das Tecnologias da Informação e Comunicação (TICs) na Avaliação Psicológica torna o processo mais ágil, preciso e confiável, permitindo o uso de diversos recursos multimídia, possibilitando obter informações que a aplicação de testes tradicionais não é capaz de proporcionar. Elas ampliam as possibilidades de aplicação e coleta de dados, automatizam tarefas manuais e favorecem avanços psicométricos, elevando a qualidade das avaliações realizadas [13], [14], [15].

Na Universidade Federal de Minas Gerais (UFMG), há um laboratório dedicado à psicometria e ao desenvolvimento de algoritmos e análises estatísticas voltadas para mensuração e predição no campo dos testes educacionais e psicológicos. Dentre os instrumentos desenvolvidos, destaca-se o Teste de Compreensão Verbal 1, criado por Gomes e Nascimento (2021) [16], que apresenta similaridade com um dos subtestes da escala WAIS-III.

Com relação à aplicação de testes de forma digital, o CFP - Conselho Federal de Psicologia divulgou uma Nota Técnica nº 07/2019 que esclarece que os testes psicológicos podem ser aplicados tanto no formato lápis e papel quanto de forma informatizada, desde que aprovados pelo SATEPSI (Sistema de Avaliação de Testes Psicológicos). No entanto, a aplicação informatizada (mediada por computador) não é o mesmo que aplicação on-line (remota). Cabe ao psicólogo conhecer o manual do teste e aplicar conforme as diretrizes específicas. A avaliação psicológica on-line é permitida, desde que respeite as normas vigentes [15].

Para Hazin et al., (2018) [17] a integração entre avaliação psicológica e neuropsicológica ainda enfrenta desafios no Brasil, especialmente no campo da neuropsicologia. Um dos principais obstáculos é conectar áreas como neurociência, psicometria moderna e tecnologia. Segundo Bilder e Reise (2019) [18], avanços significativos na prática neuropsicológica podem surgir com o uso de estratégias psicométricas e tecnológicas, como a Teoria de Resposta ao Item (TRI), algoritmos de testes adaptativos e análises de funcionamento diferencial dos itens (DIF), que contribuem para avaliações mais precisas e eficientes.

Bilder em 2011 [19] alertava para o futuro da neuropsicologia, dizendo que poderá ser transformada e impulsionada pelos avanços em neuroimagem, genética e tecnologia da informação. Os profissionais poderão utilizar métodos avaliativos digitais e em larga escala, embora a prática ainda dependa de abordagens tradicionais e menos eficientes. Segundo Miller e Barr (2017) [20] o futuro da avaliação neuropsicológica incluirá métodos híbridos - laboratoriais, remotos e automatizados, posicionando a neuropsicologia como protagonista na ciência cognitiva e comportamental.

Considerando que os atuais desafios na área tendem a se intensificar em curto prazo, torna-se essencial repensar os modelos tradicionais de avaliação psicológica e neuropsicológica. Nesse contexto, adotar abordagens inovadoras pode representar um avanço significativo na prática profissional. Uma dessas iniciativas é o desenvolvimento de uma escala de inteligência gamificada para adultos, semelhante à WAIS-III, promovendo maior acessibilidade, agilidade e precisão no processo avaliativo.

Com base no exposto acima, os autores objetivam desenvolver a Escala EPIA com a utilização de um programa de computador conhecido como *Power Point*; solicitar a avaliação da escala EPIA por 5 juízes da área de avaliação psicológica; comparar e correlacionar os resultados obtidos pelos juízes.

III. Método

A presente pesquisa classifica-se como de natureza aplicada [21], com base nos objetivos pode ser classificada como exploratória [22] e de análise mista.

Participantes: 5 juízes-psicólogos especializados e atuantes na área de avaliação psicológica acostumados a utilizar a escala WAIS-III em seus atendimentos psicoterapêuticos para jogar e avaliar a escala EPIA.

Materiais: a Escala Panhan de Inteligência para Adultos - EPIA será um instrumento restrito para uso de psicólogos, podendo ser aplicado em pessoas com mais de 18 anos. A intenção futura é que seja confiável e que forneça os escores de QI Verbal, QI de Execução e QI Total. A EPIA está construída com base na escala WAIS-III, no entanto as imagens não são as mesmas, devido aos direitos autorais, outro diferencial é o formato digital gamificado com mapa e tarefas para os participantes, devido a complexidade de tentar replicar algo semelhante aos subtestes cubos. procurar símbolos e armar objetos, na EPIA esses subtestes foram excluídos.

Por enquanto, o protótipo do jogo está construído no programa *Power Point*, futuramente será inserido em uma plataforma (site da internet) com maiores recursos para a construção do mapa e dos personagens.

Para a aplicação dos subtestes aparecerá um personagem solicitando a ajuda do participante para solucionar alguns problemas, o participante percorrerá no mapa para ir até o local determinado e concluir a tarefa. Todas as tarefas têm níveis de dificuldade partindo do mais fácil para o mais complexo. Para as tarefas com tempo para execução o participante será alertado e um relógio no canto

esquerdo da tela é mostrado. Quando as atividades solicitarem respostas verbais, o participante será avisado que as suas respostas serão gravadas para que o psicólogo possa avaliá-las futuramente e tabular as respostas, cada resposta será contabilizada com pontos para que o QI Verbal, de Execução ou Total seja calculado.

Os subtestes desenvolvidos na escala EPIA são baseados na escala WAIS e levam os mesmos nomes da escala WAIS-III:

Completar Figuras: neste subteste o objetivo é verificar se o avaliado consegue observar detalhes, capacidade de análise e síntese visual, memória semântica visual, atenção e reconhecimento de detalhe essencial, processamento visual e a velocidade de processamento implícita, pois será utilizado marcador de tempo.

Um personagem dentro de uma casa solicitará para que o participante entre e o ajude a conferir produtos comprados pela internet, o participante o ajudará a identificar o que está faltando, como por exemplo: uma cadeira sem um pé. Essa atividade tem 4 figuras para treino e 20 para que o participante identifique onde está o problema. Para cada figura o participante terá 20 segundos para a conclusão.

Compreensão: o principal objetivo deste subteste é o julgamento social, examina a capacidade de expressar as experiências sociais do avaliado. Exige conhecimento de regras de relacionamento social e permite observar a facilidade de argumentação (quando é pedido que o avaliado justifique as suas respostas). Envolve padrões convencionais de comportamento, maturidade e senso comum. É uma boa medida de avaliação pré-mórbida e sensível a danos neurológicos.

O examinando deverá responder oralmente a uma série de questões que exigem soluções para problemas cotidianos ou o entendimento de regras e conceitos sociais. São apresentadas ao avaliando 18 questões sem tempo para respondê-las. As respostas serão gravadas.

Semelhanças: o objetivo é avaliar a abstração. Envolve relações lógicas e formação de conceitos verbais, raciocínio verbal abstrato e habilidades intelectuais gerais, além de síntese e integração de conhecimentos.

É solicitado que o participante aponte semelhanças entre duas palavras, que representam objetos ou conceitos, como por exemplo: maçã e laranja; casaco e blusa. O participante precisa responder a 19 itens sem tempo para a conclusão da tarefa. As respostas serão gravadas.

Aritmética: o objetivo é verificar se o avaliando consegue resolver problemas matemáticos e como utiliza a memória operacional. Envolve a execução de cálculo mental, a compreensão de enunciados e a capacidade de raciocínio matemático. Requer a utilização da memória operacional, necessária para manipular mentalmente os elementos do problema.

Estão dispostos 19 problemas para a pessoa resolver mentalmente, iniciando com soma simples com dois algarismos. É necessário o registro de tempo.

Vocabulário: esse subteste avalia a memória semântica e inteligência cristalizada do avaliado, como também a competência linguística, conhecimentos lexicais e a capacidade de elaboração do discurso. Esse teste é considerado uma medida de inteligência cristalizada e inteligência geral.

O subteste consiste em obter do participante informações relacionada a inteligência cristalizada do participante por meio de conhecimento obtido ao longo da vida. Será solicitado ao avaliado que ele defina oralmente o significado de cada palavra apresentada na lista de palavras. As respostas do avaliando serão gravadas. Estão disponíveis 5 palavras para treino e outras 32 palavras sem tempo para a conclusão.

Informação: nesse subteste avalia-se a memória semântica e conhecimentos gerais, envolve conhecimentos adquiridos a partir da educação escolar e/ou familiar e inteligência cristalizada.

Nesse subteste o participante responderá a 28 questões sobre informações gerais, eventos comuns, objetos, lugares e pessoas. Sem tempo para a conclusão da tarefa.

Códigos: nesse subteste avalia-se a velocidade de processamento e a atenção, envolve a memória visual e requer boa caligrafia.

É solicitado ao participante que utilize uma caneta no modo apresentação do programa para que identifique algumas letras, substituindo-as por símbolos escritos corretamente e de forma individual. O avaliando terá 120 segundos para escrever o maior número de símbolos que conseguir.

Raciocínio Matricial: esse subteste avalia a inteligência fluída e a resolução de problemas. Envolve o processamento da informação visual, capacidade de distinguir os detalhes essenciais e a organização visuoespacial. É considerada uma medida de raciocínio fluído não verbal e habilidade de inteligência geral.

Esse teste é composto de quatro tipos de tarefas de raciocínio não verbal: completar padrões, classificação, analogia e raciocínio serial. O examinando deverá olhar para uma matriz em que está faltando uma parte da figura e deverá apontar ou identificar por meio do número correspondente a parte que completa a matriz entre as 6 ou 8 opções. A tarefa tem dificuldade gradativa e tempo para execução cronometrado.

Dígitos: esse subteste avalia a memória de curto prazo e memória operacional. É solicitado ao avaliando que repita verbalmente uma série de números em ordem direta e outra em ordem inversa. Esse subteste foi substituído por atividades numéricas e matemáticas com a utilização da memória operacional, inteligência cristalizada e fluída. O avaliando terá que responder oralmente sem tempo para o término.

Avaliação de juízes

Nessa avaliação os juízes responderam com sim ou não a 18 perguntas sobre a Escala EPIA, sendo 9 perguntas sobre a aparência e 9 sobre o conteúdo. As perguntas que estão relacionadas à aparência da escala, são por exemplo: a escala oferece instruções pertinentes ao usuário? As imagens são adequadas? Os ícones para voltar e cronometro, estão visíveis? Quanto ao conteúdo, há perguntas como: As tarefas propostas estão pertinentes para uma escala de inteligência? A quantidade de tarefas está suficiente? O conteúdo está compatível com as faixas etárias? Pessoas que tem dificuldade de utilizar um computador, conseguirão jogar? E há espaço para comentários sem número de linhas ou espaço definido.

Vale ressaltar que há atividades cronometradas e outras não, dessa forma, o avaliando será avisado toda vez que a atividade exigir tempo para o término da tarefa.

Procedimento: o projeto foi aprovado pelo Comitê de Ética com Seres Humanos da UMC com o número do parecer:6.855.797.

Foram escolhidas como juízas 5 psicólogas especialistas em avaliação neuropsicológica, que atuam em consultório particular com esse tipo de avaliação e que utilizam de forma constante a escala WAIS-III. Elas foram informadas sobre a Escala EPIA e se disponibilizaram a avaliá-la. Foi entregue o TCLE assinado em duas vias, os termos foram assinados pelas juízas e uma cópia devolvida a elas. Vale ressaltar que os ajustes sugeridos pelas juízas serão acatados.

Desenvolvimento do jogo: o jogo foi desenvolvido no programa *Power Point* inicialmente, com a utilização de ilustrações de aplicativos gratuitos, mesmo assim há autoria das imagens, dessa forma, as imagens foram reconstruídas com o auxílio de inteligência artificial, futuramente o teste será desenvolvido em um site para que o cálculo, tabulação e análise dos resultados de cada subteste fique disponível ao psicólogo aplicador.

IV. Resultados

A escala foi elaborada com o propósito de reduzir a ansiedade do participante durante sua aplicação. Por ser apresentada em formato gamificado e executado no computador, ela adota uma abordagem lúdica e visualmente atrativa. Acredita-se que, dessa forma, o avaliando responderá de maneira mais tranquila, evitando reações comportamentais que possam comprometer os resultados. Além disso, a proposta atende à demanda por informatização e uso de tecnologias, superando os modelos tradicionais com papel e crivos. A escala tem cenários comuns de estabelecimentos como: escola, casa, supermercado, parque e sorveteria que todas as pessoas já utilizaram ou fazem uso, com o intuito de acolher e tranquilizar o avaliando com situações já vivenciadas, por isso também as cores alegres e em estilo de desenho.

Figuras e cenas utilizadas no jogo

Na tela inicial (Figura 1) o avaliando precisará clicar inicialmente em “Como jogar”, assim que clicar será direcionado para a tela 2 (Figura 2) para obter as informações e instruções do jogo, após a leitura retornará para a tela inicial clicando na seta azul à esquerda da tela e teclará “Início”. Na tela 2 o avaliando será instruído para o uso do mouse e das setas para se movimentar no cenário do jogo.

O primeiro subteste Completar Figuras será respondido dentro da casa. Completar Figuras é um subteste que tem como objetivo avaliar a capacidade do participante de perceber detalhes visuais, realizar análise e síntese visual, utilizar a memória semântica visual, manter a atenção e reconhecer elementos essenciais. Também são observados o processamento visual e a velocidade de resposta, já que a atividade é cronometrada. Será solicitado que o participante encontre defeitos nos objetos ou figuras apresentados pelo personagem adulto.

No subteste Completar Figuras o personagem da direita solicita e orienta o avaliando para as tarefas que deverá executar, como por exemplo: “vá até a escola”, ou “vá até o supermercado”.

A seguir, são apresentadas algumas imagens e tarefas incluídas no jogo como atividades propostas aos participantes. Essas imagens fazem parte do subteste "Completar Figuras" (Figura 6), no qual o avaliado deve identificar o que está ausente em cada figura.

Figuras 1 – Tela inicial do teste, Figura, 2 – Instruções para a execução do teste, Figura 3 – Primeiro subteste com a entrada dentro da casa dos personagens e Figura 4 – Personagens

Neste estabelecimento há vários subtestes que precisam ser respondidos pelo avaliando. Assim que o avaliando entra na escola (Figura 7), é recepcionado pelos professores (Figura 8), e orientado para as atividades, como identificar itens que faltam em uma figura, exercícios de matemática e conhecimentos gerais.

Figura 5 – Orientações para o subteste Completar Figuras, Figura 6 – Estabelecimento Supermercado, 7 – Estabelecimento escolar e Figura 8 – Recepção pelos professores.

No subteste Vocabulário, o participante deverá ler palavras e explicar seus significados. Essa tarefa avalia a memória semântica, a competência linguística, o repertório lexical e a capacidade de formular discursos. É considerada uma medida de inteligência cristalizada e inteligência geral.

Já no subteste Aritmética, verifica-se a habilidade do avaliando em resolver problemas matemáticos utilizando a memória operacional. A atividade exige cálculo mental, compreensão dos enunciados e raciocínio lógico, sem o uso de instrumentos auxiliares.

Por fim, o subteste Informação avalia a memória semântica e os conhecimentos gerais adquiridos ao longo da vida escolar e familiar, também relacionados à inteligência cristalizada. Nele, o participante responde a 28 perguntas sobre fatos do cotidiano, objetos, locais, pessoas e eventos, sem limite de tempo para a conclusão.

No ambiente representado pela Figura 9 e 10, o avaliando é conduzido a novos subtestes. Após a apresentação inicial, o personagem orienta o participante quanto às tarefas a serem realizadas, como o subteste Códigos.

O subteste Códigos tem como objetivo avaliar a velocidade de processamento, a atenção, a memória visual e a habilidade motora fina, especialmente a caligrafia. Durante a atividade, o participante deve utilizar uma caneta no modo apresentação do programa para identificar letras e substituí-las por símbolos correspondentes, desenhados de forma correta e individualizada. O tempo disponível para a execução da tarefa é de 120 segundos, período em que o avaliando deve registrar o maior número possível de símbolos.

Figura 9 – Recepção no supermercado, Figura 10 – Estabelecimento sorveteria e personagem da sorveteria

Há outros personagens como a ambulante no parque que também vende sorvetes e solicita que o avaliando realize o subteste Raciocínio Matricial, esse subteste foi desenvolvido para a avaliação da inteligência fluída e da capacidade de resolução de problemas, envolve o processamento de informações visuais, a identificação de detalhes relevantes e a organização visuoespacial. Trata-se de uma medida de raciocínio não verbal e de inteligência geral. O teste é composto por quatro tipos de tarefas: completar padrões, classificação, analogias e raciocínio serial. O participante deve observar uma matriz com uma parte ausente e indicar, por meio do número correspondente, qual das 6 ou 8 opções disponíveis completa corretamente a figura. A atividade apresenta dificuldade progressiva e é realizada com tempo cronometrado.

O subteste Semelhanças é um subteste desenvolvido para a avaliação da capacidade de abstração. Ele envolve o estabelecimento de relações lógicas, a formação de conceitos verbais, o raciocínio verbal abstrato e habilidades intelectuais gerais, incluindo a síntese e integração de conhecimentos. Durante a atividade, o participante deve identificar semelhanças entre pares de palavras que representam objetos ou conceitos, por exemplo, "maçã e banana" ou "meias e sapatos". Ao todo, são apresentados 19 itens, sem limite de tempo para a conclusão. As respostas fornecidas pelo participante são registradas para análise posterior.

Durante o jogo o avaliando será orientado pelos personagens com os objetivos que terá que cumprir, qual personagem procurar para cada etapa do jogo e qual o local para a realização da tarefa. Dessa forma, o psicólogo também poderá avaliar como se comporta o seu paciente durante o jogo, é possível observar se prestou atenção na próxima tarefa e se lembra o que precisará fazer quando chegar ao local estipulado, as dificuldades e facilidades em cada etapa, pois todos os processos cognitivos podem ser avaliados neste jogo e a observação do profissional é importante durante a avaliação.

Avaliação das juízas: foi solicitado a 5 psicólogas especialistas em neuropsicologia que avaliassem o jogo enquanto jogavam, de modo geral as juízas gostaram da ideia de gamificar o teste atualmente utilizado em papel para o formato digital, estão esperançosas para a finalização com a possibilidade de cálculo, tabulação e análise digital, com o intuito de facilitar o trabalho de avaliação dos psicólogos. No quadro 1 há as respostas de todas elas.

QUADRO 1 – RESPOSTAS DAS JUÍZAS SOBRE A ESCALA

Descrição	Sim	Não
Aparência		
A escala oferece instruções pertinentes ao usuário?	5	
As imagens estão suficientes?	5	
As imagens são adequadas?	4	1
Há personagens suficientes?	5	
As setas indicativas para mudança de local no mapa, estão compreensíveis?	5	
Os ícones para voltar e cronômetro, estão visíveis?	5	
As cores são agradáveis?	5	
A quantidade de figuras por tela está adequada?	4	1
Conteúdo		
As tarefas propostas estão pertinentes para uma escala de inteligência?	5	
O nível de execução está de acordo com a proposta?	5	
O nível de complexidade das tarefas foi bem desenvolvido?	5	
A quantidade de tarefas está suficiente?	5	
A execução da ordem das tarefas está adequada?	5	
A quantidade de cenários no mapa para a execução das tarefas está adequada?	5	
O comando para iniciar e parar a gravação da voz está compreensível?	3	2
O conteúdo está compatível com a faixa etária para adultos?	5	
Pessoas que tem dificuldade de utilizar um computador, conseguirão jogar?	3	2
Você sugere a comercialização da escala?	5	

As juízas apontaram que as imagens estão boas, no entanto há algumas setas e hiperlinks que não estavam funcionando apropriadamente e esse fato dificultou a execução dos subtestes no modo apresentação, já ajustado.

Quanto as imagens, consideraram que estão boas. Uma sugeriu a sala com cores mais vibrantes, e outra juíza sugeriu as entradas dos estabelecimentos com a porta um pouco maior para identificar que se pode "entrar" pela porta. E a última sugeriu a entrada da escola "menos poluída", há muitas informações no ambiente.

Quanto ao conteúdo, acharam válida a ideia e a possibilidade de aplicação como teste futuramente, assim que estiverem prontos todos os links e o temporizador. A caneta do *Power Point* no modo apresentação não estava disponível em todas as apresentações, dessa forma, as anotações à caneta não foram possíveis. Sugeriram diminuir a quantidade de exercícios do subteste Raciocínio Matricial que atualmente está com 40 exercícios para 25 a 30 slides no máximo.

Foi aplicado teste Qui quadrado nas respostas das juízas sobre a aparência da EPIA, obtendo que nenhuma das partições apresentou $p < 0.05$, portanto não há associação estatisticamente significativa em nenhuma comparação. O resultado geral confirma que as juízas avaliaram os itens de forma homogênea, sem discrepâncias relevantes entre categorias. Quanto a avaliação do conteúdo da EPIA ($p = 0.0429$) conclui-se que existe associação significativa entre as categorias avaliadas, mas as juízas não avaliaram todos os itens de forma uniforme, há discrepância principalmente nos itens que perguntaram se pessoas sem habilidade com o computador conseguiriam jogar e sobre o ícone gravação de voz que não estava funcionando.

Como a Escala foi desenvolvida em um ambiente gamificado utilizando o *power point* não foi possível substituir alguns subtestes, dessa forma há mais subtestes que avaliam o QI verbal do que o de Execução, dificultando o QI Total, será necessário repensar novos subtestes que complementem a Escala.

A Escala EPIA foi aplicada em duas participantes por enquanto, essa aplicação não estava prevista neste momento e por isso não consta nos objetivos, foi exigência de um parecerista para a aprovação do artigo e a participação no congresso CBEB 2026. Para equilibrar a quantidade de subtestes, foram escolhidos: completar figuras, códigos e raciocínio matricial para o QI Execução e vocabulário, semelhanças e informação para o QI Verbal.

A última pergunta na ficha de avaliação para as juízas: "o teste pode ser comercializável?" Todas responderam afirmativamente.

Próximas etapas da prototipação: a próxima etapa da pesquisa será ajustar a escala de acordo com os apontamentos das juízas, instalando um temporizador, gravador de áudio no programa, elaborar novas atividades como os subtestes que foram excluídos da EPIA em decorrência de utilizar computador, são eles: cubos, procurar símbolos e armar objetos, inserir esse conteúdo em um site para que o avaliando consiga desenhar ou escrever. Assim que os próximos passos estiverem concluídos a aplicação será em outros participantes e os resultados correlacionados com a aplicação da escala WAIS-III. Será necessário avaliar a precisão e o conteúdo novamente após as alterações.

QUADRO 2 – RESPOSTAS DOS PARTICIPANTES COMPARANDO O WAIS-III E A ESCALA EPIA

Subtestes	**Participante 1 – P1**		**Participante 2 – P2**	
	WAIS	**EPIA**	**WAIS**	**EPIA**
Compl. Figuras	21	20	17	18
Vocabulário	36	37	37	41
Códigos	79	3	64	47
Semelhanças	21	26	21	30
Rac. Matricial	16	19	21	19
Informação	13	12	10	14

Os participantes obtiveram resultados semelhantes comparando os resultados brutos da WAIS-III e da Escala EPIA, no entanto, aplicando o teste Shapiro-Wilk obteve-se $p < 0.05$ no P1 e $p > 0.05$ no P2. Utilizou-se correlação de Spearman no P1, a relação é positiva, mas fraca (r 0.11). O valor de p confirma que não há associação real, apenas flutuação aleatória. Essa diferença pode ser devido ao subteste códigos que o P1 apresentou dificuldade com a caneta do *power point*. Para os resultados de P2 foi aplicado correlação de Pearson, (r 0.92), ou seja, os resultados estão associados e de forma linear.

Algumas observações foram anotadas durante a aplicação da Escala EPIA: no subteste vocabulário há algumas palavras complexas antecedendo as mais simples e mais fáceis de definir, que será ajustado. Uma das figuras do subteste completar figuras estava com a imagem escura e os participantes não conseguiram responder e no subteste informação, algumas questões terão que ser revistas, como por exemplo a pergunta: Quem era o presidente dos EUA durante a segunda guerra mundial.

Quanto ao subteste códigos os participantes fizeram utilizando a caneta disponível no *power point*, não foi agradável para os participantes desenharem com a caneta, a pontuação ficou abaixo da pontuação obtida na WAIS devido a dificuldade, futuramente esse subteste será modificado para a aplicação em um tablet com caneta.

A Escala será revista novamente antes da aplicação em novos participantes e não será comercializada antes da aprovação do SATEPSI (Sistema de Avaliação de Testes Psicológicos). Com relação ao conteúdo, precisão e validade da Escala também serão testados e comparados com o nível de dificuldade da WAIS-III.

V. DISCUSSÃO

Atualmente a sociedade está marcada por profundas transformações, impulsionadas pela crescente integração das Tecnologias Digitais de Informação e Comunicação (TDICs) em uma sociedade moldada pela cultura digital. A pandemia acelerou esse processo, evidenciando o valor e a versatilidade dessas tecnologias, que passaram a ocupar um papel central nas práticas educacionais [23].

Os Jogos Sérios aplicados à saúde têm se destacado por sua capacidade de promover mudanças comportamentais e apoiar intervenções clínicas. Entre os oito jogos analisados sete apresentavam finalidade terapêutica, enquanto apenas um tinha foco no desenvolvimento de habilidades específicas. Essa predominância evidencia que o campo tem

direcionado seus esforços para propostas voltadas à modificação de comportamento, ao aprimoramento cognitivo e ao fortalecimento da interação social. Esse cenário converge com a literatura, que reconhece os jogos sérios como ferramentas promissoras para intervenções psicológicas, sobretudo pela capacidade de engajar o usuário, oferecer feedback imediato e permitir a personalização das atividades conforme necessidades individuais. A utilização de jogos sérios na área da saúde corrobora com a proposta da Escala EPIA [24].

Lima (2025) solicitou a avaliação de juízes para o conteúdo de um questionário sobre atitudes de pessoas com deficiência auditiva, os resultados sugerem alta concordância entre os juízes indicando que o instrumento tem potencial para identificar atitudes, crenças e possíveis estigmas relacionados à deficiência auditiva, o que é fundamental para pesquisas e práticas clínicas voltadas à inclusão e ao enfrentamento de barreiras atitudinais. Nesta pesquisa sobre a Escala EPIA os juízes também apontaram concordância quanto ao conteúdo e a aparência, estão faltando outros parâmetros avaliativos como precisão, validade, além de outros detalhes que aparecerão com a aplicação em maior número de participantes antes de aprovação pelo SATEPSI. Os pareceristas solicitaram aplicação em participantes, no entanto, o número só não foi maior devido ao tempo de agendamento de disponibilidade deles [25].

Diante desse cenário, torna-se evidente que a Escala EPIA está preparado para avançar às próximas etapas de validação psicométrica, como análises de constructo e confiabilidade. Essas etapas serão essenciais para consolidar sua aplicabilidade em contextos clínicos e de avalição neuropsicológica.

Selau (2020) construiu um estudo sobre evidências de validade e fidedignidade da escala de funcionamento adaptativo para deficiência intelectual, num primeiro momento a autora destacou a importância dos procedimentos que visaram garantir a validade de conteúdo, cada etapa de construção possibilitou o aprimoramento da escala. Em um segundo momento as análises apresentaram evidências satisfatórias de validade relacionadas a estrutura interna e a variáveis critério, ou seja, o instrumento tem capacidade de mensurar o Funcionamento Adaptativo e indicar prejuízo. Tais evidências atestam o potencial do instrumento em auxiliar no diagnóstico de Deficiência Intelectual [26].

Assim como a Selau desenvolveu seu estudo e solicitou a avaliação de juízes e participantes, neste estudo a Escala EPIA também passará por análises mais rigorosas. As juízas já avaliaram a validade de conteúdo, dizendo que a Escala EPIA representa adequadamente o construto que se pretende avaliar, no entanto, nem todos os subtestes foram desenvolvidos, dessa forma, uma nova avaliação por juízes será realizada quando as etapas estiverem prontas. Segundo a American Psychological Association, a validade de conteúdo constitui uma evidência essencial para demonstrar que o instrumento mede aquilo que se propõe a medir, sendo indispensável nas fases iniciais de desenvolvimento de testes psicológicos [27].

A Escala EPIA deverá ser avaliada quanto a precisão, esta etapa é essencial para garantir que os resultados obtidos não sejam fruto de acaso ou instabilidade, mas sim reflexo real do construto avaliado. Conforme a AERA, APA e NCME (2014), instrumentos psicológicos devem apresentar evidências robustas de precisão para serem considerados adequados ao uso clínico e científico [28].

Ambas são etapas indispensáveis para que um teste psicológico seja considerado cientificamente confiável e eticamente aplicável.

Joly et al (2004) [29] já apontavam para o avanço da informatização na avaliação psicológica e a consolidação no cenário nacional e internacional. Acreditam que essa evolução tecnológica traz benefícios práticos e econômicos à atuação profissional, ao eliminar a necessidade de materiais físicos como lápis, papel e manuais impressos, além de otimizar o tempo e reduzir significativamente os erros de mensuração. Ao incorporar os recursos da psicometria moderna, garante-se maior confiabilidade dos instrumentos sem comprometer a validade ou a precisão dos resultados.

Com a perspectiva de que esse novo formato permitirá a aplicação de testes mais dinâmicos e complexos, envolvendo estímulos visuais, sonoros, tempo de reação e respeito à diversidade cultural, Joly e colaboradores estruturaram seu texto com o objetivo de estimular novas pesquisas e promover a internacionalização da avaliação psicológica informatizada, explorando todo o potencial que a tecnologia oferece para compreender os fenômenos e processos do comportamento humano [13].

Diante do que foi apresentado, é possível reconhecer os benefícios do uso das tecnologias nas áreas da educação, saúde e, em especial, da psicologia. Embora a psicologia esteja inserida no campo da saúde, ela recebe destaque neste contexto por ser o foco específico da pesquisa e a área de formação da autora. Enquanto alguns estudiosos ressaltam as vantagens dessas ferramentas, outros alertam para os cuidados necessários, a fim de evitar possíveis impactos negativos aos usuários. Existem, inclusive, pesquisas que propõem estratégias para minimizar esses riscos. No que diz respeito à aplicação e avaliação de indivíduos por meio de tecnologias, trata-se de uma tendência irreversível e voltada para o futuro.

VI. Considerações Finais

A Escala EPIA foi elaborada com base nos objetivos do projeto, utilizando o programa *PowerPoint* como plataforma de desenvolvimento. Baseada na Escala Wechsler de Inteligência para Adultos (WAIS-III), a EPIA incorporou elementos compatíveis com os recursos disponíveis no software. No entanto, três subtestes da WAIS-III não puderam ser reproduzidos ou adaptados devido às limitações técnicas do *PowerPoint*. Pretende-se futuramente desenvolver os subtestes retirados contanto que avaliem os mesmos construtos em um tablet de forma precisa.

Durante o processo de validação inicial, cinco juízas especializadas foram convidadas a avaliar o protótipo. Elas ofereceram críticas construtivas e sugestões com vistas ao aprimoramento da escala para futura comercialização. Entre os pontos destacados, mencionaram problemas com links, dificuldades no uso da caneta durante o modo apresentação, excesso de estímulos na recepção da escola, ausência de cores na sala de estar e sobrecarga de tarefas no subteste de raciocínio matricial.

As recomendações das juízas estão sendo realizadas, no entanto há as próximas etapas da prototipação que incluem a migração da escala para uma plataforma online, a

implementação de um temporizador e a aplicação do instrumento em número maior de participantes, conforme previsto no projeto.

A aplicação em dois participantes foi importante para observar o recurso lúdico e agradável da EPIA, no entanto, há ajustes a serem realizados.

A Escala EPIA não será oferecida para comercialização sem apresentar resultados satisfatórios de conteúdo e precisão e ser aprovada como favorável no SATEPSI.

Considerando que psicólogos frequentemente utilizam testes em sessões psicoterapêuticas, é importante destacar que as Escalas Wechsler apresentam custos elevados, o que dificulta o acesso à avaliação e ao diagnóstico. Nesse contexto, uma escala informatizada e acessível pode representar uma solução viável, promovendo maior agilidade na aplicação e na obtenção de resultados, especialmente em serviços-escola e clínicas. Além disso, essa proposta configura uma inovação científica ao substituir o método tradicional de tabulação manual por um sistema automatizado, facilitando a análise e interpretação por parte dos profissionais.

***Abstract*—Deep learning models have achieved excellent performance in retinal optical coherence tomography (OCT) image classification. However, overall performance metrics may provide an overly optimistic assessment when datasets are imbalanced, potentially masking poor recognition of clinically relevant minority classes. This study investigated the impact of class imbalance on OCT classification using an InceptionV3 model with transfer learning trained on the CNV, DME, DRUSEN, and NORMAL classes of the OCT2017 dataset. Two training strategies were compared: the original imbalanced dataset and an imbalance-mitigation approach combining offline augmentation of minority classes with class weighting. Although the model trained on the imbalanced dataset achieved high overall accuracy (94.0%), class-wise analysis revealed substantially lower recall for the DRUSEN class (84.8%), with frequent misclassification as CNV. In contrast, the imbalance-mitigation strategy increased overall accuracy to 96.1% and improved recall for the DME and DRUSEN classes to 96.0% and 94.4%, respectively, markedly reducing systematic confusion with CNV. The paired comparison of the 1,000 test predictions using the exact McNemar test showed that the difference between the models was statistically significant (p = 0.0055). These findings demonstrate that high overall performance metrics may conceal clinically important classification errors and underscore the importance of reporting class-wise performance measures, including precision, recall, F1-score, and confusion matrices, to ensure the reliable evaluation of deep learning models intended for diagnostic support.**

***Index Terms*—optical coherence tomography, deep learning, convolutional neural network, class imbalance, InceptionV3**

I. Introduction

Convolutional Neural Networks (CNNs) have achieved strong performance in medical image classification by learning discriminative features directly from imaging data, reducing the need for handcrafted feature extraction and supporting computer-aided diagnosis [1], [2]. Transfer learning with pre-trained CNNs is particularly effective for limited or complex medical datasets because it accelerates convergence while preserving high classification performance [1], [3].

Optical Coherence Tomography (OCT) is a primary non-invasive modality for retinal diagnosis, providing high-resolution cross-sectional images of retinal structures [4]. Deep learning has therefore been widely applied to classify choroidal neovascularization (CNV), diabetic macular edema (DME), drusen, and normal retina [3], [5], [6]. InceptionV3-based models have achieved accuracies between 96.6% and 98.4% on the OCT2017 dataset [7], depending on the experimental protocol and data partitioning strategy [2], [4], [8].

Despite these results, reliance on overall accuracy may provide an overly optimistic assessment when the dataset is imbalanced. In OCT2017, CNV and NORMAL contain substantially more images than DME and DRUSEN [7], potentially biasing optimization toward the majority classes. Consequently, high global accuracy may conceal poor recognition of under-represented diseases and clinically relevant errors [9]. Class-specific precision, recall, F1-score, and confusion matrices are therefore necessary to reveal performance differences among retinal categories.

Data augmentation, class weighting, and undersampling have been proposed to mitigate class imbalance [9]–[12]. Previous OCT studies have applied these strategies to transfer-learning architectures such as InceptionV3 and Xception, generally reporting high global and class-wise performance [13], [14]. However, many relied exclusively on balanced datasets or mitigation techniques [13], [15], without directly quantifying how the original OCT2017 distribution affects class-specific results. Thus, the extent to which imbalance inflates global metrics and reduces minority-class recognition remains insufficiently investigated [9], [16].

This study addresses this gap by comparing two InceptionV3 models under identical experimental conditions: one trained with the original OCT2017 distribution and another using offline data augmentation and class weighting. The objective is to determine whether global metrics conceal minority-class errors and whether imbalance mitigation improves without substantially compromising CNV and NORMAL performance. The comparison of global and class-specific metrics highlights the importance of class-wise evaluation for reliable OCT-based diagnostic support.

The remainder of this paper is organized as follows. Sec-

tion II describes the dataset, network architecture, imbalance-mitigation strategies, training configuration, and evaluation protocol. Section III presents the training behavior and classification results. Section IV discusses the main findings, clinical implications, and study limitations. Finally, Section V summarizes the conclusions and outlines directions for future work.

II. Methods

This section describes the experimental methodology adopted to evaluate the influence of class imbalance on retinal OCT image classification. The proposed protocol was designed to ensure a controlled comparison between two InceptionV3-based models: one trained using the original imbalanced distribution of the OCT2017 dataset and another trained with offline data augmentation and class weighting. Both models used the same image preprocessing pipeline, network architecture, optimizer, learning rate, loss function, and independent test set, so that differences in performance could be attributed primarily to the imbalance-mitigation strategy.

The following subsections present the OCT2017 dataset and data partitioning procedure, the InceptionV3 architecture and transfer-learning configuration, the strategies used to mitigate class imbalance, the model training parameters, and the evaluation protocol. Performance was assessed using global and class-specific metrics, confusion matrices, and ROC-AUC analysis, with particular attention to the underrepresented DME and DRUSEN classes.

A. Dataset

This study used the publicly available OCT2017 dataset from the Mendeley Data repository [7]. The dataset comprises retinal OCT images organized into four categories: CNV, DME, DRUSEN, and normal retina. The original training set is markedly imbalanced, containing 37,205 CNV images, 26,315 NORMAL images, 11,348 DME images, and 8,617 DRUSEN images. Consequently, CNV and NORMAL are the majority classes, whereas DME and DRUSEN are substantially underrepresented [7].

To ensure a fair comparison between the model trained on the original OCT2017 class distribution and the model trained using data augmentation and class weighting, both models were evaluated using the same independent test set. Consequently, any differences in classification performance could be attributed to the training strategy rather than to differences in the evaluation data. The test partition comprised 1,000 images equally distributed across the four categories (250 images per class). As reported by the original dataset authors, the test images were obtained from patients who were not represented in the training partition [6], ensuring complete patient-level separation between the original training and test sets.

The original OCT2017 training set was further divided into training and validation subsets. Patient identifiers were not available in the released training data; therefore, patient-level separation between these two subsets could not be guaranteed. The independent test set remained completely isolated from this partitioning procedure and, as reported by [6], contained images from patients not represented in the original training set. All images were loaded as three-channel inputs and resized to 299×299 pixels, corresponding to the input size required by the InceptionV3 architecture [17]. Before being fed into the network, the images were preprocessed using the InceptionV3-specific preprocessing function with ImageNet-pretrained weights [18].

B. Architecture and Transfer Learning

The experiments were conducted using the InceptionV3 architecture, originally developed for image recognition and characterized by Inception modules that perform convolutional operations at multiple scales [17]. A transfer learning strategy was adopted by initializing the network with ImageNet-pretrained weights [19], [20]. The convolutional base was loaded without its original classification layers and kept frozen during training to serve as a feature extractor. This approach enables the reuse of representations learned from large-scale image datasets while adapting the classifier to the OCT classification task [20], [21]. A global average pooling layer was added to the output of the convolutional base, followed by a dense layer with four neurons and a Softmax activation function [19]. Each output neuron corresponded to one of the four classes: CNV, DME, DRUSEN, and NORMAL.

C. Strategies for Mitigating Class Imbalance

Two experimental scenarios were evaluated. In the first, referred to as the imbalanced model, InceptionV3 was trained using the original OCT2017 training set without applying any techniques to compensate for class imbalance. This scenario served as the reference model and replicated the methodology proposed in [6].

In the second scenario, referred to as the imbalance-mitigated model, offline data augmentation was applied to the minority classes (DME and DRUSEN). The augmented images were generated before training, stored on disk, and added to the original training set. The training-validation split was performed subsequently by the image generators over this augmented training set. Consequently, images derived from the same original image may have been assigned to the training and validation subsets. Each image was created from a randomly selected original image and subjected to a random combination of geometric transformations. Data augmentation included rotations of up to $15°$, horizontal and vertical translations of up to 10% of the image dimensions, and horizontal flipping. Regions introduced by these transformations were filled using the nearest-neighbor interpolation method. During this process, all augmented images were resized to 256×256 pixels and saved in JPEG format. The procedure was repeated until the predefined numbers of additional DME and DRUSEN images were generated. The objective was not to equalize the number of samples across all classes, but to reduce the representation gap of the minority classes. Moderate geometric transformations were deliberately adopted to introduce variability while avoiding excessively

aggressive modifications that could substantially distort the original retinal structures.

In addition to data augmentation, class weighting was applied during training of the imbalance-mitigated model. After splitting the data into training and validation subsets, class weights were computed automatically from the class frequencies in the training subset using the `compute_class_weight` function from the scikit-learn library [22] with the parameter `class_weight = balanced`.

The weight assigned to each class was calculated as

$$w_j = \frac{n_{\text{samples}}}{n_{\text{classes}} \cdot n_j}, \tag{1}$$

where w_j denotes the weight assigned to class j, n_{samples} is the total number of training samples, n_{classes} is the number of classes, and n_j is the number of training samples belonging to class j.

Consequently, classes with lower frequencies received higher weights during loss computation, increasing the contribution of their errors to the optimization process. The two models used the same image preprocessing pipeline, feature extraction procedure, network architecture, optimizer, learning rate, loss function, validation proportion, and independent test set. The imbalanced model preserved the original training protocol adopted in the reference study [6], whereas the imbalance-mitigated model additionally used early stopping to reduce unnecessary training once validation loss ceased to improve. In both scenarios, the final weights corresponded to the epoch with the lowest validation loss observed during training. Nevertheless, because early stopping was applied only to the imbalance-mitigated model, the comparison presented in this study is between two complete training protocols rather than between two conditions differing in a single factor.

D. Training Configuration

The models were trained using the Adam optimizer [23] with a learning rate of 0.001 and the categorical cross-entropy loss function, which is appropriate for multiclass classification with Softmax output [19]. The training and validation generators used a batch size of 32 images. During testing, images were processed individually (batch size = 1) without shuffling to preserve the correspondence between image order, ground-truth labels, and model predictions.

For both the imbalanced and imbalance-mitigated models, 20% of the training images were reserved for validation, whereas the remaining 80% were used for model training. This split was implemented using the 'validation_split = 0.2' parameter of the image generators.

In the imbalanced scenario, the model was trained for 100 epochs while preserving the original OCT2017 class distribution, following the protocol described in the reference study [6]. Training and validation accuracy and loss were monitored throughout the training process. A model checkpoint monitored the validation loss and saved the weights corresponding to its minimum value, which were subsequently used for test-set evaluation.

In the imbalance-mitigated scenario, training was performed for up to 100 epochs. Validation loss was monitored using both models checkpointing and early stopping, with a patience of 15 epochs and restoration of the best model weights. The checkpoint preserved the weights associated with the lowest validation loss for final evaluation.

Training and validation accuracy and loss curves were analyzed to assess model convergence. The final comparison was performed exclusively between the imbalanced and imbalance-mitigated models using the same independent test set.

E. Evaluation Protocol

Model performance was evaluated using the same independent test set described previously, comprising 1,000 images equally distributed across the four classes. Performance was assessed using both overall accuracy and class-specific metrics. Precision, recall, and F1-score were calculated for each class. Recall represents the proportion of correctly identified images within a given class, whereas precision represents the proportion of correct predictions among all predictions assigned to that class. The F1-score was computed as the harmonic mean of precision and recall.

Macro- and weighted-average metrics were also calculated. The macro average assigns equal importance to all classes regardless of class size, whereas the weighted average accounts for the number of samples in each class. Because the test set was balanced, both averages produced identical or nearly identical values.

Absolute and normalized confusion matrices were used to identify the main patterns of misclassification. Receiver operating characteristic (ROC) curves were generated using the one-vs-rest approach, and the area under the curve (AUC) was calculated for each class as well as for the micro and macro averages. The macro-AUC was computed as the arithmetic mean of the class-specific AUC values.

The comparison between the two models included overall accuracy, class-wise precision, recall, F1-score, macro-F1, weighted F1-score, confusion matrices, and AUC. Ninety-five percent confidence intervals for overall accuracy and for class-wise recall were computed using the Wilson score interval. Because both models were evaluated on the same 1,000 test images, their paired classification outcomes were additionally compared using the exact two-sided McNemar test. The test was based on the discordant cases in which only one of the two models correctly classified a given image, with statistical significance defined at $p < 0.05$. Particular attention was given to discrepancies between global and class-specific performance, especially for DME and DRUSEN, which were underrepresented in the original training set. The analysis also evaluated whether imbalance mitigation strategies improved the recognition of these classes without substantially compromising the performance of CNV and NORMAL.

III. Results

This section presents the experimental results for the imbalanced and imbalance-mitigated models. It begins with the final

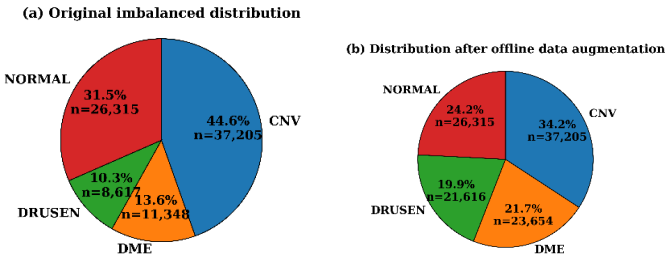

Fig. 1. Class distribution before and after imbalance mitigation: (a) original imbalanced distribution and (b) distribution after offline augmentation of the DME and DRUSEN classes.

distribution of the training data after applying the imbalance-mitigation strategy, followed by an analysis of the training behavior of both models based on the learning curves. The performance of each model is then evaluated on the independent test set using overall and class-specific metrics, followed by a comparative analysis to assess the impact of the imbalance mitigation strategies on classification performance.

A. Final Distribution of the Training Data

Figure 1 compares the original imbalanced training distribution with the distribution obtained after offline data augmentation. The original dataset retained the OCT2017 class distribution, whereas offline data augmentation increased the DME and DRUSEN classes to 23,654 and 21,616 images, respectively, while the CNV and NORMAL classes remained unchanged. In total, 12,306 DME images and 12,999 DRUSEN images were generated through data augmentation. After augmentation, the ratio between the largest class (CNV, 37,205 images) and the smallest class (DRUSEN, 21,616 images) was approximately 1.72:1. Thus, the procedure reduced the original class imbalance but did not produce a numerically uniform class distribution.

B. Training Behavior

1) Imbalanced Model: Figures 2a and 2b show the training and validation accuracy and loss, respectively, over 100 training epochs for the imbalanced model. In both figures, the blue and orange curves represent the training and validation subsets, respectively. During the initial training stage, accuracy increased rapidly, from 83.45% to approximately 89% for the training subset and from 86.08% to approximately 88% for the validation subset. Over the same period, training and validation losses decreased from 0.4635 to approximately 0.30 and from 0.3946 to approximately 0.32, respectively.

After this initial phase, the learning curves became more stable. Training accuracy continued to increase gradually, whereas validation accuracy remained predominantly between 88% and 89%. The highest validation accuracy (89.14%) was achieved at epoch 54, whereas the lowest validation loss (0.3079) was observed at epoch 63. Because validation loss was used as the model selection criterion, the weights obtained at epoch 63 were selected for the final evaluation on the test

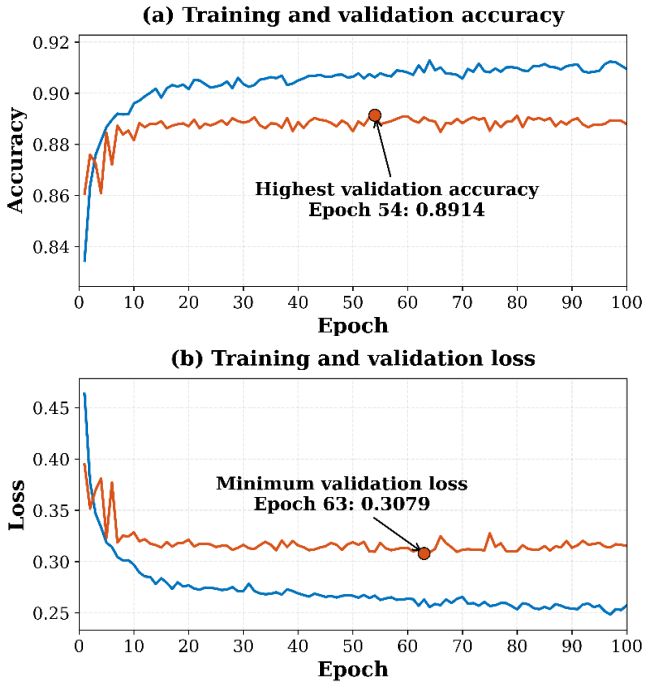

Fig. 2. Training and validation accuracy and loss of the imbalanced model over 100 epochs: (a) accuracy and (b) loss.

set. During the remaining epochs, validation loss fluctuated without further sustained improvement.

At the end of training, the model achieved accuracies of 90.95% and 88.79% on the training and validation subsets, respectively, with corresponding losses of 0.2574 and 0.3153. Overall, the learning curves indicate rapid convergence during the initial training stage, followed by stable validation performance throughout the remainder of training.

2) Imbalance-Mitigated Model: Figures 3a and 3b illustrate the training and validation accuracy and loss, respectively, over the 36 training epochs of the imbalance-mitigated model, with the blue and orange curves representing the training and validation subsets. During the initial epochs, model performance improved rapidly, with training accuracy increasing from 85.02% during the first epoch to above 90% by the fifth epoch. Validation accuracy increased from 77.48% to 84.11% by epoch 7, whereas training and validation losses decreased from 0.4272 to 0.2780 and from 0.5931 to 0.4459, respectively.

After this initial phase, training accuracy improved steadily, reaching 91.92% at epoch 36, whereas validation accuracy exhibited greater fluctuations. The highest validation accuracy (84.40%) and the lowest validation loss (0.4389) were reached at epoch 21. Thereafter, validation loss fluctuated without further improvement.

Because validation loss did not improve over the subsequent 15 epochs, training was terminated at epoch 36 by the early stopping criterion. As specified by the training configuration, the weights corresponding to the lowest validation loss at epoch 21 were restored automatically and used for the final evaluation on the test set. Overall, the learning curves indicate continuous

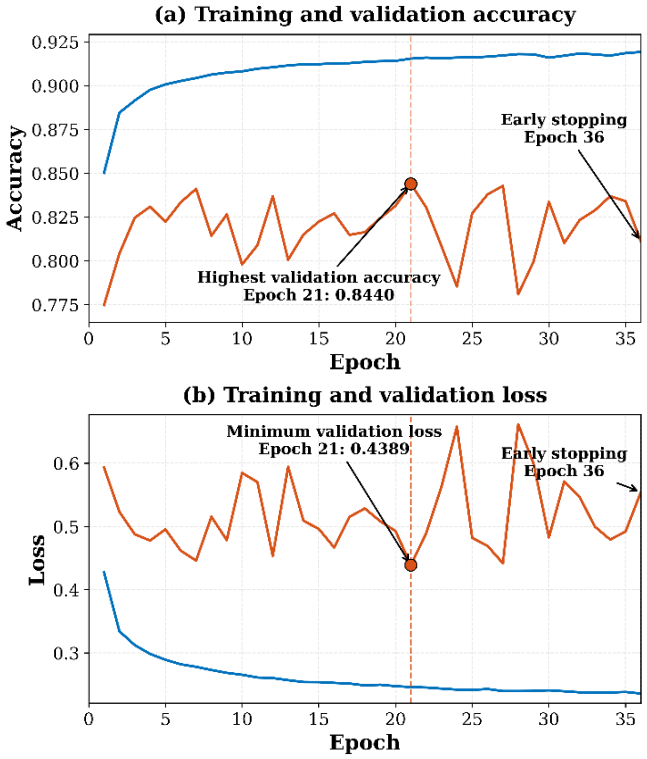

Fig. 3. Training and validation accuracy and loss of the imbalance-mitigated model over 36 epochs: (a) accuracy and (b) loss.

improvement in training performance, accompanied by greater variability in the validation subset throughout the remainder of training.

C. Performance of the Imbalanced Model on the Test Set

The imbalanced model achieved an overall accuracy of 94.00% on the test set. Because the test set contained 250 images per class, the macro and weighted averages were identical, yielding a precision of 94.73%, a recall of 94.00%, and an F1-score of 94.04%.

Despite the high overall accuracy, class-wise analysis showed that performance was not uniform across the four classes. For the CNV class, the model achieved a precision of 83.16%, a recall of 98.80%, and an F1-score of 90.31%. The corresponding values for DME were 98.72%, 92.40%, and 95.45%, respectively. DRUSEN achieved a precision of 98.60%, a recall of 84.80%, and an F1-score of 91.18%, representing the lowest recall among the four classes. For the NORMAL class, the model achieved a precision of 98.43%, a recall of 100%, and an F1-score of 99.21%.

Figure 4 presents the confusion matrices for the imbalanced model, with the absolute matrix on the left and the normalized matrix on the right. According to the absolute confusion matrix, 247 of the 250 CNV images were correctly classified, whereas two were misclassified as DME and one as DRUSEN. Among the DME images, 231 were correctly classified, while 13 were misclassified as CNV, two as DRUSEN, and four as NORMAL. For the DRUSEN class, 212 images were correctly classified,

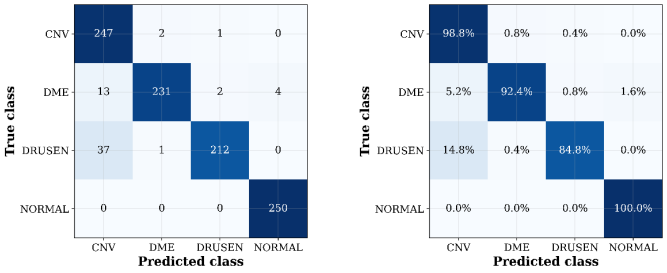

Fig. 4. Confusion matrices of the imbalanced model on the test set: absolute confusion matrix (left) and normalized confusion matrix (right).

37 were misclassified as CNV, and one as DME. All 250 NORMAL images were correctly classified.

The predominant error pattern was the misclassification of DRUSEN images as CNV, affecting 14.8% of the samples in this class. DME images were also misclassified as CNV in 5.2% of cases. These findings indicate that the high overall accuracy did not translate into uniform performance across the four classes, primarily because of the lower recall for DRUSEN.

Discriminative performance was also evaluated using one-vs-rest ROC analysis. The AUC values were 0.9975 for CNV, 0.9977 for DME, 0.9970 for DRUSEN, and 0.9993 for NORMAL. The micro-AUC was 0.9955, whereas both the macro- and weighted-average AUCs were 0.9979. These results indicate excellent overall discriminative performance; however, the confusion matrices reveal that classification errors persisted between specific classes.

D. Performance of the Imbalance-Mitigated Model on the Test Set

The imbalance-mitigated model was evaluated using the independent test set of 1,000 images, equally distributed among CNV, DME, DRUSEN, and NORMAL. It achieved an overall accuracy of 96.10%, with relatively uniform performance across all classes.

Figure 5 presents the confusion matrices of the imbalance-mitigated model, with the absolute matrix on the left and the normalized matrix on the right. According to the absolute confusion matrix, the model correctly classified 238 CNV, 240 DME, 236 DRUSEN, and 247 NORMAL images. Among the CNV images, eight were misclassified as DME and four as DRUSEN. Among the DME images, two were misclassified as CNV, three as DRUSEN, and five as NORMAL. Among the DRUSEN images, 13 were misclassified as CNV and one as DME. Among the NORMAL images, three were misclassified as DRUSEN.

Class-specific metrics were consistently high. For CNV, precision, recall, and F1-score were 94.07%, 95.20%, and 94.63%, respectively. The corresponding values were 96.39%, 96.00%, and 96.19% for DME; 95.93%, 94.40%, and 95.16% for DRUSEN; and 98.02%, 98.80%, and 98.41% for NORMAL. Because the test set was balanced, macro precision, macro recall, macro-F1, and weighted F1-score were all 96.10%.

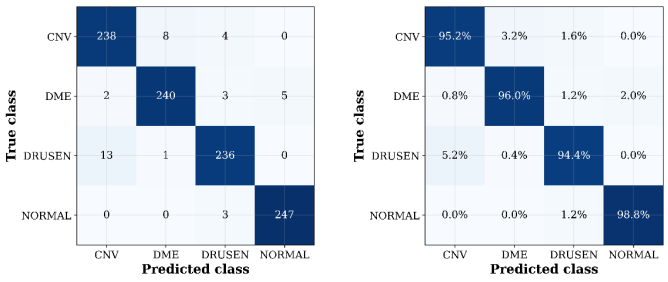

Fig. 5. Confusion matrices of the imbalance-mitigated model on the test set: absolute confusion matrix (left) and normalized confusion matrix (right).

Discriminative performance was further evaluated using one-vs-rest ROC analysis. The AUC values were 0.9952 for CNV, 0.9960 for DME, 0.9964 for DRUSEN, and 0.9986 for NORMAL. The micro-AUC was 0.9970, while the macro- and weighted-average AUCs were both 0.9966.

Overall, the imbalance-mitigated model achieved an accuracy and macro-F1 score of 96.10%, with AUC values above 0.995 for every class. Although DRUSEN had the lowest recall, its F1-score remained high at 95.16%. These results indicate that the imbalance-mitigation strategy promoted more uniform classification performance without compromising overall accuracy.

E. Comparison Between the Imbalanced and Imbalance-Mitigated Models

Both models were evaluated using the same independent test set of 1,000 images, equally distributed among CNV, DME, DRUSEN, and NORMAL. Therefore, performance differences can be attributed to the imbalance-mitigation strategy rather than to variations in the evaluation data.

The main global performance metrics improved consistently. Accuracy increased from 94.00% for the imbalanced model to 96.10% for the imbalance-mitigated model. Macro-F1 increased from 94.04% to 96.10%, while macro precision and macro recall increased from 94.73% and 94.00% to 96.10%, respectively. The weighted F1-score showed a similar improvement, indicating more uniform performance across the four classes. The 95% confidence intervals for overall accuracy were 92.35–95.31% for the imbalanced model and 94.71–97.13% for the imbalance-mitigated model. The corresponding intervals for class-wise recall were 96.53–99.59% and 91.80–97.23% for CNV, 88.44–95.08% and 92.79–97.81% for DME, 79.83–88.72% and 90.82–96.64% for DRUSEN, and 98.49–100.00% and 96.53–99.59% for NORMAL. The paired analysis of the 1,000 test images identified 53 discordant predictions between the two models. Among these, 37 images were incorrectly classified by the imbalanced model but correctly classified by the imbalance-mitigated model, whereas 16 showed the opposite pattern. The exact two-sided McNemar test indicated a statistically significant difference between the classifiers ($p = 0.0055$).

Both models achieved high AUC values. The micro-AUC increased from 0.9955 to 0.9970, whereas the macro-AUC changed slightly from 0.9979 to 0.9966. This difference arises because AUC measures discrimination across multiple thresholds, whereas accuracy, recall, and F1-score reflect performance at the selected classification threshold. Thus, despite the small reduction in macro-AUC, the imbalance-mitigated model achieved better global and class-specific performance.

The class-wise recall values differed markedly between the two models. For the imbalanced model, recall was 98.80% for CNV, 92.40% for DME, 84.80% for DRUSEN, and 100.00% for NORMAL. After applying the imbalance-mitigation strategies, the corresponding values were 95.20%, 96.00%, 94.40%, and 98.80%.

The largest gain occurred for DRUSEN, whose recall increased by 9.60 percentage points. DME recall increased by 3.60 points, whereas CNV and NORMAL recall decreased by 3.60 and 1.20 points, respectively. Nevertheless, recall remained above 95% for both majority classes, showing that improved minority-class recognition did not substantially compromise their performance.

The confusion matrices support this result. DRUSEN images misclassified as CNV decreased from 37 cases (14.80%) to 13 (5.20%), while DME-to-CNV errors decreased from 13 to two. The imbalance-mitigation strategy reduced the tendency of the imbalanced model to assign minority-class images to CNV, the largest training class.

The same trend was observed for the class-wise F1-scores. The F1-score increased from 90.31% to 94.63% for CNV, from 95.45% to 96.19% for DME, and from 91.18% to 95.16% for DRUSEN. For NORMAL, it decreased slightly from 99.21% to 98.41%.

The increase in the CNV F1-score, despite its lower recall, resulted from the improvement in precision from 83.16% to 94.07%. Fewer DME and DRUSEN images were incorrectly classified as CNV, reducing false positives and making CNV predictions more reliable.

Overall, the imbalance-mitigation strategy produced more uniform performance across all classes. It improved DME and DRUSEN recognition, reduced systematic confusion with CNV, and increased accuracy and macro-F1 without substantially compromising CNV and NORMAL. These results show that global metrics alone may conceal clinically relevant class-specific errors and reinforce the importance of class-wise evaluation in imbalanced medical image classification.

IV. Discussion

The InceptionV3 model trained with the original OCT2017 distribution achieved 94.0% accuracy and a macro-F1 score of 94.04%. However, DRUSEN recall was only 84.8%, demonstrating that strong global metrics may conceal clinically relevant weaknesses in underrepresented classes. Therefore, accuracy should be interpreted together with class-specific precision, recall, F1-score, and confusion matrices.

The confusion matrices showed that the imbalanced model most frequently misclassified DRUSEN as CNV, with the same tendency observed for DME to a lesser extent. Because CNV

and NORMAL were the largest classes, they exerted greater influence during optimization and shifted decision boundaries toward the majority classes. Minority diseases consequently became more difficult to distinguish, particularly when their imaging characteristics overlapped with CNV. Similar results were reported in [5], where a fusion model achieved 98.7% accuracy and 99.1% AUC but still identified DRUSEN as the most difficult class because of its limited representation and structural similarity to CNV. Likewise, [24] showed that aggregate metrics may hide clinically important class-specific deficiencies.

To mitigate this effect, offline data augmentation was combined with class weighting, improving minority-class representation without discarding original images. Accuracy increased from 94.0% to 96.1%, while DRUSEN recall rose from 84.8% to 94.4% and DME recall from 92.4% to 96.0%. This improvement was also supported by the paired statistical analysis. Among the 53 test images for which the models disagreed in correctness, the imbalance-mitigated model corrected 37 errors made by the imbalanced model, whereas the reverse occurred in 16 cases. The exact McNemar test confirmed that this asymmetry was statistically significant ($p = 0.0055$). The gains in macro recall and macro-F1 indicate a more uniform distribution of performance across the four retinal categories.

The confusion matrices further confirmed the reduction in majority-class bias. DRUSEN-to-CNV errors decreased from 37 cases (14.8%) to 13 (5.2%), while DME-to-CNV errors fell from 13 to two. Although CNV recall declined from 98.8% to 95.2%, its precision increased from 83.16% to 94.07%, raising the CNV F1-score from 90.31% to 94.63%. Thus, the modest decrease in sensitivity was offset by a substantial reduction in false-positive CNV predictions, illustrating why precision, recall, and F1-score should be interpreted jointly. Considering recall alone would favor the model trained on the original class distribution, whereas the combined metrics show that the imbalance-mitigated model produced more dependable predictions by substantially reducing false-positive classifications.

Unlike undersampling strategies, such as that evaluated in [24], the proposed approach reduced imbalance without removing original training images, which is relevant in medical imaging because annotated data are costly and difficult to obtain. The imbalance-mitigated model also produced results consistent with previous OCT2017 transfer-learning studies. Adel et al. [13], for example, reported accuracies between 93% and 98% for balanced InceptionV3 and Xception models. However, the present study compared the original distribution with the distribution obtained after imbalance mitigation under identical architectural, preprocessing, and testing conditions. Therefore, the observed improvements can reasonably be attributed to the imbalance-mitigation strategy rather than to classifier modifications.

From a clinical perspective, reducing false-positive CNV predictions may prevent DME and DRUSEN cases from being incorrectly assigned to CNV, potentially avoiding unnecessary referrals, additional examinations, and inappropriate management. Recall remained above 95% for CNV and NORMAL, while the largest gains occurred for DME and DRUSEN. This redistribution is advantageous for clinical decision-support systems, where consistent recognition across diseases is more important than maximizing performance for the most frequent categories.

The ROC results should also be interpreted together with threshold-dependent metrics. Both models achieved AUC values above 0.99 for all classes, yet the imbalanced model concentrated errors in minority categories. AUC measures ranking performance across several decision thresholds, whereas accuracy, precision, recall, and F1-score describe performance at the selected operating point. Consequently, ROC curves alone are insufficient to characterize multiclass medical classifiers and should be analyzed together with confusion matrices and class-wise metrics.

The lower validation accuracy of the imbalance-mitigation model compared with its test accuracy does not necessarily indicate overfitting. The validation subset preserved the distribution produced after augmentation, whereas the independent test set contained equal numbers of images from each class. Because these datasets followed different distributions, their metrics are not directly comparable. Moreover, model selection based on minimum validation loss, early stopping, and restoration of the best weights reduced the likelihood of overfitting.

This study has three main limitations. First, it was restricted to OCT2017, so the findings may not generalize to images acquired with different devices, protocols, institutions, clinical settings, or patient populations. External multicenter validation is therefore required. Second, data augmentation and class weighting were applied simultaneously, preventing individual contributions from being isolated. Third, the validation subset of the imbalance-mitigated model was defined after offline data augmentation. Images derived from the same original image may therefore have been assigned to both the training and the validation subsets, and patient identifiers were not available to enforce patient-level separation between them. This limitation is restricted to the selection of the final weights by validation loss and to the early stopping criterion, since no reported performance metric was computed on the validation subset. All results reported in this study were obtained on the independent test set, which contained no augmented images and, as reported in [6], comprised images from patients not represented in the original training set. Future ablation studies should evaluate these techniques separately and compare them with undersampling, oversampling, focal loss, class-balanced loss, and cost-sensitive learning. Generative adversarial networks and diffusion models could also be investigated for minority-class synthesis, together with probability calibration and optimized decision thresholds.

The purpose of this study was not to maximize accuracy through increasingly complex architectures, but to determine how class imbalance affects model evaluation. The results show that excellent aggregate performance may still conceal systematic deficiencies in clinically important minority classes.

Therefore, a classifier with more balanced recognition across diseases may be preferable to one with slightly higher global performance but persistent errors in underrepresented categories.

Overall, class imbalance produced not only a modest reduction in accuracy, but also a systematic bias against minority retinal diseases. Combining offline augmentation with class weighting improved their recognition while preserving high global performance. These findings reinforce the importance of class-wise evaluation and imbalance mitigation in clinically reliable deep learning systems for retinal OCT classification.

V. Conclusions and Future Works

This study evaluated class imbalance in retinal OCT classification using two InceptionV3 models trained under identical conditions. The imbalanced model achieved 94.0% accuracy and a macro-F1 score of 94.04%, but DRUSEN recall was only 84.80%, with 14.80% of its images misclassified as CNV. This result shows that high global performance can conceal systematic errors in minority classes.

Combining offline data augmentation with class weighting increased accuracy and macro-F1 to 96.10%. Recall improved from 92.40% to 96.00% for DME and from 84.80% to 94.40% for DRUSEN. DRUSEN-to-CNV errors decreased from 37 to 13, while DME-to-CNV errors decreased from 13 to two. Performance for CNV and NORMAL remained above 95% recall. The paired analysis suggests that the imbalance-mitigation strategy may have contributed to improved classification performance compared with the imbalanced model.

These findings demonstrate that accuracy and AUC should be complemented by class-specific precision, recall, F1-score, and confusion matrices. The imbalance-mitigation strategy produced more uniform performance across the four classes and reduced bias toward the majority class.

Future studies should isolate the effects of data augmentation and class weighting through ablation experiments and compare them with undersampling, oversampling, focal loss, class-balanced loss, and cost-sensitive learning. Generative adversarial networks and diffusion models should also be assessed for minority-class augmentation.

External validation should include different OCT devices, institutions, acquisition protocols, and patient populations, with patient-level separation among data partitions. Further work should investigate probability calibration, uncertainty estimation, class-specific thresholds, and alternative convolutional, transformer-based, and hybrid architectures.

***Summary*Alzheimer's Disease (AD) is the leading cause of dementia in the elderly, presenting significant challenges for differential diagnosis, especially in relation to Frontotemporal Dementia (FTD). This study aims to evaluate the performance of machine learning algorithms for automatic classification of EEG signals, facilitating the differential diagnosis between AD, FTD, and healthy aging. A public database with records of 88 individuals (36 AD, 23 FTD, 29 controls) was used, subjected to balancing by SMOTE and feature selection via Genetic Algorithms and Particle Swarm Optimization. Eleven classified individuals were evaluated in the WEKA environment with validation (10 folds, 5 repetitions). The results demonstrated the superiority of the Random Forest with 200 trees, which achieved 96.2% accuracy and a Kappa index of 0.943 in the test set, with a sensitivity of 96.6% for AD and a specificity of 96.0% for controls. Analysis of the confusion matrix revealed low error rates between classes, including in the clinical challenge of distinguishing AD versus FTD. It is concluded that the proposed approach shows potential as an objective and non-invasive tool to aid in the differential diagnosis of dementias, contributing to earlier and more personalized interventions.**

***Keywords*Alzheimer's disease; Frontotemporal dementia; electroencephalography; machine learning; differential diagnosis**

I. Introductiondog

The increase in life expectancy observed in recent decades has been accompanied by an increase in the prevalence of neurodegenerative diseases, notably Alzheimer's Disease (AD), which currently represents the leading cause of dementia in the elderly [1]. According to the World Health Organization (WHO), approximately 10 million new cases of dementia are reported annually, totaling around 57 million people living with some form of this condition in 2021 [1]. Projections indicate that this number could reach 152 million by 2050, representing one of the greatest public health challenges of the 21st century [2].

Despite advances in knowledge about the pathophysiology of AD, early and accurate diagnosis remains a significant clinical challenge. Currently, the diagnostic process is predominantly based on subjective clinical assessments, combined with neuropsychological tests, such as the Mini-Mental State Examination (MMSE), and neuroimaging exams [3]. This approach, although widely used, presents important specificities, particularly in the early stages of the disease, such as in Mild Cognitive Impairment (MCI), where symptoms can be subtle and nonspecific [4].

One of the main obstacles is differential diagnosis, that is, distinguishing AD from other neurodegenerative dementias, especially Frontotemporal Dementia (FTD), as well as the process of healthy cognitive aging itself [5], [6]. The symptomatic overlap between these conditions frequently leads to diagnostic errors, compromising the prognosis and the effectiveness of therapeutic interventions [7]. Studies indicate that diagnostic error rates between AD and FTD can reach up to 30% in early stages, when assessed exclusively by clinical criteria [8]. This diagnostic imprecision delays the start of specific therapies and impacts patients' quality of life.

In this context, Electroencephalography (EEG) has emerged as a promising tool for investigating functional biomarkers in neurodegenerative diseases [9]. It is a non-invasive and low-cost technique that records brain electrical activity with high temporal resolution [10]. Studies demonstrate that AD is associated with characteristic changes in oscillatory patterns, notably a deceleration of the dominant rhythm, with increased power in the delta and theta frequency ranges, and a reduction in the alpha and beta ranges [11], [12]. Such changes preceding the more evident clinical manifestations and brain atrophy can be detected by neuroimaging, making EEG a potential source of early biomarkers [13].

In parallel, Artificial Intelligence (AI) and Machine Learning (ML) have become established as tools capable of extracting complex and non-linear patterns from biomedical signals, overcoming the limitations of traditional visual analysis [14]. Classification algorithms can analyze large volumes of EEG data, identifying electrophysiological signatures associated with different neurodegenerative conditions [15].

However, most of these studies focus on problems of classifying AD versus controls, not addressing the challenge of differential diagnosis in multiclass scenarios that include other

dementias [18]. Furthermore, the literature lacks work that performs a systematic comparison between different machine learning algorithms using the same experimental protocol, database and evaluation analyses, which makes it difficult to identify the most appropriate approach for clinical applications.

Given this scenario, the present work aimed to evaluate the performance of Machine Learning algorithms, implemented in the WEKA environment, for automatic classification of EEG signals focusing on the differential diagnosis of Alzheimer's Disease versus Frontotemporal Dementia and healthy aging, employing a methodology based on signal feature extraction, attribute selection through genetic algorithms and particle swarm optimization (PSO), and classification using 11 distinct algorithms.

II. BasisTe-mail

A. Alzheimer's disease and differential diagnosis

Alzheimer's disease (AD) is the leading cause of dementia in older adults, characterized by progressive cognitive decline associated with the accumulation of β-amyloid and hyperphosphorylated tau proteins in brain tissue [1], [2]. The differential diagnosis (the process of distinguishing one condition from others with similar symptoms) between AD and FTD constitutes a significant clinical challenge, since both present overlapping initial manifestations, such as changes in memory and behavior [3], [4].

Studies indicate that diagnostic error rates between AD and FTD can reach up to 30% in initial targets when based exclusively on clinical criteria [5]. This diagnostic imprecision compromises the prognosis, delays specific therapeutic interventions, and impacts the quality of life of patients and caregivers [6]. In this context, the identification of objective biomarkers that help distinguish between these conditions becomes fundamental for adequate clinical management and for the development of personalized therapeutic approaches.

B. Electroencephalography

EEG is a non-invasive technique that records brain electrical activity using electrodes placed on the skin of the ear. The captured signal reflects the sum of postsynaptic potentials generated by populations of pyramidal neurons in the cerebral cortex, offering excellent temporal resolution (milliseconds) for the analysis of neural dynamics [8]. The acquisition follows the International 10-20 System, which standardizes the placement of 19 electrodes on the metallic lobes, ensuring reproducibility and symmetrical coverage [9].

The EEG signal is classically composed of five main rhythms: delta (0.5-4 Hz), theta (4-8 Hz), alpha (8-13 Hz), beta (13-25 Hz), and gamma (25-45 Hz), each associated with different functional states of the brain [10]. In the context of neurodegenerative diseases, AD is associated with characteristic alterations of these rhythms, notably a slowdown of the spectrum (increased power in the delta and theta bands, accompanied by a reduction in the alpha and beta bands), as well as loss of signal complexity and synchronization [11], [12]. In FTD, the alterations are less consistent, but studies report differences in connectivity patterns and spectral distribution in relation to AD and healthy controls [13]. Such alterations precede brain atrophy detectable by neuroimaging, potentially positioning EEG as a promising source of early biomarkers for the differential diagnosis of dementias [14].

C. Machine Learning for EEG Classification

Machine Learning comprises techniques that allow computational systems to identify patterns in data from examples, without explicit programming [15]. In the context of this work, supervised classification is employed, in which a model is trained with previously labeled data (e.g., DA, DFT, control) to predict the class of new samples [16].

Raw EEG signals have high dimensionality, making it necessary to remove features that compactly represent relevant information. These can be obtained in different domains: time (mean, variance, entropy); frequency (power spectral density by bands - delta, theta, alpha, beta, gamma); and time-frequency (wavelet transform) [17]. After separation, feature selection techniques such as Genetic Algorithms (GA), inspired by natural evolution, and Particle Swarm Optimization (PSO), based on collective behavior, can be applied to reduce dimensionality and eliminate redundancies [18].

In the scientific literature, different algorithms have been used for EEG classification, with this study highlighting: Bayesian Networks, Support Vector Machines (SVMs), and Decision Trees (J48, Random Tree, and Random Forest).

For performance evaluation in biomedical classification problems, different metrics can be used, such as: accuracy, which represents the overall proportion of correct answers; Kappa index, which measures chance-adjusted agreement; sensitivity (also called recall or true positive rate), which measures the proportion of correctly identified positive instances among those that affect the class of interest; specificity (true negative rate), which assesses the proportion of correctly identified negative instances among all those that do not belong to the class of interest; and the area under the ROC curve (AUC-ROC), which provides an overall measure of the model's discriminative ability between classes, regardless of the decision limits adopted.

III. Methodology

A. Database

The database used in this study was published by Miltiadous [19] and is publicly available in the OpenNeuro repository. The dataset contains secure, closed-eye EEG recordings from 88 individuals distributed into 36 patients with Alzheimer's Disease (AD), 23 patients with Frontotemporal Dementia (FTD), and 29 health controls (HC). Signals were acquired with 19 scalp electrodes (international 10-20 system), a sampling frequency of 500 Hz, and a resolution of 10 μV/mm. The cognitive status of the participants was assessed using the Mini-Mental State Examination (MMSE), with mean scores of 17.75 (SD = 4.5) for the AD group, 22.17 (SD = 8.22) for the FTD group, and 30 for the HC group. All records are in the standardized BIDS (Brain Imaging Data Structure) format, facilitating reproducibility and processing by computational tools.

B. Feature preprocessing and selection

Initially, the original database was partitioned into a training set (75%) and a test set (25%), maintaining the proportion between the classes. The training set was subjected to the SMOTE (Synthetic Minority Over-sampling Technique), an innovative technique in the WEKA environment, to equalize the number of instances among the three classes (DA, DFT, and CN), avoiding bias in the classifieds resulting from the original imbalance.

From the balanced training set, two feature selection techniques were applied: (i) Genetic Algorithms (GA), referenced as EVO base; and (ii) Particle Swarm Optimization (PSO), referenced as PSO base. Both techniques were employed to identify subsets of features most relevant for class discrimination, reducing dimensionality and eliminating redundancies.

At the end of this process, three training datasets were generated for the experiments: (1) balanced dataset without feature selection (BSA); (2) balanced dataset with selection by Genetic Algorithms (EVO); and (3) balanced dataset with selection by Particle Swarm Optimization (PSO).

C. Classification and experimental setup

The training set (75%), after balancing via SMOTE and, when applicable, subjected to feature selection techniques (EVO and PSO), was used for the classification stage in the WEKA software environment. Eleven classification algorithms were evaluated: Bayes Net (BN), Support Vector Machines (SVM) with linear kernels, polynomial of degree 2 and polynomial of degree 3 (parameter C = 0.01), Random Tree (RT), J48 and Random Forest (RF) with 100, 200, 300, 400 and 500 trees.

For each of the three training sets (balanced without selection, balanced with EVO selection, and balanced with PSO selection), experiments were conducted in the WEKA Experimenter module, employing 10-fold, 5-repetition cross-validation to estimate model performance. This protocol allows for the evaluation of classifier stability and generalization against data variability, using only the training set for parameter testing and model selection, without any contamination from the test set, which is occasionally separated for the final validation stage.

D. Selection of the best model and validation on the test set.

Following the cross-validation phase, in which all 11 classified models were evaluated on the three training datasets (balanced without selection, balanced with EVO selection, and balanced with PSO selection), the best combination was identified. The selection considered only the complete set of metrics (accuracy, Kappa index, sensitivity, specificity, and ROC area), with special emphasis on the Kappa index. In addition, practical aspects such as the computational cost associated with each model, particularly relevant for clinical applications, were considered.

The means and standard deviations of the observations in the cross-validation were calculated using Jamovi software, allowing for comparison between the models and the construction of box plot graphs to visualize the distribution of the results.

The classifier that presented the best balance between superior performance (especially in terms of Kappa), low variability between repetitions, and computational predictions was selected for the validation stage, performed on the test set (25%). From this validation, the confusion matrix and final performance statistics were generated, representing an estimate of the model's behavior on data not used in the training.

IV. π and Discussion

The experiments conducted on the training sets of the three bases (balanced without selection, balanced with EVO selection, and balanced with PSO Optimization selection) revealed significant performance differences among the evaluated subjects. Tables I, II, and III present the means and standard deviations of the metrics obtained in the validation with 10 folds and 5 repetitions for each base.

The results demonstrate that Random Forest-based models significantly outperformed all other evaluated algorithms in terms of accuracy, Kappa index, and statistical robustness, corroborating recent findings in the literature on EEG classification in dementia. In the three databases tested, Random Forest configurations achieved average accuracies exceeding 94%, with Kappa indices between 0.916 and 0.956, values that indicate near-perfect agreement between predictions and actual labels.

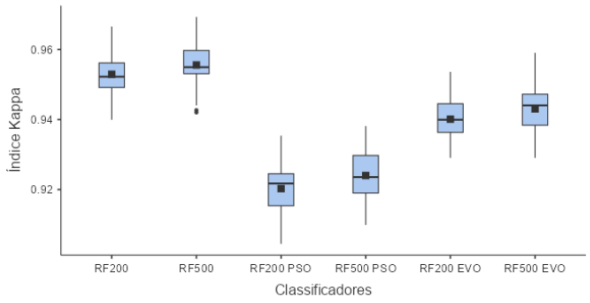
A. Abbreviations and acronyms

Define abbreviations and acronyms the first time they are used in the text, even if they have already been defined in the abstract. Abbreviations such as IEEE, SI, MKS, CGS, AC, DC, and RMS do not need to be defined. Do not use abbreviations in the title or headings unless they are unavoidable.



The classified SVM models performed worse, with accuracies ranging from 34.6% to 68.0% depending on the kernel and dataset used. The linear kernel (SVM 1) obtained the worst results, with an accuracy close to 40% in datasets without selection and EVO, and only 34.6% in the PSO dataset. Polynomial kernels of degree 2 and 3 improved progressively, but still lagged behind the tree-based models. The SVM 1 model in the PSO dataset showed even worse results, with a Kappa index of only 0.020, indicating a highly random performance.

The classifications based on single trees (J48 and RT) achieved intermediate results, with accuracies between 77.9% and 82.9%. J48 proved to be superior to RT in all datasets, reaching 82.9% accuracy in the dataset without selection. However, both presented higher standard deviations than the models.*Random Forest*, decreasing stability in validation repetitions. The BN's performance was limited, with accuracies between 59.0% and 62.9%, corroborating the literature that points to limitations of Bayesian models for EEG signal classification due to the violation of the conditional suspension of independence between features.

Among the variations of Random Forest, a consistent pattern is observed: increasing the number of trees produces marginal performance gains, but with diminishing returns. The model with 100 trees already shows high accuracies (94.4% to 96.5%), while the configuration with 500 trees achieves the highest absolute values in all datasets. However, the maximum difference between RF 200 and RF 500 is only 0.3% in accuracy and 0.003 in the Kappa index (PSO baseline), clinically insignificant values when considering the inherent variability of the problem.

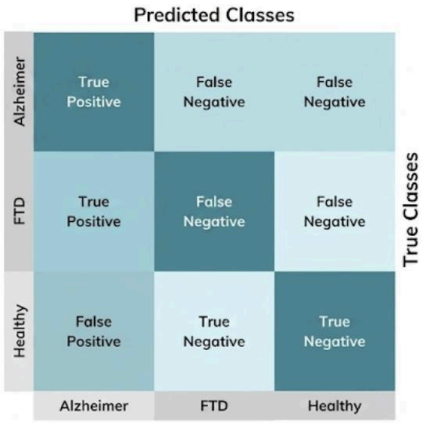
Additionally, the*Random Forest*With 200 trees, it stands out for having the lowest standard deviations among all configurations evaluated (0.38 in the no-selection base, 0.46 in the PSO base, and 0.41 in the EVO base), providing greater consistency and reproducibility of results. This aspect is particularly relevant for clinical applications, where the stability of the model in the face of small variations in the input data is as important as average performance.

FIGURE I - BOX PLOTS OF THE KAPPA INDICES OF THE RANDOM FOREST CLASSIFIERS

RF: Random Forest; PSO: Particle Swarm Optimization; EVO: Genetic Algorithms.

Computational cost was also considered in the analysis. Although not systematically measured, we observed that the execution time of RF 500 was significantly higher than that of RF 200, especially in datasets with feature selection, where the search space complexity is greater. Recent studies report that the marginal performance gain provided by forests with more than 200 trees justifies the exponential increase in computational cost, particularly in scenarios with time or resource constraints.

Regarding the impact of feature selection techniques, it is observed that the base without selection produced the best results for all configurations.*Random Forest*, with accuracies between 96.5% and 97.0%. The databases with PSO and EVO selection obtained superior performance, with an average reduction of 1.8% and 0.8% in accuracy, respectively. This finding suggests that, for the set of features used (relative power of the five frequency bands), feature selection may have eliminated information relevant to the discrimination between classes, possibly due to the complementary nature of the different spectral bands in the differential diagnosis of dementias. Alternatively, the parameters used in the selection algorithms may not have been optimized for the specific task, opening perspectives for future investigations.



In light of these findings, the*Random Forest*with 200 trees applied to the balanced dataset without feature selection was selected as the final model for evaluation in the test set. This choice is based on the best relationship between: (1) high diagnostic performance (accuracy 96.9%, Kappa 0.953); (2) statistical robustness, i.e., lower standard deviation between repetitions; (3) balance between sensitivity (0.976) and specificity (0.975); and (4) computational predictions for clinical applications.

The results obtained after validating the Random Forest with 200 trees in the test set are presented in Table IV and in the confusion matrix shown in Figure II.

TABLE IV - RESULTS OF THE RANDOM FOREST WITH 200 TREES IN THE TEST SET

Metric	Result
Precision	96.20%
Kappa Index	0.943
Sensitivity	0.962
Specificity	0.971
ROC Area	0.997

FIGURE II - CONFUSION MATRIX OF THE RANDOM FOREST RESULTS WITH 200 TREES IN THE TEST SET.

DFT:Frontotemporal dementia.

The results in the test set reinforce the generalizability of the selected model, with metrics consistent with those observed in the validation. The accuracy of 96.20% and the Kappa index of 0.943 do not indicate overfitting.*overadjustment*g) during training, demonstrating that the model is able to maintain its performance in the presence of non-visible data.

Analysis of the confusion matrix reveals clinically important patterns. For the Alzheimer's disease class, out of 5,496 real instances, 5,308 (96.6%) were correctly identified, with errors distributed among 96 classifications as FTD (1.7%) and 92 as healthy controls (1.7%). The high sensitivity for AD is particularly relevant as it minimizes false negatives, i.e., Alzheimer's patients who would otherwise fail to receive appropriate treatment.

In the Frontotemporal Dementia class, out of 5,496 actual instances, 5,280 (96.1%) were correctly defined, with 147 errors observed as AD (2.7%) and 69 as control (1.3%). Confusion between AD and FTD was expected, as it reflects the symptomatic and electrophysiological overlap between these dementias, constituting the main clinical challenge of differential diagnosis [5], [6].

For the safety checklist class, out of 5,496 actual instances, 5,274 (96.0%) were correctly identified, with errors including 167 classifications as AD (3.0%) and 55 as FTD (1.0%). The 96.0% specificity indicates low false positive rates, meaning that particularly high levels of individuals are incorrectly diagnosed with some form of dementia, a crucial aspect for avoiding incidental interventions and negative psychological impact.

Class-specific statistics reinforce the model's consistency: AUC-ROC values close to 1.0 (0.996 to 0.997) indicate excellent discriminatory capacity between the three classes, while Matthews demonstration coefficients (MCC) between 0.932 and 0.950 confirm the quality of the predictions even considering the original data imbalance.

Compared to recent studies in the literature, the performance achieved is among the highest for multiclass EEG classification in dementia. Miltíado*and others.*[19], using the same database with a leave-one-subject-out approach, reported accuracies of 77.01% for AD vs CN classification with Random Forest. The superior performance in this work (96.2% in a multiclass scenario) can be attributed to the SMOTE balancing strategy, validation with repetitions, and optimization of the number of trees.

V. CONCLUSION

This work investigated a machine learning algorithm application for multiclass classification of EEG signals, focusing on the differential diagnosis of Alzheimer's Disease versus Frontotemporal Dementia and healthy aging. The results showed that Random Forest classifiers performed best, and for the validation stage, the Random Forest with 200 trees was selected, considering the results of evaluations and clinical applications, and observing computational cost. This model, applied to a balanced dataset without attribute selection, achieved superior performance to the other classifiers, with an accuracy of 96.2% and a Kappa index of 0.943 in the test set. The high sensitivity for Alzheimer's (96.6%) and specificity for height controls (96.0%) reinforce the robustness of the model for clinical applications.

The methodology employed, including SMOTE balancing, cross-validation with repetitions, and systematic comparison of 11 classifiers in the WEKA environment, proved adequate for the proposed problem, allowing the identification of the configuration with the best balance between diagnostic performance and computational predictions. The results obtained surpassed recent studies in the literature that used the same database, highlighting the value of the adopted approach.

From a clinical standpoint, the developed model offers an objective and non-invasive tool to aid in the differential diagnosis of dementias, contributing to the reduction of subjectivity inherent in isolated clinical evaluation. The non-invasive nature and low cost of EEG, combined with improved performance, position the approach as promising for applications in primary screening and longitudinal monitoring, especially in resource-limited settings.

Limitations of the study include the lack of external validation with independent databases and the need to investigate the importance of spectral characteristics for each diagnostic class. Future studies could explore the combination of different data modalities (EEG, neuroimaging, blood biomarkers), as well as evaluate the generalization of the models to other clinical situations and contexts.

In summary, Artificial Intelligence applied the demonstrated EEG signals with the potential to transform the differential diagnosis of dementia into a practice based on quantitative evidence, allowing for earlier and more personalized interventions, with a positive impact on the quality of life of patients and caregivers.

Abstract*—Introduction: Hypoxic burden metrics are emerging as alternatives to the Apnea-Hypopnea Index (AHI) in obstructive sleep apnea (OSA). Among those, Respiratory Event Desaturation Transient Area (REDTA) and Desaturation Severity 100 (DesSev100) are area-based metrics designed to quantify cumulative nocturnal oxygen desaturation. However, differences in their methodological definitions may influence the resulting estimates of hypoxic burden. Objective: To investigate whether REDTA and DesSev100 provide equivalent estimates of hypoxic burden in patients with OSA. Methods: This retrospective methodological study analyzed 33 type III polysomnography recordings from adult patients. REDTA was implemented in Octave according to its original description. DesSev100 was calculated using the ABOSA software. An adjusted version of DesSev100 was also generated to equalize the normalization factors of both metrics. Numerical values were compared using paired t-tests, and agreement was assessed using Bland–Altman analysis, including mean bias, 95% limits of agreement, and proportional bias. Results: REDTA and DesSev100 showed a strong positive correlation (Pearson's $r = 0.857$, 95% CI: 0.728–0.927). Nevertheless, REDTA numeric values were significantly higher than DesSev100 (mean difference = 13.65, CI: 7.21–20.10; $t(32) = 4.315$, $p < 0.001$). Significant differences remained after the normalization adjustment of DesSev100 (mean difference = 5.30 %·h, CI: 3.35–7.26; $t(32) = 5.527$, $p < 0.001$). Bland–Altman analysis showed 95% limits of agreement ranging from -5.50 %·h to 16.10 %·h, with a proportional bias. Conclusions: REDTA and DesSev100 quantify related aspects of nocturnal hypoxic burden but showed limited agreement and cannot be considered numerically interchangeable. Persistent differences after normalization suggest that methodological factors, including event selection and area integration strategies, influence the resulting estimates. These findings highlight the importance of considering metric-specific characteristics when comparing studies and interpreting hypoxic burden measurements in OSA.

***Index Terms*—obstructive sleep apnea; hypoxic burden; oxygen desaturation; polysomnography.**

I. Introduction

The Apnea-Hypopnea Index (AHI) remains the diagnostic gold standard for Obstructive Sleep Apnea (OSA). However, it does not capture the cumulative physiological burden of hypoxemia. This has led to the development of index, time, and area-based indicators of the intensity of blood oxygen desaturation [1], [2].

Metrics such as Hypoxic Burden (HB), Desaturation Severity (DesSev), and the Respiratory Event Desaturation Transient Area (REDTA) have emerged as more robust predictors of cardiovascular disease (CVD) mortality compared to traditional clinical indices [3]–[5]. However, different algorithms and baseline definitions coexist without a clear consensus on the superiority of any specific metric for predicting concrete clinical outcomes [2].

This uncertainty highlights the need for comparative studies to evaluate the performance of these tools in real-world clinical settings. Limitations to conducting such studies include the lack of openly accessible software to calculate metrics and published descriptions that explain the calculations but do not aim for their implementation. Currently, one exception is the ABOSA (Automatic Blood Oxygen Saturation Analysis) software [6]. This implements the DesSev and, according to two recent reviews of the literature [1], [2], the REDTA.

The objective of this study is to compare the REDTA and the DesSev. We aim to show that, due to fundamental differences in methodology, such as event definition and sampling window, these metrics are not interchangeable and provide non-equivalent assessments of the hypoxic burden.

II. Methods

All data were collected from polysomnographic records in which patients were informed and consented to the use of their data in future scientific studies conducted at the Clementino Fraga Filho University Hospital (HUCFF), provided that the anonymity and confidentiality of the information were preserved.

A. Study Design and Sample Selection

This is a retrospective, methodological, and comparative study focused on hypoxic burden metrics in OSA. The sample

This work was partially founded by CAPES and Instituto de Ciência, Tecnologia e Inovação de Maricá (ICTIM), Brazil.

consisted of type III polysomnography recordings (ApneaLink Air, ResMed, US) obtained from adult patients evaluated at the HUCFF outpatient sleep clinic for a clinical diagnosis of OSA. A total of 35 records were randomly selected.

B. Desaturtion Metrics

The study compared the values of two emerging desaturation area-based metrics:

1) REDTA (Respiratory Event Desaturation Transient Area): designed using a fixed 100% baseline and a temporal window determined according to respiratory event duration, as

$$REDTA = \frac{\sum_{i=1}^{N} Area_i}{3600}. \quad (1)$$

Where the area corresponding to an individual respiratory event i is defined as (Fig. 1)

$$Area_i = \int_{t_{mid}}^{t_{end_window}} [100 - SpO_2(t)]\, dt. \quad (2)$$

In these equations:

- N: number of respiratory events in the recording;
- t_{mid}: beginning of the integration window, located midway through the respiratory event;
- t_{end_window}: end of the integration window, extending for twice the event duration after the end of the event. If the integration window of two consecutive events overlaps, t_{mid} of the second is moved to t_{end_window} of the first.
- 3600: scaling factor to express the final value in $\%\,\mathrm{h}$.

Following the original description of REDTA [5], saturation values considered artifacts ($<50\%$ or $>100\%$) were ignored for the area calculation. However, these samples were counted for the determination of the integration window.

2) DesSev100 (Desaturation Severity 100): implemented in the ABOSA [6], it accumulates the area between 100% and the saturation curve within each automatically identified desaturation event (Fig. 2),

$$DesSev = \frac{\sum_{i=1}^{n} DesArea_i}{TST_{second}}. \quad (3)$$

In this equation:

- n: number of identified desaturation events;
- $DesArea_i$: area of an individual desaturation event;
- TST_{second}: Total Sleep Time (TST) expressed in seconds.

ABOSA automatically identifies desaturations, independently of respiratory events. These are identified from user defined minimum depth and duration thresholds, along with other fixed rules regarding event distances and desaturation rate. A detailed description is found in [6]. In the current study, minimum depth was chosen as 4% to match the respiratory event criteria, and minimum duration was $3\,\mathrm{s}$. A desaturation expands only from a maximum to a minimum, with the posterior increase in saturation treated as a separate recovery event. The recovery identification uses only fixed parameters and does not need to be identified for every desaturation [6].

In addition to the upper and lower saturation value bounds used to classify artifacts, ABOSA includes an additional criterion based on values > 30 after squaring a high-pass filtered version of the saturation signal [6]. A safety margin of $1\,\mathrm{s}$ before and after each sample classified as an artifact is added. If the resulting artifact region is $<5\,\mathrm{s}$, it is replaced by linear interpolation. The presence of artifacts excludes the entire desaturation or recovery event from the analysis.

A comparison of (1) and (3) reveals that they do not yield directly equivalent values due to their different normalization factors and units. While REDTA uses a fixed scale factor of 3600 to represent cumulative desaturation, DesSev100 is normalized by TST in seconds, representing a time-weighted average severity. To ensure a consistent scale for the comparative analysis, a mathematical adjustment was performed by standardizing the denominator based on the TST in hours,

$$DesSev_{adj} = DesSev \cdot TST_{hours} = \frac{\sum_{i=1}^{n} DesArea_i}{3600}. \quad (4)$$

C. Data Acquisition and Signal Processing

For population characterization, sex, age, height, weight, body mass index (BMI), neck circumference (NC), abdominal circumference (AC), and Epworth Sleepiness Scale (ESS) scores were collected from all participants.

Respiratory events were manually scored by a single specialist. The scoring followed the recommendations of the American Association of Sleep Medicine, considering hypopneas with the 4% desaturation rule. Due to the absence of electroencephalographic data, arousals could not be considered for hypopnea, and there was no sleep staging. Furthermore, TST was considered equal to the total recording time during which the oxygen saturation signal was available, as default in ABOSA for this situation.

PSG and event data were extracted in the universal European Data Format (EDF) for the calculation of the desaturation metrics. REDTA was implemented by the authors in the Octave programming language, following the original description of the metric [5], summarized above. The DesSev100 was calculated directly in the ABOSA 1.2.2 [7]. The denominator-modified DesSev100 was calculated using the output tables of ABOSA. The AHI was computed from all the events identified in the EDF file, divided by the total time between the marks for the start and end of the scoring window.

D. Statistical Analysis

Descriptive statistics were calculated and expressed as mean $\pm$ standard deviation. Differences in numerical values between the REDTA and the DesSev100 metric provided by the ABOSA software or the adjusted version were assessed using the paired t-test. The association between the metrics was assessed using Pearson's correlation coefficient. Agreement between REDTA and adjusted DesSev100 was assessed using Bland–Altman analysis, including mean bias, 95% limits of agreement, and proportional bias. This last was also assessed

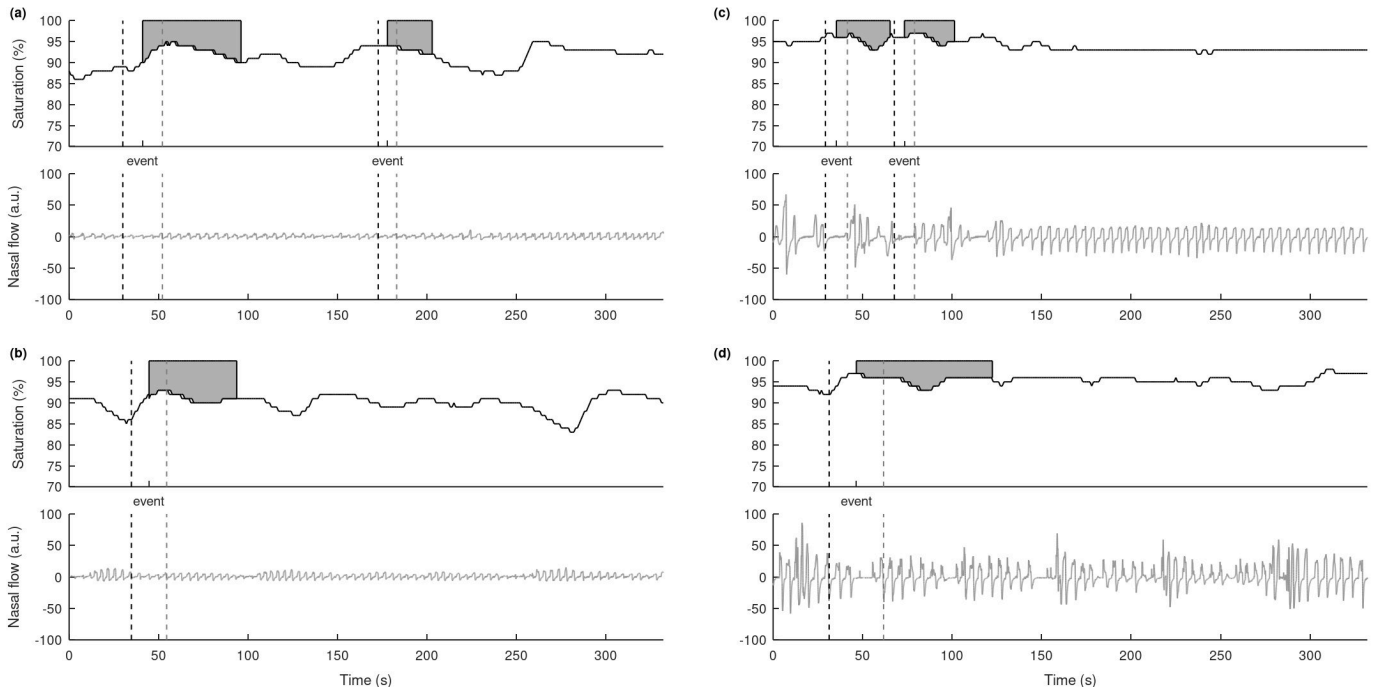

Fig. 1. Examples of saturation and nasal flow curves for two patients (panels a/c, and b/d) from the analyzed population showing the area used in the Respiratory Event Desaturation Transient Area (REDTA) metric. The manually scored respiratory events are marked with vertical dashed lines, from the black to the light gray. The area considered as desaturation related to one event (gray shade) extends from the middle of the event to twice the event duration after its end. The upper limit is 100%, and the lower the saturation curve. The metric considers only the occurrence of a respiratory event, integrating the described region even if it does not cover the entire desaturaion (a), corresponds to saturation drops lower than 3% considered in the guidelines (b and c), or extends after a recovery from desaturation (d). Only events that start in the graphs' time interval are shown.

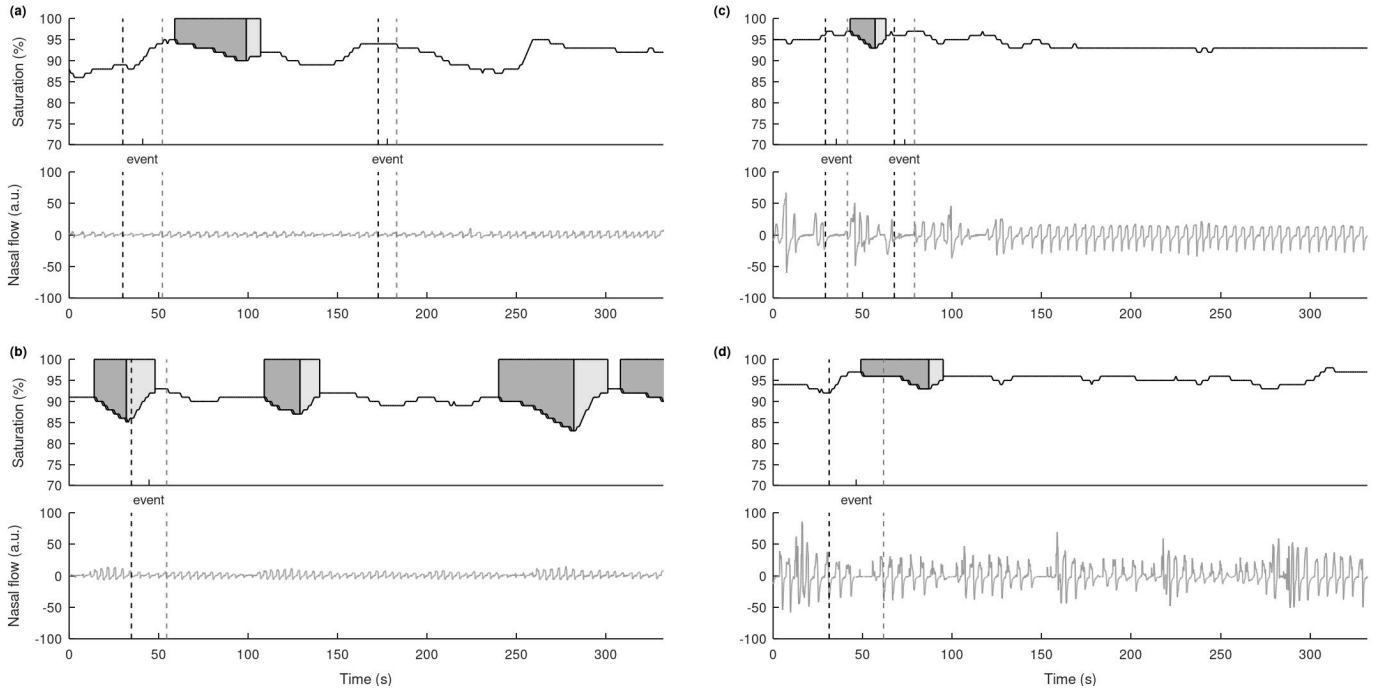

Fig. 2. Examples of saturation and nasal flow curves for two patients (panels a/c, and b/d) from the analyzed population showing the area used in the Desaturation Severity 100 (DesSev100) metric. The manually scored respiratory events are marked with vertical dashed lines, from the black to the light gray. The area considered in the metric (dark gray shaded) is the one between 100% and the saturation curve within the time interval automatically identified as corresponding to a desaturation of, at least, 4%. The recovery of saturation is also automatically identified, with the corresponding area shown (light gray shaded). The desaturation identification follows a series of rules and does not considers the information about respiratory event. Thus, it may not include some saturation drops of 4% (a) or changes in saturation after respiratory events that are lower than the chosen threshold (b); while including desaturations not time related to events (c). Only events that start in the graphs' time interval are shown.

TABLE I
PARTICIPANT CHARACTERISTICS (N = 33)

Female, n (%)	21 (63.6)
Age (years)	52.5 ± 15.6
Body Mass Index ($\mathrm{kg\,m^{-2}}$)	33.5 ± 5.9
Height (m)	1.66 ± 0.09
Weight (kg)	92.0 ± 21.3
Epworth Sleepiness Scale	12.2 ± 5.1
Neck circumference (cm)	39.9 ± 5.9
Abdominal circumference (cm)	107.7 ± 18.0

Data is mean ± SD

using reduced major axis linear regression [8]. For all estimates, 95% confidence intervals (CI) were calculated. All statistical analyzes were performed using JASP software, with a significance level of 5%.

III. RESULTS

During the analysis, two patients were excluded due to the absence of the saturation signal. The final 33 sample was predominantly female (63.6%), aged 52.5 ± 15.6 years, and had a BMI of $33.5 \pm 5.9\,\mathrm{kg\,m^{-2}}$ (Table I).

The DesSev100 calculated in ABOSA cannot be considered the same metric as REDTA. A positive correlation was observed between REDTA and DesSev100 (Pearson's $r = 0.857$, 95% CI: 0.728–0.927), indicating that both metrics quantify related aspects of nocturnal hypoxic burden. However, as expected from their different normalization factors, significant differences were observed between the numerical values of REDTA ($15.55 \pm 19.94\,\%\,\mathrm{h}$) and DesSev100 ($1.89 \pm 2.10\%$), with a mean difference of $13.65\,\%\,\mathrm{h}$ (95% CI: 7.21–20.10; $t(32) = 4.315$, $p < 0.001$).

The discrepancy between the methods was not explained only by the difference in normalization. Adjusting DesSev100 to use the same normalization factor as REDTA increased its values ($10.25 \pm 15.02\,\%\,\mathrm{h}$), but a significant difference between the metrics persisted (mean difference = $5.30\,\%\,\mathrm{h}$, 95% CI: 3.35–7.26; $t(32) = 5.527$, $p < 0.001$). Bland–Altman analysis showed 95% limits of agreement ranging from $-5.50\,\%\,\mathrm{h}$ to $16.10\,\%\,\mathrm{h}$ and indicated a proportional bias (Fig. 3a). This bias was confirmed by a slope of 0.753 (CI: 0.715–0.793) significantly different from unity in a reduced major axes regression between adjusted DesSev100 and REDTA. Additionally, the difference between the metrics had a positive correlation with whole night average oxygen saturation (Fig. 3b - $r = 0.450$, $p = 0.009$). Thus, the difference between the metrics is larger for more severe patients and those with lower overall saturation.

Both hypoxic burden metrics were significantly associated with AHI (Fig. 4). REDTA, which is based on the respiratory events, had a larger positive correlation with AHI ($r = 0.799$, 95%: 0.628–0.897, $p < 0.001$) than DesSev100 ($r = 0.695$; 95%: 0.461–0.838; $p < 0.001$). Still, both metrics exhibited variability around the regression lines, especially for larger AHI, reinforcing that they incorporate information beyond the frequency of respiratory events.

IV. DISCUSSION

The present study compared two area-based hypoxic burden metrics, REDTA and DesSev100, using the same set of type III polysomnography recordings with manually scored respiratory events. The main finding was that, although both metrics showed a strong correlation, they were not numerically equivalent. Significant differences persisted even after adjusting the denominator of DesSev100 to match the normalization adopted by REDTA. Thus, the observed differences between the methods are related to their methodological definitions rather than to mathematical scaling alone.

The DesSev100 calculated in ABOSA should not be considered the same metric as REDTA. Two reviews of methods to evaluate hypoxic burden indicate that the ABOSA software can be used to calculate REDTA [1], [2]. Even the study validating the ABOSA software seems to make such equivalence between the metrics, citing the REDTA study as previous findings using the DesSev100 [6]. The strong correlation observed between REDTA and DesSev100 ($r = 0.857$) indicates that both metrics quantify related characteristics linked to nocturnal hypoxic burden. They are based on the integration of oxygen desaturation areas using the same fixed reference value and increase with the number, duration, and depth of desaturation events. However, as the metrics are expressed in different units (REDTA in $\%\,\mathrm{h}$, DesSev100 in $\%$), our findings of significantly different numerical values were to be expected. This would lead to incorrect risk classification if one used any threshold derived from the true REDTA calculation in patients scored using DesSev100 as a REDTA-like metric. Of note, a recent study showed that DesSev100 and REDTA differ in their capacity as predictors of cardiovascular related mortality outcomes when calculated in the same patients [9].

Importantly, the difference between the metrics extends beyond their units. The different units exist because whereas REDTA uses a fixed scaling factor, DesSev100 is normalized by TST. After we adjusted DesSev100 to use the same denominator adopted by REDTA, significant differences remained. These differences may be explained by the distinct definitions of the desaturation areas. REDTA is linked to manually scored respiratory events and quantifies desaturation burden within predefined temporal windows based on those events. In contrast, DesSev100 is based on the automated identification of oxygen desaturation, regardless of direct temporal correspondence with respiratory events. As shown in the examples of Figs. 1 and 2, REDTA can include regions that are smaller or larger than a desaturation event of DesSev100. It also includes regions with drops in saturation that are lower than the 4% minimum configured in the ABOSA. Meanwhile, DesSev100 may include more desaturation events than the scored respiratory events, or the rules considered by ABOSA may not classify as desaturation intervals where saturation drops by 4%.

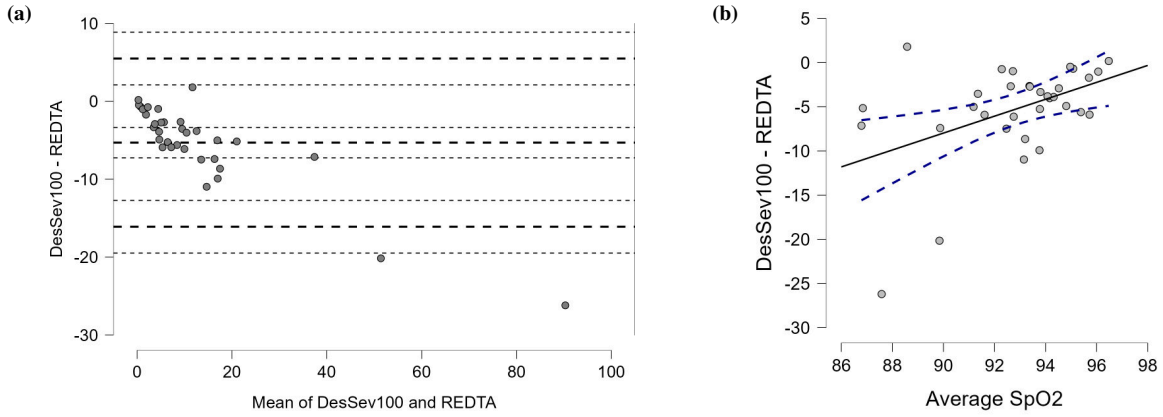

Fig. 3. Analyzes of the difference between REDTA and the adjusted DesSev100. (a) Bland–Altman plots of the metrics showing their mean bias and 95% limits of agreement (thick dashed lines), with the confidence intervals of each value (dashed lines). The asymmetry on the horizontal axis indicates a proportional bias. (b) Correlation of the difference between the metrics and the whole night average of saturation ($r = 0.450$, $p = 0.009$). The dots represent each of the 33 patients. The black line is a linear regression with blue-dashed lines confidence interval. REDTA = Respiratory Event Desaturation Transient Area; DesSev = Desaturation severity; SpO2 = peripheral oxygen saturation.

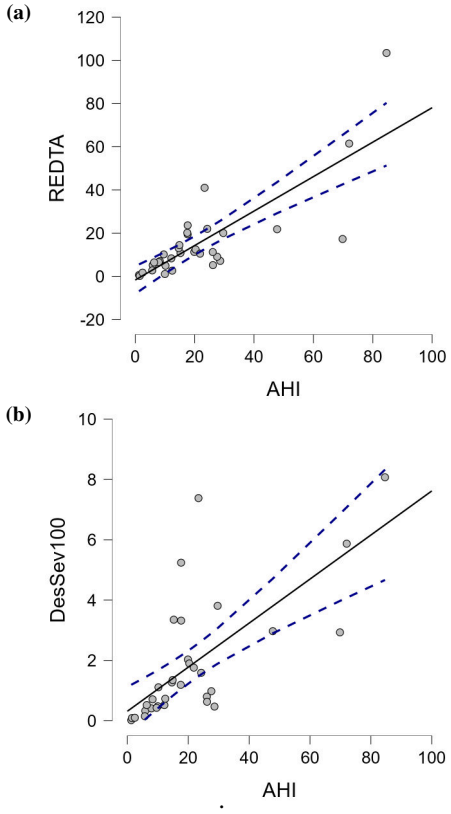

Fig. 4. Correlation of REDTA (4a - $r = 0.799$, 95%: 0.628–0.897, $p < 0.001$) and DesSev100 (4b - $r = 0.695$; 95%: 0.461–0.838; $p < 0.001$) with apnea-hypopnea index (AHI). The dots represent each of the 33 patients. The black line is a linear regression with blue-dashed line confidence interval. REDTA = Respiratory Event Desaturation Transient Area; DesSev = Desaturation severity.

An additional difference in area definitions is that ABOSA separates the decrease and increase in saturation into different events. Thus, if most desaturations are linked to a respiratory event, there should be a tendency for smaller areas for DesSev100. This is in line with our finding of significantly higher REDTA, with only two patients showing higher adjusted DesSev100. The ABOSA calculates a similar area-based metric for recoveries (RecSev100), which could be added to DesSev100. This addition could increase the number of differences with the opposite sign and decrease the mean difference between metrics. However, as our examples show, including recoveries would not be sufficient to make integrated regions equal. Moreover, given the fixed reference saturation value, it would be expected that a lower overall oxygen saturation leads to an increase in the differences caused by the area definitions. Accordingly, our results indicate a partial correlation between the metrics difference and the whole night saturation average ($r = 0.450$). Noteworthy, the Bland–Altman plot suggests a proportional bias between the metrics, which was confirmed by a regression between REDTA and adjusted DesSev100. Hence, considering both metrics as interchangeable could have a greater impact on patients who are in the highest risk.

Hypoxic burden metrics may reflect deeper physiological consequences of OSA than the number of events. Both REDTA and DesSev100 showed strong associations with AHI, indicating that hypoxic burden metrics remain related to the conventional index used for OSA diagnosis and severity classification. The correlation was strongest for REDTA, which depends directly on manually scored respiratory events used for AHI calculation. In contrast, DesSev100 is based on the automated identification of desaturations, not requiring direct correspondence with respiratory events. The variability around the regression line is, at least, partially explained by the area-based metrics incorporating information related to the depth and duration of oxygen desaturations. As a result, they may provide a more comprehensive assessment of nocturnal hypoxic exposure. This characteristic has been proposed as a possible explanation for the more consistent association between hypoxic burden metrics and cardiovascular outcomes reported in previous studies [3].

This study has some limitations. First, the sample size

was not based on a power calculation, and all patients were from a single center. The use of paired comparisons and the effect sizes observed indicate an adequate sample. A larger, independent, multicentric sample could provide greater variability in flow, oxygen saturation, and respiratory event patterns, allowing for a more robust assessment of the potential sources of discrepancy between the metrics. Such a sample could also improve the generalizability of the findings across different patient populations and recording conditions. However, it is also expected to highlight edge cases with even more extreme differences between the metrics. Second, only type III polysomnography recordings were available, precluding the use of electroencephalographic criteria and sleep-stage information. The definition of TST has a direct influence on the value of DesSev100, but sleep-staging could also influence the respiratory event scoring. Third, respiratory events were scored by a single evaluator. Due to inherent variability in visual data scoring, the exact numerical values are specific to this evaluator, but the observed differences are unlikely to depend only on event identification. Additionally, if the agreement between REDTA and DesSev100 is dependent on the evaluator, this reinforces that the metrics are not interchangeable in clinical practice. Finally, the implementation of REDTA required the development of a custom algorithm, since currently available software solutions do not allow direct processing of manually scored respiratory events according to the original definition of the metric. Nevertheless, this implementation ensured methodological fidelity to the original REDTA description and enabled a direct comparison with DesSev100 under controlled conditions.

V. Conclusions

REDTA and DesSev100 appear to quantify related dimensions of nocturnal hypoxic burden, as demonstrated by the correlation observed between them. However, the persistence of significant differences after mathematical normalization and the systematic nature of the disagreement between the methods indicate that these metrics should not be considered interchangeable. Methodological choices related to event selection and area integration substantially influence the final quantification of hypoxic burden and should be carefully considered when comparing studies and establishing clinical thresholds.

***Abstract*—Redes Bayesianas (BN) são utilizadas em diversos domínios, como áreas médicas, tendo poder para apoiar diagnóstico e prognóstico. Entretanto, a construção de suas tabelas de probabilidade condicional (CPTs) não é simples, exigindo aquisição de dados ou uso de conhecimento especializado. O foco deste trabalho é investigar se modelos de linguagem de grande escala (LLMs) são capazes de aproximar, por meio de um procedimento sequencial de decisões locais, a solução do método de inferência *Most Probable Explanation* (MPE), utilizando apenas a semântica das variáveis, sem acesso às suas CPTs. O método foi avaliado em dez BN de domínios médicos distintos, comparando as configurações preditas pelo LLM com a solução MPE exata sob diferentes condições de evidência, incluindo evidências definidas tanto de acordo com quanto de forma independente da solução MPE. A acurácia por variável obtida variou de 60.7% a 100% entre as redes, mas essa variação não se mostrou explicada de forma estatisticamente significativa por características estruturais isoladas, como profundidade ou número de pais max., sugerindo que fatores semânticos específicos de cada domínio pesam mais do que a topologia da rede. Além disso, uma métrica de correspondência da configuração conjunta (*exact match*) revela que a acurácia por variável superestima substancialmente a capacidade do método de recuperar a solução MPE completa, e que essa capacidade se degrada de forma acentuada quando a evidência não é consistente com o MPE. Esses resultados indicam que LLMs podem oferecer uma aproximação de baixo custo para inferência MPE em BN ainda não parametrizadas, mas sujeita a limitações importantes, tanto teóricas — a inferência sequencial local não garante a solução conjunta ótima — quanto práticas — sensibilidade à consistência da evidência e a fatores semânticos ainda não plenamente caracterizados.**

***Index Terms*—Redes Bayesianas, Most Probable Explanation, Large Language Models, inferência, semântica**

I. Introdução

Redes Bayesianas (Bayesian Network - BN) constituem uma classe fundamental de modelos probabilísticos gráficos no campo do aprendizado de máquina e da inteligência artificial (Pearl, 1988; Koller and Friedman, 2009; Darwiche, 2009). Esses modelos combinam conhecimento especializado e dados observacionais para representar relações de dependência condicional entre variáveis aleatórias em um domínio específico. Formalmente, uma BN é definida por um grafo direcionado acíclico, no qual os nós representam variáveis e as arestas indicam relações de dependência probabilística, juntamente com um conjunto de tabelas de probabilidade condicional (Conditional Probability Tables — CPTs) que quantificam essas relações.

A estrutura do grafo informa as dependências condicionais que permitem uma representação da distribuição de probabilidade sobre o conjunto de variáveis (Koller and Friedman, 2009). Essa propriedade torna as BN adequadas para tarefas de inferência probabilística. Dada uma evidência (uma atribuição de valor a uma ou mais variáveis), é possível inferir a distribuição das variáveis restantes.

O processo de inferência possui diferentes objetivos, como a estimação de probabilidades marginais ou a identificação da explicação mais provável (Most Probable Explanation — MPE), que corresponde à configuração das variáveis não observadas que maximiza a probabilidade conjunta condicionada às evidências (Dechter, 1996). Diferentemente da inferência marginal, que envolve inferência de variáveis específicas, a inferência MPE é formulada como um problema de otimização global, no qual a ideia é atribuir os valores mais prováveis para todas as variáveis que não são tratadas como evidência.

Entretanto, para realizar as inferências, é necessário utilizar as probabilidades de cada nó, armazenadas em CPTs, cuja obtenção ainda representa um desafio. Em aplicações reais, sua construção frequentemente requer grandes volumes de dados para estimação estatística ou a elicitação de conhecimento especializado por parte de especialistas do domínio (Heckerman et al., 1995). Este processo pode ser custoso, suscetível a viés e, em muitos casos, limitado pela escassez de dados ou pela dificuldade de formalizar o conhecimento especializado.

Por outro lado, modelos de linguagem de grande escala (Large Language Models — LLMs) têm apresentado avanços em tarefas que envolvem raciocínio e inferência baseados em linguagem natural (Brown et al., 2020; Wei et al., 2023). Treinados em grandes conjuntos de dados textuais, esses mod-

elos capturam padrões estatísticos e semânticos complexos, permitindo a realização de inferências baseadas em conhecimento implícito através do raciocínio causal (Kıcıman et al., 2024). Embora não representem explicitamente distribuições probabilísticas no formato tradicional de modelos gráficos, evidências recentes sugerem que LLMs são capazes de aproximar relações causais e dependências entre variáveis de forma qualitativa (Bubeck et al., 2023).

Diante disso, é natural perguntar-se se LLMs conseguem captar padrões através da semântica para aproximar a configuração mais provável em uma rede. O trabalho propõe utilizar LLMs para aproximar inferências MPE utilizando apenas a semântica de variáveis em BN, sem a utilização das CPTs, visando simular uma situação onde a estrutura é construída mas não há valores atribuídos para cada variável. Dessa forma, busca-se entender até onde a linguagem pode ser usada como uma alternativa para aproximar inferências em redes que estão em construção e não possuem dados integrados.

II. Trabalhos relacionados

LLMs foram empregados amplamente em várias áreas, incluindo a medicina, desde tarefas tão simples como triagem e resposta a questões de conhecimento médico até fornecer suporte direto na formulação do diagnóstico diferencial (Singhal et al., 2023; Nori et al., 2023). Revisões recentes da literatura descrevem dezenas de trabalhos propondo modelos LLM para fazer prognósticos de doenças em áreas tão distintas quanto oncologia, doenças infecciosas, radiologia e emergência (Omar et al., 2024; Zhou et al., 2025). Avaliações em configurações reais, isto é, em serviços de urgência, demonstram que sistemas baseados em LLMs conseguem gerar propostas diagnósticas de qualidade ao nível de médicos especialistas (Niset et al., 2025). Contudo, essa mesma literatura ressalva que esses sistemas parecem por vezes mal calibrados, são suscetíveis a produzir ”saltos de raciocínio” de uma execução a outra e a reproduzir vieses demográficos que comprometem o seu uso de forma autônoma (Kesmen et al., 2026).

Ao mesmo tempo e de modo independente da evolução dos LLMs, as BN consolidaram-se como uma técnica de suporte à decisão clínica amplamente utilizada, tendo sido aplicadas em problemas de diagnóstico diferencial e prognóstico em áreas que vão desde as doenças cardiovasculares até aos distúrbios neurodegenerativos e o câncer (Polotskaya et al., 2024). Por exemplo, foram desenvolvidos sistemas especialistas baseados em BNs para a previsão de angina instável a partir de dados clínicos (Vila-Francés et al., 2013). Esta adoção deve-se à capacidade do formalismo para representar incerteza e relações causais entre variáveis clínicas, em um cenário clínico onde a interpretabilidade da decisão é tão importante quanto a sua precisão (Polotskaya et al., 2024). Contudo, essa mesma literatura admite que a construção destas redes, seja pela elicitação do conhecimento de especialistas ou mesmo pelo processo de aprendizagem a partir de dados, continua sendo uma tarefa trabalhosa e um dos maiores entraves à sua adoção (Polotskaya et al., 2024).

Kesmen et al. (2026) procuram combinar o uso de raciocínio em linguagem natural dos LLMs e do formalismo probabilístico de BN, ao invés de vê-los como abordagens contrárias. O framework MoBayes apresenta uma arquitetura que abstrai o raciocínio probabilístico do componente linguístico em sistemas de auxílio à decisão clínica conversacionais, preservando os cálculos de probabilidades e frequências formalizados pela BN enquanto empresta a interface em linguagem natural ao LLM (Kesmen et al., 2026). Em uma tarefa de diagnóstico de dor torácica, LLMs de uso geral tiveram o seu comportamento de inquirição de informação e raciocínio diagnóstico comparado com políticas ótimas extraídas de BN treinadas em dados clínicos reais, demonstrando discrepâncias substanciais na forma como cada abordagem escolhe as evidências (Safranek et al., 2026). Trabalhos prévios também propuseram frameworks bayesianos para orientar a coleta iterativa da história clínica com o auxílio de LLMs em condições médicas recorrentes, com o objetivo de tornar o processo diagnóstico mais explicável e reprodutível (Suraj, 2025).

Semelhante à ideia deste estudo, uma corrente recente explora a utilização de LLMs diretamente como substitutos para a elicitação especializada de CPTs. Nafar et al. (2025) investigam a capacidade de estimativa probabilística de vários LLMs, aproveitando o conhecimento armazenado nestes modelos para parametrizar BN específicas, com experimentos sobre um conjunto de oitenta redes de domínio público em áreas desde a saúde até as finanças. Os resultados indicam que as distribuições extraídas de LLMs superam tanto benchmarks aleatórios como uniformes, podendo inclusivamente atuar como priors especializados para afinar distribuições estimadas a partir de poucos dados observacionais. De modo complementar, Sekulovski et al. (2026) aproveitam LLMs para elicitar não só os valores das CPTs, como também para identificar relações de dependência condicional entre variáveis em modelos gráficos, enquanto Shaposhnyk et al. (2025) consideram LLMs como substitutos da elicitação humana para a construção de um modelo causa-efeito probabilístico na área biomédica e da saúde. Estes estudos mostram que LLMs podem servir como fonte de conhecimento probabilístico estruturado, mas concentram-se principalmente na etapa de *parametrização* do modelo, isto é, na geração prévia das CPTs, sem investigar de que forma esse conhecimento semântico pode ser reutilizado durante o processo de inferência, particularmente na resolução de problemas de otimização global, como a MPE. Este é o foco do presente estudo.

III. Metodologia

O experimento foi estruturado para avaliar o desempenho de LLMs na tarefa de inferência probabilística em diferentes BN do domínio médico. Para cada rede considerada, subconjuntos de variáveis foram selecionados como evidência (isto é, variáveis com valores atribuídos), e o modelo foi utilizado para inferir o valor das outras variáveis não observadas. As predições obtidas foram comparadas com aquelas produzidas

por inferência MPE exata, adotada como referência (*ground truth*) probabilística.

O procedimento proposto se subdivide em dois módulos complementares: (i) uma etapa de **Compilação**, na qual um LLM é utilizado para gerar, para cada variável da rede, uma tabela de decisões semânticas maximizadas equivalente a uma CPT tradicional; e (ii) uma etapa de **Inferência**, na qual as tabelas pré-compiladas são combinadas para aproximar a solução do problema de MPE mediante consultas diretas, sem novas chamadas ao modelo.

A. Fase da meta-compilação

A requisição feita ao modelo combina dois tipos de informação, produzidos em duas etapas offline, executadas uma única vez por rede antes de qualquer condicionamento a evidência: *notas de relacionamento* e *contexto de inferência da variável* (detalhado na Seção III-B).

Na primeira etapa, uma única requisição ao LLM gera, para cada variável não-raiz X_i, uma nota de relacionamento textual descrevendo qualitativamente como seus pais influenciam seu valor. O prompt utilizado[1] recebe a estrutura completa da rede, domínio, pais, filhos e variáveis que compartilham ao menos um pai de cada variável não-raiz, e solicita um parágrafo único para cada variável cobrindo cinco aspectos: (i) o pai dominante e sua direção de influência; (ii) como pais secundários modulam, atenuam ou interagem com esse efeito principal; (iii) regras explícitas de preferência entre os valores de domínio dada uma combinação específica de pais; (iv) como sinais de retroalimentação vindos de variáveis filhas devem reforçar ou sobrepor a pressão local dos pais; e (v) um erro de raciocínio comum que o próprio LLM tende a cometer para aquela variável.

B. Compilação

Seja $B = (G, \mathcal{D})$ uma BN, onde G é um grafo acíclico direcionado e $\mathcal{D}$ representa os domínios de suas variáveis. Seja E um conjunto de variáveis de evidência observadas. O problema clássico de MPE consiste em encontrar uma atribuição conjunta para todas as variáveis que não são de evidência que maximize a probabilidade a posteriori condicionada a E, isto é,

$$X^* = \arg\max_{X \notin E} P(X \mid E).$$

Utilizando apenas um LLM como fonte de conhecimento semântico, sem considerar as distribuições de probabilidade, aproximamos uma solução por meio de um processo de predição sequencial, no qual cada variável da rede é inferida a partir de um oráculo $\mathcal{M}$ (o LLM), condicionado às informações contextuais disponíveis.

Exemplo 1: Para tornar o procedimento concreto, considere a rede didática simples da Figura 1 (não associada aos datasets avaliados neste trabalho) composta por três variáveis: Fumante (X_1) e Poluição (X_2), ambas sem pais, e Falta de ar (X_3), cujos pais são X_1 e X_2.

[1]https://github.com/VictorRagazzi/pgm-llm-inference-reorganizado/blob/0ebe49115a1b66b59a6e3582299ab37fdd0a9a75/src/pgm_llm_inference/mpe/relationship_generation.py

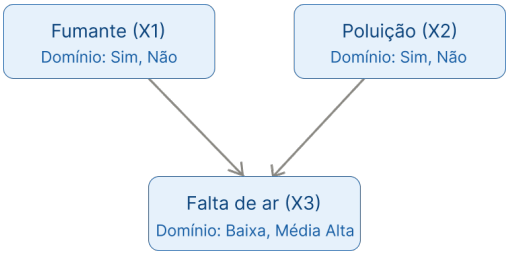

Fig. 1. Rede Bayesiana didática de três variáveis usada como exemplo ilustrativo do procedimento de compilação.

Para inferir X_3, é realizada uma **única** requisição ao oráculo $\mathcal{M}$. Essa requisição não pergunta pelo valor de X_3 isoladamente: ela envia, de uma só vez, o nome da variável, seu domínio e a tabela de contexto $\mathcal{R}_{X_3}$, contendo todas as combinações possíveis de valores dos pais X_1 e X_2, neste caso binário com quatro linhas. O oráculo responde com a tabela já preenchida por completo, atribuindo a cada linha o valor de domínio que maximiza sua resposta:

$$T_{X_3} = \begin{cases} \textit{Média} & \text{se } X_1 = \textit{Sim}, X_2 = \textit{Não}, \\ \textit{Alta} & \text{se } X_1 = \textit{Sim}, X_2 = \textit{Sim}, \\ \textit{Baixa} & \text{se } X_1 = \textit{Não}, X_2 = \textit{Não}, \\ \textit{Média} & \text{se } X_1 = \textit{Não}, X_2 = \textit{Sim}. \end{cases}$$

Para uma variável raiz como Poluição (X_2), que não possui pais, o conjunto $\mathrm{pa}(X_2) = \emptyset$ e, portanto, a tabela de contexto $\mathcal{R}_{X_2}$ possui uma única linha, correspondente à configuração vazia. Nesse caso, a requisição ao oráculo $\mathcal{M}$ não condiciona a resposta a nenhuma variável pai, retornando diretamente o valor de domínio mais provável a priori para X_2:

$$T_{X_2} = \big(\textit{Sim}\big).$$

Ou seja, o mesmo mecanismo de requisição única se aplica indistintamente a nós com e sem pais: a única diferença está na cardinalidade de $\mathcal{R}_i$, que degenera para 1 quando X_i é um nó raiz, reduzindo a tabela compilada a um único valor fixo, análogo a uma probabilidade marginal a priori. O mesmo procedimento se repete para X_1 (Fumante), também raiz, completando a compilação das três variáveis da rede didática.

O mesmo procedimento é repetido para todas as demais variáveis, resultando em um conjunto de tabelas pré-computadas, análogas a CPTs tradicionais da rede. Assim, a etapa de compilação requer uma requisição ao LLM para cada variável da rede, além de uma requisição adicional destinada à geração das notas de relacionamento (Seção III-A), totalizando exatamente $N+1$ requisições por rede, onde N é o número de variáveis (nós) da rede. Durante a etapa de inferência, quando a evidência fixa os valores dos pais de uma variável, a entrada correspondente é recuperada diretamente por consulta à tabela já compilada, sem qualquer chamada adicional ao LLM.

É importante ressaltar que o procedimento descrito nesta seção constitui uma **aproximação heurística** da inferência MPE, e não uma reformulação equivalente do problema de

otimização original. Ao decidir cada variável (X_i) sequencialmente, escolhendo o valor localmente ótimo com base apenas em seus pais, pode-se obter a solução global ótima em estruturas específicas. No entanto, em geral, essas decisões locais não garantem a configuração conjunta que maximiza a probabilidade posterior.

C. Inferência

A inferência aplica uma atribuição de evidência concreta ao conjunto de tabelas semânticas. Dada a evidência $\mathbf{e}$, os valores das variáveis observadas são fixados diretamente a partir de $\mathbf{e}$. As variáveis restantes (não pertencentes a E) são então percorridas em ordem topológica π: começando com $\hat{\mathbf{x}} = \emptyset$, cada variável X_i é visitada sucessivamente, e sua decisão é recuperada por meio de uma consulta direta à tabela T_i, usando o contexto atual $\mathbf{S}_i$ como chave. Esse contexto é formado pela combinação dos valores de evidência de quaisquer pais fixados por $\mathbf{e}$ com as decisões já acumuladas em $\hat{\mathbf{x}}$ para os demais pais, os quais garantidamente já foram resolvidos anteriormente na ordem topológica, uma vez que π respeita a estrutura de dependência do grafo. O valor recuperado $\hat{x}_i$ é então anexado a $\hat{\mathbf{x}}$, e o processo se repete até que todas as variáveis não pertencentes a E tenham recebido uma atribuição. A atribuição final $\hat{\mathbf{x}}$ é retornada como a configuração MPE prevista.

Como todas as decisões foram geradas durante a compilação, a etapa de inferência propriamente dita não requer qualquer chamada ao LLM: seu custo computacional é determinado exclusivamente pelo número de consultas às tabelas T_i, uma por variável não pertencente a E.

Exemplo 2: Aplicando esse processo ao cenário da Figura 1 com evidência $X_2 = Sim$, a ordem topológica resolve sucessivamente X_1 (retornando *Não* via tabela T_1) e X_3, retornando Média via consulta a T_3 com a chave:

$$\{X_1 = \textit{Não}, X_2 = \textit{Sim}\},$$

obtendo a configuração conjunta final:

$$\hat{\mathbf{x}} = \{X_1 = \textit{Não},\ X_3 = \textit{Média}\},$$

obtida por meio de duas consultas a tabelas pré-compiladas, sem qualquer chamada ao LLM.

IV. Setup experimental

Para avaliar o método proposto, foram utilizadas 10 BN de domínios distintos da medicina, com diferentes tamanhos e complexidades estruturais, obtidas do repositório `bnlearn` (Scutari, 2010). As características de cada rede são apresentadas na Tabela I. Nesta tabela, o número de pais max. corresponde ao maior valor, entre todos os nós da rede, do número de pais; já a profundidade corresponde ao maior caminho dirigido do grafo, medido em número de arestas, considerando as variáveis raiz como tendo profundidade zero em relação a si mesmas.

O modelo de linguagem utilizado em todos os experimentos foi o DeepSeek-V4-Pro, escolhido pela boa relação entre custo computacional e desempenho em raciocínio. Todas as inferências foram realizadas com temperatura igual a 0.0, tornando as respostas determinísticas.

TABLE I
Características das Redes Bayesianas utilizadas.

Domínio	Nós	Arestas	Pais máx.	Profundidade
TDAH	19	18	1	1
Sintomas de Covid-2	12	30	9	9
Sintomas de Covid-1	12	11	1	1
Gonorreia	10	9	3	3
Hepatite	70	123	6	7
Monitoramento de UTI	37	46	4	10
Alergia-2	8	8	2	4
Alergia-1	8	12	3	3
Diabetes	9	11	4	3
Doenças pediátricas	20	25	2	4

Para cada rede, o procedimento de Compilação descrito na Seção III-B foi executado uma única vez, gerando as tabelas semânticas T_i para todas as variáveis com exatas $N + 1$ requisições à LLM, sendo N o número de nós da rede e mais uma requisição para a meta-compilação. Em seguida, a etapa de Inferência foi aplicada repetidamente, variando o conjunto de evidência E, sem novas chamadas ao LLM.

O número de variáveis de evidência foi incrementado progressivamente, de 1 até 50% do total de nós da rede. Para cada tamanho de evidência, foram realizadas 3 repetições, cada uma com um subconjunto de variáveis de evidência escolhido aleatoriamente, de forma a reduzir o efeito de uma escolha particular de evidência sobre o resultado. Em cada repetição, o valor inferido pelo modelo para as variáveis não observadas foi comparado ao valor produzido por inferência MPE exata.

A hipótese para essa abordagem é que o fornecimento de mais evidência gere mais contexto sobre o caso clínico e melhore as decisões do LLM em relação ao MPE exato.

Os valores atribuídos às variáveis de evidência foram definidos de acordo com a própria solução MPE exata e **incondicional** da rede. Essa escolha isola o comportamento do LLM na etapa de decisão condicionada a uma evidência coerente com o alvo, mas constitui um viés experimental, uma vez que cenários clínicos reais podem apresentar evidências (sintomas, achados de exame) que não são necessariamente consistentes com a explicação mais provável. O impacto dessa escolha é quantificado na Seção V-C, onde um segundo cenário, com evidência definida de forma independente do MPE, é comparado ao protocolo original.

Em cada repetição, os valores inferidos para as variáveis não observadas foram comparados aos valores obtidos por inferência MPE exata na mesma rede e com o mesmo conjunto de evidências. A acurácia foi calculada como a proporção de variáveis cujo valor predito coincidiu com o valor da solução MPE exata:

$$\mathrm{Acc}(E) = \frac{\text{Número de variáveis corretamente inferidas}}{\text{Número total de variáveis não observadas}}.$$

Além da acurácia por variável, foi calculada a correspondência da configuração conjunta (*exact match*), que atribui

valor 1 quando a configuração MPE é recuperada completamente, e 0 caso contrário.

V. Resultados

Inicialmente, os resultados serão apresentados para cada dataset com apenas uma evidência. Em seguida, será realizada uma análise se o aumento do número de evidências agrega valor nas inferências realizadas, e se o critério usado para definir os valores de evidência afeta esse comportamento. Por fim, investiga-se quais fatores estruturais e de nível de variável estão associados ao desempenho do método.

A. Acurácia por dataset

A Tabela II apresenta a acurácia média obtida em cada uma das dez redes avaliadas, na condição em que os valores de evidência são definidos de acordo com a solução MPE (Seção IV). TDAH e Sintomas de Covid-2 atingem acurácia de 100%, em contrapartida, redes como Alergia-2 (65.3%), Alergia-1 (64.6%), Diabetes (61.3%) e Doenças pediátricas (60.7%) apresentam os piores desempenhos médios, na faixa de sessenta por cento.

TABLE II
Acurácia média por nó e correspondência exata de inferência MPE via LLM para cada uma das dez Redes Bayesianas avaliadas.

Dataset	Acurácia por var. (%)	Exact match (%)
TDAH	100.0	100.0
Sintomas de Covid-2	100.0	100.0
Sintomas de Covid-1	92.7	33.3
Gonorreia	87.6	16.0
Hepatite	79.3	0.0
Monitoramento de UTI	79.1	0.0
Alergia-2	65.3	0.0
Alergia-1	64.6	0.0
Diabetes	61.3	0.0
Doenças pediátricas	60.7	0.0

A recuperação do MPE completo se mostra uma tarefa difícil, já que qualquer variável inferida incorretamente já resulta em uma taxa de 0, e essa dificuldade é refletida nos resultados obtidos na Tabela II.

B. Efeito da proporção da evidência

A Figura 2 detalha a acurácia média em função da proporção de variáveis de evidência para as dez redes avaliadas deste trabalho. O comportamento observado não é uniforme entre os domínios, permitindo identificar três padrões distintos, por exemplo: TDAH mantém acurácia de 100% independentemente da proporção de evidência; Hepatite, Monitoramento de UTI e Doenças pediátricas melhoram conforme a evidência aumenta (de aproximadamente 70% para 84%, 71% para 83% e 53% para 70%, respectivamente); e Gonorreia e os dois datasets de Alergia pioram (Gonorreia de aproximadamente 90% para 84%, e Alergia-1 e 2 de aproximadamente 80% para 60% ou menos).

Já o *exact match* permanece nulo na maioria das redes independentemente da proporção de evidência, diferente da tendência gradual observada na acurácia por variável, com algumas exceções.

C. Efeito do critério de definição da evidência

Os experimentos citados foram realizados utilizando valores de evidência definidos de acordo com a própria solução MPE exata da rede; denominamos essa condição *evidência MPE-consistente*. Também foi realizado um segundo experimento, nas mesmas dez redes, em que os valores de evidência foram definidos de forma independente da solução MPE, sendo contraditórios entre o MPE e entre si; denominamos essa segunda condição *evidência MPE-inconsistente*. Comparando as duas condições, a acurácia média por variável cai de 80.1% (MPE-consistente) para 58.2% (MPE-inconsistente), e a taxa de *exact match* cai de 26.2% para 10.6%, como visto na Figura 3.

D. Fatores associados ao desempenho

Os resultados das seções anteriores revelam que o desempenho do método proposto provavelmente é determinado pelo domínio do dataset: diferenças de acurácia entre redes de tamanho semelhante (por exemplo, Sintomas de Covid-2 e Doenças pediátricas, com 12 e 20 nós, mas desempenhos de 100% e 60.7%, respectivamente) sugerem que a estrutura por si só não explica o padrão observado. Testando a hipótese formalmente via correlação de Spearman entre as métricas (acurácia por variável e *exact match*) e características estruturais em nível de rede (número de nós, arestas, número de pais máximo e profundidade; $n = 10$), nenhuma das correlações testadas se mostrou estatisticamente significativa (por exemplo, acurácia $\times$ profundidade: $\rho = -0.068$, $p = 0.852$; *exact match* $\times$ profundidade: $\rho = -0.366$, $p = 0.298$). Esse resultado demonstra que não há evidência estatística de que a profundidade, o número de pais max ou o tamanho da rede, isoladamente, expliquem o desempenho do método, e a hipótese que melhor explica, é que a acurácia depende do domínio da rede. O caso de Sintomas de Covid-2, uma das rede estruturalmente mais complexa do conjunto (número de pais max. 9, profundidade 9) atingindo 100% de acurácia, mostra essa desconexão entre a complexidade da rede e o desempenho.

Como a análise anterior é limitada pelo número de redes disponíveis (n=10), complementamos-na com uma comparação em nível de variável. Para cada variável avaliada nas dez redes, relacionamos seu número de pais (grau de entrada) à acurácia obtida especificamente para aquela variável, o que eleva substancialmente o tamanho amostral em relação à análise por rede (Figura 4: $n = 39$ para variáveis sem pais, $n = 89$ para uma variável pai, $n = 48$ para duas, $n = 18$ para três e $n = 6$ para quatro; categorias com $n < 4$ foram omitidas). Nessa análise, observa-se uma tendência de queda na acurácia conforme o número de pais aumenta (de aproximadamente 0.93 para variáveis sem pais a aproximadamente 0.47 para variáveis com quatro pais), acompanhada de dispersão crescente entre as categorias intermediárias.

Ademais, os experimentos da Seção V-A demonstram o efeito de uma evidência selecionada aleatoriamente em cada rede, então, é justo pensar se a posição da evidência selecionada, pode afetar o resultado do método. Foi realizado

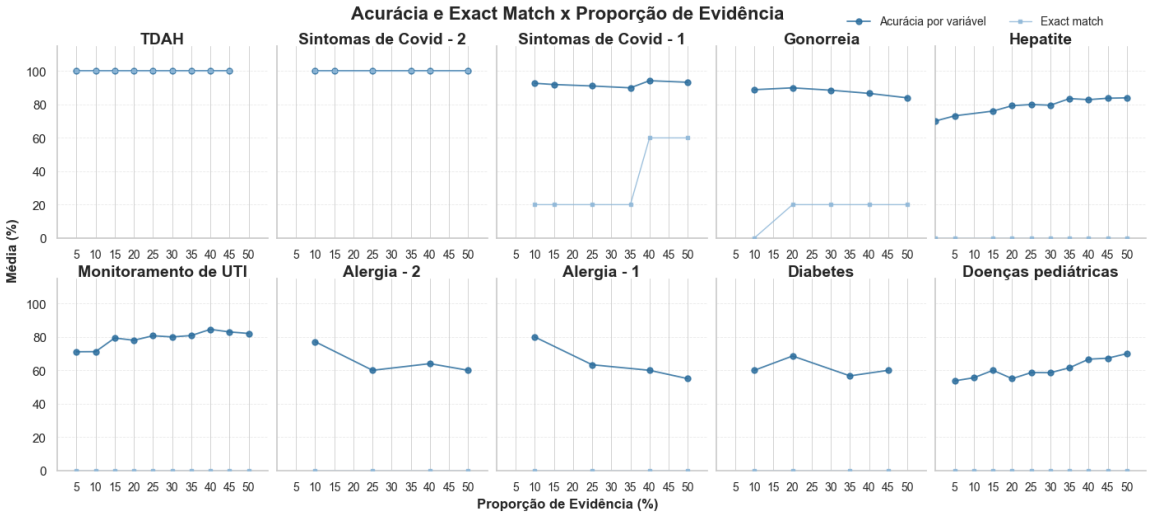

Fig. 2. Acurácia média de inferência MPE via LLM em função da proporção de variáveis de evidência. O eixo horizontal representa faixas percentuais do total de nós (5% a 50%), usadas para agregar os resultados entre redes de tamanhos distintos; o protocolo experimental (Seção IV) parte de 1 variável de evidência.

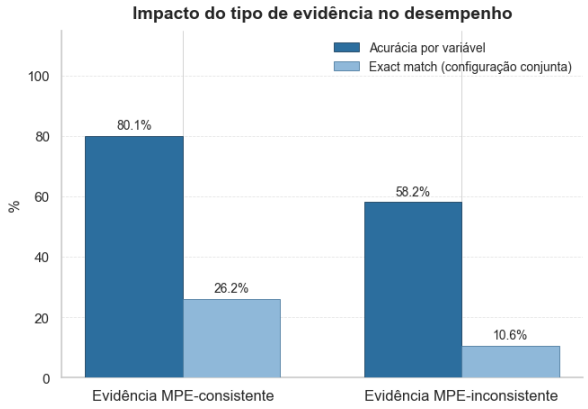

Fig. 3. Acurácia média por variável e taxa de *exact match* da configuração conjunta, comparando evidência definida de acordo com o MPE (evidência MPE-consistente) e evidência definida de forma independente do MPE (evidência MPE-inconsistente), agregadas sobre as dez redes avaliadas.

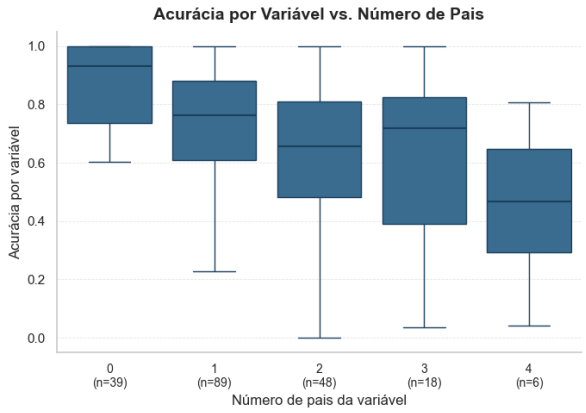

Fig. 4. Acurácia por variável em função do número de pais da variável, agregada sobre as dez redes avaliadas. Categorias com $n < 4$ (5, 6 e 9 pais) foram omitidas.

um experimento exaustivo em que, para cada uma das dez redes, cada variável foi utilizada individualmente como única evidência, associando o resultado à profundidade topológica normalizada do nó-evidência (0 = raiz, 1 = folha mais funda).

A Figura 5 apresenta a acurácia por variável em função da posição normalizada da evidência, agregada sobre as dez redes ($n = 205$ execuções). Observa-se uma fraca tendência de aumento da acurácia à medida que a evidência se afasta da raiz e se aproxima das folhas, confirmada pela correlação de Spearman entre posição normalizada e acurácia ($\rho = 0.294$, $p = 1.84 \times 10^{-5}$) e entre posição normalizada e *exact match* ($\rho = 0.250$, $p = 3.03 \times 10^{-4}$), ambas estatisticamente significativas, embora de magnitude modesta.

VI. Discussão

Os resultados apresentados na Seção V-D indicam que, embora as características estruturais da rede consideradas isoladamente (número de nós, arestas, número de pais max. e profundidade) não expliquem estatisticamente o desempenho do método, o número de pais de cada variável está associado a uma queda de acurácia por variável: variáveis com mais pais impõem um contexto maior para o LLM decidir corretamente durante a Compilação, o que pode gerar acúmulo de erro nas decisões, mesmo não se traduzindo em uma correlação significativa quando agregada em nível de rede. Esse padrão entre número de pais e acurácia, mostra uma oportunidade de evoluir o método na etapa de Compilação (Seção III-B), e não na etapa de Inferência (que é puramente combinatória, dado que as tabelas já estão compiladas): a qualidade de

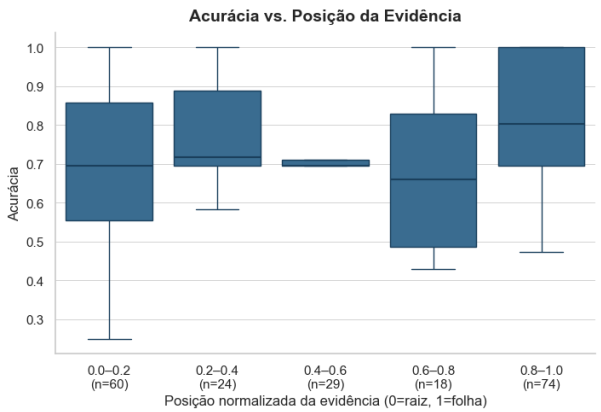

Fig. 5. Acurácia por variável em função da posição normalizada da evidência (0 = raiz, 1 = folha mais funda), agregada sobre as dez redes avaliadas.

cada T_i depende de quão bem o LLM consegue traduzir o significado real da variável e de seus pais para uma decisão local, sem conhecer a distribuição de probabilidade subjacente. Variáveis raiz representam um caso especial desse problema, pois sua tabela compilada consiste em um único valor a priori, determinado exclusivamente pelo conhecimento de mundo do modelo, sem nenhum pai que o possa corrigir. Embora, em média, variáveis-raiz tenham desempenho alto, nos casos específicos em que o prior do LLM diverge da distribuição real da população onde a rede foi construída (como se observou na variável `Massa corporal` da rede de Diabetes), ele é propagado para toda a cadeia de inferência seguinte.

Uma solução que pode resolver o problema de perda de acurácia com o aumento de contexto de pais, seria a adição de notas descritivas. Essas notas apresentariam descrições sobre como cada variável se influencia, semelhante às notas de relacionamento, entretanto, geradas por especialistas entendidos das relações entre variáveis e de possíveis vieses que uma LLM pode considerar, ao pensar em um escopo geral, e não focado no dataset. Essas notas podem trazer um poder de raciocínio para o oráculo semelhante a uma estratégia de prompt já conhecida na literatura, a estratégia de *few-shot* (Brown et al., 2020).

O efeito da proporção de evidência (Figura 2) confirma parcialmente essa leitura. Em Hepatite, Monitoramento de UTI e Doenças pediátricas, mais evidência tende a melhorar a acurácia, consistente com a hipótese de que mais contexto factual reduz a ambiguidade da inferência para o LLM. Entretanto, em Gonorreia e Diabetes esse efeito não se confirma: a acurácia se mantém estável ou piora levemente conforme mais variáveis são fixadas como evidência.

A. Limitações

É importante enfatizar que os resultados aqui relatados devem ser interpretados como evidência de que o procedimento proposto *aproxima*, sob determinadas condições, a solução do MPE, não como demonstração de que a inferência sequencial local seja equivalente à otimização conjunta global. Todos os experimentos foram conduzidos com um único modelo LLM.

Outra observação é que quando a evidência deixa de estar alinhada com a explicação mais provável, tanto a acurácia por variável quanto, de forma ainda mais acentuada, o *exact match* da configuração conjunta se deterioram (Figura 3), sugerindo que os ganhos observados com mais evidência no protocolo original dependem, ao menos em parte, de essa evidência ser informativa e coerente com o alvo. Entretanto, essa análise pode ser tão enviesada quanto utilizar apenas evidências condizentes, já que os valores das evidências foram definidos de forma a serem contraditórios entre o MPE e entre si, sendo casos pouco representativos do mundo real.

Essas lacunas não comprometem os achados centrais deste trabalho, mas devem ser investigadas antes que o método seja considerado maduro para validação clínica.

B. Implicações práticas

Os resultados apontam para um próximo passo: o uso de metadados adicionais gerados por especialistas humanos, completando o contexto gerado na fase da meta-compilação (Seção III-A). Poderá ser útil nos casos em que o método atual falha, em casos de variáveis raízes cujos valores não são intuitivos a partir do conhecimento de mundo do LLM, ou em redes cujas relações de causa e efeito são também ocultas pela semântica. Um metadado explícito dizendo qual a distribuição de uma variável raiz naquele grupo de estudos, em vez da distribuição baseada no conhecimento geral do LLM, pode ser o viés necessário que corrige precisamente o erro que se vê.

Do ponto de vista prático, o método proposto não é um substituto da inferência de probabilidade exata quando se tem acesso a dados e à BN completa (com CPTs numéricas). O seu valor está em ser uma solução para o caso em que esses dados não existem ou não estão disponíveis, mas o conhecimento de domínio necessário para descrever qualitativamente as relações de causa e efeito entre variáveis está disponível, seja na forma de conhecimento médico geral, seja via o conhecimento do especialista como nota. Neste caso, os resultados indicam que o método consegue aproximar bem (acima de 60% de acerto, chegando a 100% em algumas redes) a solução exata do MPE, em especial em redes onde a semântica das variáveis é mais clara.

VII. Conclusão

Em suma, este trabalho mostrou que um LLM, utilizando apenas a semântica das variáveis e um procedimento de decisões sequenciais locais, consegue aproximar a solução do MPE em BN de domínio médico, com acurácia por variável entre 60.7% e 100% entre as dez redes avaliadas. Essa aproximação, no entanto, é heurística e não uma reformulação equivalente da otimização conjunta, sendo sensível à consistência da evidência fornecida e não garantindo a recuperação da configuração MPE completa. O método proposto se mostra, assim, uma alternativa de baixo custo para cenários em que uma BN ainda não possui CPTs numéricas, mas o conhecimento de domínio necessário para descrever as relações entre variáveis está disponível, e deve-se, antes de

qualquer uso em contextos clínicos reais, ser complementado por notas de especialistas ou por metadados adicionais que mitiguem as limitações identificadas.

VIII. Agradecimentos

Os autores agradecem à Fundação de Amparo à Pesquisa do Estado de Minas Gerais (FAPEMIG), do Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) e da Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) pelo apoio financeiro concedido, essencial para o desenvolvimento desta pesquisa.

***Abstract*—Autism Spectrum Disorder (ASD) diagnosis in children typically relies on multiple assessments conducted by specialists, whose high financial cost may limit access for low-income populations and restrict the availability of these services within public healthcare systems. These limitations also contribute to the scarcity of structured datasets suitable for training machine learning models. Moreover, available diagnostic reports are often heterogeneous in format and require substantial preprocessing to extract structured information. To address these challenges, this work presents a methodology for generating ASD-related data based on expert knowledge combined with synthetic data generation techniques. The proposed approach uses expert-defined scenarios to generate synthetic datasets for training and internally evaluating machine learning models related to the pre-screening of ASD in children aged 0 to 6 years.**

I. Introduction

Diagnosing Autism Spectrum Disorder (ASD) requires the integration and assessment of multiple behavioral, social, cognitive, and developmental aspects [3]. Reaching an accurate diagnosis is a challenging task because ASD encompasses a broad spectrum of presentations, with each individual exhibiting different characteristics and varying levels of support needs. Furthermore, the diagnostic process depends not only on the clinical expertise of the professional but also on the active collaboration of parents or caregivers [4]. In addition to these intrinsic diagnostic challenges, comprehensive ASD assessments are often time-consuming and costly, as they typically require the administration of multiple standardized instruments over several clinical sessions. These financial and logistical demands may limit access to diagnosis among low-income populations and pose additional challenges for publicly funded healthcare systems, such as the Brazilian Unified Health System (SUS).

Furthermore, gathering reliable clinical data becomes even more complex when focusing on early childhood, specifically the age group from 0 to 6 years. Obtaining structured data within this developmental period is particularly challenging, as early ASD-related characteristics can be subtle and often overlap with typical developmental variability or other neurodevelopmental conditions. Moreover, younger children typically display camouflaging behaviors less frequently and less intensely, factor which can facilitate the identification. Consequently, early childhood is widely recognized as an important period for identification and intervention, as timely therapeutic support may contribute to the development of communication, social, adaptive, and cognitive skills [20]. Early intervention can reduce long-term support needs, generating a positive financial impact on care budgets.

One possible strategy for supporting ASD pre-screening and referral processes is the use of machine learning methods. However, a major challenge is that such models typically require large amounts of high-quality data for training [6]. In this context, high quality implies that the data accurately represent real-world clinical diversity, allowing the model's generalizability to be evaluated across independent environments, such as different hospitals or clinical settings. In the case of ASD, structured datasets are scarce. Besides the limited access to diagnostic assessments, the available information is often embedded in heterogeneous clinical reports that must be extracted, standardized, filtered, and preprocessed before it can be used for machine learning. This entire process is labor-intensive, time-consuming, and costly, which largely explains the scarcity of high-quality datasets for developing reliable machine learning models related to ASD pre-screening, particularly in the Brazilian context [7].

Synthetic data generation has been investigated as a strategy for supporting machine learning research when access to sufficiently large and structured datasets is limited. For tabular data, probabilistic graphical models, copula-based methods, and conditional probabilistic generators seek to preserve different statistical properties of a reference dataset. However, statistical similarity alone does not guarantee predictive utility, privacy, or generalization to independent populations. Therefore, the quality of synthetic data must be evaluated using complementary criteria. [1] A more detailed discussion of synthetic data generation and evaluation methodologies is presented in the following section.

In this paper, we investigate an approach for generating data that can be used to train machine learning models through a

two-step framework. The first step consists of eliciting domain knowledge from an ASD specialist through interviews and structured meetings. The objective is to identify relevant predictive variables and extract inference rule scenarios based on the specialist's expertise aiming to translate complex cognitive relations and jointly characterize scenarios associated with positive or negative ASD-related classifications (hypothetical individuals) rooted in her clinical experience. The resulting rule base represents our initial reference dataset, where each individual corresponds to an expert-defined and clinically plausible combination of characteristics. These rules represent structured expert knowledge rather than clinical records from evaluated children. Knowledge elicitation from domain experts has long been recognized as a fundamental step in the development of expert systems and knowledge-based decision-support systems [9].

The second step focuses on the application of synthetic data generation techniques to produce additional samples for training machine learning models related to ASD prescreening research. The use of synthetic data has emerged as a potential strategy for addressing data scarcity in machine learning applications, particularly in healthcare, where privacy constraints and the high cost of data collection often limit the availability of large, high-quality datasets [11]. Nevertheless, synthetic data reproduce only the information available in the source dataset and cannot, by themselves, establish clinical representativeness.

To evaluate the proposed data generation framework, we conducted a series of computational experiments using machine learning classifiers and a fuzzy rule-based classifier (without learning). In particular, we evaluated three methods for generating binary synthetic data: a Gaussian Copula model, a Bayesian Network, and a conditional Beta-Bernoulli model [12]. To prevent generative data leakage, the reference scenarios were partitioned before fitting the generators. In each cross-validation fold, every generator was fitted exclusively using the reference training partition, while the held-out reference scenarios remained isolated from generator fitting, synthetic data generation, classifier training, and model selection.

The experiments were designed to investigate three main questions regarding the generated synthetic data. First, we assessed how well the synthetic data preserve the statistical properties and dependency structure of the expert-defined reference dataset. Second, we investigated whether classifiers trained on synthetic data can transfer the learned patterns to held-out reference scenarios that were not used to fit either the generator or the classifier. Third, we evaluated whether augmenting the reference training data with synthetic samples provides consistent predictive improvements over reference-only and synthetic-only training.

Because synthetic data quality is multidimensional , the generators were evaluated using complementary measures of statistical fidelity, diversity, and predictive utility [2]. We also examined whether the relative performance of the generators remained consistent across classifiers with different inductive biases, including linear models (Logistic Regression), kernel-based methods (Support Vector Machines), tree-based ensembles (Random Forest and XGBoost), and fuzzy rule-based systems.

This distinction is essential because statistical alignment does not guarantee optimal predictive transfer, nor do improvements in AUC-ROC reliably reflect gains in MCC, sensitivity, specificity, or overall stability. Therefore, instead of relying on a single metric, model and generator selection was based on a heuristic interpretation of each evaluation dimension and its variance across repeated cross-validation partitions.

II. Reference Dataset Construction and Synthetic Data Generation

This section describes the construction of the expert-defined reference dataset and the generation of synthetic binary samples. The framework comprises knowledge elicitation, variable selection, and synthetic data generation.

A. Knowledge Elicitation from an ASD Specialist

Developing predictive machine learning models for Autism Spectrum Disorder (ASD) requires datasets that adequately capture relevant clinical and contextual variables. However, existing options present significant limitations [4], [28]. For instance, benchmark datasets such as the one by [8] rely on ten Q-CHAT screening items [13] and basic demographics, omitting critical developmental factors highlighted by domain specialists (e.g., language acquisition milestones, developmental regression, and detailed clinical history). Furthermore, its caregiver-report nature, minimal representation of the Latino population and other populations, and limited documentation restrict its applicability to local clinical contexts.

To overcome these contextual gaps, we elicited domain knowledge from a neuropsychologist (Regina C. Antão Lima) with over ten years of experience in assessing ASD and other neurodevelopmental conditions. Following established expert system methodologies [9], this knowledge acquisition process was conducted in two main stages: feature identification and scenario formulation.

First, the specialist identified 34 binary predictive attributes (features) considered critical for clinical observation and ASD assessment. These variables were derived from standard assessment instruments recommended in the literature and are essential for differentiating ASD-related characteristics from those associated with other neurodevelopmental conditions. In this framework, a value of 1 indicates the presence of the corresponding attribute, whereas a value of 0 indicates its absence. The complete set of 34 attributes is detailed in Table I.

In the second stage, the objective was to formulate inference rules representing specific combinations of these 34 characteristics associated with positive or negative ASD classifications. Given the high density and manual synthesis required for each expert-defined decision rule, this process yielded a compact reference dataset of 40 clinically plausible scenarios. Although small in volume, each instance explicitly represents complex combinations of behavioral and developmental traits, such as

severe impairments in social interaction paired with delayed language acquisition, providing a domain-validated foundation for interpretable screening.

At the end of this process, the initial reference dataset comprised 40 expert-defined scenarios (instances), each represented by the 34 binary predictive attributes and one binary target assigned according to the elicited expert rules. However, a critical limitation must be acknowledged: these scenarios represent structured expert knowledge rather than clinical observations of independently assessed children. Furthermore, the manual acquisition and processing of this dataset required translating highly nuanced clinical judgments into simplified binary attributes, a data treatment step that inherently introduces subjectivity and may obscure the gradual severity of ASD symptoms. Consequently, these instances carry biases inherent to expert elicitation and should not be interpreted as actual patient records or as a statistically representative sample of the broader ASD population. Nonetheless, this simplified representation was necessary to enable a practical framework for future real-world deployment and to facilitate validation by other domain specialists.

TABLE I
PREDICTIVE ATTRIBUTES ELICITED FROM THE ASD SPECIALIST.

ID	Attribute	ID	Attribute
V1	Repetitive behaviors	V18	Aversion to parties
V2	Sensory hypersensitivity	V19	Avoidance of physical affection
V3	Theory of mind difficulties	V20	Atypical use of toys
V4	Learning difficulties	V21	Delayed speech
V5	Poor motor coordination	V22	Impaired speech
V6	Hyperactivity	V23	Atypical language (echolalia)
V7	Repetitive motor movements	V24	Social interaction difficulties
V8	Unusual body postures	V25	Limited interest in toys
V9	Developmental regression	V26	Limited visual communication
V10	Inflexibility	V27	Restricted interests (hyperfocus)
V11	Inappropriate emotional response	V28	Loss of interest
V12	Lack of danger awareness	V29	Difficulty understanding speech
V13	Sleep or pain abnormalities	V30	Excessive fears
V14	Impulsiveness	V31	Frequent screaming
V15	Oral sensory-seeking behaviors	V32	Conflicts with peers
V16	Difficulty accepting limits	V33	Lack of friendships
V17	Lack of independence	V34	Reduced facial expression

To accommodate user accessibility and streamline future evaluation, the 34 attributes were defined as concise feature names for technical modeling (as summarized in Table I), but originally formulated as behavioral questions (e.g., assessing pacing or continuous jumping instead of a raw label like "agitation"). This questionnaire-based representation ensures the framework remains intuitive for non-expert respondents and facilitates validation by other domain specialists.

B. Synthetic Data Generation

The resulting dataset was relatively small compared with its dimensionality, consisting of 40 expert-defined scenarios described by 34 binary predictor variables. Among these scenarios, 28 were assigned to the ASD-positive class and 12 to the non.

A strategy that has been successfully employed to mitigate data scarcity in medical applications is the generation of synthetic data [11], [27], [26].

Synthetic data generation has been investigated as a strategy for increasing the amount of training data while preserving relevant statistical properties of the original dataset. Its use has been explored in healthcare and other data-constrained applications [1].

In this study, we evaluated two synthetic data generation approaches for binary data: the Gaussian Copula and the Conditional Beta–Bernoulli generator. These methods were selected because they represent complementary strategies for modeling dependencies between predictor variables and the target. Both generators were trained strictly on the training fold of each cross-validation partition, while the corresponding test fold remained isolated for final evaluation.

To prevent data leakage, both generators were trained strictly on the training fold of cross-validation partition, leaving the test fold entirely isolated for model evaluation.

Conditional Beta-Bernoulli (Conditional Independence): Estimates the target class prior $P(y)$ and generates attributes X_j conditionally and independently given the class label, $P(X_j = 1 \mid y)$, with additive Laplace smoothing ($\alpha = 1.0$). As a conservative and computationally efficient baseline, it minimizes parameter variance and overfitting risk, though it omits direct feature-to-feature correlations. Binary Gaussian Copula (Joint Dependency): Captures the joint distribution of features and targets by mapping observed marginal probabilities and pair-wise binary correlations into a continuous Gaussian latent space. Synthetic continuous vectors are sampled from a Multivariate Normal distribution and converted back to binary values using quantile thresholding ($\alpha = 0.5$). This approach explicitly preserves complex clinical symptom co-occurrences.

Comparing these two paradigms isolates the effect of inductive bias on synthetic transfer. Exploring whether modeling complex feature interactions provides superior predictive utility or whether a simpler, lower-variance generator proves more resilient Although Bayesian Networks were also preliminary investigated, they were ultimately excluded from the final framework, as their predictive performance and evaluation metrics were unsatisfactory given the sample size constraints.

III. CLASSIFIERS, METRICS, AND VALIDATION PROTOCOL

The synthetic datasets were evaluated from complementary perspectives to determine whether they preserve relevant properties of the expert-defined reference data and whether the generated samples provide useful information for ASD-related classification experiments. The evaluation comprised three main dimensions: statistical fidelity, predictive utility, and sample diversity.

Statistical fidelity was evaluated by comparing the marginal distributions, target prevalence, and pairwise dependency structures of the synthetic and reference data. Correlation Root Mean Squared Error (RMSE) was used to summarize differences between attribute frequencies and between the corresponding association matrices. In addition, a classifier two-sample test was employed to assess whether synthetic and reference samples could be distinguished computationally.

Sample diversity and exact-record overlap were also examined to identify limited coverage of the reference space or excessive reproduction of expert-defined scenarios.

Predictive utility was assessed by training classifiers under reference-only, synthetic-only, and augmented training conditions. The evaluated algorithms included Logistic Regression (LR) , Support Vector Machines (SVM) , Random Forests (RF) , Extreme Gradient Boosting (XGBoost) , and fuzzy rule-based classifiers. These models represent different learning assumptions: LR provides a linear probabilistic baseline, SVM supports margin-based and potentially nonlinear decision boundaries, RF and XGBoost represent nonlinear interactions through tree-based ensembles, and fuzzy classifiers provide an interpretable rule-based representation. Using classifiers with different learning mechanisms makes it possible to examine whether the predictive relationships captured by each generator remain useful across modeling approaches. However, performance differences among classifiers do not necessarily indicate poor synthetic-data quality, since each model has its own inductive bias and sensitivity to the data structure. Therefore, predictive utility was evaluated using complementary metrics, including MCC, F1-score, AUC-ROC, sensitivity, specificity, and balanced accuracy, rather than relying on a single performance measure.

To prevent information leakage, the reference scenarios were partitioned before any data-dependent operation. For each cross-validation partition, the synthetic generator and classifier were fitted exclusively using the reference training fold, while the corresponding held-out reference fold remained isolated for final evaluation. All reported results therefore represent internal computational validation against expert-defined scenarios and should not be interpreted as evidence of clinical performance or population-level representativeness.

A. Classifiers

Evaluating multiple classifiers provides a comprehensive assessment of the quality of the generated synthetic data from different learning perspectives. If the synthetic datasets adequately preserve the statistical characteristics and predictive relationships present in the original dataset, consistent classification performance is expected across different learning algorithms. Conversely, substantial variations in predictive performance may indicate that important structural properties of the original data have not been preserved during the synthetic data generation process.

B. Selection of Metrics

The predictive performance of the classifiers was evaluated using standard metrics for binary classification derived from the confusion matrix, namely True Positives (TP), True Negatives (TN), False Positives (FP), and False Negatives (FN) [14]. The following performance measures were considered:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}, \tag{1}$$

$$\text{Sensitivity (Recall)} = \frac{TP}{TP + FN}, \tag{2}$$

$$\text{MCC} = \frac{TP \cdot TN - FP \cdot FN}{\sqrt{M}}. \tag{3}$$

where $M = (TP+FP)(TP+FN)(TN+FP)(TN+FN)$. Confusion matrices were also analyzed to provide a detailed assessment of the specific classification errors.

In addition, the Area Under the Receiver Operating Characteristic Curve (AUC-ROC) was used to evaluate the discriminative ability of each classifier independently of the decision threshold [15].

Selecting the most appropriate evaluation metrics for classification tasks is often challenging, as each metric presents distinct advantages and limitations. In many scenarios, metrics behave complementarily, where optimizing one may lead to the degradation of another. This requires a strategic balance or the selection of a primary representative benchmark.

In the evaluation of machine learning models, traditional metrics such as Accuracy and F1-Score are commonly utilized as standard benchmarks for classification performance [23]. However, relying solely on these metrics can inadvertently mask poor classification performance, especially when dealing with highly imbalanced and scarce datasets. To address this limitation, Chicco and Jurman [29] demonstrated that the Matthews Correlation Coefficient (MCC) provides a substantially more robust assessment under such constraints.

In parallel, when translating these computational models into clinical practice, the context of early screening for Autism Spectrum Disorder must be considered. In this domain, primary healthcare objectives demand a strong focus on sensitivity (recall). This priority stems from the fact that facilitating early interventions within the crucial window of high neuroplasticity requires maximizing the identification of potential cases to avoid false negatives. Indeed, clinical gold-standard tools, such as the M-CHAT-R/F [30], are intentionally designed with high sensitivity to capture the maximum number of suspected cases, even at the expense of generating temporary false positives.

Consequently, a hierarchical evaluation strategy is adopted in this study. The MCC is established as our gold-standard metric due to its reliable statistical properties in small and imbalanced sample sizes. Nevertheless, models will also be rigorously evaluated using the AUC-ROC to specifically assess their class separability thresholds. Concurrently, sensitivity will be monitored to guarantee a strict clinical focus on maximizing early screening detection, thereby preventing missed cases prior to specialist referral. Finally, standard Accuracy is utilized strictly as a final baseline verification to provide a conventional measure of overall performance.

C. Methodological Safeguards

The following experimental protocol was applied to all datasets (original, synthetic, and augmented), ensuring a fair comparison among the evaluated data generation strategies.

1) Experimental Rigor and Methodological Safeguards: To ensure reliable performance estimates and robust generalization, all experiments were conducted using repeated stratified k-fold cross-validation [16]. Stratification enforces the original class distribution across all training and testing folds, thereby mitigating sampling bias. To strictly prevent data leakage [5], a rigorous separation between training and evaluation partitions was maintained for all model training and tuning were performed exclusively within the training folds, ensuring no test data information influenced the learning process [18]. Classifier stability was evaluated by computing the mean and standard deviation and confidence intervals of the metrics across all iterations [6]. In synthesis, combining repeated stratified validation, strict data leakage prevention [5], and variance analysis mitigates the risk of biased conclusions. This framework provides a statistically sound foundation to confirm whether the synthetic data reliably preserves relevant features for subsequent clinical modeling.

2) Machine Learning Benchmarking and Synthetic Data Evaluation: The quality of the generated synthetic data was validated through its empirical utility across diverse machine learning algorithms. Beyond verifying statistical similarity to the original sample, this approach assesses whether the synthetic data effectively preserves the underlying clinical patterns defined by the experts.

D. Classifier Selection and Experimental Scenarios

As previously outlined, the validation of the generated synthetic data was conducted by training a diverse suite of machine learning algorithms, which were subsequently evaluated using the metrics detailed in the preceding section (AUC-ROC, F1-Score, Sensitivity, Specificity, MCC, and Accuracy). To provide a comprehensive assessment of synthetic data quality, the models were evaluated under two primary experimental paradigms: Train Synthetic, Test Real (TSTR) and Data Augmentation (Aug).

However, the dataset used in this study does not consist of actual clinical records from real patients. Rather, it comprises data representing hypothetical individuals, constructed based on expert knowledge. Therefore, throughout these experiments, we use the term "reference data" instead of "real data" to denote the original expert-knowledge-based dataset. Accordingly, the TSTR and Augmentation paradigms are adapted to this setting by replacing the term real data with reference data while preserving the underlying experimental protocols.

- **Train Synthetic, Test Reference (TSTR):** In this paradigm, the models are trained exclusively on synthetic data and evaluated on the held-out expert-defined scenarios. These scenarios represent hypothetical individuals (reference) rather than clinical records. This setting evaluates the predictive utility and transferability of the synthetic data within the expert-defined knowledge base.
- **Data Augmentation (AUG):** This paradigm combines the expert-defined reference scenarios with synthetic samples in the training set, thereby increasing its size while keeping model evaluation strictly restricted to held-out hypothetical individuals. The objective is to investigate whether synthetic samples provide complementary information to the expert-defined tabular data and consequently improve the generalization and robustness of the classifiers. Although data augmentation is widely explored in image-based applications, this study examines whether a similar strategy can effectively complement scarce tabular data.

While the TSTR paradigm is instrumental in measuring statistical fidelity, the data augmentation strategy evaluates the practical utility of synthetic data as a sample expansion mechanism, which is especially critical in data-constrained environments. Empirical observations indicate that even when the volume of available real-world samples is limited, their retention within the training set significantly bolsters model stability and reliability, consistently outperforming models trained exclusively on synthetic data [19]. This trend reinforces the vital complementarity between real/reference and synthetic data distributions.

IV. Results

The experiments evaluated two synthetic data generators: Conditional Beta-Bernoulli and Gaussian Copula in combination with classifiers based on different learning mechanisms.

The evaluation employed 10 repetitions of stratified 4-fold cross-validation, resulting in 40 fold-level evaluations for each experimental configuration. A different random seed was used in each repetition to account for variability associated with data partitioning, synthetic sampling, and model initialization. Within each fold, the generator was fitted exclusively to the reference training partition, while the corresponding reference validation partition remained isolated from both generator fitting and classifier training.

The Train on Real, Test on Real (TRTR) paradigm was adapted in this study as a train-test procedure using the reference data. The results obtained under this scenario were used as the internal predictive baseline. This approach was inspired by the conventional TRTR protocol; however, the term "reference" is used here as well because the dataset consists of expert-defined scenarios rather than clinical observations. The baseline measures the ability of each classifier to generalize to held-out scenarios from the expert-defined reference dataset without using synthetic samples. Because the dataset comprises only 40 expert-defined scenarios, the reported means and standard deviations should be interpreted as measures of internal computational performance and variability rather than as evidence of clinical generalization. This constitutes a limitation of the present study.

A. Statistical Fidelity of the Synthetic Data

Figure 1 summarizes the statistical fidelity results obtained for the evaluated generators and synthetic sample sizes. Fidelity was assessed using complementary measures, since no single metric can fully characterize the quality of tabular synthetic data. MAE and correlation RMSE were used to quantify discrepancies in marginal attribute frequencies and dependency structures between the reference and synthetic datasets, while the Classifier Two-Sample Test (C2ST) evaluated their distinguishability under the specified testing protocol.

Across the evaluated range of synthetic sample sizes, the fidelity curves generally exhibited a decrease in error followed by an approximately stable region. This pattern suggests that increasing the number of generated samples improves the stability of the empirical estimates obtained from the learned distributions.

The Gaussian Copula achieved the lowest MAE (Fig. 1.A) and RMSE (Fig. 1.B) values, providing the strongest overall statistical fidelity according to these measures. Nevertheless, the Conditional Beta-Bernoulli generator remained competitive under other criteria, particularly with respect to target-prevalence preservation (Fig. 1.C) and the proportion of synthetic records that were exactly identical to complete records in the corresponding training partition (Fig. 1.D). Therefore, the results do not indicate that one generator was uniformly superior. Instead, they reveal complementary strengths and a trade-off between reproducing the statistical structure of the reference data and avoiding direct reproduction of training records.

The C2ST AUC remained below approximately 0.60 for both generators across the evaluated configurations, indicating that the reference and synthetic datasets were relatively difficult to distinguish under the adopted testing protocol. Image (D) provides a separate descriptive measure of exact overlap by quantifying the proportion of synthetic records that are identical to complete records observed in the corresponding training partition. The lower overlap observed for the Conditional Beta-Bernoulli generator indicates less direct reproduction of the training records in this experiment. Graphic (C) complements this analysis by showing the extent to which each generator preserves the global target prevalence.

In addition to this empirical performance, the Conditional Beta-Bernoulli model has lower structural complexity and greater conceptual simplicity. Based on its competitive statistical fidelity, adequate preservation of target prevalence, lower exact overlap, and simpler formulation, it was selected for the subsequent predictive-utility and augmentation analyses. This selection was made before those analyses and does not imply that the generator is superior across every evaluation dimension. Rather, it reflects the objectives of the subsequent experiments, which focus on predictive transfer and the practical use of synthetic samples for classifier training.

B. Predictive Utility Across Generators and Classifiers

Statistical similarity does not necessarily imply predictive usefulness. Therefore, predictive utility was evaluated through

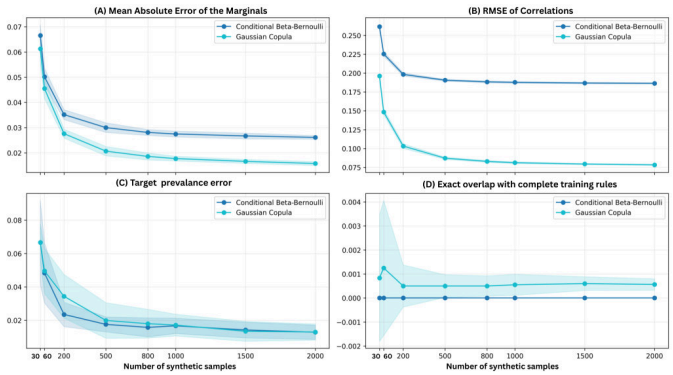

Fig. 1. Statistical fidelity and distinguishability of the synthetic datasets across generators and sample sizes. Lower marginal and dependency errors indicate greater fidelity

the Train on Synthetic, Test on Reference (TSTR) protocol. In this scenario, each classifier was trained exclusively on samples produced by a generator fitted to the reference training fold and evaluated on the corresponding held-out reference fold.

Figure 2 presents the mean MCC obtained for each combination of generator Conditional Beta–Bernoulli, classifier, and synthetic sample size. The results reveal that predictive transfer depends on the interaction between the generator and classifier. Moreover, the heatmap in Figure 2 also indicates that increasing the number of synthetic samples leads to monotonic improvements for every classifier, except for SVM model.

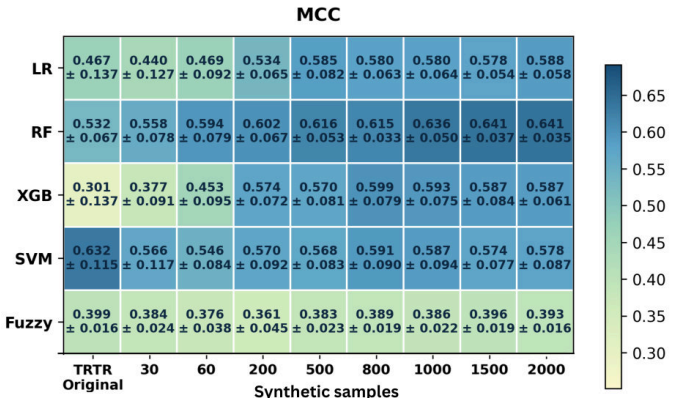

Fig. 2. Mean MCC under TSTR using the Conditional Beta-Bernoulli generator across classifiers. TRTR denotes the reference-only internal baseline

C. Utility Analysis at the Selected Operating Point

Analyzing Figure 1, we chose to conduct the remaining analysis using 800 Conditional Beta-Bernoulli samples. This operating point was selected because the curves in Figure 1 indicate that, beyond 800 samples, the performance approaches a stable region across all graphs. In addition, the results presented in Figure 2 using 800 samples are similar to or close to the best results achieved by each classifier, indicating that this choice provides a reasonable balance between statistical fidelity and utility.

Table II reports the results obtained using 800 Conditional Beta–Bernoulli samples for sensitivity, specificity, F1-score, and AUC-ROC. The comparison includes the TSTR results and the corresponding TRTR baseline for each classifier. Accuracy and MCC are discussed as complementary metrics but are not included in this table.

TABLE II
PERFORMANCE WITH 800 CONDITIONAL BETA–BERNOULLI SAMPLES.

Model	Sens.	Spec.	F1	AUC-ROC
Conditional Beta-Bernoulli - TSTR				
LR	0.796 ± 0.051	0.808 ± 0.040	0.842 ± 0.033	0.836 ± 0.020
RF	0.814 ± 0.028	0.833 ± 0.000	0.858 ± 0.021	0.818 ± 0.022
XGB	0.807 ± 0.042	0.800 ± 0.043	0.846 ± 0.032	0.829 ± 0.033
SVM	0.793 ± 0.058	0.800 ± 0.043	0.837 ± 0.036	0.848 ± 0.021
Expert-defined reference data – TRTR				
LR	0.718 ± 0.052	0.767 ± 0.102	0.782 ± 0.043	0.762 ± 0.042
RF	0.882 ± 0.041	0.600 ± 0.053	0.856 ± 0.025	0.814 ± 0.031
XGB	0.768 ± 0.048	0.533 ± 0.105	0.776 ± 0.042	0.715 ± 0.046
SVM	0.882 ± 0.048	0.733 ± 0.086	0.882 ± 0.033	0.846 ± 0.019

The results in Table II show that predictive performance varied according to both the classifier and the evaluation metric. Among the metrics reported in the table, Random Forest achieved the highest sensitivity, specificity, and F1-score under TSTR. Complementary results, not shown in the table, indicate that Random Forest also achieved the highest accuracy (0.820 ± 0.020) and MCC (0.636 ± 0.027). Therefore, no classifier was uniformly superior across all criteria. RF provided the strongest threshold-dependent performance according to MCC, while SVM showed the best ranking-based discrimination according to AUC-ROC.

Overall, the comparison across metrics indicates that the predictive utility of synthetic data was classifier-dependent. Logistic Regression and XGBoost showed the most consistent improvements over the TRTR baselines, whereas Random Forest achieved stronger threshold-dependent performance according to specificity, F1-score, accuracy, and MCC, despite a reduction in sensitivity. SVM maintained similar ranking-based discrimination according to AUC-ROC but showed weaker threshold-dependent performance. These results highlight the importance of evaluating synthetic data using complementary metrics, since no classifier consistently dominated across all evaluation criteria.

Instead, the results suggest that the Conditional Beta-Bernoulli generator preserved predictive relationships that could be transferred to held-out scenarios within the expert-defined knowledge base, particularly when used with Logistic Regression, Random Forest, and XGBoost.

D. Augmentation Analysis

The augmentation experiment evaluated whether adding synthetic samples to the reference training fold improved predictive performance on the corresponding held-out reference fold. Three training strategies were compared: reference-only training (TRTR), synthetic-only training (TSTR), and augmented training (AUG). In all three scenarios, evaluation was performed on expert-defined reference scenarios that were not used to fit either the generator or the classifier.

For AUG, 30 synthetic samples were added to each reference training fold. This quantity was selected because it approximately matches the number of reference scenarios available for training in each fold, resulting in a nearly balanced contribution from reference and synthetic data. Maintaining the same total training size across TRTR and AUG would require discarding part of the already limited reference training data. Therefore, the adopted experiment evaluates the practical effect of adding synthetic observations rather than isolating the effect of data source under a strictly size-matched design. A controlled analysis of different reference-to-synthetic proportions is left for future work.

Random Forest was selected for this analysis because it showed favorable predictive utility, particularly in terms of MCC and accuracy, in the preceding TSTR experiments. Figure 3 presents bar plots of F1-score, sensitivity, and MCC for the three training strategies. Each bar plot summarizes the distribution of results obtained across the 10 repetitions of stratified 4-fold cross-validation, allowing the comparison of median performance, dispersion, and the occurrence of unstable results.

The distributions show that augmentation slightly improves the MCC while not affecting the F1-score or sensitivity values. As can be observed, AUG remained close to the reference-only strategies across several measures. In particular, the results obtained for MCC are consistent with the findings reported in [2], [19], which indicate that the use of augmentation tends to outperform models trained exclusively on synthetic data.

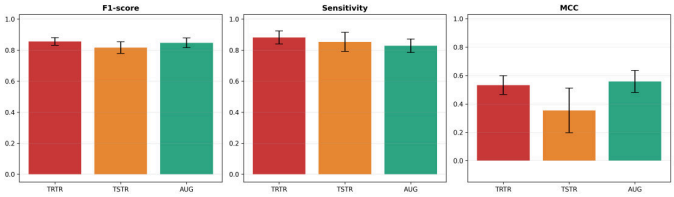

Fig. 3. F1-score, sensitivity, and MCC under reference-only (TRTR), synthetic-only (TSTR), and augmented (AUG) training. AUG combines 30 reference scenarios with 30 synthetic samples and is evaluated on the corresponding held-out reference fold.

V. CONCLUSION

This paper investigates whether synthetic data generation methods applied to tabular data derived from expert knowledge can be useful for identifying children aged 0 to 6 years who may be at risk of ASD. Our hypothesis is that, if the proposed approach to deal with problems with scarce datasets demonstrates consistent statistical fidelity and predictive utility within the expert-defined reference dataset, it may provide a methodological foundation for future studies using real clinical data.

Because classification performance is strongly dependent on training data quality, high-fidelity synthetic datasets would be expected to yield classification outcomes comparable to those obtained using real-world data. The combined results reveal a trade-off between statistical fidelity and predictive

utility. Gaussian Copula most closely reproduced the statistical properties of the reference data, whereas Conditional Beta–Bernoulli produced the strongest predictive performance across the evaluated classifiers. At the classifier level, RF achieved the highest MCC at the selected operating point of 800 synthetic samples. The results support the computational potential of expert-derived synthetic data for reproducing and transferring patterns within the reference knowledge base, but they do not establish clinical validity or population representativeness.

For future work, several directions are planned to extend this research. First, the expert-defined reference dataset should be further assessed by incorporating the perspectives of additional specialists. An initial consultation process involving three other experts has already been initiated to discuss the main clinical attributes, decision rules, and scenario formulations. Based on this process, we intend to develop a structured and accessible validation form that can support systematic expert review, facilitate the acquisition of additional datasets, and improve the consistency of future knowledge elicitation. A second point is the evaluation of the proposed framework using independent datasets containing observations from clinically assessed children. Such datasets would enable a more realistic assessment of external generalization, population representativeness, and potential clinical applicability. The current results should therefore be interpreted as an initial internal validation within the expert-defined knowledge base, rather than as evidence of clinical performance.

Future studies should also investigate the effect of hyperparameter optimization for the machine-learning classifiers, decision-threshold calibration, and the adjustment of the weights used in the fuzzy rule-based models. These procedures should be conducted exclusively within the training partitions, preferably using nested validation or a separate development set, in order to avoid optimistic estimates and preserve the leakage-aware design of the current protocol. Additional analyses may also examine different reference-to-synthetic proportions, sample sizes, and augmentation strategies.

***Abstract*—Prostate-specific antigen (PSA) is widely used in forensic laboratories as a presumptive biochemical marker of seminal fluid, but no consensus exists regarding the optimal cutoff value, and the statistical robustness of PSA concentration bands as predictors of genotyping success has not been formally tested. This study evaluated the diagnostic accuracy of PSA as an indicator of male sexual contact in 160 intimate samples from living victims of sexual violence processed at the Forensic Molecular Genetics Section of the Scientific Police of Paraná, Brazil (2023–2024), and assessed, through chi-square tests of independence with Bonferroni-corrected pairwise comparisons, which PSA concentration bands differ significantly from one another in male DNA detection and STR genotyping outcomes. Sensitivity, specificity, PPV, and NPV were calculated at three cutoffs (0.08, 1.0, and 4.0 ng/mL), yielding an estimated ROC AUC of 0.89. The chi-square test of independence confirmed a significant association between PSA band and male DNA detection (χ^2=70.78, df=5, p=7.06×10^{-14}) and between PSA band and STR genotyping outcome (χ^2=43.58, df=10, p=3.91×10^{-6}). However, Bonferroni-corrected pairwise comparisons revealed that statistically significant differences in male DNA detection were confined to comparisons between the lowest band (<0.07 ng/mL) and every other band; no significant differences were found among bands above 0.08 ng/mL. This indicates that, given the present sample size and the conservative Bonferroni correction, the apparent dose-response gradient observed descriptively across intermediate bands (0.08–0.99, 1–4, 4–10, 10–99 ng/mL) did not reach statistical significance, a pattern compatible with a Type II error arising from the conservative Bonferroni correction and the limited size of the two smallest strata (n=13 and n=14), rather than definitive proof of the absence of a true biological gradient, and that the only comparison robust to correction is that between PSA below versus above approximately 0.07–1.0 ng/mL. These findings refine the interpretation of PSA as a forensic triage parameter: rather than supporting a continuous dose-response relationship, the data support a simplified two-tier stratification (low vs. moderate-to-high PSA) for screening purposes in living victims.**

Keywords*—*prostate-specific antigen, forensic genetics, sexual violence, STR genotyping, ROC curve

I. Introduction

The investigation of sexual violence crimes depends fundamentally on the analysis of biological evidence collected from victims and crime scenes. In Brazil, official public security statistics confirm the scale of the problem: 87,545 rape and statutory rape cases were registered in 2024 alone, the highest figure in the historical series, averaging one reported case every six minutes nationwide [1]. This volume, combined with documented underreporting, makes forensic evidence even more central to the production of legal proof. In this context, forensic genetics has consolidated itself as a strategic field, with continuous advances in laboratory methodology and infrastructure across the country.

Unlike post-mortem casework, evidence collection in living victims is constrained by a narrow biological window: seminal biomarkers such as PSA degrade progressively after the assault, and victims frequently delay seeking forensic examination due to psychological distress, fear of revictimization, or limited access to specialized care, particularly outside large urban centers. This operational reality means that, in practice, forensic laboratories routinely receive intimate samples collected at variable and often suboptimal intervals after the alleged assault, with PSA concentrations that may already be in the lower analytical range by the time testing occurs. Consequently, establishing which PSA concentration bands carry genuinely distinct diagnostic information, rather than relying on cutoffs validated primarily in post-mortem or controlled experimental settings, has direct relevance for how laboratories triage and interpret evidence from this specific, time-sensitive population.

Prostate-specific antigen (PSA) is the principal biochemical indicator used in the routine of forensic genetics laboratories for the presumptive identification of seminal fluid. PSA is a glycoprotein produced by prostatic epithelial cells, present at high concentration in seminal fluid, and its detection is considered strong presumptive evidence of semen presence [2], [3]. A recent clinical case report reaffirms that PSA testing remains the standard presumptive screening approach in forensic examinations of sexual violence victims,

underscoring its continued centrality in casework despite known limitations [4].

Henky and Arijana [5] demonstrated, in a comparative study using vaginal swabs from sexual violence victims, that the PSA rapid test outperforms sperm microscopy, with sensitivity of 84.6%, specificity of 100%, and overall accuracy of 87.5%, using the SRY gene as the gold standard for confirmation of male material. Sperm microscopy, in the same population, presented sensitivity of only 23.1%, indicating a high risk of false-negative results, particularly in victims who performed genital hygiene after the assault.

A further challenge concerns the absence of consensus on the ideal PSA cutoff for forensic seminal fluid determination. Reference values vary widely across studies and laboratories: the traditional clinical threshold of 4.0 ng/mL, originally established for prostatic disease screening, coexists with more sensitive forensic cutoffs such as 1.0 ng/mL and 0.08 ng/mL, adopted by different laboratories in an attempt to balance sensitivity and specificity. A recent study by Ruff et al. [6], using ROC curve analysis on 460 forensic samples from sex crime investigations, identified an optimal cutoff of 0.085 ng/mL, with an area under the curve (AUC) of 0.848. This lack of standardization highlights the need for studies evaluating different cutoff values in specific populations and laboratory contexts.

Beyond serological screening, quantification of Y-chromosome DNA by qPCR, known as Y-Screening, has been increasingly adopted as a molecular triage step for sexual assault evidence kits, determining which samples proceed to STR genotyping [7], [8]. A 2025 validation study of a Y-screening workflow using a commercial qPCR kit confirmed that this approach reliably predicts which samples are likely to yield informative downstream STR profiles, supporting its use to triage casework and preserve evidentiary material [8]. Despite these individual advances, the literature still lacks studies that systematically integrate PSA concentration, rather than its qualitative positive/negative classification, with molecular quantification and genotyping outcomes; SWGDAM [7] explicitly identifies this gap, calling for research correlating quantification data with the success of genetic typing.

A methodological limitation common to dose-response analyses of this kind is that descriptive trends across multiple concentration bands are frequently presented without formal statistical testing of whether adjacent or non-adjacent bands actually differ from one another. When more than two categories are compared pairwise, the probability of a spurious significant result increases with the number of comparisons performed, a problem addressed by applying a Bonferroni correction to the significance threshold following a significant overall chi-square test of independence [9], [10]. This stepwise approach, an omnibus chi-square test followed by Bonferroni-corrected pairwise 2×2 comparisons, provides a statistically rigorous means of identifying precisely which categories drive an observed association, rather than assuming that all visually apparent differences are equally robust.

The present study addresses both gaps. First, it evaluates, in a cohort restricted to living victims of sexual violence, the diagnostic accuracy of PSA for indicating male sexual contact across three forensic cutoff values, using qPCR-based male DNA detection as the reference standard. Second, and as its central methodological contribution, it applies chi-square tests of independence with Bonferroni-corrected pairwise comparisons to formally test which PSA concentration bands differ significantly in male DNA detection and STR genotyping outcome, determining whether the apparent dose-response gradient reported in prior descriptive analyses withstands rigorous statistical scrutiny or whether it is in fact driven by a single, more limited threshold.

From a biomedical engineering standpoint, this distinction is operationally important: a triage rule based on a continuous dose-response assumption implies a fundamentally different decision architecture than one based on a single robust threshold. By identifying which comparisons survive correction for multiple testing, this study provides a more conservative and defensible empirical basis for the design of computer-assisted triage tools that combine PSA concentration with Y-chromosome quantification in forensic genetics laboratory workflows.

II. Materials and Methods

A. Study Design and Sample

This retrospective study analyzed data from biological traces collected from living female victims of sexual violence, processed at the Forensic Molecular Genetics Section of the Scientific Police of Paraná, Brazil, between 2023 and 2024. The analyzed cohort comprised 160 intimate samples (vaginal, anal, vulvar, and oral swabs) obtained from living victims. Collected variables included PSA concentration (ng/mL), qPCR-based Y-chromosome DNA quantification result, and STR genotyping outcome, classified as viable genetic profile, non-viable profile, or absence of amplification. Records with incomplete data or compromised identification were excluded (Figure 1).

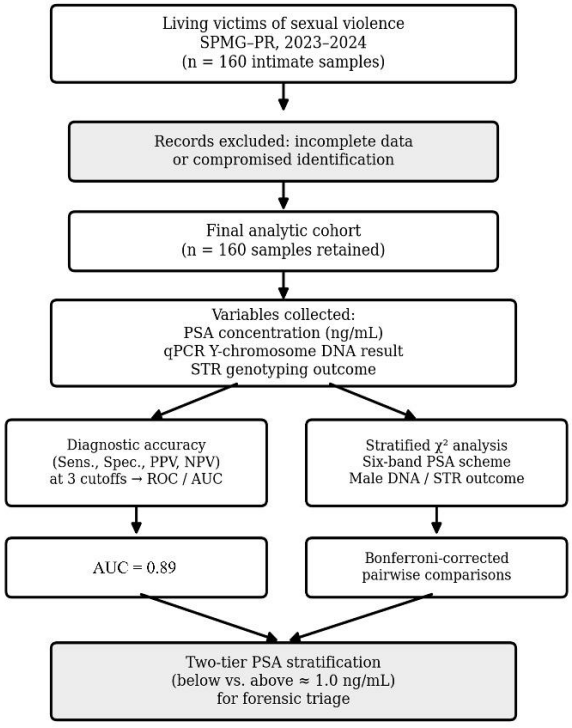

Fig. 1. Study flow diagram, from sample identification through the two analytical branches (diagnostic accuracy and stratified chi-square analysis) to the resulting two-tier PSA stratification proposal.

This study was approved by the Scientific Committee of the Scientific Police of Paraná, in accordance with the ethical principles set forth in the Declaration of Helsinki for research involving human subjects. Data were collected from institutional records of the Forensic Molecular Genetics Section of the Scientific Police of Paraná and used exclusively for research purposes in accordance with institutional guidelines.

B. *Reference Standard*

The gold standard for confirming male sexual contact was the qPCR-based quantification of male DNA. Samples were classified as positive for male DNA presence according to qPCR results, independent of the PSA outcome, allowing PSA performance to be assessed against an objective molecular reference rather than circumstantial case information.

C. *Diagnostic Accuracy Analysis*

Sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were calculated for three PSA cutoff values commonly cited in forensic and clinical practice: 0.08 ng/mL, 1.0 ng/mL, and 4.0 ng/mL. A receiver operating characteristic (ROC) curve was constructed from the three corresponding sensitivity/specificity pairs, and the area under the curve (AUC) was estimated using the trapezoidal rule.

D. *Stratified Chi-Square Analysis*

Samples were stratified into PSA concentration bands using a six-band scheme (<0.07, 0.08–0.99, 1–4, 4–10, 10–99, and >100 ng/mL), defined a priori from established forensic and clinical cutoffs. A chi-square (χ^2) test of independence was performed to test the global association between PSA band and (i) male DNA detection (positive/negative) and (ii) STR genotyping outcome (viable profile/non-viable profile/no amplification). The selection of these specific ranges is justified by the lack of consensus in the literature regarding the optimal prostate-specific antigen (PSA) cut-off value for confirming the presence of semen, with previous studies reporting various thresholds, including 0.04 [6], 1 [12], 4 [13], and 10 [14] ng/mL.

When the overall χ^2 test was significant, all possible pairwise 2×2 sub-tables were subsequently tested to identify which specific band comparisons drove the global association. Because multiple pairwise comparisons inflate the family-wise Type I error rate, a Bonferroni correction was applied: the conventional significance threshold (α=0.05) was divided by the number of pairwise comparisons performed (15 comparisons for the six-band scheme, yielding a corrected threshold of $p<0.00333$) [9], [10]. All statistical analyses were performed using Python (SciPy, NumPy, Pandas), with visualization in Matplotlib.

The Bonferroni correction was chosen over less conservative alternatives (e.g., Benjamini–Hochberg false discovery rate control) because the present analysis is explicitly confirmatory rather than exploratory: the six concentration bands were defined a priori from established forensic and clinical cutoffs rather than derived from the data, and the goal was to identify only those band contrasts robust enough to support an operational triage threshold, accepting a more conservative family-wise error rate in exchange for higher confidence in any comparison that survived correction. For each 2×2 sub-table, expected cell frequencies were inspected, and Fisher's exact test was substituted for the chi-square approximation whenever any expected count fell below 5, ensuring that significance levels were not inflated by small-sample violations of the chi-square assumptions.

III. Results

A. *Diagnostic Accuracy of PSA in Living Victims*

Among the 160 samples from living victims, diagnostic performance varied considerably across the three evaluated cutoffs. Table I summarizes sensitivity, specificity, PPV, and NPV for each cutoff value.

TABLE I. DIAGNOSTIC ACCURACY OF PSA BY CUTOFF VALUE – LIVING VICTIMS (N = 160)

Cutoff (ng/mL)	Sens. (%)	Spec. (%)	PPV (%)	NPV (%)
0.08	90.5	72.7	89.7	74.4
1.0	75.0	86.4	93.6	56.7
4.0	63.8	88.6	93.7	48.2

The lowest cutoff, 0.08 ng/mL, produced the highest sensitivity (90.5%) at the cost of lower specificity (72.7%), whereas increasing the cutoff to 1.0 and 4.0 ng/mL progressively favored specificity at the expense of sensitivity. The NPV declined sharply as the cutoff increased (from 74.4% at 0.08 ng/mL to 48.2% at 4.0 ng/mL), indicating that higher cutoffs substantially increase the risk of false-negative results in this population. The ROC curve constructed from the three sensitivity/specificity pairs yielded an estimated AUC of 0.89, consistent with good discriminative performance of PSA in living victims.

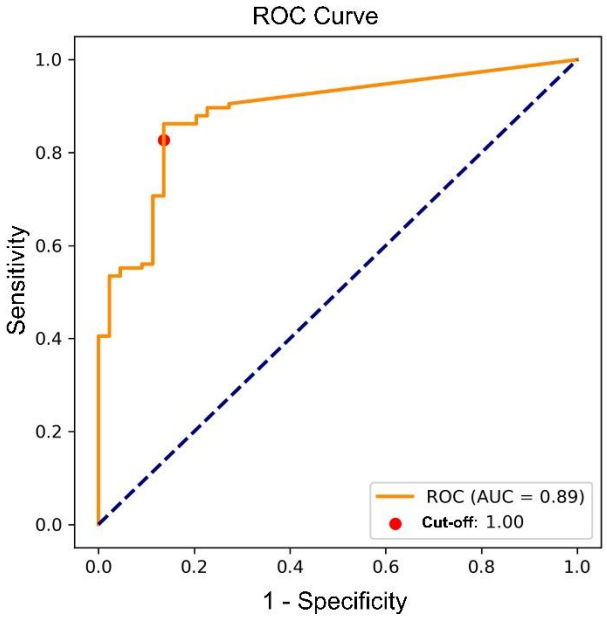

Fig. 2. Receiver operating characteristic (ROC) curve for PSA at the cutoff = 1.0 ng/mL, with male DNA quantification by qPCR as the reference standard. AUC = 0.89.

B. *Descriptive Distribution Across PSA Bands*

Table II presents the distribution of male DNA detection and STR genotyping outcomes across the six PSA concentration bands. Descriptively, the proportion of samples positive for male DNA and the proportion yielding a viable

genetic profile both increased with PSA concentration, ranging from 25.6% and 7.0%, respectively, in the lowest band (<0.07 ng/mL), to 100.0% and 91.7% in the highest band (>100 ng/mL).

TABLE II. MALE DNA DETECTION AND STR GENOTYPING OUTCOME BY PSA CONCENTRATION BAND – LIVING VICTIMS

PSA band (ng/mL)	n	Male DNA+ (%)	Viable profile (%)
< 0.07	43	25.6	7.0
0.08–0.99	24	75.0	33.3
1–4	14	92.9	64.3
4–10	13	76.9	76.9
10–99	30	93.3	76.7
> 100	36	100.0	91.7

C. Chi-Square Test of Independence: Global Association

The chi-square test of independence confirmed a statistically significant global association between PSA band (six-band scheme) and male DNA detection (χ^2=70.78, df=5, $p=7.06\times10^{-14}$), as well as between PSA band and STR genotyping outcome (χ^2=43.58, df=10, $p=3.91\times10^{-6}$). These results confirm that PSA concentration band is not independent of either outcome, formally supporting the descriptive pattern observed in Table II.

D. Bonferroni-Corrected Pairwise Comparisons

A significant omnibus χ^2 result indicates that an association exists somewhere among the bands, but does not indicate which specific bands differ from one another [9], [10]. Pairwise 2×2 chi-square tests were therefore performed for every band combination within the six-band scheme, with significance assessed against the Bonferroni-corrected threshold of p<0.00333 (15 comparisons).

For male DNA detection, only the five comparisons involving the lowest band (<0.07 ng/mL) against every other band reached statistical significance after correction (Table III). None of the ten remaining pairwise comparisons among bands at or above 0.08 ng/mL, including comparisons such as 0.08–0.99 vs. 1–4 ng/mL, 1–4 vs. 4–10 ng/mL, or 10–99 vs. >100 ng/mL, achieved statistical significance.

TABLE III. BONFERRONI-CORRECTED PAIRWISE COMPARISONS FOR MALE DNA DETECTION ACROSS THE SIX PSA BANDS

Comparison	χ^2	p-value	Sig.[a]
<0.07 vs 0.08–0.99	13.38	2.55×10^{-4}	Yes
<0.07 vs 1–4	16.95	3.84×10^{-5}	Yes
<0.07 vs 4–10	9.14	2.50×10^{-3}	Yes
<0.07 vs 10–99	29.93	4.47×10^{-8}	Yes
<0.07 vs >100	42.00	9.15×10^{-11}	Yes
0.08–0.99 vs 1–4	0.88	0.349	No
0.08–0.99 vs 4–10	0.00	1.000	No
0.08–0.99 vs 10–99	2.25	0.134	No
0.08–0.99 vs >100	7.42	0.006	No
1–4 vs 4–10	0.39	0.534	No
1–4 vs 10–99	0.00	1.000	No
1–4 vs >100	0.25	0.621	No
4–10 vs 10–99	1.05	0.306	No
4–10 vs >100	5.29	0.021	No
10–99 vs >100	0.73	0.394	No

[a] Significant at Bonferroni-corrected threshold p<0.00333.

A similar pattern was observed for STR genotyping outcome, although the significant threshold (p<0.00111, for 45 comparisons across the three outcome categories) was considerably more conservative due to the larger number of three-way pairwise comparisons. Only two comparisons remained significant: viable profile vs. no amplification between the <0.07 and >100 ng/mL bands (χ^2=11.88, $p=5.66\times10^{-4}$), and viable profile vs. non-viable profile between the 0.08–0.99 and >100 ng/mL bands (χ^2=12.59, $p=3.87\times10^{-4}$). All other pairwise comparisons among intermediate bands, including several that could not be calculated due to insufficient cell frequencies, did not reach significance.

IV. DISCUSSION

The 0.08 ng/mL cutoff achieved the best balance for screening purposes in this cohort, maximizing sensitivity (90.5%) and thereby minimizing the risk of overlooking male DNA presence. This finding aligns with Ruff et al. [6], who identified a comparably low optimal cutoff (0.085 ng/mL) with similar AUC (0.848 vs. 0.89 in the present study) in an independent sample of 460 forensic specimens. The progressive loss of NPV at higher cutoffs (74.4% at 0.08 ng/mL versus 48.2% at 4.0 ng/mL) reinforces that adopting the traditional clinical threshold of 4.0 ng/mL in a forensic screening context would leave nearly half of PSA-negative samples still harboring detectable male DNA.

The central contribution of this study lies in the stratified chi-square analysis, which qualifies how the dose-response pattern in Table II should be interpreted. While the descriptive proportions suggest a smooth, continuous increase in both male DNA positivity and genotyping success as PSA concentration rises, the Bonferroni-corrected pairwise comparisons demonstrate that this is not statistically the case. The only band comparisons that reliably distinguish themselves are those contrasting the lowest band (PSA below approximately 0.07–1.0 ng/mL) against any higher band; comparisons among bands at or above roughly 1.0 ng/mL do not differ significantly from one another, despite visually appearing to form a gradient. The selection of these specific ranges is justified by the lack of consensus in the literature regarding the optimal prostate-specific antigen (PSA) cut-off value for confirming the presence of semen, with previous studies reporting various thresholds, including 0.04, 1, 4, and 10 ng/mL.

This result has a direct practical implication: rather than treating the six PSA bands as a fine-grained continuous predictor, the data support a simplified two-tier stratification for forensic triage purposes, samples below approximately 1.0 ng/mL versus samples above 4.0 ng/mL, as the statistically defensible operating distinction, with the intermediate range (1.0–4.0 ng/mL) representing a zone in which the present data cannot statistically distinguish a true diagnostic plateau from a gradient obscured by limited statistical power and a consequent risk of Type II error, particularly given the n=13 and n=14 strata and the conservative Bonferroni threshold, rather than necessarily reflecting a smoothly graded transition. This refinement is consistent with general statistical guidance recommending that descriptive trends across ordered categories be confirmed by formal pairwise testing with correction for multiple comparisons before being interpreted as a true dose-response relationship [9], [10].

From a forensic genetics workflow standpoint, this finding also has implications for triage protocol design. A previous validation study of Y-chromosome qPCR screening as a predictor of downstream STR success demonstrated that quantification-based triage can reliably flag samples likely to yield informative profiles [8]. The present results suggest that any analogous triage rule built on PSA concentration should be calibrated around the single robust threshold identified here (approximately 1.0 ng/mL), rather than assuming that finer PSA gradations carry proportionally finer-grained predictive information, since the statistical evidence for differentiating among bands above this threshold is not robust given the present sample size.

The pattern observed here is also consistent with broader comparative literature on PSA rapid testing. Henky and Arijana [5] reported that PSA testing substantially outperformed sperm microscopy in vaginal swabs from living victims, with sensitivity of 84.6% against an SRY-based gold standard, a figure close to the 90.5% sensitivity obtained at the 0.08 ng/mL cutoff in the present cohort, despite differences in reference standard and population. Taken together with the comparably low optimal cutoff reported by Ruff et al. [6] using ROC analysis in an independent sample of 460 forensic specimens, this convergence across three distinct cohorts and laboratories strengthens the case that a forensic PSA cutoff considerably below the traditional clinical threshold of 4.0 ng/mL is broadly appropriate for sexual assault screening in living victims, rather than being an artifact specific to a single laboratory population.

This analysis was restricted to living victims and does not address the distinct dynamics of PSA in post-mortem or clothing/object samples, where degradation and contamination patterns differ substantially [11]. The relatively small number of samples in some PSA bands (n=13–14 in two strata) limits the statistical power of pairwise comparisons involving those bands, and several three-way STR outcome comparisons could not be calculated due to insufficient cell frequencies, a limitation that should be addressed through replication in larger or pooled cohorts. The chi-square approach used here treats PSA concentration as categorical; future work should also model PSA as a continuous predictor (e.g., via continuous-cutoff ROC analysis or logistic regression) to complement the categorical stratification presented here.

Finally, the lack of standardized time-since-assault data prevented controlling for PSA degradation, which may confound variability within intermediate bands. Additionally, while our cohort (n = 160) is comparable to previous studies, it is smaller than larger series (e.g., Ruff et al. [6]); thus, external validation in independent Brazilian laboratories is warranted to ensure the generalizability of the proposed two-tier stratification before routine clinical implementation.

V. Conclusion

In this cohort of living victims of sexual violence, PSA demonstrated good diagnostic accuracy as a presumptive indicator of male sexual contact (AUC=0.89), with the 0.08 ng/mL cutoff offering the most favorable sensitivity-specificity balance. Chi-square tests of independence confirmed a significant global association between PSA concentration band and both male DNA detection and STR genotyping outcome; however, Bonferroni-corrected pairwise comparisons demonstrated that, under the present sample size, this association is statistically attributable almost entirely to the contrast between the lowest PSA band and all higher bands. Given the conservative correction applied and the limited size of two intermediate strata (n=13–14), this finding should be interpreted as an absence of demonstrated statistical significance for a finer gradient, potentially reflecting a Type II error, rather than definitive evidence against one. These findings support a simplified two-tier PSA stratification (below versus above approximately 1.0 ng/mL) as the statistically robust basis for forensic triage decisions in living victims, while cautioning against over-interpreting finer-grained descriptive trends that do not survive correction for multiple comparisons. Future work should extend this analysis to continuous-cutoff ROC and logistic regression frameworks and explore the joint predictive value of PSA and Y-chromosome quantification for STR genotyping success.

***Abstract*—Transcutaneous spinal direct current stimulation (tsDCS) has emerged as a promising non-invasive neuromodulation technique for Major Depressive Disorder (MDD). This study investigated the effects of tsDCS on depressive symptoms, quality of life, and suicidal ideation in MDD, evaluating therapeutic persistence. In a longitudinal case comparison, two female MDD patients completed 15 sessions of tsDCS (2.5 mA, 20 min/session) over three weeks. Standardized clinical assessments (HAM-D, BDI-II, WHOQOL-BREF, SIQ) were performed at baseline, mid-treatment, post-treatment, and at a 90-day follow-up. Both participants showed marked reductions in depressive symptoms and suicidal ideation, accompanied by improvements in psychological quality of life after treatment. At follow-up, one participant maintained the clinical benefits, whereas the other experienced symptom recurrence associated with antidepressant tapering and psychosocial stressors. The intervention was well tolerated, with only mild transient adverse effects. These findings suggest that tsDCS may represent a safe and promising adjunctive treatment for MDD, although larger controlled studies are needed to confirm its long-term effectiveness.**

***Index Terms*—Major depressive disorder (MDD), transcutaneous spinal direct current stimulation (tsDCS), non-invasive neuromodulation, depression, quality of life, suicidal ideation.**

I. Introduction

Major Depressive Disorder (MDD) is characterized by the persistent presence of depressed mood, diminished interest or pleasure in previously valued activities, and cognitive, behavioral, and neurovegetative changes that significantly impair social, occupational, and personal functioning, with symptom severity varying across individuals [1]. Although conventional treatment for MDD, consisting of selective serotonin reuptake inhibitors combined with psychotherapy, is effective for many patients, a substantial proportion fail to achieve a satisfactory therapeutic response or experience challenges related to treatment adherence, symptom recurrence, and adverse effects [2]. These limitations have driven the search for complementary and innovative therapeutic strategies.

Non-invasive neuromodulation techniques have emerged as promising therapeutic approaches for MDD, demonstrating favorable outcomes in reducing depressive symptoms. Among the available modalities, transcutaneous spinal direct current stimulation (tsDCS) has gained attention as a novel intervention. This technique involves the application of low-intensity direct current over specific segments of the spinal column, thereby modulating the activity of central neural circuits [3]. Initially investigated for conditions such as chronic and neuropathic pain, stroke, spinal cord injury, and Alzheimer's disease, tsDCS has shown benefits associated with improvements in quality of life, mood, and depressive symptoms [4]–[7].

Recent evidence suggests that anodal tsDCS applied over the T10 thoracic spinal segment may modulate interoceptive pathways involved in the integration of bodily states and emotional processing, thereby influencing brain structures frequently implicated in the pathophysiology of MDD, such as the thalamus and the insular cortex [8]. Furthermore, tsDCS has demonstrated a favorable safety and tolerability profile, making it a potentially accessible, and easy-to-administer intervention. In light of these findings, tsDCS represents a promising therapeutic approach for MDD, underscoring the importance of investigating its clinical effects in individuals with the disorder.

II. Objective

The present study aimed to investigate the effects of transcutaneous spinal direct current stimulation (tsDCS) on depressive symptoms, psychological quality of life, and suicidal ideation in two patients with major depressive disorder (MDD). Additionally, the study evaluated the persistence of these effects at follow-up and the safety and tolerability of the intervention.

III. Methodology

A. Participants

This longitudinal comparative case series was based on a subset of participants from a larger clinical study investigating the effects of tsDCS in patients with MDD. The present case series included two female participants diagnosed with MDD who underwent a protocol of tsDCS. The selection process took place after recruitment, during which the participants underwent a clinical assessment conducted by a psychiatrist from the research team to confirm all eligibility criteria. Participants were eligible if they were aged 18–65 years, met the diagnostic criteria for MDD according to the DSM-5, had a minimum score of 18 on the Hamilton Depression Rating Scale (HAM-D), and had stable pharmacological and/or psychotherapeutic treatment for at least four weeks prior to enrollment. Participants were excluded if the diagnosis of MDD was not confirmed, if they presented severe psychiatric comorbidities, had undergone neuromodulation within the previous six months, reported illicit drug use or substance abuse, had medical conditions contraindicating electrical stimulation, were pregnant or breastfeeding, had implanted electronic devices, had unstable clinical treatment or changed medication during the study, or presented significant suicide risk.

Once deemed eligible, the participants provided written informed consent and completed the baseline assessment, which included the Beck Depression Inventory-II (BDI-II), the HAM-D, the World Health Organization Quality of Life-BREF (WHOQOL-BREF), and the Suicidal Ideation Questionnaire (SIQ). At the pre-intervention (baseline) assessment, Participant 1, aged 25 years, scored 18 on the HAM-D, whereas Participant 2, aged 52 years, scored 22. Following the baseline assessment, participants underwent the intervention protocol.

B. Research Ethics Committee (REC)

This project was approved by the Research Ethics Committee (REC) of the Santos Dumont Institute (ISD), CAAE: 86722925.5.0000.0129 on April 14th 2026. Prior to the initial assessment, all participants signed the Informed Consent Form and the Authorization Form for voice recording and image capture (photos and videos), in accordance with ethical standards for research involving human subjects as set forth by the National Health Council (Brazil; National Health Council, 2012).

This research adhered to the ethical standards required by Resolution No. 466/12 of the National Health Council (CNS), which regulates research involving human subjects.

C. Intervention Protocol

Participants underwent 15 sessions of tsDCS administered over three weeks (five sessions per week), using a direct current intensity of 2.5 mA for 20 minutes per session. The intervention protocol did not include any cognitive tasks; participants remained in the prone position at rest throughout the stimulation sessions. The anodal electrode was positioned over the T10 vertebral level, while the cathodal electrode was placed over the C3 cervical region (Figure 1). Throughout the intervention, participants were continuously monitored for discomfort and potential skin reactions. Psychological assessments were conducted at four time points: baseline(T0), mid-treatment (T1; 7th session), post-intervention (T2; 15th session), and at the 90-day follow-up(T3), to evaluate the persistence of treatment effects and the potential recurrence of symptoms.

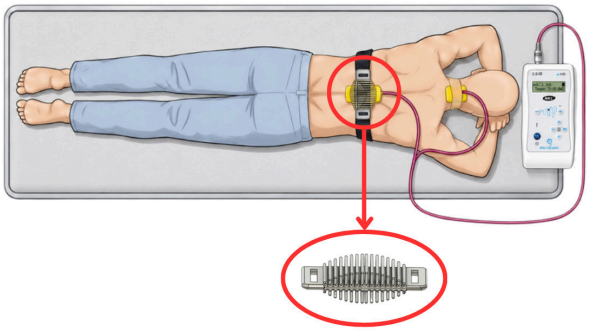

Fig. 1. Electrode Placement. The anodal electrode was positioned over the T10 vertebral level, while the cathodal electrode was placed over the C3 cervical region

D. Equipment

The tsDCS was delivered using a Micro Estim Foco Research stimulator (NKL, Brazil) with saline-soaked (0.9% NaCl) surface electrodes (5 × 7 cm). The anodal electrode was positioned over the T10 vertebral level and secured using a customized anatomical adapter designed in Autodesk Fusion 360 and three-dimensionally printed with thermoplastic polyurethane (TPU). The adapter was used to promote better contact between the electrode and the spine, conforming to the curvature of the subject's body. The cathodal electrode was positioned over the C3 cervical region and secured with kinesiology tape.

E. Assessments Instruments

Standardized instruments were used to assess depressive symptoms, quality of life, suicidal ideation, and intervention safety. These included the Beck Depression Inventory-II (BDI-II), the Hamilton Depression Rating Scale (HAM-D), the World Health Organization Quality of Life-BREF (WHOQOL-BREF), the Suicidal Ideation Questionnaire (SIQ), and a Safety and Tolerability Questionnaire.

IV. Results

A. Depressive Symptoms

At baseline (T0; Figure 2), Participants 1 and 2 presented HAM-D scores of 18 and 22, respectively, indicating moderate depressive symptoms. Throughout the intervention, a progressive reduction in HAM-D scores was observed in both participants (T1 and T2), with both reaching a score of 4 by the end of the 15th session. At follow-up, Participant 1 maintained the clinical improvements (HAM-D = 6), whereas Participant 2 experienced a relapse of depressive symptoms, with the HAM-D score returning to a level close to baseline (HAM-D = 21).

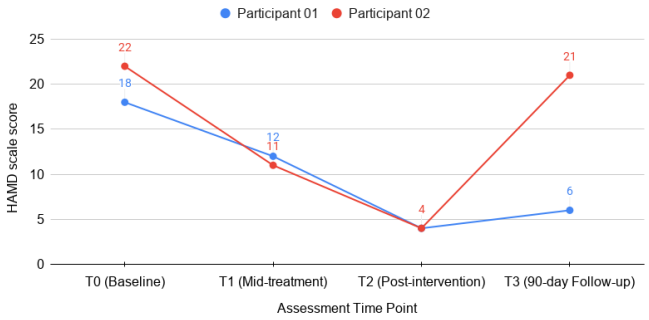

Fig. 2. Comparison of HAM-D scores

At baseline, as assessed by the Beck Depression Inventory-II (BDI-II) (T0; Figure 3), Participants 1 and 2 scored 33 and 57, respectively, indicating moderate to severe depressive symptoms. Throughout the intervention (T1 and T2), both participants showed a consistent reduction in BDI-II scores, reaching 6 (Participant 1) and 20 (Participant 2) by the end of the 15th session. At follow-up, Participant 1 maintained the clinical improvement (BDI-II = 6), whereas Participant 2 experienced a relapse, with the BDI-II score returning to the baseline level (BDI-II = 58).

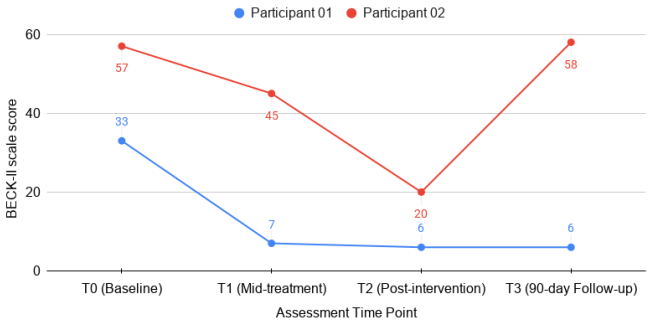

Fig. 3. Comparison of BDI-II scores

B. Quality of Life

Quality of life was assessed using the psychological domain of the WHOQOL-BREF (Figure 4). At baseline, Participants 1 and 2 scored 33.33 and 20.83, respectively. After the intervention, both participants demonstrated improvements in psychological quality of life. At the intermediate assessment, scores increased to 62.50 for Participant 1 and 37.50 for Participant 2, reaching 66.67 and 62.50, respectively, by the end of the intervention. At follow-up, Participant 1 maintained the final score (66.67), whereas Participant 2 showed a decline, with the score decreasing to 8.33.

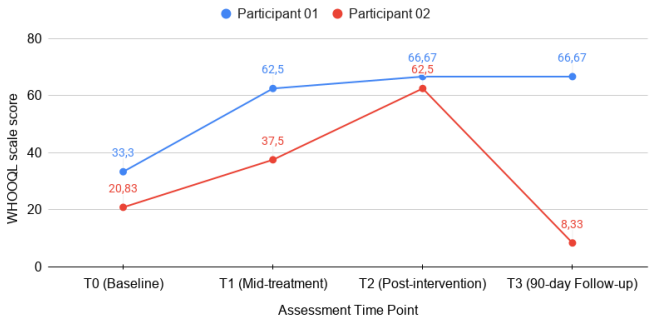

Fig. 4. Comparison of WHOQOL-BREF scores

C. Suicidal Ideation

The results of the Suicidal Ideation Questionnaire (SIQ) (Figure 5) showed baseline scores of 47 for Participant 1 and 151 for Participant 2. After the intervention, both participants exhibited a progressive reduction in suicidal ideation. At the intermediate and final assessments, Participant 1 scored 25 and 14, respectively, whereas Participant 2 scored 122 and 27. At follow-up, Participant 1 maintained the downward trend, with an SIQ score of 6, while Participant 2 experienced a recurrence of suicidal ideation, with the score increasing to 118.

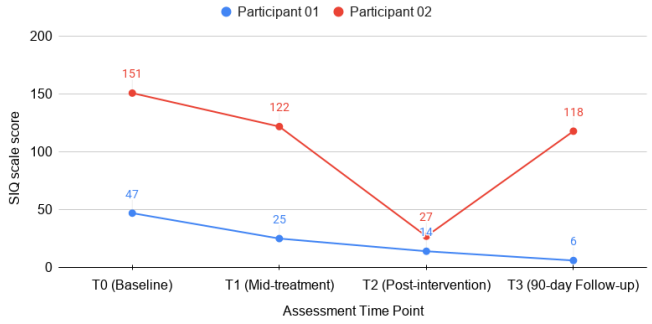

Fig. 5. Comparison of SIQ scores

D. Safety and Tolerability

tsDCS demonstrated a preliminary safety profile and feasibility in both participants, with no serious adverse events or permanent protocol interruptions. The main reported effects included tingling, burning sensations, itching, and erythema at the electrode sites, which were transient and restricted to the current ramp-up phase. Participant 1 predominantly reported low discomfort levels (1 to 5 points). Conversely, Participant 2 exhibited greater skin sensitivity, reporting discomfort scores

between 5 and 8 points and occasional burning sensations that required brief pauses before resuming stimulation. As both participants completed all 15 sessions, these findings suggest that the protocol is safe and feasible for future clinical investigations, provided that individual tolerability is monitored.

V. Discussion

The findings of this study suggest that transcutaneous spinal direct current stimulation (tsDCS) was able to promote clinical improvement in both participants during the intervention period, as evidenced by reductions in depressive symptoms and suicidal ideation, as well as improvements in quality of life. However, the main finding was not solely the initial clinical response, but rather the difference in the maintenance of these effects throughout the follow-up period. While Participant 1 maintained the benefits achieved after the 15 stimulation sessions, Participant 2 experienced a recurrence of symptoms, returning to scores close to those observed at baseline when measured at the follow-up, 90 days after the end of the intervention.

This difference becomes particularly relevant when considering that both participants exhibited similar responses during the intervention period. At the end of the protocol, Participant 1 showed reductions in scores to HAM-D = 4, BDI-II = 6, and SIQ = 14, whereas Participant 2 reached HAM-D = 4, BDI-II = 20, and SIQ = 27. Additionally, both participants achieved scores consistent with a good perception of quality of life in the psychological domain (WHOQOL-BREF = 66.7 and 62.5, respectively). These results indicate that tsDCS promoted clinical improvement in both participants, despite the greater baseline symptom severity observed in Participant 2.

However, the follow-up assessment revealed an important divergence between the two cases. Participant 1 maintained the clinical improvements achieved during the intervention, remaining in remission of depressive symptoms (HAM-D = 6), whereas Participant 2 experienced a recurrence of symptoms, as evidenced by increased HAM-D (21), BDI-II (58), and SIQ (118) scores, accompanied by a marked decline in quality of life (WHOQOL-BREF = 8.33). These findings suggest that an initial clinical response to tsDCS does not necessarily predict the long-term maintenance of therapeutic benefits.

The observed effects may be related to the ability of tsDCS to modulate neural circuits involved in emotional regulation. Recent evidence suggests that stimulation at the T10 thoracic level may influence interoceptive pathways connecting the spinal cord to brain regions involved in emotional processing, including the thalamus and the insular cortex, thereby contributing to changes in mood perception and stress responses [8]. Although these mechanisms require further investigation, they provide a plausible explanation for the concurrent improvements observed in depressive symptoms, quality of life, and suicidal ideation.

Consistent with this broad neuromodulatory effect, another important finding was the agreement across the different outcome measures. Reductions in HAM-D and BDI-II scores were accompanied by improvements in psychological quality of life and decreases in suicidal ideation, suggesting that the clinical benefits extended beyond the alleviation of depressive symptoms and were reflected in subjective well-being and the reduction of clinical risk. Likewise, this consistency across outcomes was also evident during the deterioration observed at follow-up, as the recurrence of symptoms in Participant 2 was accompanied by a decline in quality of life and an increase in suicidal ideation.

The recurrence observed in Participant 2, however, highlights the vulnerability of treatment outcomes to external factors. At the time of clinical deterioration, the participant was undergoing antidepressant tapering and experiencing significant psychosocial stressors. Previous evidence has demonstrated that pharmacological agents can enhance and prolong the neuroplastic effects induced by direct current stimulation, whereas medication withdrawal may reduce the persistence of these stimulation-induced adaptations [9]. More recent clinical evidence also supports the importance of maintaining pharmacotherapy after the acute phase of neuromodulation. A meta-analysis by Wang et al. [10] showed that combining brain stimulation techniques with antidepressant medication was more effective in preventing depressive relapse over 6 to 12 months than either intervention alone. According to the authors, antidepressants may exert a synergistic effect by enhancing neuroplastic mechanisms, including increased brain-derived neurotrophic factor (BDNF) signaling, thereby facilitating the consolidation of stimulation-induced therapeutic effects. Similarly, Woodham et al. [11] reported that sustained clinical remission following home-based transcranial direct current stimulation was more frequently observed among participants who remained under active treatment, either through continued antidepressant use or maintenance stimulation sessions. In the present case, antidepressant tapering, together with psychosocial stressors, may therefore have contributed to the gradual loss of the neuroplastic adaptations promoted by tsDCS and the recurrence of depressive symptoms, although this hypothesis cannot be confirmed within the present study. These findings suggest that, although neuromodulation may induce meaningful neurophysiological and clinical improvements, the long-term maintenance of its therapeutic effects likely depends on a favorable clinical and psychosocial context [12]. As demonstrated in this case, medication instability and social stress may outweigh the benefits of spinal stimulation.

Regarding safety, the intervention showed a favorable profile and was well tolerated by both participants. Adverse events were mild, transient, and consistent with those previously described for transcutaneous electrical stimulation techniques. Despite the greater sensitivity reported by Participant 2, who occasionally required brief pauses during stimulation, neither participant discontinued the protocol, reinforcing the clinical feasibility of the technique.

The limitations of this study include its case series design, the small sample size, and the absence of a control or sham stimulation group, which limit the generalizability of the findings and prevent the establishment of causal relationships. In particular, without a control or sham condition, it

is not possible to determine whether the observed clinical improvements were specifically attributable to tsDCS or were partly related to placebo effects, spontaneous fluctuations or remission of depressive symptoms, or the therapeutic contact associated with the 15 intervention sessions. Therefore, the clinical improvements observed in both participants should be interpreted cautiously and cannot be attributed exclusively to the neuromodulation intervention. Nevertheless, the present findings contribute to the preliminary evidence regarding the application of tsDCS in MDD and reinforce the need for future controlled studies with larger samples to investigate the efficacy of tsDCS, the durability of its therapeutic effects, and potential biomarkers capable of predicting clinical response to the intervention.

VI. Conclusion

Transcutaneous spinal direct current stimulation (tsDCS) represents a potential complementary approach for the treatment of Major Depressive Disorder (MDD). The findings of this study demonstrated a favorable clinical course in both participants throughout the 15 stimulation sessions, with reductions in depressive symptoms, improvements in quality of life, and decreased suicidal ideation measured exactly after the intervention. However, the follow-up assessment, measured 90 days after the intervention, revealed that the maintenance of treatment effects may vary between individuals, as observed in Participant 2, who experienced a recurrence of symptoms after the end of the intervention, but with a confounding factor of interrupting their current medication. These findings highlight the importance of investigating factors associated with the duration and persistence of therapeutic effects induced by tsDCS. Despite the inherent limitations of a case study design, these results contribute to the understanding of the therapeutic potential of tsDCS and reinforce the need for future studies employing different stimulation protocols, extended follow-up periods, and investigations of physiological biomarkers to further elucidate its mechanisms of action, clinical applicability, and effectiveness in the management of MDD.

Acknowledgment

The authors gratefully acknowledge the financial support provided by the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) and the Fundação de Apoio à Pesquisa do Estado do Rio Grande do Norte (FAPERN) through the Programa de Fomento à Ciência, Tecnologia e Inovação do Rio Grande do Norte (FUCITERN). The authors also thank the Edmond and Lily Safra International Institute of Neuroscience (IIN-ELS), Instituto Santos Dumont, for providing the facilities and infrastructure where part of this study was conducted. Special thanks are extended to Dr. Jales Clemente for his contribution to the psychiatric assessment and confirmation of Major Depressive Disorder diagnoses prior to participant enrollment. The authors also thank Ana Luiza Matos da Silva and José Roberto Gurgel Dantas for their contribution to the development of the adapter used for T10 spinal stimulation, Gabrielly Blasques Oliveira Albuquerque and Isadora Medeiros Cortez for their valuable assistance during the intervention sessions, and all the participants for their cooperation and commitment throughout the study.

***Resumo* — A Tomografia por Emissão de Pósitrons associada à Tomografia Computadorizada (PET-CT) constitui uma das modalidades mais tecnológicas da medicina nuclear atual, sendo amplamente utilizada na detecção, estadiamento e monitoramento de diversas patologias. A qualidade das imagens obtidas e a confiabilidade dos resultados dependem diretamente da correta execução dos testes de controle de qualidade do equipamento. Neste contexto, os Procedimentos Operacionais Padronizados (POPs) desempenham papel fundamental na padronização, rastreabilidade e segurança das atividades realizadas. Este estudo teve como objetivo elaborar e padronizar POPs para os testes de controle de qualidade em sistemas PET-CT, com base em recomendações nacionais e internacionais vigentes. Para isso, foi realizada uma pesquisa bibliográfica e documental em normas regulatórias e guias técnicos, seguida da identificação dos principais testes aplicáveis à rotina clínica e da elaboração dos respectivos procedimentos. Como resultado, foram desenvolvidos POPs contendo objetivo, responsabilidades, materiais necessários, metodologia de execução, critérios de aceitação e registros obrigatórios. A padronização proposta contribui para o fortalecimento da garantia de qualidade nos Serviços de Medicina Nuclear, promovendo maior segurança aos pacientes, confiabilidade diagnóstica, conformidade regulatória e otimização dos processos operacionais.**

***Palavras-Chave* — PET-CT, Controle de Qualidade, Procedimento Operacional Padronizado, Medicina Nuclear, Garantia de Qualidade**

I. Introdução

A Tomografia por Emissão de Pósitrons associada à Tomografia Computadorizada (PET-CT) constitui uma das principais modalidades diagnósticas da Medicina Nuclear moderna, permitindo a aquisição simultânea de informações funcionais e anatômicas em um único exame (IAEA, 2009).

A qualidade das imagens produzidas pelos sistemas PET-CT dependem diretamente do desempenho adequado dos componentes PET e CT, bem como da correta calibração dos equipamentos envolvidos no processo de aquisição e reconstrução das imagens (AAPM, 2019).

Falhas relacionadas aos detectores do PET, sistemas eletrônicos, alinhamento espacial entre as modalidades ou componentes do tomógrafo podem resultar em degradação da qualidade da imagem e comprometer tanto a interpretação visual, quanto a qualificação da atividade radioativa (NEMA, 2018).

Neste contexto, programas de garantia de qualidade têm sido amplamente recomendados por organismos internacionais, como a International Atomic Energy Agency (IAEA), a American Association of Physicists in Medicine (AAPM) e a National Electrical Manufacturers Association (NEMA), com o objetivo de assegurar a manutenção do desempenho dos equipamentos ao longo do tempo (AAPM, 2018).

Entretanto, a efetividade desses programas depende da existência de procedimentos claramente documentados, capazes de orientar a execução dos testes de forma uniforme e rastreável. Os Procedimentos Operacionais Padronizados (POPs) representam uma ferramenta essencial para a padronização das atividades, contribuindo para a redução da variabilidade operacional e para a conformidade com requisitos regulatórios aplicáveis aos serviços de Medicina Nuclear (IAEA, 2013).

Dessa forma, o presente estudo tem como objetivo elaborar Procedimentos Operacionais Padronizados destinados ao controle de qualidade em sistemas PET-CT, fundamentados em recomendações nacionais e internacionais reconhecidas na área.

II. Metodologia

Trata-se de um estudo metodológico de natureza descritiva, desenvolvido por meio de pesquisa bibliográfica e documental, além de observados testes de qualidade e seus resultados realizados em um Serviço de Medicina Nuclear.

Foram consultadas publicações da IAEA, documentos da AAPM, normas da NEMA, regulamentações da Comissão Nacional de Energia Nuclear (CNEN) e demais documentos relacionados ao controle de qualidade em PET-CT.

Além disso, foi observada a rotina de testes de qualidade diários, semanais, mensais e anuais realizados no setor PET-CT de um Serviço de Medicina Nuclear, assim como os resultados obtidos.

A seleção dos testes de qualidade contemplou os procedimentos recomendados conforme preconizado pelas referências consultadas e, a partir das informações levantadas, foi elaborada uma estrutura padronizada para os POPs contendo identificação do documento, objetivo, responsabilidades, materiais necessários, procedimento operacional, critérios de aceitação, ações corretivas, registros obrigatórios e referências técnicas.

III. Fundamentação teórica

A. Sistemas PET-CT

Os sistemas PET-CT representam uma das mais importantes inovações da imagem médica nas últimas décadas, combinando a informação funcional fornecida pela PET com a informação anatômica obtida pela CT (TOWNSEND, 2008).

A modalidade PET utiliza radiofármacos emissores de pósitrons para a avaliação de processos metabólicos e fisiológicos. Após a emissão do pósitron e sua aniquilação com um elétron do meio, são produzidos dos fótons de 511 keV emitidos em direções opostas, permitindo a reconstrução tomográfica da distribuição do radiofármaco no organismo (CHERRY et al., 2012).

A incorporação do CT ao sistema PET possibilitou significativa melhoria na localização anatômica das lesões e na correção de atenuação das imagens, aumentando a precisão diagnóstica e reduzindo o tempo total de aquisição dos exames (TOWNSEND, 2008).

Atualmente, o PET-CT é amplamente empregado no diagnóstico, estadiamento, avaliação de resposta terapêutica e detecção de recidivas em diversos tipos de neoplasias, sendo considerado um dos principais recursos diagnósticos da oncologia moderna (BOELLAARD et al., 2015).

B. Garantia e Controle de Qualidade em PET-CT

A garantia de qualidade compreende um conjunto de atividades planejadas e sistemáticas destinadas a assegurar que os equipamentos operem dentro de parâmetros previamente estabelecidos, produzindo resultados confiáveis e reprodutíveis (IAEA, 2009).

Segundo a IAEA, os programas de garantia de qualidade devem contemplar os testes periódicos destinados à avaliação do desempenho dos sistemas PET e CT, incluindo verificações diárias, mensais, trimestrais e anuais (IAEA, 2009).

Os testes de controle de qualidade aplicados têm como objetivo avaliar o desempenho dos detectores, sistemas eletrônicos, algoritmos de reconstrução e processos de quantificação da atividade radioativa, por exemplo (NEMA, 2018).

A implementação de programas estruturados de controle de qualidade contribui para a detecção precoce de falhas, redução de artefatos, aumento da vida útil dos equipamentos e melhoria da qualidade diagnóstica dos exames (AAPM, 2019).

De acordo com a AAPM, a realização periódica dos testes de qualidade é essencial para assegurar a estabilidade quantitativa dos exames PET e a confiabilidade dos valores de SUV utilizados na rotina médica para avaliação final (AAPM, 2019).

C. Procedimentos Operacionais Padronizados

Os Procedimentos Operacionais Padronizados constituem documentos formais destinados à descrição detalhada das atividades realizadas em uma organização, estabelecendo responsabilidades, etapas operacionais e critérios para a execução das tarefas (ANVISA, 2017).

Em Serviços de Medicina Nuclear, a utilização de POPs é particularmente relevante devido à complexidade tecnológica dos equipamentos e aos requisitos regulatórios relacionados à proteção radiológica e à garantia de qualidade (IAEA, 2013).

A implementação de programas estruturados de controle de qualidade contribui para a detecção precoce de falhas, redução de artefatos, aumento da vida útil dos equipamentos e melhoria da qualidade diagnóstica dos exames (AAPM, 2019).

IV. Resultados

A. Estrutura dos Procedimentos Operacionais Padronizados

Como resultado deste estudo, foi desenvolvida uma estrutura padronizada para a elaboração dos Procedimentos Operacionais Padronizados aplicáveis ao controle de qualidade em sistemas PET-CT.

Cada POP foi constituído por: identificação do documento, objetivo, campo de aplicação, responsabilidades, materiais e equipamentos necessários, procedimento operacional, critérios de aceitação, ações corretivas, registros, referências, fluxograma operacional.

A padronização dessa estrutura visa facilitar a elaboração, implementação e atualização dos documentos, além de favorecer a rastreabilidade das atividades desenvolvidas.

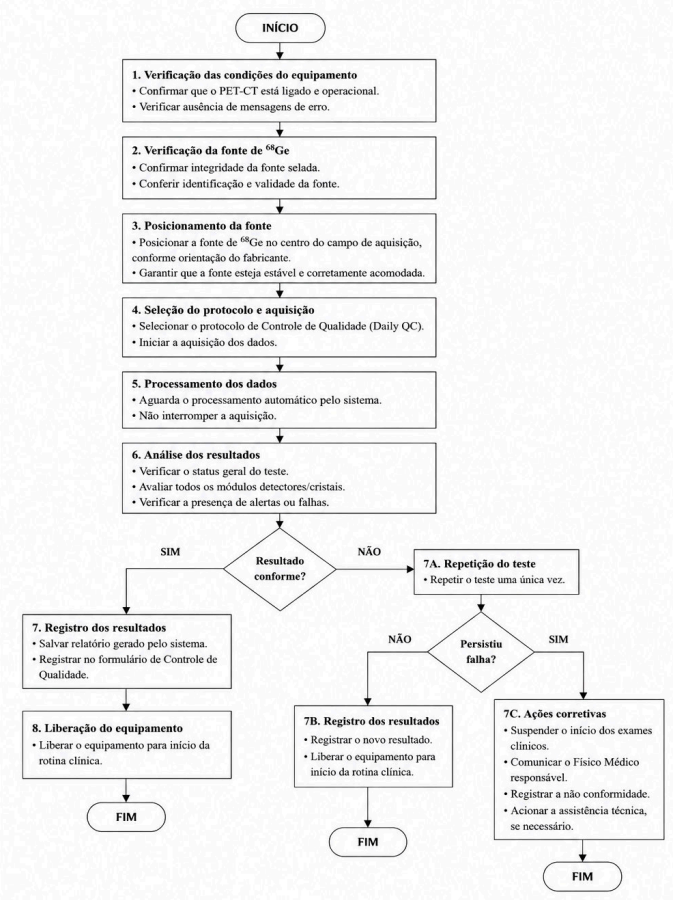
B. POP para Teste Diário de Uniformidade

Com o objetivo de ilustrar a aplicação prática do procedimento elaborado, exemplificamos neste artigo o POP específico para o teste diário de uniformidade do PET utilizando fonte selada de Germânio-68.

O procedimento descreve as etapas de preparação do equipamento, posicionamento da fonte, aquisição dos dados, análise dos resultados e registro das informações.

O objetivo do teste é avaliar a uniformidade de resposta dos detectores do sistema PET, verificando a estabilidade e o desempenho do equipamento.

Os materiais necessários são: Fonte de Germânio-68 (Ge-68) adequada ao equipamento, sistema PET-CT, formulário ou sistema de registro dos resultados.



O procedimento é descrito no fluxograma (figura 1) completo do teste de uniformidade realizado diariamente no sistema PET-CT. O processo inicia-se com a verificação das condições operacionais do equipamento e integridade da fonte radioativa, seguida pelo posicionamento adequado da fonte e execução da aquisição do controle de qualidade.

Após a aquisição, o software do equipamento realiza a análise dos dados e gera o resultado dos teste. Quando os parâmetros avaliados encontram-se dentro dos limites estabelecidos pelo fabricante, o sistema emite o resultado de aprovação. Caso seja identificado resultado de reprovação, podem ser realizadas verificações complementares, como a repetição do teste.

A representação gráfica do processo permite visualizar de forma objetiva as etapas operacionais, os pontos de decisão e as ações corretivas associadas aos diferentes resultados possíveis, contribuindo para a padronização das atividades e para a

segurança operacional do serviço.

C. Análise comparativa

Com o objetivo de verificar a aderência dos POPs elaborados às recomendações técnicas reconhecidas internacionalmente, foi realizada uma análise comparativa entre os testes contemplados neste estudo e aqueles recomendados pelos principais órgãos de referência na área de Medicina Nuclear e Física Médica. A Tabela 1 apresenta a correlação entre os testes propostos e as recomendações da International Atomic Energy Agency (IAEA), American Association of Physicists in Medicine (AAPM), National Electrical Manufacturers Association (NEMA), European Association of Nuclear Medicine (EANM) e European Federation of Organisations for Medical Physics (EFOMP).

Observa-se que os procedimentos desenvolvidos contemplam os principais testes recomendados internacionalmente para monitoramento do desempenho dos sistemas PET-CT, evidenciando a compatibilidade da proposta com os requisitos atualmente adotados em programas de garantia de qualidade

D. Indicadores Quantitativos dos POPs Desenvolvidos

Com o objetivo de caracterizar quantitativamente os produtos gerados durante o desenvolvimento deste estudo, foram definidos indicadores relacionados à estrutura documental elaborada para o Programa de Controle de Qualidade em sistemas PET-CT.

A elaboração dos POPs foi baseada na análise de normas, diretrizes e documentos técnicos nacionais e internacionais, resultando na construção de uma estrutura padronizada capaz de contemplar os principais testes de controle de qualidade aplicáveis aos sistemas PET-CT.

A Tabela 2 apresenta os principais indicadores quantitativos obtidos durante o desenvolvimento do estudo.

TABELA 2
INDICADORES QUANTITATIVOS DO ESTUDO DE CONTROLE DE QUALIDADE PARA PET-CT

Indicador	**Quantidade**
Procedimentos Operacionais Padronizados Elaborados	10
Testes de controle de qualidade	12

contemplados	
Fluxogramas operacionais desenvolvidos	10
Matrizes de controle de qualidade elaboradas	1
Descrição de não conformidade	1
Referências normativas internacionais analisadas	5
Referências bibliográficas utilizadas	12
Componentes do sistema PET-CT contemplados	3

Fonte: Elaborado pela autora (2026).

Os resultados demonstram que a proposta desenvolvida não se restringe à elaboração isolada de procedimentos operacionais, abrangendo também elementos de gestão da qualidade, rastreabilidade documental e monitoramento sistemático do desempenho dos equipamentos.

A inclusão de fluxogramas operacionais, matrizes de controle de qualidade e tabelas de tratamento de não conformidades contribui para a integração dos procedimentos em um programa estruturado de garantia da qualidade, alinhado às recomendações da IAEA, AAPM, NEMA, EANM e EFOMP.

Além disso, os indicadores apresentados evidenciam que a proposta contempla tanto aspectos relacionados ao desempenho dos equipamentos, quanto aspectos gerenciais voltados à documentação, rastreabilidade e melhoria contínua dos processos, elementos considerados fundamentais para programas modernos de garantia da qualidade em Serviços de Medicina Nuclear (IAEA, 2013).

A quantificação dos produtos gerados permite demonstrar a abrangência do trabalho e fornece subsídios para futuras etapas de implementação, validação e monitoramento do desempenho dos POPs em ambiente clínico.

V. Discussão

Os resultados obtidos neste estudo demonstram que a elaboração de Procedimentos Operacionais Padronizados constitui uma estratégia viável para a estruturação de programas de controle de qualidade em sistemas PET-CT. Embora diversas instituições disponibilizem recomendações relacionadas aos testes de desempenho desses equipamentos, observa-se que tais documentos frequentemente apresentam caráter normativo e técnico, exigindo adaptação para a realidade operacional dos serviços de Medicina Nuclear (AAPM, 2019).

A padronização proposta neste trabalho busca reduzir a variabilidade na execução dos testes de controle de qualidade por meio da definição clara de responsabilidades, etapas operacionais, critérios de aceitação e ações corretivas. Segundo a IAEA, a existência de procedimentos formalmente documentados representa um dos pilares dos programas ed garantia da qualidade, contribuindo para a uniformidade dos processos e para a rastreabilidade das informações produzidas (IAEA, 2013).

Entre os procedimentos elaborados, destaca-se o POP destinado ao teste diário de uniformidade com fonte de Ge-68. Esse teste é considerado uma das verificações mais importantes da rotina operacional dos sistemas PET-CT, pois possibilita a identificação precoce de alterações no desempenho dos detectores e dos sistemas eletrônicos associados ao equipamento (NEMA, 2018).

Sob a perspectiva regulatória, a adoção de POPs contribui para o atendimento aos requisitos relacionados à garantia de qualidade e à proteção radiológica estabelecidos para os Serviços de Medicina Nuclear. A documentação estruturada das atividades facilita processos de auditoria, inspeções regulatórias e programas de acreditação institucional, além de demonstrar o compromisso do serviço com a melhoria contínua da qualidade (CNEN, 2021).

Portanto, os resultados obtidos sugerem que a elaboração de POPs representa uma ferramenta relevante para a organização das atividades de controle de qualidade em PET-CT, contribuindo para a segurança operacional, a confiabilidade diagnóstica e a conformidade com as normas nacionais e internacionais.

VI. Conclusão

A qualidade das imagens produzidas pelos sistemas PET-CT depende diretamente da execução adequada dos testes de controle de qualidade e da manutenção do desempenho dos equipamentos ao longo do tempo.

Neste contexto, o presente estudo teve como objetivo elaborar POPs destinados às principais atividades de controle de qualidade em sistemas PET-CT, fundamentados em normas, recomendações técnicas e princípios de garantia da qualidade reconhecidos nacional e internacionalmente.

Como resultado, foi proposta uma estrutura padronizada para a elaboração dos POPs e desenvolvido um conjunto de procedimentos aplicáveis aos principais testes recomendados para sistemas PET-CT, incluindo o teste diário de uniformidade com fonte de Ge-68.

A proposta apresentada contribui para a uniformização das rotinas operacionais, para a rastreabilidade documental e para o fortalecimento dos programas de garantia da qualidade em Medicina Nuclear, fornecendo subsídios técnicos e implementação de padronização e melhoria contínua nos processos relacionados ao controle de qualidade em PET-CT.

***Resumo*—O Teste do Suor é o padrão-ouro para o diagnóstico da Fibrose Cística, exigindo a dosagem quantitativa de cloretos em microvolumes. Os Centros de Referência frequentemente enfrentam desafios logísticos e geográficos entre os pontos de coleta e os laboratórios de análise, tornando necessária a avaliação de protocolos de armazenamento temporal das amostras.**

Objetivo: Avaliar preliminarmente a estabilidade temporal da concentração de cloretos em soluções padrão impregnadas em papel-filtro e mantidas sob refrigeração controlada por até 28 dias.

Métodos: Foram utilizadas 60 unidades de papel filtro qualitativo Whatman número 1 saturadas com três soluções padrão de referência, representativas das faixas de baixa, intermediária e alta concentração de cloretos, com cinco unidades analisadas por ponto temporal. As análises quantitativas foram realizadas por titulometria. Para cada concentração e tempo foram calculadas medidas descritivas e intervalos de confiança. A comparação global entre os períodos foi realizada pelo teste de Kruskal–Wallis e, quando aplicável, por comparações pós-hoc com correção para múltiplos testes.

Resultados: Não foram observadas diferenças globais entre os tempos para as soluções de menor e maior concentração. Para a solução intermediária, entretanto, foi observada diferença global entre os períodos, com aumento das concentrações no último período de armazenamento e aproximação do ponto de decisão clínica.

Conclusão: Os resultados são compatíveis com estabilidade analítica preliminar nas condições estudadas para as faixas de menor e maior concentração, enquanto a faixa intermediária requer cautela, especialmente em períodos prolongados e nas proximidades dos limites diagnósticos. Os achados devem ser confirmados em estudos com suor humano, microvolumes clínicos e maior tamanho amostral.

***Index Terms*—Fibrose Cística, Teste do Suor, Conservação de Espécimes Biológicos, Estabilidade Química, Titrimetria**

I. Introdução

O diagnóstico da Fibrose Cística (FC), doença caracterizada por infecções crônicas e recorrentes do pulmão, insuficiência pancreática e manifestações gastrintestinais típicas, é confirmado por um médico através de achados clínicos e exames laboratoriais [1].

O Teste do Suor (TS) é atualmente o principal exame indicativo da doença, pois indica os níveis de cloreto no suor, os quais estão elevados em fibrocísticos [2]. Considerado exame padrão-ouro, o TS é simples, indolor e não invasivo. Seu protocolo prevê as seguintes etapas: estimulação das glândulas sudoríparas, coleta do suor e dosagem quantitativa dos cloretos presentes no suor [3].

No Brasil, a Portaria SAS/MS nº 224/2010 normatizou a dosagem quantitativa de cloretos no suor como o teste mais fidedigno no processo diagnóstico de FC no Brasil [14].

Em 2015, a Portaria nº 2.099 atualizou os critérios técnicos para habilitação dos Centros de Referência (CRs), estabelecendo coulometria e titulometria como métodos aceitos para análise confirmatória [15].

Recentemente, a Portaria Conjunta SAES/SECTICS nº 5, de 30 de abril de 2024, aprovou a nova atualização do Protocolo Clínico e Diretrizes Terapêuticas da Fibrose Cística (PCDT). Essa normativa consolida o consenso técnico-científico e estabelece os parâmetros nacionais vigentes para o diagnóstico, tratamento e mecanismos de regulação e controle da doença no âmbito do Sistema Único de Saúde (SUS) [16].

A primeira etapa essencial do Teste do Suor consiste na estimulação das glândulas sudoríparas, a qual deve ser executada obrigatoriamente por meio da técnica de iontoforese por pilocarpina. Na etapa subsequente, a coleta do suor pode ser realizada utilizando gaze esterilizada livre de cloretos, papel filtro qualitativo ou sistemas modernos de microtúbulos em espirais de plástico.

A janela temporal máxima admitida para a coleta é de 30 minutos, sendo exigido um microvolume mínimo de 15 µL ou uma massa de 75 mg de amostra biológica para que o ensaio possua viabilidade analítica e não seja classificado como coleta insuficiente.

A última etapa do TS, foco deste trabalho, consiste na dosagem analítica quantitativa fundamentada na determinação da concentração de íons cloreto na amostra, cujos limiares clínicos balizam o diagnóstico de Fibrose Cística entre improvável, menor ou igual a 29 mEq/L; inconclusivo, entre 30 e 59 mEq/L; ou indicativo de Fibrose Cística, quando maior ou igual a 60 mEq/L.

Embora o PCDT atual aponte a coulometria automatizada como método de eleição, o presente trabalho empregou a dosagem titulométrica por meio do reagente comercial Hanna® HI3815 para avaliar o impacto do armazenamento refrigerado estendido por até 28 dias.

A opção deliberada pela técnica titulométrica justifica-se por consolidar-se como um método consagrado e validado há décadas pela literatura científica internacional [8], além de apresentar um custo operacional significativamente baixo em relação às demais metodologias, pois a titulometria demanda apenas vidrarias básicas e insumos de alta acessibilidade econômica.

Na técnica titulométrica, um reagente com concentração conhecida é titulado na solução cuja concentração se deseja determinar. Com o auxílio de um indicador, como a difenilcarbazona, o ponto de neutralização é identificado através da alteração da coloração da mistura reagente+solução. A concentração de cloretos é diretamente proporcional ao volume de reagente pipetado ou titulado na solução [9], [10].

Outro ponto a destacar consiste nos complexos desafios logísticos frequentemente enfrentados pelos Centros de Referência em Fibrose Cística. Em muitos cenários, a coleta do suor não ocorre no mesmo prédio ou período em que a equipe técnica laboratorial está disponível para realizar a dosagem imediata dos cloretos [2].

Há realidades regionais em que o laboratório credenciado para a análise dista centenas de quilômetros do ponto de coleta. Nesse contexto, viabilizar a dosagem de cloretos em dia e local distintos, eliminando o risco de perda ou comprometimento da amostra, evitaria a necessidade de repetição do exame e pouparia os pacientes de um desgaste físico e emocional significativo, com especial destaque para a população pediátrica.

A avaliação preliminar da estabilidade de cloretos impregnados em papel-filtro sob refrigeração constitui uma etapa experimental necessária antes da investigação de protocolos de armazenamento de amostras reais de suor.

A demonstração de estabilidade em soluções padrão pode subsidiar estudos subsequentes destinados à avaliação da matriz biológica e das condições clínicas de coleta.

O objetivo deste trabalho foi realizar uma avaliação preliminar da estabilidade temporal da concentração de cloretos em soluções padrão impregnadas em papel-filtro qualitativo e armazenadas sob refrigeração por até 28 dias, como etapa pré-clínica para o desenvolvimento de protocolos de conservação aplicáveis às amostras do TS.

II. Materiais e Métodos

O presente estudo utilizou exclusivamente soluções padrão certificadas de cloreto, não tendo sido empregadas amostras biológicas de suor humano.

Dessa forma, o protocolo avaliou a estabilidade do analito em uma matriz experimental controlada impregnada em papel-filtro, sem reproduzir integralmente os possíveis efeitos de constituintes biológicos, pH, viscosidade e demais interferentes presentes no suor.

Para a realização do trabalho, utilizou-se o reagente titulométrico Hanna® HI3815 e papel filtro qualitativo Whatman® nº 1 em todas as amostras.

Foram empregadas três soluções padrão (SSx) com concentrações de cloretos conhecidas e certificadas: SS1 (21 mEq/L), SS2 (49 mEq/L) e SS3 (101 mEq/L), fornecidas originalmente junto ao kit de testagem do cloridrômetro Clorochek® (ElitechGroup®).

Foram recortadas 60 peças de papel filtro com dimensões de 2,0 cm $\times$ 1,5 cm, manipuladas exclusivamente com o auxílio de uma pinça de aço inoxidável.

Todas as pesagens foram realizadas em uma balança semi-analítica (Marte®, modelo AD500). Inicialmente, cada peça de papel seca foi acondicionada em um coletor universal estéril de plástico, devidamente identificado de forma sequencial (1 a 60).

Determinou-se, então, a massa inicial do conjunto (papel seco + recipiente).

Na sequência, as diferentes soluções de referência (SS1, SS2 e SS3) foram depositadas em recipientes independentes.

As peças de papel foram imersas em suas respectivas soluções por 30 segundos, sendo o volume de saturação determinado de forma visual. As amostras foram preparadas e dosadas com temperatura ambiental mínima do laboratório de 21,4°C e máxima de 24,7°C.

A saturação do papel-filtro empregada neste protocolo teve finalidade experimental e não reproduziu diretamente o microvolume mínimo de 15 µL ou a massa de 75 mg recomendados para amostras clínicas do Teste do Suor.

Essa condição deverá ser reproduzida em etapa posterior de validação com matriz biológica.

Figura 1. Preparo das amostras.

As amostras foram organizadas em três grupos de 20 unidades, conforme as concentrações de referência (Tabela I).

A massa da solução absorvida pelo papel foi calculada a partir da diferença entre o peso do conjunto saturado (papel úmido + recipiente) e o peso do conjunto seco inicial.

Tabela I
Grupos das concentrações utilizadas como referência

Grupo	Quantidade (un)	Concentração esperada (mEq/L)
1	20	21 ± 2
2	20	49 ± 4
3	20	101 ± 8

Conhecido o volume líquido de solução em cada papel, procedeu-se à dosagem titulométrica para determinar a concentração de cloretos.

No primeiro dia do experimento (Dia 0), uma subamostra de cinco unidades de cada grupo, totalizando 15 amostras, foi submetida à dosagem imediata.

As 45 amostras remanescentes devidamente lacradas foram armazenadas em ambiente refrigerado (Fig. 2) com termostato ajustado para 8°C, cuja temperatura mínima do refrigerador foi de 5°C e a máxima de 9°C.

As três etapas subsequentes seguiram cronogramas específicos de armazenamento sob refrigeração, cujas dosagens foram realizadas em intervalos de 7, 14 e 28 dias para a Bateria 01 (SS1); e intervalos de 7, 21 e 28 dias para as Baterias 02 (SS2) e 03 (SS3).

Essa distribuição totalizou 20 determinações analíticas por faixa de concentração e 60 ensaios no escopo global do estudo.

Considerando que os pontos temporais intermediários não foram uniformes entre as três baterias experimentais, essa assimetria decorreu da disponibilidade laboratorial para realização do experimento, especialmente por se tratar de estudo inicial.

Por essa razão, as análises temporais foram conduzidas separadamente para cada concentração, considerando os tempos efetivamente disponíveis.

Figura 2. Armazenagem em refrigerador.

Os dados foram registrados em planilha eletrônica e reanalisados estatisticamente considerando separadamente cada concentração de referência.

Para cada ponto temporal foram calculados média, desvio padrão, intervalo de confiança de 95% da média, viés absoluto e viés percentual em relação à concentração nominal.

A normalidade foi explorada pelo teste de Shapiro–Wilk.

Como as unidades experimentais analisadas em cada tempo eram independentes, considerando o reduzido tamanho amostral ($n = 5$ por ponto) e a ocorrência de distribuição não normal em pelo menos um grupo, a comparação global entre os tempos foi realizada pelo teste não paramétrico de Kruskal–Wallis.

Quando identificada diferença global, foram realizadas comparações par a par pelo teste de Mann–Whitney, com correção de Holm para múltiplas comparações.

Como análise complementar, foi calculada ANOVA de uma via. Adotou-se nível de significância de 5%.

A ausência de diferença estatisticamente significativa não foi interpretada isoladamente como demonstração de equivalência ou estabilidade clínica.

III. Resultados

A distribuição individual das dosagens titulométricas obtidas para as 20 amostras pertencentes à Bateria 01, com concentração nominal esperada de 21 ± 2 mEq/L, ao longo dos respectivos tempos de armazenamento entre 0, 7, 14 e 28 dias está ilustrada na Fig. 3.

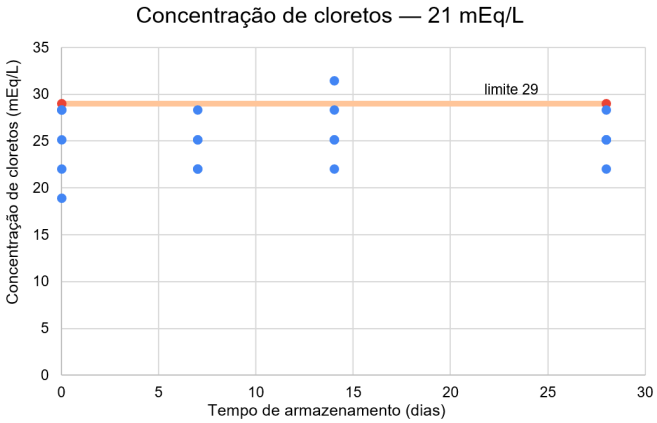

Figura 3. Concentração de cloretos da solução de referência de 21 mEq/L em função do tempo de armazenamento refrigerado.

Para o grupo de amostras da Bateria 02, correspondente à faixa intermediária, com valor de referência de 49 ± 4 mEq/L, o perfil individualizado das dosagens nos diferentes intervalos temporais entre 0, 7, 21 e 28 dias é apresentado na Fig. 4.

Observou-se maior concentração dos resultados junto ao limite superior no Dia 28, enquanto a avaliação de normalidade indicou distribuição não normal nesse ponto temporal.

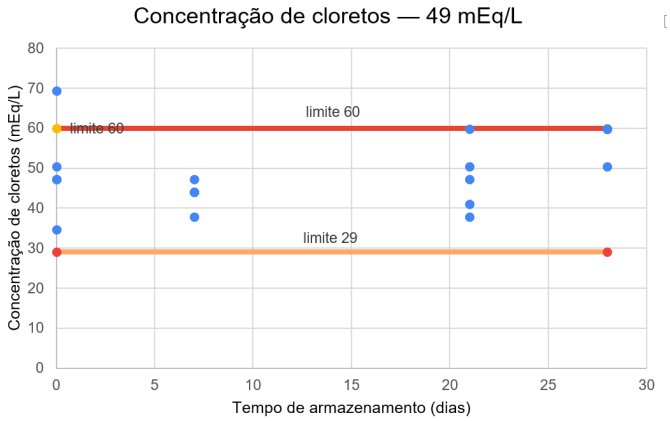

Figura 4. Concentração de cloretos da solução de referência de 49 mEq/L em função do tempo de armazenamento refrigerado.

Na Fig. 5, observa-se o comportamento das amostras da Bateria 03, formuladas na faixa francamente indicativa da doença, com valor de referência de 101 mEq/L.

Apesar da dispersão observada, as medidas permaneceram acima do limite diagnóstico de 60 mEq/L nos períodos avaliados.

A análise descritiva por ponto temporal é apresentada na Tabela II.

Para cada combinação de concentração e tempo são apresentados média, desvio padrão, intervalo de confiança de 95%, viés absoluto e viés percentual em relação ao valor nominal.

Tabela II
ESTATÍSTICA DESCRITIVA DAS CONCENTRAÇÕES DE CLORETOS SEGUNDO O TEMPO DE ARMAZENAMENTO

Nominal (mEq/L)	Dia	n	Média (mEq/L)	DP	IC95% (mEq/L)	Viés (mEq/L)	Viés (%)
21	0	5	24,57	4,11	19,47–29,67	+3,57	+17,00
21	7	5	24,57	2,64	21,30–27,84	+3,57	+17,00
21	14	5	26,46	3,59	22,00–30,92	+5,46	+26,00
21	28	5	25,20	2,23	22,43–27,97	+4,20	+20,00
49	0	5	49,77	12,48	34,27–65,27	+0,77	+1,57
49	7	5	43,47	3,45	39,19–47,75	-5,53	-11,29
49	21	5	47,25	8,63	36,54–57,96	-1,75	-3,57
49	28	5	57,96	4,23	52,71–63,21	+8,96	+18,29
101	0	5	102,06	10,59	88,91–115,21	+1,06	+1,05
101	7	5	98,91	18,98	75,34–122,48	-2,09	-2,07
101	21	5	97,65	18,64	74,51–120,79	-3,35	-3,32
101	28	5	107,73	10,77	94,35–121,11	+6,73	+6,66

DP: desvio padrão; IC95%: intervalo de confiança de 95% da média. O viés foi calculado em relação à concentração nominal da solução de referência.

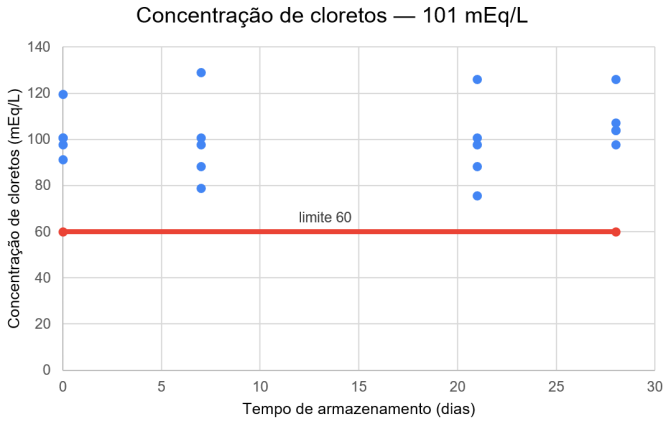

Figura 5. Concentração de cloretos da solução de referência de 101 mEq/L em função do tempo de armazenamento refrigerado.

A comparação global entre os tempos é apresentada na Tabela III.

Para a concentração nominal de 21 mEq/L não foi observada diferença entre os períodos avaliados (Kruskal–Wallis, $H = 0{,}892$; $p = 0{,}827$).

Resultado semelhante foi observado para 101 mEq/L ($H = 3{,}003$; $p = 0{,}391$).

Para a solução nominal de 49 mEq/L, entretanto, foi detectada diferença global entre os períodos ($H = 8{,}012$; $p = 0{,}0458$).

Tabela III
COMPARAÇÃO GLOBAL ENTRE OS TEMPOS DE ARMAZENAMENTO

Nominal (mEq/L)	H Kruskal–Wallis	p	ANOVA p
21	0,892	0,8274	0,7681
49	8,012	**0,0458**	0,0673
101	3,003	0,3911	0,7330

Na análise pós-hoc da faixa de 49 mEq/L, nenhuma comparação par a par permaneceu estatisticamente significativa após a correção de Holm.

A maior diferença foi observada entre os Dias 7 e 28 (Mann–Whitney, p bruto $= 0{,}0088$; p ajustado $= 0{,}0527$).

Portanto, o teste global sugere heterogeneidade temporal nessa faixa, mas o reduzido número de unidades por período limita a identificação precisa de quais tempos diferem entre si.

O resultado da Bateria 02 no Dia 28 merece atenção particular.

A média aumentou para $57{,}96 \pm 4{,}23$ mEq/L, com IC95% de 52,71 a 63,21 mEq/L. Esse intervalo expressa a incerteza em torno da média do grupo e não deve ser interpretado como probabilidade de uma amostra individual ultrapassar o ponto de decisão clínica de 60 mEq/L.

Quatro das cinco determinações desse período apresentaram valor de 59,85 mEq/L, muito próximo do limite entre a faixa intermediária e a faixa indicativa de Fibrose Cística.

Esse agrupamento de resultados próximo ao limite clínico recomenda cautela na extrapolação de 28 dias de armazenamento para amostras situadas próximas aos pontos de decisão diagnóstica.

Na faixa nominal de 21 mEq/L observou-se viés positivo em todos os tempos, inclusive no Dia 0, com médias entre 24,57 e 26,46 mEq/L.

Esse comportamento sugere contribuição do próprio método titulométrico e de sua resolução analítica, e não necessariamente efeito exclusivo do armazenamento.

Para 101 mEq/L, apesar da maior dispersão observada nos Dias 7 e 21, não houve evidência estatística de alteração global entre os tempos.

A ausência de significância estatística nas faixas de 21 e 101 mEq/L deve ser interpretada como ausência de evidência de alteração detectável nas condições avaliadas, e não como demonstração formal de equivalência.

A interpretação de estabilidade também requer critérios de aceitabilidade analítica ou clínica previamente definidos.

IV. DISCUSSÃO

Desde o estabelecimento do Teste do Suor há mais de cinco décadas, o manejo de microvolumes biológicos tem se configurado como um desafio persistente na rotina laboratorial, uma vez que a quantidade de amostra obtida varia tipicamente entre 20 µL e 70 µL.

A técnica titulométrica aqui utilizada destaca-se por prescindir de maquinários complexos ou de alto custo, demandando apenas vidrarias básicas de laboratório e micropipetas de precisão.

O princípio baseia-se na reação entre um titulado constituído pela solução padrão de cloreto impregnada no papel-filtro e um titulante de concentração conhecida, solução de nitrato de mercúrio, utilizando a difenilcarbazona como indicador químico.

O ponto de neutralização total dos cloretos, ou ponto de viragem (*endpoint*), é identificado visualmente quando a mistura transita de uma coloração alaranjada para um complexo violeta (Fig. 6).

Uma vantagem prática do reagente Hanna® HI3815 foi seu custo-benefício, estimado em aproximadamente R$ 0,50 por dosagem, viabilizando a realização do experimento.

Figura 6. Ilustração da dosagem titulométrica.

A introdução do componente temporal e térmico neste estudo permitiu uma avaliação inicial da estabilidade do cloreto em matriz experimental controlada.

Frente aos desafios logísticos dos Centros de Referência, esses resultados preliminares sustentam a investigação da refrigeração como estratégia potencial para flexibilizar o intervalo entre coleta e dosagem.

Entretanto, a aplicação clínica desse procedimento depende de confirmação em amostras reais de suor e de critérios prévios de aceitabilidade analítica e diagnóstica.

Este estudo apresenta limitações que devem ser consideradas na interpretação dos resultados.

O experimento foi conduzido com soluções padrão certificadas de cloreto impregnadas em papel-filtro, e não com suor humano, não reproduzindo integralmente composição biológica, pH, viscosidade e possíveis interferentes da matriz clínica.

Foram avaliadas apenas cinco unidades em cada ponto temporal, os períodos intermediários não foram uniformes entre as três concentrações e a saturação experimental do papel-filtro não corresponde diretamente aos microvolumes utilizados na rotina clínica.

Além disso, não foram incluídas concentrações deliberadamente posicionadas junto aos pontos de decisão de 29/30 e 59/60 mEq/L.

Estudos subsequentes deverão utilizar suor humano e, preferencialmente, dividir cada amostra em alíquotas destinadas à dosagem imediata e após diferentes períodos de armazenamento, permitindo análise longitudinal de viés e manutenção da classificação diagnóstica.

V. Conclusões

Nas condições experimentais avaliadas, as soluções padrão de 21 e 101 mEq/L apresentaram comportamento compatível com estabilidade analítica preliminar ao longo dos períodos estudados, sem evidência de diferença global entre os tempos.

Para a solução de 49 mEq/L, foi observada diferença temporal global e elevação da média para 57,96 mEq/L no Dia 28. Quatro das cinco determinações desse período foram de 59,85 mEq/L, valor muito próximo do ponto de decisão clínica de 60 mEq/L, o que recomenda cautela na interpretação de períodos prolongados de armazenamento próximos aos limites diagnósticos.

Esses resultados constituem evidência pré-clínica inicial e não permitem estabelecer segurança clínica ou validar o armazenamento de amostras reais de suor por 28 dias.

Estudos subsequentes deverão incluir suor humano, microvolumes compatíveis com a rotina clínica, maior tamanho amostral, critérios prévios de aceitabilidade e concentrações especificamente posicionadas próximas aos limites diagnósticos.

***Abstract*— Therapeutic ultrasound (TUS) is a common treatment modality employed in Physical Therapy practice. One of the most important treatment objectives is to promote pain relief in joints. To this end, laboratory-fabricated tissue-mimicking phantoms representing skin and tendon were developed using plasticized poly (vinyl chloride) (PVCP). TUS was applied to a multilayer tissue-mimicking phantom composed of skin, tendon and cortical bone simulating treatment of the infrapatellar region of the knee. Thermal images were acquired using an infrared camera (Flir systems®) to evaluate the temperature distribution during an ultrasound therapy protocol. Thermal imaging demonstrated a non-uniform temperature distribution across the phantom layers. Greater heating near the cortical bone phantom was observed at 1MHz reaching approximately 60 °C in only 5 minutes of application, suggesting that differences in tissue properties may influence the spatial distribution of heating.**

***Keywords*—ultrasonic therapy, patella, knee, heating.**

I. INTRODUCTION

Phantoms are materials developed to reproduce the physical properties and behavior of biological tissues. Their use has been described in the literature since the 1960s, encompassing applications such as equipment calibration and simulation of different biological tissue characteristics for research and development purposes [1]. Tendons are structures of the musculoskeletal system distributed across various regions of the human body, transmitting the forces produced during muscle contraction. This mechanism enables joint movement and contributes to the stability and efficiency of the body movement [2, 3]. When injured, they lead patients to seek Physiotherapy treatment, where one of the resources is Therapeutic Ultrasound (TUS). Therefore, TUS dosage varies according to the application time, intensity and wave frequency to produce thermal and non-thermal effects [4]. Thermal effects include increase of blood flow, metabolism and extensibility of collagen fibers, muscle spasm reduction and pain relief. Non-thermal effects include cavitation and micromassage which stimulate fibroblast activity, increase protein synthesis and regenerate soft and bone tissues [5, 6, 7].

Although TUS has been used for decades, there is still a lack of robust scientific evidence to support the dosages employed for specific clinical conditions. To date, TUS continues to be used largely on an empirical basis by physiotherapists, as relatively few methodologically rigorous clinical trials have established the effectiveness of TUS parameters.

The objective of this study was to evaluate the TUS protocol proposed for application to the infrapatellar region of the knee, based on the treatment parameters reported in [8], using a multilayer phantom. The protocol consisted of: 1-MHz frequency, continuous mode, spatial average temporal peak (I_{SAPT}), intensity of 1.2 W/cm^2, effective radiating area (ERA) 7 cm^2, and an application time of 8 minutes.

II. METHODOLOGY

The methodology consisted of four main stages: 1) phantom fabrication, 2) evaluation of the acoustic properties and 3) application of TUS on the multilayer phantom.

1) Phantom fabrication

The skin-mimicking phantom was prepared using 100mL of PVCP 2132LP (MF Manufacturing CO., Fort Worth, TX, USA) and 3 g of 140-mesh graphite powder (B'Herzog , Rio de Janeiro, Brazil). The PVCP was mixed in a glass beaker with the graphite powder, which had been previously sieved and weighed [9].

The tendon phantom was constructed at the Ultrasound Laboratory in the Biomedical Engineering Program (COPPE/UFRJ) using plasticized poly (vinyl chloride) – PVCP, obtained as Plastisol resin (M-F Manufacturing Co., Inc, Fort Worth, TX, USA), glycerol, and poly (vinyl chloride) – PVC powder . The proportion of the materials was: 15 wt% glycerol and 10wt% PVC powder [10].

For both phantoms the equipment used included a two-stage vacum pump (Ecotools, model ET190), a glass vacuum desiccator (PHX-210), and a microwave oven (Blue Touch®, Electrolux, model PM023E, Rio de Janeiro, Brazil).

To remove air bubbles, the mixture was placed in a vacuum desiccator for 30 min. It was then heated in a microwave oven at 70% power in a 2-min interval until it reached approximately 180°C. After a 24-h curing period, the phantom's thickness and acoustic properties were assessed at the Ultrasound Laboratory (PEB/COPPE/UFRJ).

The skin phantom is rectangular (14cm length x 14 cm width), thickness 3.55 ± 0.10 mm. The tendon phantom is cylindrical with 6.5 cm perimeter and thickness : 8.17 ± 0.18 mm. The cortical bone phantom is rectangular with 13 cm width x 18 cm length and 1.03 thickness.

Cortical bone Phantom is a commercial Phantom (Epoxi Resin Sawbones©, Vashon, Washington, USA), with parameters specific mass 1700.59 $kg.m^{-3}$, acoustic speed 2924.31 $m.s^{-1}$ and attenuation coefficient 6.15 $dB.cm^{-1}.MHz^{-1}$.

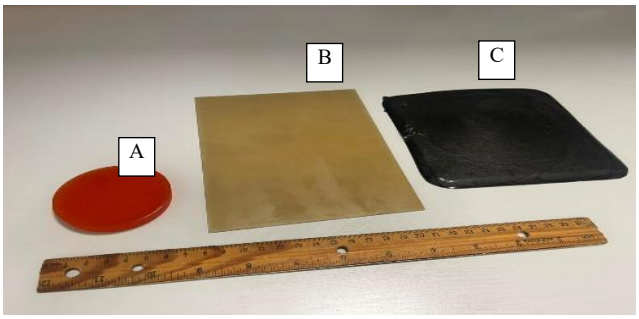

Fig 1: A: Tendon phantom: B: Bone Phantom; C: Skin phantom.
Source: the authors.

2) Evaluation of the acoustic properties

The acoustic properties were measured in an acoustic tank at the laboratory [Fig. 2] and are presented in Table 1, according to [11, 12].

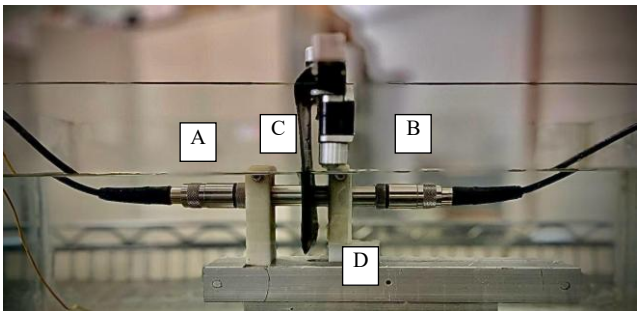

Fig 2: A: Emitter transducer; B: Receiver Transducer: C: Skin phantom; D: Sample holder.
Source: the authors.

Table 1. Acoustic Properties of the skin and tendon Phantoms were measured at the laboratory, while cortical bone phantom presents nominal measures from the manufacturer. S: speed [$m.s^{-1}$] and AC: Attenuation coefficient [$dB.cm^{-1}.MHz^{-1}$].

Skin phantom	S	1491.32 ± 4.83
	AC	0.94 ± 0.01
Tendon phantom	S	1251.47 ± 67.52
	AC	3.94 ± 0.74
Cortical Bone phantom	S	2924.31
	AC	6.15

3) Application of TUS on the multilayer phantom

The present work aims to evaluate the heating promoted by an Ultrasound therapy device (UST) applied on a multilayer phantom. The UST used (Sonopulse III, Ibramed) is shown in Fig 3. The irradiation parameters were: 1MHz-frequency, Effective radiation area (ERA) 8 cm^2, Nominal intensity 1.0 W/cm^2, Nominal power 8.0 W, continuous mode and 5 minutes of application time. The output power was measured ten times using a Radiation force balance (Ohmic instruments), so nominal and estimated power were, respectively: 8.0 W and 8.787 ± 0.017 W.

Fig. 3. TUS equipment (Sonopulse III®, Ibramed Indústria Brasileira de Equipamentos Médicos Ltda., Amparo, SP, Brazil).
Source: the authors.

The reference clinical protocol [8] utilized equipment with an ERA of 7 cm2, an intensity of 1.2 W/cm2, a nominal power of 8.4 W and a dynamic transducer for an application duration of 8 minutes. In the present study, a commercial transducer (Sonopulse III) was employed with an ERA 8 cm2, a nominal intensity of 1.0 W/cm2, and an estimated power of 8.7 W. The application duration was set to 5 minutes, shorter than the time suggested in the clinical protocol, since the laboratory transducer application was stationary, with the transducer secured to support.

The experimental setup was based on the clinical application of TUS on the infrapatellar tendon in the knee [Fig 4].

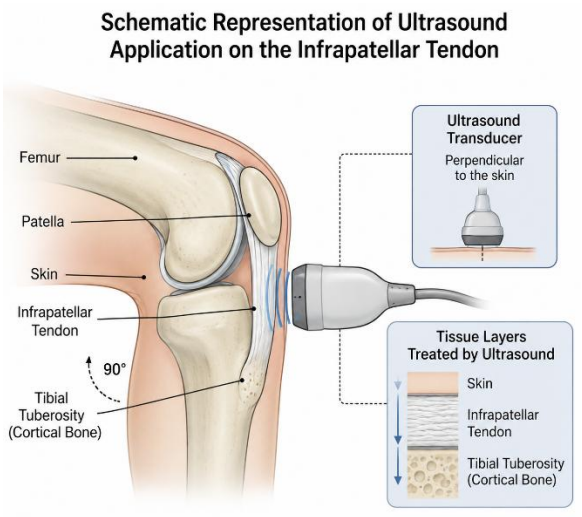

Fig 4: Schematic representation of TUS on the infrapatellar tendon in the knee. Source: the authors.

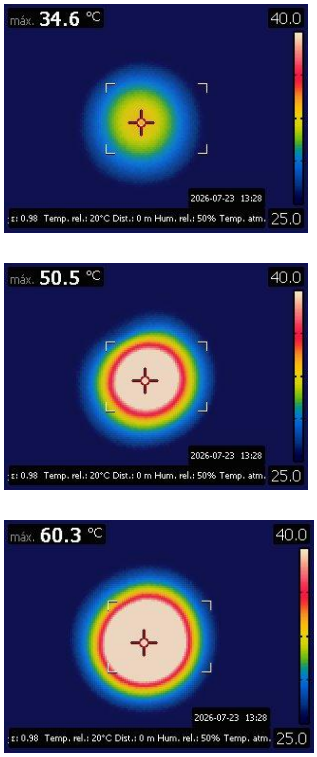
The experimental set up [Fig 5] consisted of TUS transducer positioned on the skin phantom, coupled with gel. The phantoms interfaces were also filled with gel to minimize the acoustic impedance difference between them. The UST transducer was positioned stationary on the multilayer phantom and the acoustic beam propagated sequentially through the skin, tendon and cortical bone phantoms, before reaching the absorbing medium. After 5 min of irradiation the transducer was moved laterally to allow the infrared camera (FLIR E64501, FLIR SYSTEMS), to capture the heating pattern across each phantom layer. The phantoms were manually separated to enable the acquisition of thermal images of the individual layers. Then, to allow the phantoms to cool between experiments, they were immersed in a beaker containing cold water for 5 min, before the next experimental procedure was performed. A total of five experiments were performed, and the temperature data were analyzed using Excel®.

B: Anterior view of the ultrasound transducer accoupled with the multilayer phantom (skin/ tendon/ cortical bone phantoms) and absorbing medium). Source: the authors.



RESULTS

Five experiments were performed on heating the multilayer phantom by the UST (Table 2).

Table 2. Multilayer phantom heating experiments, initial and final temperatures [°C].

Experiments 1	Initial temperature [°C]	Final Temperature [°C]
Skin phantom	23.5	34.8
Tendon phantom	23.5	52.5
Bone phantom	23.5	62.0
2		
Skin phantom	23.5	33.5
Tendon phantom	23.5	48.8
Bone phantom	23.5	64.5
3		
Skin phantom	24.2	34.8
Tendon phantom	24.2	50.5
Bone phantom	24.2	60.3
4		
Skin phantom	24.5	34.6
Tendon phantom	24.5	49.9
Bone phantom	24.5	61.7
5		
Skin phantom	22.8	35.1
Tendon phantom	22.8	65.1
Bone phantom	22.8	72.2

The average temperature after the irradiation for skin phantom was 34.56 ± 0.62 °C, for tendon phantom was 53.36 ± 6.70 °C and for bone phantom was 64.14 ± 4.75 °C. An example of the thermal images is shown in Fig. 6.

Tendon phantom

Cortical bone phantom

Fig 6: Thermal images registered after irradiation by UST. Temperature can be observed on the left and upper side of the images, temperature of skin phantom was 34.6 °C, tendon phantom was 50.5 °C and cortical bone phantom was 60.3 °C. Source: the author

III. DISCUSSION

The findings of this study demonstrate the thermal behavior of therapeutic ultrasound (TUS) applied to a complex multilayer phantom (skin/ tendon/ cortical bone), providing relevant information about energy deposition in the infrapatellar region of the knee.

The application of PVCP phantoms provides a useful approach for mimicking tissue layers and for investigating the thermal response to TUS, with different dosages [10,12]. This work may provide an estimation of temperature distribution behavior within skin, tendon and bone layers during ultrasound irradiation. However, the findings should be interpreted with caution and should not be directly extrapolated to in vivo conditions. Unlike biological tissues, the phantom does not reproduce blood perfusion, which can contribute to heat dissipation, and the ultrasound transducer was maintained in a stationary position throughout irradiation. Consequently, the localized energy deposition and resulting temperature increase may differ from those occurring during clinical treatment, in which the transducer is typically moved continuously over the treatment area.

For this reason, the irradiation time was reduced to 5 minutes in the present study, rather than the 8-minute application reported in [8], in order to minimize the risk of excessive heating inside the phantoms under stationary irradiation conditions.

The physical stability of PVCP allowed repeated ultrasound exposures and thermal measurements and the present experimental model should therefore be considered a simplified representation of the clinical scenario of the TUS application on the infrapatellar region.

The variability observed across the experimental trials, particularly the higher temperature recorded during the fifth trial (65.1 °C in the tendon and 72.2 °C in the bone) reflects the high sensitivity of the static model to slight operational variations, such as coupling gel thickness, minor fluctuations in applied manual pressure and acoustic beam alignment.

Thermal images revealed a non-uniform temperature distribution along the phantom layers. The skin phantom exhibited the lowest temperature increase, followed by the tendon and cortical bone layers. This finding was expected, given that the attenuation coefficient of the tendon is approximately four times that of the skin , while that of cortical bone is approximately six times higher than that of the skin. Although acoustic attenuation occurs as the ultrasound beam propagates through the tissues, more pronounced heating may occur near the cortical bone region at 1MHz. This behavior may be attributed not only to the higher attenuation coefficient bone, but also to the acoustic impedance mismatch at the tissue interfaces, particularly between the tendon and cortical bone, which may result in partial reflection of the acoustic beam and alter the local distribution of the acoustic energy.

Such behavior highlights a critical clinical concern: target tissues located deep in and close to the periosteal margins may suffer excessive temperature elevations if the spatial distribution of energy is not properly considered.

The obtained values exceed the safe therapeutic limit (40 – 45 °C) and would induce thermal damage in vivo within this range. However, the primary objective of this study was to map the relative heating distribution pattern across interfaces (skin/ tendon/ bone) under a simplified scenario. The phantom model employed lacks blood perfusion and the transducer remained static. Although these physiological and operational factors significantly reduce temperature elevation in actual clinical practice, it is critical to emphasize the importance of continuous transducer movement in clinical settings to prevent tisse damage.

Infrared thermography was selected because it enables direct visualization of the surface thermal pattern. The use of thermocouples would only allow point measurements at the phantom interfaces, which was not the objective of this study. Visualizing the temperature pattern requires fast handling and separation of the layers, so the elapsed time causes thermal loss. The combined use of integrated thermocouples with continuous thermography is planned for subsequent studies.

A randomized crossover clinical study [13] involving 24 healthy participants evaluated high-intensity continuous ultrasound (HICUS) applied to the knee (1MHz, 2.5W/cm^2, 100% duty cycle, 5 minutes). The intervention significantly reduced infrapatellar fat pad stiffness and improved tissue gliding, with effects maintained at subsequent assessments. This study used the same ultrasound frequency, 100% duty cycle and exposure time, but a higher intensity and a moving transducer during irradiation.

Static application represents a simplified, “worst-case” thermal condition. Simulating manual scanning introduces operator-dependent variability. Automating this movement at 4 cm/s using a computerized mechanical setup is already planned in the laboratory. Furthermore, we intend to increase the sample size and compare devices from different manufacturers. Nevertheless, the present study is distinguished by its novelty in evaluating the thermal pattern of a multilayered PVCP phantom simulating the infrapatellar region irradiated by therapeutic ultrasound.

IV. CONCLUSION

The present study demonstrated a non-uniform thermal distribution following TUS application to a multilayer PVCP phantom representing the skin, tendon and cortical bone of the infrapatellar region. The skin exhibited the lowest temperature increase, whereas greater heating was observed in the tendon and cortical bone layers, suggesting that tissue-specific acoustic properties and impedance differences influence the spatial distribution of ultrasound-induced energy.

The PVCP phantom provided a useful controlled model for investigating TUS heating. The low number of repetitions and evaluation of a single TUS dosage is considered a limitation. Further studies should increase the number of experiments, investigate other TUS dosages, and evaluate different skin and tendon thicknesses to better characterize the thermal behavior of TUS under varying conditions. In addition, the transducer movement should be considered, as performed in clinical practice, to better represent the dynamic conditions of therapeutic ultrasound application.

***Abstract*—Tetrapyrrolic macrocycles constitute a class of compounds widely distributed in nature whose electronic, photochemical, and photophysical properties make them highly relevant for biomedical applications, particularly photodynamic therapy. Protoporphyrin IX has emerged as a promising photosensitizer due to its biocompatibility; however, its intrinsic tendency to aggregate significantly compromises its photodynamic performance. In this study, the aggregation behavior of protoporphyrin IX dimethyl ester in solution was investigated using one- and two-dimensional nuclear magnetic resonance spectroscopy to elucidate how aggregation influences proton chemical shifts and to correlate these variations with the preferred supramolecular organization adopted by the molecule. Experiments were performed at concentrations ranging from 2.82 to 33.8 mmol L^{-1} using an 800 MHz spectrometer. Comparison with previously reported studies revealed inconsistencies in earlier spectroscopic assignments, and the present approach enabled the establishment of more robust proton assignments supported by multidimensional nuclear magnetic resonance correlations. The spectroscopic data indicates the formation of aggregates that cannot be strictly described by classical H-, J-, or T-type organizations but are better represented as hybrid or distorted supramolecular arrangements involving tilted macrocycles. This study provides a high-resolution spectroscopic characterization that contributes to a deeper understanding of porphyrin aggregation phenomena and establishes a structural framework that may support the rational development of next-generation photosensitizers for photodynamic therapy.**

Keywords—photodynamic therapy, protoporphyrin IX, aggregation, nuclear magnetic resonance spectroscopy

I. INTRODUCTION

Porphyrins are a class of tetrapyrrolic macrocycles widely distributed in nature, consisting of four N-heterocyclic pyrrole units interconnected through methine bridges to form a planar π-conjugated ring system [1,2]. These aromatic structures exhibit an 18π-electron delocalization pathway [3], which gives rise to unique electronic, photochemical, and photophysical properties. The ability of porphyrinic macrocycles to participate in photoinduced processes has been extensively exploited in photodynamic therapy (PDT).

Protoporphyrin IX (PpIX), a natural precursor of the heme group, has been widely investigated as a photosensitizer for PDT owing to its intrinsic biocompatibility [4]. Upon visible-light excitation, these molecules are promoted to excited singlet states and subsequently undergo intersystem crossing to the triplet state, which can transfer energy or electrons to molecular oxygen, leading to the generation of reactive oxygen species (ROS) [5]. The resulting oxidative stress promotes cellular damage and cell death, supporting the clinical relevance of PDT, particularly in oncological applications.

Tetrapyrrolic macrocycles exhibit an intrinsic tendency toward aggregation [6]. This behavior arises from their high π-electron density, which favors intermolecular interactions that are energetically more favorable than interactions with the surrounding medium, including biological fluids such as blood circulation [6,7]. In general, aggregation compromises photodynamic performance by promoting non-radiative deactivation pathways of the excited singlet state and reducing the efficiency of intersystem crossing responsible for the formation of the excited triplet state [8].

The aggregation phenomenon results from a delicate balance between attractive σ–π interactions and repulsive π–π interactions between molecules in the aggregated state [9]. According to the proposed model, J-type (slipped face-to-face) and T-type (edge-to-face) arrangements are energetically favored, whereas H-type (face-to-face) organizations maximize π–π repulsion and are therefore less stable [9]. Aggregate formation is influenced by peripheral substituents at the β-pyrrolic and meso positions, as well as by metal coordination at the porphyrin core [10]. Furthermore, physicochemical parameters, including polarity, temperature, pH, and concentration, also modulate this process [6,10].

Throughout the evolution of PDT, several strategies have been proposed to minimize aggregation, including the isolation of naturally occurring derivatives, sterically hindered macrocycle design [11], and nanoencapsulation approaches [12]. Despite these advances, aggregation remains a major limitation, negatively affecting therapeutic performance and hindering structural characterization by spectroscopic techniques, including nuclear magnetic resonance (NMR) spectroscopy.

Porphyrins exhibit pronounced diamagnetic anisotropy, which is reflected in characteristic NMR chemical shifts,

with inner protons typically appearing between −2 and −4 ppm and meso protons resonating between 8 and 12 ppm [13]. Aggregation perturbs this spectroscopic pattern, causing signal broadening and chemical shift variations due to intermolecular interactions that alter the local magnetic environment. Classical studies investigated these effects by systematically varying parameters such as concentration and temperature [14,15].

Recent advances in NMR instrumentation, including multidimensional experiments, pulsed-field gradients, and cryogenically cooled magnets [16], now allow these systems to be revisited with significantly improved resolution and sensitivity, enabling a more detailed description of porphyrin aggregates.

Moreover, a comprehensive understanding of photosensitizer aggregation has become increasingly relevant for biomedical engineering, as this phenomenon directly influences physicochemical stability, singlet oxygen generation, and overall therapeutic performance in photodynamic therapy. These mechanistic insights may ultimately support the rational design of molecular systems with greater translational potential for clinical diagnostic and therapy systems applications.

II. Objective

To investigate the influence of aggregation on the diamagnetic anisotropy of protoporphyrin IX dimethyl ester using nuclear magnetic resonance spectroscopy and to establish spectroscopic correlations that may contribute to the rational development of photosensitizers for photodynamic therapy applications.

III. Materials and Methods

A. General Information

This study was conducted within a multidisciplinary research environment involving the Centro de Inovação, Tecnologia e Educação (CITE), Resix Invent, and the Central Analítica do Instituto de Química da Universidade de São Paulo. The synthetic strategies employed are well established in the literature [11] and are part of the expertise developed by the research group affiliated with the Center for Research on Redox Processes in Biomedicine (REDOXOME – CEPID-FAPESP, Process No. 2013/07937-8).

B. Synthesis of Protoporphyrin IX Dimethyl Ester (PpIX DME)

Disodium protoporphyrin IX salt (1.00 g, ≥ 90%) was dissolved in 20 mL of a methanol/sulfuric acid solution (19:1, v/v) and stirred at room temperature (25 °C) for 24 h under light-protected conditions. The reaction mixture was extracted with dichloromethane (100 mL) and subsequently neutralized by the slow addition of ammonium hydroxide solution (150 mL, 28–30%) in an ice bath until pH 11 was reached. Gentle stirring was maintained for 10 min to avoid emulsion formation. The organic phase was extracted three times with dichloromethane (10 mL), dried over anhydrous sodium sulfate, filtered, and concentrated under reduced pressure. The resulting product was precipitated with methanol and stored protected from light and heat.

C. Sample Preparation

Twelve PpIX DME solutions were prepared in deuterated chloroform containing 0.05% (v/v) tetramethylsilane ($CDCl_3$/TMS). Concentrations ranged from 2.82 to 33.8 mmol L^{-1} while maintaining a constant final volume of 600 µL for all samples. The initial sample was prepared by dissolving 1.00 mg of PpIX DME in 600 µL of $CDCl_3$/TMS, corresponding to a concentration of 2.82 mmol L^{-1} (PpIX DME 1). Subsequent samples were prepared cumulatively by adding successive 1.00 mg portions of PpIX DME to the preceding solution while maintaining a constant total volume until the maximum concentration of 33.8 mmol L^{-1} (PpIX DME 12) was reached.

D. NMR Experiments

One-dimensional proton nuclear magnetic resonance (^{1}H NMR) spectroscopy and two-dimensional homonuclear correlation experiments, including correlation spectroscopy (^{1}H–^{1}H COSY) and nuclear Overhauser effect spectroscopy (^{1}H–^{1}H NOESY), were performed using a Bruker Avance III spectrometer (Germany, 2012) operating at 800 MHz and 25 °C.

One-dimensional ^{1}H NMR spectra, as well as two-dimensional ^{1}H–^{1}H COSY and ^{1}H–^{1}H NOESY spectra, were acquired for PpIX DME 1 and PpIX DME 12. For the intermediate concentrations, only one-dimensional ^{1}H NMR spectra were recorded.

IV. Results and Discussion

The ^{1}H NMR spectra acquired at different concentrations exhibited systematic variations in both chemical shifts and proton assignments, demonstrating that the magnetic environment is strongly modulated by aggregation phenomena. The molecular structure and proton numbering scheme of PpIX DME are shown in Figure 1 to facilitate the interpretation of the spectroscopic data discussed throughout this section.

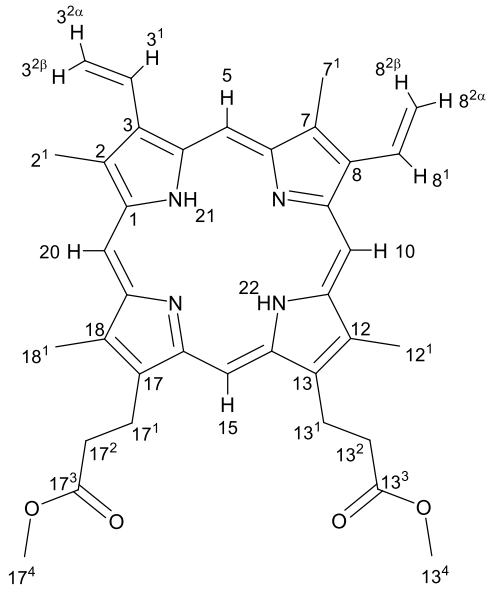

Figure 1. Molecular structure and proton numbering scheme of PpIX DME used for NMR assignments throughout this study.

Complete proton assignments are presented in Table 1 and were established through the combined interpretation of one-dimensional ^{1}H NMR and two-dimensional ^{1}H–^{1}H COSY and ^{1}H–^{1}H NOESY experiments. Chemical shift variations (Δδ) were quantified by calculating the differences between the proton resonances observed at the lowest and highest concentrations investigated.

Table 1. Proton assignments and concentration-dependent chemical shift variations of PpIX DME.

Group	Position	PpIX DME 1	PpIX DME 12	Δδ
Meso	H-5	10.23	9.90	0.33
	H-10	10.18	9.93	0.25
	H-15	10.04	9.81	0.23
	H-20	10.09	9.78	0.31
Vinyl	H-3^1	8.29	8.10	0.19
	H-8^1	8.29	8.15	0.14
	H-3$^{2\beta}$ H-8$^{2\beta}$	6.38	6.28	0.10
	H-3$^{2\alpha}$ H-8$^{2\alpha}$	6.19	6.12	0.07
Methylene	H-13^1 H-17^1	4.41	4.29	0.12
	H-13^2 H-17^2	3.28	3.21	0.07
Methyl	H-2^1	3.72	3.55	0.17
	H-7^1	3.71	3.54	0.17
	H-12^1	3.62	3.51	0.11
	H-18^1	3.64	3.49	0.15
Methoxy	H-13^4 H-17^4	3.66 3.66	3.65 3.65	0.01
Inner	H-21 H-22	-3.68	-4.19	0.51

The present results demonstrate that several proton resonances are significantly affected by aggregation and undergo signal permutation as concentration increases. Although previous studies have reported that most proton assignments of PpIX DME could be readily achieved using only one-dimensional ^{1}H NMR without the need for chemical shift reagents or specialized solvents [15], the current findings reveal important limitations in this approach when applied to a complex tetrapyrrolic macrocycle undergoing concentration-dependent aggregation.

The largest upfield chemical shift variations were observed for the inner pyrrolic protons H-21 and H-22, and the meso protons H-5 and H-20. This behavior indicates that nuclei located near the center of the macrocycle are particularly sensitive to changes in the magnetic environment induced by aggregation. These observations reflect the diamagnetic anisotropy generated by the aromatic ring current of the tetrapyrrolic system, whose influence becomes more pronounced as intermolecular interactions intensify.

Interestingly, the meso protons exhibited signal permutation throughout the concentration series, as illustrated in Figure 2. This behavior suggests that the aggregation process does not strictly follow classical J-, T-, or H-type supramolecular organizations. Instead, the spectroscopic evidence supports the formation of a hybrid arrangement in which different regions of the porphyrin macrocycle experience distinct magnetic environments.

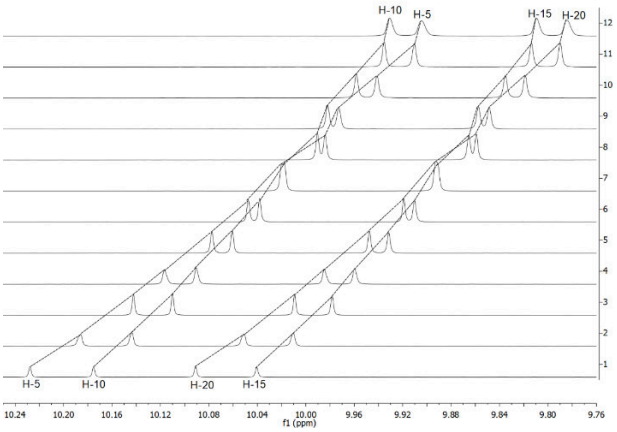

Figure 2. Concentration-dependent changes in the chemical shifts of meso protons.

The methyl groups also exhibited concentration-dependent signal permutation (Figure 3). Furthermore, the data indicates that aggregation-induced perturbations gradually decrease as the structural distance from the macrocyclic core increases. This trend is particularly evident when comparing the methyl and methoxy substituents.

Among the methyl groups, H-2^1 and H-7^1 exhibited the largest chemical shift variations. Their enhanced sensitivity may be attributed to their proximity to the vinyl substituents, which contribute to electronic delocalization within the macrocycle and amplify the influence of intermolecular interactions.

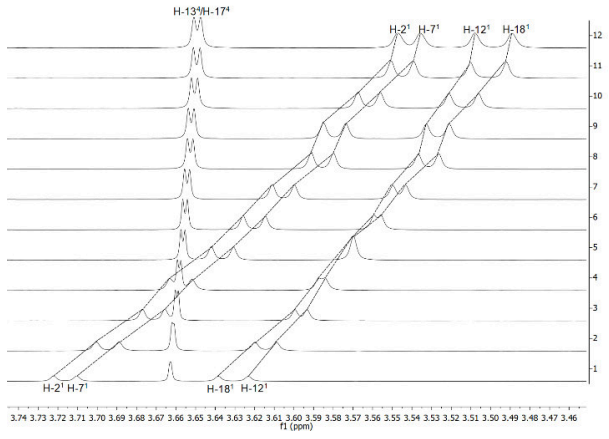

Figure 3. Concentration-dependent changes in the chemical shifts of methyl and methoxy groups.

In contrast, the methoxy protons H-13^4 and H-17^4 displayed minimal chemical shift variations, indicating a relatively low sensitivity to aggregation-induced perturbations. Nevertheless, these groups provide additional

insight into the supramolecular organization of the system. The progressive increase in signal separation observed with increasing concentration suggests the existence of steric repulsion at specific intermolecular contact regions.

This interpretation is consistent with previously reported crystallographic observations for PpIX DME [17] and further supports the presence of a hybrid supramolecular arrangement involving tilted macrocycles in the aggregated state.

V. Conclusion

The comprehensive nuclear magnetic resonance spectroscopic analysis presented in this study enabled the unequivocal assignment of proton resonances in protoporphyrin IX dimethyl ester, overcoming ambiguities previously reported in the literature. The observed variations in proton chemical shifts were strongly influenced by aggregation-induced diamagnetic anisotropy associated with the aromatic tetrapyrrolic system, highlighting the sensitivity of these nuclei to changes in the local magnetic environment. The spectroscopic evidence obtained throughout the concentration series indicates that the aggregated state of protoporphyrin IX dimethyl ester cannot be adequately described by idealized H-, J-, or T-type supramolecular organizations. Instead, the data supports the formation of hybrid supramolecular arrangements involving relative tilting between neighboring macrocycles, revealing the structural complexity of intermolecular interactions in solutions. These findings reinforce the capability of high-field nuclear magnetic resonance spectroscopy to elucidate subtle structural changes associated with porphyrin aggregation and establish a robust spectroscopic framework for investigating aggregation-prone aromatic systems. To complement these findings, computational simulations are envisioned as future work to investigate the structural organization of the porphyrinic dimer and further validate the proposed geometric distortion. From a biomedical engineering perspective, this study provides relevant contributions to the structural characterization of photosensitizers intended for photodynamic therapy. The methodological approach described herein may serve as a reference for the investigation of other porphyrin-based systems, while the mechanistic insights obtained may support the rational design of next-generation photosensitizers with improved physicochemical stability and enhanced therapeutic performance. Ultimately, a deeper understanding of aggregation phenomena may contribute to the development of more efficient molecular platforms for clinical diagnostic and therapy systems, thereby supporting the advancement of photodynamic therapy toward more predictable and clinically translatable applications.

Conflict of Interest

The authors declare that they have no known financial interests or personal relationships that could have appeared to influence the work reported in this study.

Resumo—Este artigo descreve a arquitetura de hardware e a instrumentação de um monitor multiparamétrico destinado a apoiar as medidas de prevenção da pneumonia associada à ventilação mecânica (PAV) em unidades de terapia intensiva (UTI) que atendem pacientes neonatais, pediátricos e adultos. O equipamento integra, em uma única plataforma embarcada, três subsistemas em malha fechada: controle da pressão do balonete do tubo endotraqueal, aspiração subglótica contínua e temporização da mudança de decúbito, além de uma interface que parametriza as faixas de ajuste conforme o perfil do paciente. O projeto adota como requisitos de entrada a norma geral ABNT NBR IEC 60601-1 e suas normas colaterais aplicáveis, e estabelece como requisito de desempenho um desvio inferior a 5% entre o valor medido e o valor alvo em cada módulo. São apresentados o protocolo de verificação em bancada — grandezas avaliadas, condições por perfil de paciente, tamanho amostral e número de ciclos — e as planilhas de registro correspondentes. São apresentados os registros da campanha de verificação interna conduzida segundo esse protocolo. Os ensaios normativos em laboratório acreditado e a avaliação clínica encontram-se em execução; consequentemente, este trabalho não apresenta resultados de conformidade normativa nem desfechos assistenciais. Este desenvolvimento foi apoiado pela Fundação de Amparo à Pesquisa e Inovação do Estado de Santa Catarina (FAPESC) por meio do edital Impulsiona SC 2024.

Termos Índice—arquitetura de hardware, dispositivos médicos, instrumentação biomédica, pneumonia associada à ventilação mecânica, unidade de terapia intensiva, verificação em bancada.

I. Introdução

O suporte ventilatório invasivo consolidou-se, ao longo das últimas cinco décadas, como recurso central no tratamento da insuficiência respiratória. A aplicação de pressão positiva às vias aéreas por meio de uma prótese traqueal associa-se, contudo, a efeitos adversos reconhecidos: instabilidade hemodinâmica, sobretudo em pacientes hipovolêmicos; redução dos mecanismos locais de defesa, com aumento da frequência de infecções respiratórias; e lesão induzida pela ventilação mecânica, relacionada às pressões alveolares atingidas em pulmões heterogêneos [1].

Entre esses efeitos, a pneumonia associada à ventilação mecânica (PAV) destaca-se pela frequência e pela gravidade no ambiente de terapia intensiva [1], [2]. Trata-se de infecção relacionada à assistência à saúde cujo diagnóstico permanece heterogêneo entre serviços e protocolos, o que dificulta a comparação direta entre estudos epidemiológicos e a consolidação de séries nacionais [2], [4].

A letalidade associada à PAV varia amplamente entre as coortes publicadas, com relatos que se distribuem aproximadamente entre 20% e 60%, a depender da população estudada, do critério diagnóstico adotado e da gravidade basal dos pacientes [3], [4]. A evolução para insuficiência respiratória grave e sepse é a via clínica mais temida.

Do ponto de vista econômico, a PAV prolonga o tempo de ventilação mecânica e de internação e concentra parcela expressiva do consumo de antimicrobianos nas unidades de terapia intensiva, estimada em cerca de metade de todo o uso de antibióticos nessas unidades, o que contribui para a pressão seletiva e para a resistência bacteriana no ambiente hospitalar [2], [4].

As medidas preventivas consolidadas em protocolos assistenciais combinam: (i) elevação da cabeceira do leito entre 30° e 45°, para reduzir o risco de aspiração de conteúdo gástrico; (ii) aspiração das secreções acumuladas no espaço subglótico; (iii) manutenção da pressão do balonete do tubo endotraqueal dentro da faixa recomendada [5], [6]; e (iv) mudança programada de decúbito, com finalidade de mobilização e alívio de áreas pulmonares dependentes [9], [10]. Nas populações neonatal e pediátrica, a indicação de cânulas com balonete e a respectiva faixa de ajuste de pressão apresentam particularidades documentadas na literatura e desigualdade de adoção entre os serviços brasileiros [7], [8].

Este artigo tem por objetivo descrever a arquitetura de hardware e a instrumentação do monitor desenvolvido e formalizar o protocolo de verificação em bancada de cada módulo, incluindo as planilhas de registro das medições. Não são objeto deste trabalho a

demonstração de conformidade normativa, que depende de ensaios executados por laboratório acreditado, nem a avaliação de desfechos clínicos, que depende de estudo controlado específico.

II. Arquitetura do Equipamento

O equipamento é organizado em uma plataforma embarcada única, que hospeda três subsistemas funcionais e uma interface homem-máquina (IHM) de tela sensível ao toque. Cada subsistema executa uma malha de controle independente sobre a grandeza que lhe compete, com aquisição contínua, comparação com o valor alvo ajustado pelo operador e atuação corretiva. A Tabela I consolida a especificação de instrumentação e de atuação de cada módulo; os campos de faixa de medição, resolução e incerteza são resultados de medição a partir dos componentes empregados no projeto.

A. Módulo de controle da pressão do balonete

O módulo mantém a pressão interna do balonete do tubo endotraqueal no valor alvo definido pelo profissional assistencial, dentro da faixa habilitada para o perfil de paciente selecionado. A pressão é adquirida continuamente por transdutor acoplado à linha de insuflação; o erro em relação ao valor alvo é processado pelo controlador embarcado, que comanda a unidade de insuflação e a válvula de alívio. O requisito de projeto estabelece desvio inferior a 5% entre a pressão medida e a pressão alvo em regime permanente. Os limites de alarme são configuráveis pelo operador (Fig. 1) e tratados conforme os requisitos de sistemas de alarme indicados na Seção III.

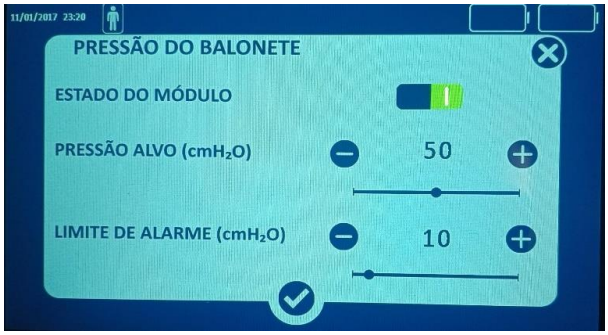

Fig. 1 meramente ilustrativa. Tela de ajuste do controle de pressão do balonete.

B. Módulo de aspiração subglótica

O módulo aplica pressão negativa regulada à porta de aspiração subglótica do tubo endotraqueal, mantendo aspiração contínua no valor alvo definido para o perfil de paciente selecionado. A estrutura de controle é análoga à do módulo anterior: medição contínua, comparação com o valor alvo e atuação sobre a fonte de vácuo, com requisito de projeto de desvio inferior a 5% em regime permanente e limites de alarme configuráveis (Fig. 2).

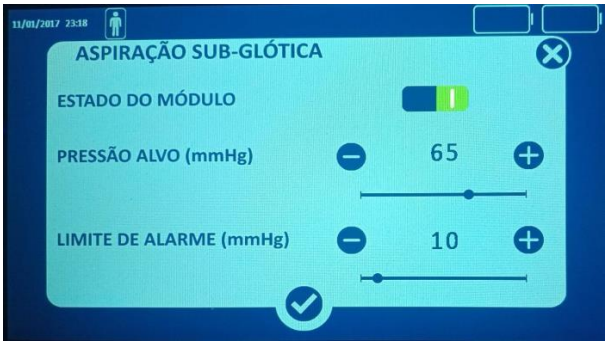

Fig. 2 meramente ilustrativa. Tela de ajuste da aspiração subglótica.

A pesquisa de anterioridade conduzida pelos autores não identificou equipamento eletrônico de uso corrente que execute o controle contínuo dessa variável de forma integrada; as soluções localizadas operam por meios mecânicos ou por aspiração intermitente manual. Essa observação refere-se ao escopo da busca realizada e não constitui levantamento exaustivo de mercado.

C. Módulo de decúbito do paciente

O módulo controla a rotação do paciente sobre o próprio eixo longitudinal, por meio de estrutura aplicada ao leito, com intervalo de alteração ajustável pelo operador (Fig. 3). A função é habilitada para os perfis pediátrico e adulto. O requisito de projeto estabelece desvio inferior a 5% tanto para o ângulo de posicionamento quanto para a temporização do ciclo programado.

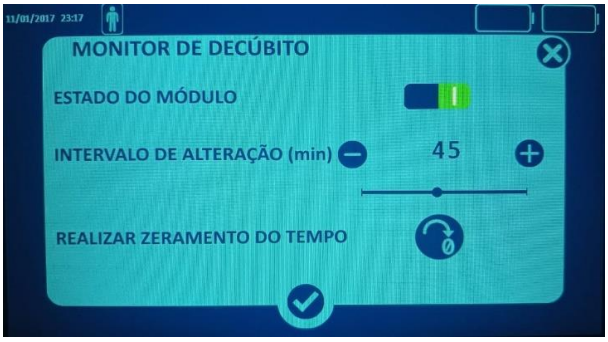

Fig. 3 meramente ilustrativa. Tela de ajuste do módulo de decúbito.

D. Interface integradora multiparamétrica

A operação inicia-se pela seleção do perfil de paciente — neonatal, pediátrico ou adulto (Fig. 4) —, que define as faixas de ajuste e os limites de alarme habilitados em cada módulo. Essa parametrização por faixa etária está alinhada às diferenças de indicação e de ajuste descritas para cânulas com balonete nas populações neonatal e pediátrica [7], [8], e pode ser revista pelo profissional assistencial durante a evolução do paciente.

Fig. 4 meramente ilustrativa. Tela de seleção do perfil do paciente.

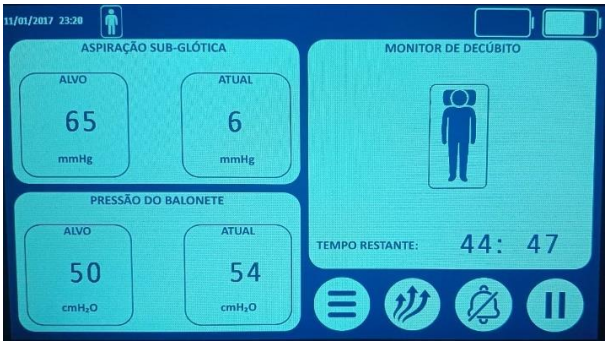

Fig. 5 meramente ilustrativa. Tela funcional de uso, com os três módulos integrados.

A tela funcional de uso (Fig. 5) apresenta simultaneamente os valores alvo e medidos dos módulos de aspiração subglótica e de pressão do balonete, o estado do módulo de decúbito e o tempo restante para a próxima mudança de posição. A Fig. 6 mostra a vista frontal do protótipo montado.

Fig. 6 meramente ilustrativa. Vista frontal do protótipo.

TABELA I
ESPECIFICAÇÃO DE INSTRUMENTAÇÃO E ATUAÇÃO POR MÓDULO

Módulo	Grandeza controlada	Faixa de medição	Erro (%)	Incerteza declarada	K
Pressão do balonete	Pressão positiva	0 – 100cmH_2O	0,001	0,02cmH_2O	2,00
Aspiração subglótica	Pressão negativa	0 – 110mmHg	0,004	0,02mmHg	2,00
Decúbito	Ângulo / tempo	360°	0,001	0,02°	2,00

k é o fator de abrangência da incerteza expandida.

III. Normatizações Aplicáveis

O projeto adota como requisitos de entrada as normas técnicas publicadas pela Associação Brasileira de Normas Técnicas (ABNT) na série Norma Brasileira (NBR), correspondentes às normas da International Electrotechnical Commission (IEC — Comissão Eletrotécnica Internacional). Padroniza-se, neste artigo, a designação ABNT NBR IEC 60601-1 para a norma geral e ABNT NBR IEC 60601-1-X para as normas colaterais, nas edições vigentes na data de submissão. A Tabela II relaciona cada norma, o respectivo objetivo regulatório e o ponto do projeto em que o requisito incide.

Registra-se que as normas foram empregadas como requisitos de projeto e como referência para os ensaios internos de verificação descritos na Seção IV. A demonstração de conformidade depende de ensaios executados por laboratório acreditado, com emissão dos respectivos relatórios, os quais não haviam sido concluídos até a submissão deste trabalho.

TABELA II
NORMAS ADOTADAS, OBJETIVO REGULATÓRIO E INCIDÊNCIA NO PROJETO

Norma	Escopo	Objetivo regulatório	Incidência no projeto
ABNT NBR IEC 60601-1	Equipamento eletromédico — requisitos gerais para segurança básica e desempenho essencial	Estabelecer os requisitos gerais de segurança elétrica, mecânica e térmica e exigir a definição formal do desempenho essencial do equipamento	Isolação, correntes de fuga e proteção contra choque; definição do desempenho essencial de cada um dos três módulos
ABNT NBR IEC 60601-1-2	Norma colateral: compatibilidade eletromagnética	Estabelecer níveis de emissão e de imunidade a perturbações eletromagnéticas no ambiente de uso previsto	Qualificação do conjunto eletrônico embarcado e da fiação de sensores e atuadores
ABNT NBR IEC 60601-1-6	Norma colateral: usabilidade (engenharia de fatores humanos)	Exigir a aplicação de um processo de engenharia de usabilidade que reduza o risco de erro de uso	Projeto da IHM, fluxo de seleção do perfil de paciente e de ajuste dos valores alvo
ABNT NBR IEC 60601-1-8	Norma colateral: sistemas de alarme	Padronizar categorias de prioridade, sinalização audível e visual e comportamento das condições de alarme	Alarmes de desvio de pressão do balonete e de pressão de aspiração subglótica
ABNT NBR IEC 60601-1-9	Norma colateral: projeto ecologicamente consciente	Exigir a consideração do impacto ambiental ao longo do ciclo de vida do equipamento	Seleção de materiais, embalagem e orientações de descarte
ABNT NBR IEC 60601-1-10	Norma colateral: controladores fisiológicos em malha fechada	Estabelecer requisitos para o desenvolvimento e a validação de controladores que atuam sobre variável fisiológica em malha fechada	Malhas de controle dos módulos de pressão do balonete e de aspiração subglótica

IV. Protocolo de Verificação em Bancada

Esta seção define o protocolo de ensaios internos de verificação, cuja execução gera os registros apresentados na Seção V. O protocolo é aplicado a cada módulo isoladamente e, em uma segunda etapa, ao equipamento integrado, em cada um dos perfis de paciente habilitados.

A. Grandezas avaliadas

- Erro em regime permanente: diferença percentual entre o valor medido pelo padrão de referência e o valor alvo ajustado, após estabilização.
- Estabilidade (deriva): variação do valor medido em ensaio contínuo de 24 h, mantidas constantes as condições de ensaio.
- Tempo de resposta: intervalo t90 entre a aplicação de um degrau no valor alvo e o alcance de 90% do novo valor.
- • Repetibilidade: desvio-padrão das medições obtidas sob condições de ensaio idênticas e repetidas.
- Desempenho do sistema de alarme: latência entre a instalação da condição de alarme e a respectiva sinalização, e contagem de falsos positivos e falsos negativos.
- Exatidão do controle de decúbito: erro angular em relação ao ângulo alvo e erro de temporização do intervalo programado.

B. Condições de ensaio

Cada grandeza é avaliada nos perfis neonatal, pediátrico e adulto, sobre simulador de via aérea e pulmão de teste com balonete de características declaradas. Para o módulo de decúbito, utiliza-se carga instrumentada representativa da massa de cada perfil. A Tabela III consolida a matriz de ensaios, incluindo os campos de tamanho amostral e de número de ciclos, que devem ser declarados para cada condição antes do início da campanha.

C. Rastreabilidade metrológica

As medições de referência são obtidas com padrões calibrados e rastreáveis, cujos dados de identificação, faixa, incerteza e validade de certificado são registrados na Tabela IV. A incerteza do padrão deve ser, no mínimo, quatro vezes menor que a tolerância verificada, de modo que o requisito de 5% possa ser avaliado com margem adequada.

D. Tratamento dos dados

Para cada condição de ensaio são calculados a média, o desvio-padrão, o valor máximo absoluto do erro e o intervalo de confiança de 95%. A conformidade ao requisito de projeto é declarada quando o limite superior do intervalo de confiança do erro permanece inferior a 5% do valor alvo. Os resultados são reportados sempre acompanhados do tamanho amostral e do número de ciclos executados.

TABELA III
MATRIZ DE ENSAIOS POR MÓDULO E PERFIL DE PACIENTE

Módulo	Perfil	Valor alvo ajustado	n	Ciclos	Duração do ensaio
Pressão do balonete	Neonatal	15cmH_2O	20	5	24 horas
Pressão do balonete	Pediátrico	25cmH_2O	20	5	24 horas
Pressão do balonete	Adulto	40cmH_2O	20	5	24 horas
Aspiração subglótica	Neonatal	2mmHg	20	5	24 horas
Aspiração subglótica	Pediátrico	10mmHg	20	5	24 horas
Aspiração subglótica	Adulto	50mmHg	20	5	24 horas
Decúbito	Pediátrico	90°	20	24	24 horas
Decúbito	Adulto	90°	20	24	24 horas

O módulo de decúbito não é habilitado para o perfil neonatal.

V. Consolidação da Arquitetura e Registro dos Ensaios

A. Fundamentação bibliográfica das funções implementadas

Os parágrafos desta subseção sintetizam evidências da literatura que fundamentaram a escolha das três funções implementadas. Trata-se de fundamentação bibliográfica: os achados descritos referem-se aos estudos citados e não constituem resultados obtidos com o equipamento apresentado neste artigo.

A manutenção da pressão do balonete dentro da faixa recomendada é associada, na literatura, à redução do extravasamento de secreções contaminadas para as vias aéreas inferiores, que ocorre quando a pressão é insuficiente, e à prevenção da lesão isquêmica da mucosa traqueal, associada a pressões excessivas [5], [6]. O monitoramento periódico ou contínuo por manômetro ou sistema automatizado é descrito como fator de redução da microaspiração [1], [3], e a variabilidade de adoção de protocolos e de instrumentos de medida entre serviços brasileiros foi documentada tanto em unidades de adultos [5], [6] quanto em unidades neonatais e pediátricas [7], [8].

A aspiração subglótica é descrita como medida complementar, por remover as secreções acumuladas acima do balonete antes de sua migração para o trato respiratório inferior; revisões sistemáticas associam o uso de tubos com lúmen para aspiração subglótica à redução das taxas de PAV e do tempo de ventilação mecânica [4]. O efeito é descrito como mais consistente quando a aspiração é programada e não apenas reativa [2], [4].

A mudança programada de decúbito é apresentada na literatura de enfermagem e de terapia intensiva como cuidado voltado à mobilização do paciente crítico e ao alívio de áreas pulmonares dependentes [9], com repercussões hemodinâmicas que devem ser consideradas na definição do intervalo de mudança [10]. Associada à elevação da cabeceira entre 30° e 45°, contribui para reduzir o refluxo gastroesofágico e a probabilidade de aspiração de conteúdo gástrico [1], [9].

As três medidas atuam em elos distintos da cadeia fisiopatológica da PAV, o que sustenta a organização de protocolos que as integram, os chamados pacotes (bundles) de prevenção [2], [4]. A integração dessas funções em uma única plataforma instrumentada é a

motivação de projeto do equipamento descrito na Seção II.

B. Planilhas de registro dos ensaios

As Tabelas V a VII constituem as planilhas de registro dos ensaios definidos na Seção IV, preenchidas com os resultados da campanha de verificação interna. Cada série é reportada com o tamanho amostral, o número de ciclos e o padrão de referência empregado, conforme declarado nas Tabelas III e IV. O critério de conformidade da Seção IV.D é atendido em todas as séries: o limite superior do intervalo de confiança de 95% do erro permanece inferior a 1,1% do valor alvo nos módulos de pressão e a 0,2% no módulo de decúbito, contra o requisito de projeto de 5%. As grandezas reportadas seguem as definições da Seção IV.A e o critério de conformidade da Seção IV.D.

TABELA V
REGISTRO DOS ENSAIOS DOS MÓDULOS DE PRESSÃO

REGISTRO DOS ENSAIOS DO MÓDULO DE DECÚBITO

Perfil	Ângulo alvo	Intervalo alvo	n	Ciclos	Erro angular médio (%)	DP (%)	Erro máx. (%)	Erro de temporização (%)
Pediátrico	90°	1 hora	20	24	0,1	0,05	0,25	0,002
Adulto	90°	1 hora	20	24	0,1	0,05	0,25	0,002

TABELA VII
REGISTRO DO DESEMPENHO DO SISTEMA DE ALARME

Condição de alarme	Limite ajustado	n eventos	Detecções	Latência média (s)	Latência máx. (s)	Falsos positivos	Falsos negativos
Pressão do balonete acima do limite	alvo + 10 cmH_2O	20	20	5,00	10,00	0	0
Pressão do balonete abaixo do limite	alvo − 10 cmH_2O	20	20	3,50	7,00	0	0
Pressão de aspiração fora da faixa	alvo ± 5 mmHg	20	20	5,00	8,00	3	0
Falha de temporização do decúbito	intervalo alvo ± 5 min	20	20	2,00	5,00	0	0
Desconexão / oclusão de linha	n.a.	20	20	5,00	8,00	0	0

Classificação de prioridade e sinalização conforme os requisitos da ABNT NBR IEC 60601-1-8 (Tabela II). O limite é expresso como desvio em relação ao valor alvo ajustado em cada perfil de paciente. Detecções: eventos induzidos que foram anunciados pelo equipamento; falsos negativos = n eventos − detecções. Falsos positivos: anunciações ocorridas em janela de observação sem condição de alarme presente, cuja duração deve ser declarada.

VI. Limitações e Direções Futuras

A. Ausência de análise de sensibilidade a perturbações

O protocolo apresentado avalia o comportamento dos módulos sob condições nominais e degraus aplicados ao valor de referência, mas não contempla, nesta etapa, análise de sensibilidade a perturbações representativas do uso clínico. Entre as perturbações não avaliadas encontram-se: vazamento progressivo no balonete e nas conexões; variações de complacência e de resistência do sistema respiratório; alterações da pressão positiva expiratória final; oclusão parcial da linha de aspiração por secreção; e variações de temperatura e umidade no ambiente de operação. A ausência dessa análise limita a extrapolação do desempenho verificado em bancada para o ambiente assistencial e constitui a próxima etapa prevista do trabalho.

B. Ensaios normativos pendentes

Os registros das Tabelas V a VII resultam de verificação interna conduzida pela equipe de desenvolvimento e não substituem ensaio normativo. Os ensaios previstos pelas normas relacionadas na Tabela II não haviam sido concluídos até a submissão deste manuscrito. A conformidade só poderá ser afirmada mediante relatórios de ensaio emitidos por laboratório acreditado, e as afirmações deste artigo limitam-se, portanto, à adoção das normas como requisitos de entrada do projeto.

C. Avaliação clínica e tratamento estatístico inferencial

Não foi conduzido, até o momento, estudo clínico comparando a incidência de PAV entre grupos assistidos com e sem o dispositivo. Prevê-se, como direção futura, estudo controlado com cálculo prévio de tamanho amostral e de poder estatístico, comparação da incidência por testes de hipótese apropriados, análise do tempo até o evento e apresentação de intervalos de confiança de 95%. A concordância entre a pressão indicada pelo equipamento e a medida pelo padrão de referência deverá ser avaliada por análise de Bland-Altman, com relato dos limites de concordância.

VII. Conclusão

Apresentou-se a arquitetura de hardware e a instrumentação de um monitor que integra, em plataforma embarcada única, o controle da pressão do balonete do tubo endotraqueal, a aspiração subglótica contínua e a temporização da mudança de decúbito, com parametrização das faixas de ajuste por perfil de paciente. As normas da família ABNT NBR IEC 60601-1 foram adotadas como requisitos de entrada do projeto e orientaram a definição do desempenho essencial de cada módulo, conforme consolidado na Tabela II.

O requisito de desvio inferior a 5% entre o valor medido e o valor alvo foi atendido na verificação interna documentada nas Tabelas V a VII, com margem de pelo menos uma ordem de grandeza em relação ao limite especificado. Trata-se, contudo, de verificação conduzida pela própria equipe de desenvolvimento, cuja confirmação depende dos ensaios normativos descritos na Seção VI. Não são reivindicados, portanto, conformidade normativa comprovada por relatório de ensaio nem benefício assistencial atribuível ao equipamento, cuja demonstração depende do estudo clínico descrito na Seção VI.

Reconhecimento

A CSE Equipamentos e Serviços registra publicamente o agradecimento pelo incentivo financeiro concedido pela Fundação de Amparo à Pesquisa e Inovação do Estado de Santa Catarina (FAPESC) ao desenvolvimento deste equipamento, por meio do edital Impulsiona SC 2024.

***Abstract*—Cow's milk protein allergy (CMPA) presents with varied clinical manifestations, which can make it difficult to record the evolution of symptoms and monitor infants suspected of having this condition. This work presents NeoTrack CMPA, a mobile system developed to support the longitudinal recording of symptoms in infants up to six months of age. The application uses a structured questionnaire with conditional questions to record gastrointestinal, cutaneous, respiratory, and behavioral manifestations, as well as information related to feeding. At the end of each assessment, the system organizes the data and generates a report in PDF format, which can be shared with healthcare professionals. The application was developed in React Native with TypeScript and preliminarily evaluated through the monitoring of an infant with a confirmed CMPA diagnosis by a healthcare professional. The records obtained before and after 30 days of a cow's milk protein exclusion diet were compared. The results demonstrated the disappearance of cutaneous manifestations and the reduction of gastrointestinal, respiratory, and behavioral symptoms initially recorded. The application allowed for the structured documentation of these changes and the production of comparative reports for monitoring clinical evolution. Although the evaluation was limited to a single case and does not allow for establishing the clinical validity of the system, the results indicate the functional viability of NeoTrack APLV as a complementary tool for recording and communication between caregivers and healthcare professionals.**

Keywords— allergy to cow's milk protein; mobile health applications; infants; symptom monitoring.

I. INTRODUCTION

Cow's milk protein allergy (CMPA) is an adverse immunological reaction to proteins present in cow's milk and is one of the most frequent food allergies in the first years of life. Its clinical manifestations can involve different systems, including gastrointestinal, cutaneous, and respiratory symptoms, as well as behavioral changes such as irritability and persistent crying [1], [2]. This diversity of signs, associated with the possibility of immediate or delayed reactions, can make it difficult to recognize the evolution of the condition, especially when information depends exclusively on the memory and observation of caregivers.

The investigation of cow's milk protein allergy (CMPA) requires a clinical evaluation conducted by a healthcare professional, considering the patient's history, the symptoms presented, and their temporal relationship with exposure to cow's milk protein. Depending on the mechanism involved and the infant's clinical condition, the process may include an elimination diet followed by reassessment and, when indicated and performed under professional supervision, an oral food challenge test [1], [2]. In this context, the systematic recording of observed manifestations over time can contribute to documenting changes in the clinical picture and provide more organized information during follow-up.

However, daily monitoring is usually carried out by caregivers outside the clinical setting, which can result in incomplete, scattered, or poorly standardized records. The absence of a structured history makes it difficult to compare different moments, such as the periods before and after a dietary intervention. Furthermore, symptoms belonging to different categories can vary independently, making a tool capable of gathering them into a single longitudinal record relevant, without replacing the assessment or decision of the healthcare professional.

Mobile health technologies have the potential to support the continuous recording of information, facilitate the visualization of symptom evolution, and promote communication between users and professionals. Studies on applications designed for food allergies and intolerances have identified functionalities such as food diaries, reaction records, and the sharing of clinical information [3], [4]. Despite this potential, evaluations of these tools also point to limitations related to the quality of information, the participation of healthcare professionals in development, and the suitability of functionalities to the specific needs of users [3], [4]. In the case of cow's milk protein allergy (CMPA) in infants, there is a need for solutions aimed at the child's caregiver, capable of structuring symptoms from different systems and generating a history that can be presented during professional follow-up.

Given this scenario, this work presents NeoTrack APLV, a mobile system designed for the longitudinal monitoring of symptoms in infants up to six months old suspected of having cow's milk protein allergy. The application organizes information on feeding and gastrointestinal, cutaneous, respiratory, and behavioral manifestations through a structured questionnaire with conditional questions. At the end of the completion, the data are consolidated into a report that can be stored and shared with healthcare professionals. The main contributions of this work include: i) the digital structuring of the record of symptoms related to APLV; ii) the generation of reports for comparison between different

moments of follow-up; iii) the implementation of a mobile application aimed at caregivers of infants; and iv) a preliminary evaluation of its applicability in the longitudinal follow-up of a real case.

II. Related Works

The use of mobile technologies in monitoring food allergies has been investigated as a strategy to facilitate symptom recording, dietary control, and access to information about potential allergens. These applications can assist patients and caregivers in organizing data produced outside the clinical setting, allowing them to document episodes, identify temporal relationships, and share information during professional follow-up.

Mandracchia et al. [3] analyzed mobile applications designed for people with food allergies and intolerances and identified functionalities related to ingredient lookup, identification of potentially unsuitable foods, meal logging, and reporting of adverse reactions. The authors observed, however, that many solutions focus on dietary restriction or product lookup, offering limited resources for structured monitoring of symptom progression.

In an assessment of the quality of applications aimed at food allergies, Wu et al. [4] found significant differences regarding the reliability of information, usability and the involvement of health professionals in the development of the tools. These aspects are particularly relevant in applications related to child health, in which inaccurate information or inadequate interpretations can influence the decisions of those responsible. Therefore, such systems should be presented as complementary recording and communication instruments, and not as autonomous diagnostic or therapeutic guidance tools.

Other digital solutions employ electronic diaries to associate food consumption with the occurrence of clinical manifestations. This type of record can reduce the user's reliance on memory and make the temporal relationship between exposure, dietary intervention, and symptom progression clearer [5]. However, general-purpose tools do not always account for the particularities of cow's milk protein allergy (CMPA) in infants, such as the type of feeding, the diversity of clinical manifestations, and the need for complete filling out by the caregiver.

NeoTrack APLV differs from these approaches because it was developed specifically for monitoring infants up to six months old with suspected CMPA (Cow's Milk Protein Allergy). The system gathers, in a single flow, information on feeding and gastrointestinal, cutaneous, respiratory, and behavioral manifestations. Furthermore, it uses conditional questions to adapt the questionnaire to the answers provided and generates standardized reports that allow for comparison at different points in the follow-up.

Thus, the main contribution of NeoTrack APLV is not in performing automated diagnoses, but in the longitudinal structuring of information observed by caregivers. This proposal seeks to meet a specific need in the monitoring process: transforming everyday observations, often scattered, into organized records that can complement the assessment conducted by the healthcare professional.

III. Materials and Methods

The development of NeoTrack APLV was organized into three main stages: defining the requirements and structuring the questionnaire, implementing the mobile application, and conducting a preliminary assessment of its applicability. The system was designed to record information from infants up to six months old, with completion performed by a caregiver. Its purpose is to document the evolution of symptoms and facilitate the sharing of information with healthcare professionals, without making a diagnosis or recommending therapeutic interventions.

A. Defining the requirements and structuring the questionnaire

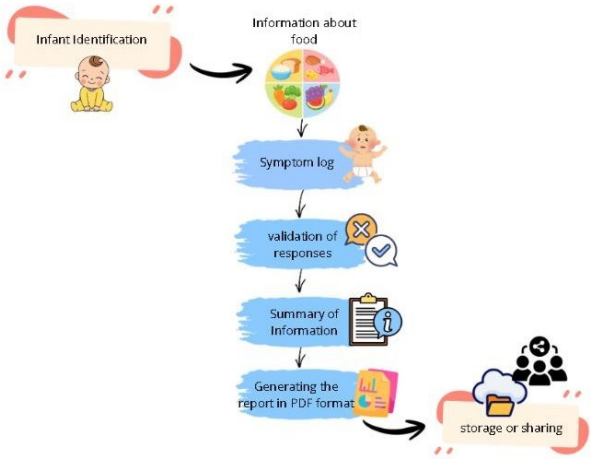
The development of NeoTrack APLV was motivated by the author's experience while monitoring her two children with manifestations related to cow's milk protein allergy (CMPA). In the first case, the diversity of symptoms and the difficulty in organizing them over time contributed to making the investigation process more time-consuming. Subsequently, the experience gained allowed the author to recognize and record with greater attention similar manifestations observed in her second child. From this experience, the need for a tool to assist other caregivers in the systematic recording of symptoms and in communicating this information to healthcare professionals was identified.

Based on this need and the clinical manifestations described in the guidelines used as a basis [1], [2], the system requirements were defined and the questionnaire was structured. The application was designed to collect identification data, age, type of food and symptoms observed by the person responsible. The manifestations were organized into gastrointestinal, skin, respiratory and behavioral categories, allowing information to be gathered that, in everyday life, could remain dispersed or depend solely on the memory of those responsible.

The author's personal experience contributed to the identification of the problem and the initial definition of the functionalities. However, the content of the questionnaire was structured based on the literature and guidelines consulted and is not presented as a validated clinical instrument.

B. Mobile application development

NeoTrack APLV was developed with the React Native framework and the TypeScript language, using the Expo environment to implement and run the application. The organization of the screens and navigation was carried out with Expo Router, while the interface components were implemented with React Native Paper. Additional resources were used to select and process dates, validate data, adapt the interface to the virtual keyboard and generate documents.



The user workflow comprises: i) access to the home screen; ii) infant identification; iii) filling in information about feeding and symptoms; iv) validation of responses; v) presentation of a summary; and vi) generation and sharing of the repor.

The data from each completed form is organized into a PDF document, identified by the date and time it was created. The report compiles the information provided by the party responsible and can be stored or shared using the resources

available on the mobile device. This functionality was developed to allow the storage of records made at different times and the sharing of information with healthcare professionals.

Fig. 1 should show the general workflow of NeoTrack APLV, from completing the questionnaire to generating and sharing the report.

Fig. 1. General workflow for using NeoTrack APLV, including identification, symptom recording, response validation, summary presentation, and report generation.

C. *System functional verification*

Following implementation, the functional verification of NeoTrack APLV was conducted exclusively by the author herself. During this stage, the functionalities foreseen in the system were explored, including infant identification, filling in information about feeding and symptoms, presenting conditional questions, validating mandatory fields, reviewing responses, and generating and sharing the report.

The author also completed data entry corresponding to different stages of the monitoring process, allowing verification of whether the system adequately organized the information and enabled comparison between the recorded symptoms. The functioning of the conditional rules, the consistency of the dates, the restriction of the age range covered, and the structure of the information presented in the generated document were observed.

This stage involved functional usability testing of the application with a single patient, who was the newborn son of the author. The test was conducted in a real-use context to verify the proper functioning of the implemented features, including symptom recording, clinical information monitoring, and report generation. No external users, caregivers of other children, or healthcare professionals participated in the testing.

Therefore, the results demonstrate the technical and functional performance of the application in this specific case but do not allow for the generalization of its usability, user acceptance, the clinical validity of the questionnaire, or the effectiveness of the system for monitoring cow's milk protein allergy (CMPA).

IV. Results

A. *Implemented functionalities*

The development resulted in a mobile application capable of guiding the caregiver through a structured flow of recording information related to the infant. The system includes screens for identification, selection of the assessment date, characterization of feeding, and recording of gastrointestinal, cutaneous, respiratory, and behavioral manifestations. The main implemented interfaces are shown in Fig. 2.

Conditional questions allow the content presented to be adapted according to the answers provided, so that supplementary fields are only displayed when related to the selected manifestation. Validation messages have also been implemented to identify missing required fields, inconsistent dates, and information incompatible with the age range covered by the application, as exemplified in Fig. 2(d).

Before generating the document, NeoTrack APLV presents a summary of the recorded information, allowing the responsible party to review the data, as shown in Fig. 2(e). After confirmation, the system generates a report in PDF format, automatically named with the application identification, date, and time of creation. The document can be stored or shared using the resources available on the device.

Fig. 2. Main interfaces of NeoTrack APLV: (a) home screen; (b) infant identification; (c) recording of manifestations; (d) information validation; and (e) summary prior to report generation.

B. *Generating the reports*

The report produced by the system organizes, in a single document, the identification data, information about feeding, and the manifestations selected during completion. The inclusion of the date and time allows distinguishing records made at different times, enabling the creation of a documentary history. An example of the structure of the report generated by NeoTrack APLV is shown in Fig. 3.

As observed in Fig. 3, the information is presented in an organized manner, seeking to facilitate its consultation and sharing with healthcare professionals. However, the document does not contain a diagnosis, automatic classification of the condition, or therapeutic recommendation. Its purpose is to reproduce, in a standardized way, the information provided by the responsible party.

Fig. 3. Example of a report generated by NeoTrack APLV, containing recorded information on feeding and observed manifestations in the infant.

C. *Functional verification*

In the verification conducted by the author, it was possible to follow the complete application flow presented in Fig. 1, from the identification of the infant to the generation and sharing of the report. The conditional questions were presented according to the selected answers, while the validation mechanisms prevented progress when mandatory information was missing or inconsistent.

Fillings were also carried out representing different moments, allowing us to verify whether the information was organized separately in the respective reports. The execution demonstrated that the system implements the expected functional flow and produces documents that can be used to compare records made on different dates. Fig. 3 exemplifies the type of document produced at the end of this process.

These results should be interpreted as a demonstration of technical functionality based on the use of the application by the author and her newborn son, who was the patient monitored during the evaluation. The verification allowed the functionality of the system to be assessed in a real case, but did not provide sufficient data regarding usability, user acceptance, comprehension of the questions, completion time, or professional evaluation of the content. Similarly, it is not possible to establish the clinical validity of the questionnaire or the effectiveness of the application in monitoring cow's milk protein allergy (CMPA).

V. Discussion

NeoTrack APLV was developed to transform everyday observations made by caregivers into structured records, organized according to information about feeding and gastrointestinal, cutaneous, respiratory, and behavioral manifestations. The workflow shown in Fig. 1 and the interfaces shown in Fig. 2 demonstrate that this information has been integrated into a single data entry sequence, from infant identification to data review and report generation.

The use of conditional questions helps to direct completion, as it allows additional fields to be presented only when related to previous answers. Furthermore, the validations implemented seek to reduce the occurrence of incomplete or inconsistent records. However, as the verification was carried out exclusively by the author, it is still not possible to say whether the organization of the questionnaire, the terminology used and the sequence of questions are clear enough for other responsible parties.

Applications focused on food allergies often include features related to ingredient identification, product lookup, and reaction logging [3]. NeoTrack APLV presents a distinct approach by being specifically directed at the longitudinal recording of symptoms in infants up to six months of age. The system does not seek to identify safe foods or establish a diagnosis, but to organize the manifestations reported by the caregiver and produce documents corresponding to different moments of follow-up.

The report exemplified in Fig. 3 constitutes one of the system's main functionalities, as it gathers the information provided during completion into a single document. This feature can reduce reliance on scattered notes and retrospective recall by those responsible. However, the report's usefulness for clinical practice should still be evaluated by healthcare professionals, considering aspects such as the relevance of the information, clarity of presentation, and effective contribution to consultation.

Studies analyzing apps related to food allergies point to variations in the quality of information, usability, and the participation of healthcare professionals in their development [3], [4]. These aspects also represent points of attention for NeoTrack APLV. Although the questionnaire content was based on the manifestations described in the consulted guidelines [1], [2], the instrument has not been submitted to validation by experts. Consequently, the app should be considered an early-stage technological tool, and not a validated clinical instrument.

Another important limitation is the lack of testing with the target audience. The author's personal experience contributed to the identification of the problem and the initial definition of the functionalities, but it does not replace a systematic evaluation with different user profiles. Those responsible may have different levels of education, familiarity with mobile technologies and understanding of terms related to symptoms, factors that can influence the completion and quality of records.

Usability tests, clinical evaluations, accessibility analyses, or comparisons with other forms of record-keeping were not conducted. Therefore, the results presented only demonstrate that the planned functionalities were implemented and executed in the environment used by the author. It is not possible to conclude, at this stage, that NeoTrack APLV improves diagnosis, reduces the time required to investigate the condition, or produces clinical benefits.

As a continuation of this work, it is recommended that the questionnaire content be evaluated by professionals with experience in pediatric food allergies and that usability tests be conducted with caregivers of infants. Subsequent studies could assess the clarity of the questions, the completion time, the ease of navigation, and the usefulness of the reports during professional follow-up. Features such as an integrated history of records, alerts for new assessments, expansion to other age groups, and secure integration with health information systems could also be incorporated.

VI. Conclusion

This work presented NeoTrack APLV, a mobile system developed to support the longitudinal recording of symptoms in infants up to six months old with suspected allergy to cow's milk protein. The solution organizes information related to

food and gastrointestinal, skin, respiratory and behavioral manifestations, using conditional questions and validation mechanisms to conduct completion.

The implemented system allows for the review of recorded information and the generation of reports in PDF format, which can be stored and shared with healthcare professionals. The functional verification conducted by the author herself demonstrated the execution of the planned workflow, from infant identification to report generation, including the functioning of the conditional questions and implemented validations.

However, no tests were conducted with caregivers, healthcare professionals, or patients, nor were there any formal usability and accessibility assessments or clinical validation of the questionnaire. Therefore, the results presented are limited to demonstrating the technical functioning of the application, and do not allow us to affirm its effectiveness in monitoring cow's milk protein allergy (CMPA) or its contribution to the diagnostic process.

As future work, it is proposed to validate the questionnaire content with specialists in pediatrics and food allergy and to conduct instrument validation before assessing its clinical applicability. Usability tests should also be performed with caregivers from different profiles, as well as independent evaluations by healthcare professionals, considering the clarity of the questions, completion time, interpretation errors, and usefulness of the information provided.

Features such as integrated history, alerts for new assessments, support for other age groups, and secure integration with health information systems could also be incorporated. Thus, NeoTrack APLV constitutes an initial technological proposal with the potential to support the organization of information provided by caregivers, without replacing the assessment and conduct of healthcare professionals.

ACKNOWLEDGEMENTS

The authors would like to thank LAPSIM – Laboratory of Acquisition and Processing of Medical Signals and Images of the Biomedical Engineering course at the Federal University of Rio Grande do Norte (UFRN) for the technical support, infrastructure and support for the development of this work.

***Abstract*—Neonatal seizures represent critical neurological manifestations in Neonatal Intensive Care Units (NICUs), with nearly 50% of events in the first days of life remaining entirely subclinical and detectable solely through continuous electroencephalogram (EEG) monitoring. In low- and middle-income countries like Brazil, scaling such specialized neuromonitoring is severely bottlenecked by high equipment costs and a shortage of pediatric neurophysiologists. To bridge this gap, we introduce the NeuroSUS-RN platform: a scalable, low-cost Artificial Intelligence of Things (AIoT) video-EEG ecosystem tailored for universal deployment within Brazil's Universal Health System (SUS) NICUs.**

We also present preliminary data from neonates monitored in the university's NICU, demonstrating the clinical feasibility and signal quality of the platform in real-world scenarios. Looking forward, we plan to implement complementary serological tests within the platform framework to help determine and screen for the most common neurological disorders underlying the country's clinical reality. By shifting complex diagnostic computing from high-end GPU clusters to the bedside, the CNI platform mitigates cloud dependency and structural infrastructure barriers, offering a viable pathway toward the universalization and democratization of advanced neonatal neuroprotection.

***Index Terms*—NICU, electrographic seizures, SUS**

I. Introduction

A major challenge in neonatal neuroprotection is that brain injury manifestations in critically ill newborns are clinically unusual and frequently lack visible physical correlates. In fact, approximately 50% to 80% of neonatal seizures are purely electrographic, occurring with no reliable clinical signs and remaining entirely invisible to bedside observation. Continuous electroencephalography (EEG) combined with synchronous video monitoring (video-EEG), is the gold standard for accurate bedside diagnosis and seizure management. Despite its critical diagnostic value, conventional continuous video-EEG remains virtually absent from the clinical routine of NICUs across the developing world due to operational and financial bottlenecks.

This clinical deficit is especially pronounced in the context of Hypoxic-Ischemic Encephalopathy (HIE) and regional epidemics. While HIE affects a modest 1 to 3 per 1,000 live births in developed nations, its incidence surges dramatically to as many as 26 per 1,000 live births in developing countries. In Brazil alone, over 15,000 to 20,000 newborns are affected by HIE annually [1]. Moreover, recent regional public health crises like the Brazilian outbreak of congenital Zika virus syndrome is a sad example of how unmanaged neonatal brain injuries can catastrophically compound permanent developmental impairments [2]. As prolonged convulsive events directly correlate with cumulative, irreversible cerebral damage, real-time bedside screening and immediate physiological telemetry are vital to altering patient trajectories and improving neonatal survivability [3].

To address this critical equity gap, we present a scalable technological framework designed to expand access to neonatal neurological monitoring through affordable, edge-computed engineering. We also show here preliminary results of neurological monitoring of high risk neonates (N=4) obtained in the NICU. Developed through an interdisciplinary collaboration between the Brain Institute (ICe/UFRN) and the

Januário Cicco Maternity School (MEJC/UFRN), we introduce a low-cost, wireless Artificial Intelligence of Things (AIoT) platform integrating video-EEG to other NICU monitoring devices. The battery-operated system combines a lightweight EEG (the software also displays amplitude-integrated EEG - aEEG) with video. Embedded machine learning algorithms deployed on a hybrid ESP32/ARM processing architecture enable real-time signal quality assessment, artifact reduction, and seizure detection directly at the bedside, without dependence on cloud connectivity or high-performance computing infrastructure. By reducing complexity, preserving patient privacy, and targeting an estimated manufacturing cost of approximately $200 USD per unit at scale, this platform provides an accessible and self-contained solution tailored to the clinical and socioeconomic challenges of Brazil's Universal Health System (SUS) and other resource-limited healthcare environments.

II. Methods

A. Data acquisition and real-time analysis

We implemented a wireless platform for real-time neurophysiological and systemic monitoring in neonatal intensive care environments. The system consists of battery-operated devices organized in a master–subordinate architecture: a central bedside processing and imaging hub, a wireless EEG module, and an optional lightweight foot-mounted pulse oximetry/heart rate sensor. The central hub integrates CMOS imaging and far-infrared thermal sensing, using local computer vision algorithms to identify patient landmarks, track motor activity, and dynamically adjust thermal measurements while preserving privacy by extracting features without storing raw video. The EEG module incorporates precision analog front-end circuitry with instrumentation amplifiers, transient suppression, filtering, and 24-bit analog-to-digital conversion for high-fidelity cortical signal acquisition. A quick-disconnect magnetic electrode interface with spring-loaded contacts enables stable recordings while reducing electrode displacement during neonatal care procedures. All data streams are synchronized through a local time-reference system, while flexible firmware updates allow adaptation between automated seizure detection using amplitude-integrated EEG (aEEG) and high-resolution conventional EEG acquisition. To optimize data transmission, raw high-bandwidth signals are locally stored, whereas processed metrics, vital signs, and neurological alerts are transmitted through low-power long-range communication protocols, enabling scalable tele-neurological monitoring in resource-limited healthcare settings.

Data monitoring was performed using Neo-EEG, an open-source, web-based platform for real-time EEG visualization, recording, and analysis. Signals are acquired by an eight-channel, 24-bit analog-to-digital converter (ADS1299) driven by an ESP32 microcontroller, which streams the data over WiFi (UDP) at a 250 Hz sampling rate. Neo-EEG follows a client–server architecture, in which a Python/FastAPI backend receives the stream and broadcasts it to the browser over WebSocket, while a React frontend renders all eight channels as a real-time clinical montage with an adjustable time window and amplitude gain. Digital filtering is applied to the signal, a 60 Hz notch filter to suppress power-line interference, together with configurable band-pass and band-reject (IIR) filters to restrict the recording to the EEG band of interest and reject residual noise. Each session combines the EEG signals, exported as CSV, with time-synchronized USB-camera video, exported as MP4, preserving frame-level alignment between the two streams.

B. Head phantom

A neonatal head phantom was developed to evaluate the performance of the EEG acquisition system under controlled and reproducible conditions. The phantom was fabricated using electrically conductive PLA with a bulk resistivity of approximately 120–200 Ω/cm and a sparse internal infill structure designed to achieve electrical conductance properties comparable to the combined impedance characteristics of neonatal skin, connective tissue, and skull layers. Conductive wires embedded internally within the phantom were used to deliver realistic neonatal EEG signals, reproducing microvolt-level cortical activity obtained from an open-access EEG data repository. The signals were replayed through two EEG channels using the audio output interface of a laptop, allowing the assessment of signal acquisition, amplification, filtering, and wireless transmission performance under conditions representative of neonatal EEG monitoring. This approach enabled validation of the platform's ability to capture low-amplitude electrophysiological signals while providing a practical and low-cost alternative for system testing and calibration.

C.Ethics committee

This research is being conducted in accordance with the requirements established by the Research Ethics Committee, under approval CAAE n 91421925.6.0000.5537, at Maternidade Escola Januário Cicco (MEJC/UFRN), with strict adherence to data anonymization protocols.

D. Preliminary NICU recordings

Data were collected from 4 high risk newborn patients at the MEJC NICU, with gestational ages ranging from 27 to 37 weeks and birth weights ranging from 870 g to 2390 g.

III. Results

EEG acquisition system was evaluated using the neonatal head phantom (Fig. 1A) with a 7-lead EEG montage (Fig. 1B) and an additional ECG channel (channel 8), and its performance was compared against a commercial reference system (BrainAmp DC, Brain Products GmbH). Phantom head recordings demonstrated the capability of the proposed platform to capture and reproduce low-amplitude neonatal EEG signals across multiple channels, with signal morphology and temporal patterns consistent with the reference acquisition system. SNR, common mode rejection ratio and other signal parameters will be published in the future elsewhere. The measured baseline noise levels remained within the expected range for the implemented acquisition electronics, using a common reference configuration for all channels.

To demonstrate the feasibility of the proposed video-EEG platform in a clinical setting, we also present the preliminary results of continuous neuromonitoring (1–3 h) performed in four high-risk neonates admitted to the NICU of the Federal

University of Rio Grande do Norte (UFRN). The main clinical and demographic characteristics of the enrolled neonates are summarized in Table 1, including gestational age at birth, sex, birth weight, 1- and 5-minute Apgar scores, corrected (postmenstrual) age at the time of EEG recording, and the clinical indication for neuromonitoring.

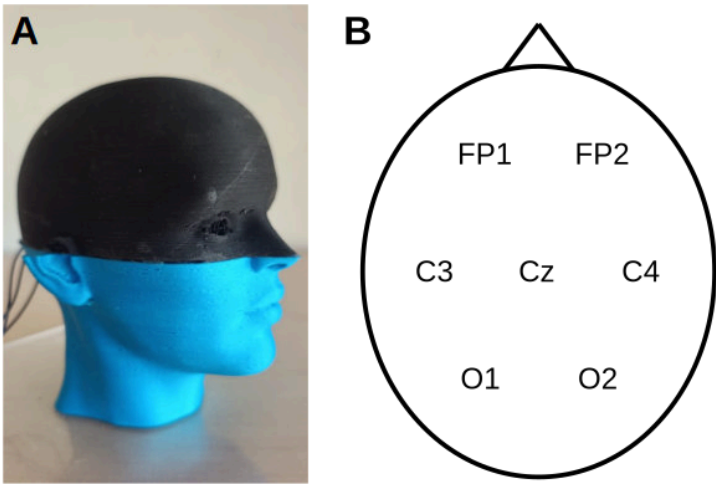

Figure 1: (A) Head phantom and (B) electrode montage.

Table 1. Clinical characteristics of the neonates

	Sex	GA at birth	Birth weight	APGAR (1'/5')	Corrected age at exam
Baby 1	Male	32w6d	1460g	6/7	35w6d (PMA)
Baby 2	Female	37w1d	2390 g	7/8	41w4d (PMA)
Baby 3	Male	28w3d	870 g	6/9	1 month 15 days
Baby 4	Male	27w5d	1215 g	8/8	42.4 days

GA, gestational age; PMA, postmenstrual age; w, weeks; d, days.

The association between Apgar scores and neonatal seizure activity has been extensively studied, though findings vary according to gestational age and birth weight. In a large population-based cohort of over 1.2 million term infants, [4] found that the adjusted hazard ratio for cerebral palsy increased steadily with decreasing five-minute Apgar scores, and reported that associations between Apgar scores and epilepsy, while less pronounced than for cerebral palsy, still showed increased hazard ratios in infants with a five-minute Apgar score of 7 or less and a ten-minute score of 8 or less. However, this association appears to be substantially weaker, or even absent, in preterm and low-birth-weight populations (data not shown).

An expected inverse correlation between Apgar scores and EEG findings has been reported specifically in full-term and normal-birth-weight infants, whereas no significant correlation was found in preterm or low-birth-weight groups [5]. This distinction may help explain the pattern observed in our cohort: the three neonates presenting brief rhythmic discharges (Babies 2, 3, and 4) had 5-minute Apgar scores ≥8, while Baby 1, the only neonate without this EEG finding, had the lowest 5-minute score [4] in the sample. Rather than reflecting a protective effect of higher Apgar scores, this pattern is consistent with the notion that, in preterm infants, seizure activity is driven predominantly by factors independent of immediate perinatal asphyxia, such as gestational age itself.

The incidence of neonatal seizures has been shown to rise sharply with decreasing gestational age [6], a trend also reflected in our sample, where the two most extremely preterm neonates (Babies 3 and 4, born at 28w3d and 27w5d) were both among those presenting rhythmic discharges. Similarly, abnormal aEEG patterns have been shown to occur at comparable rates in newborns with low (0–5) and higher (>6) Apgar scores [7], reinforcing that Apgar alone is an unreliable predictor of EEG abnormality in this population. Given the small sample size (n=4), no statistical association between Apgar scores and EEG findings could be established in the present study; however, we believe that Apgar vs. seizure correlation will be an important metric for the evaluation of our system.

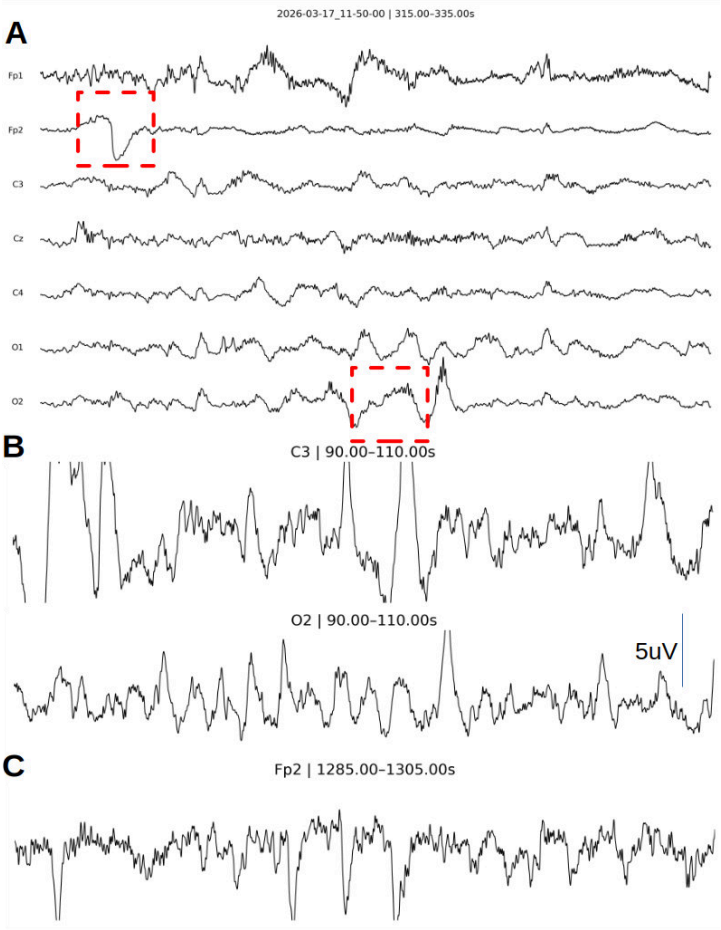

Figure 2: EEG traces obtained from the four neonatal patients during monitoring. A. 20s recording from Baby 1 showing frontal sharp transients and delta brush. B. C3 and O2 of Baby 2 (20s) showing a >10s seizure event. C. Brief rhythmic discharge (<10s) Baby 3.

Representative findings from Baby 1 illustrate the cortical maturation patterns and pathological findings described above. Delta brushes, delta waves with superimposed beta oscillations were prominently present (e.g. O2 in Fig. 1A), a pattern consistent with the neonate's gestational age of 36 weeks. Asystematic frontal sharp transients were also identified over Fp1 and Fp2, a finding physiologically expected during the transition to term. In Baby 2, a focal electrographic seizure was captured, consisting of a 10-second ictal event restricted to channel C3, with clear evolution in frequency and morphology (a rhythmic theta-delta pattern) characterizing a focal electrographic discharge without apparent generalization. Isolated sharp waves were additionally observed over O2, without synchrony with the central ictal event, suggesting irritative activity independent of the main seizure focus. Movement artifacts and low-frequency oscillations, likely reflecting respiratory interference, were also recorded, along with synchronous technical transients across all channels attributable to the experimental nature of the acquisition hardware. For Baby 3, a well-characterized episode of brief rhythmic discharge was observed in the frontocentral region, lasting 5 seconds. All four neonates were receiving phenobarbital at the time of the EEG recording. This is a relevant clinical detail, as phenobarbital remains the most widely used first-line antiseizure medication in neonates, despite a variable and often limited response rate [8-10]. Recent cohort data indicate that fewer than 40% of neonates achieve seizure freedom following first-line treatment with phenobarbital [10].

Notably, Babies 3 and 4 were receiving additional antiseizure medications beyond phenobarbital, with Baby 4 whose EEG indication was treatment-refractory seizure, under a regimen of four concurrent antiseizure medications. This escalation in pharmacological treatment reflects the well-documented limitations of phenobarbital monotherapy in achieving seizure control, particularly in cases of refractory neonatal seizures, which often require sequential or combined second and third-line agents such as levetiracetam, phenytoin, or midazolam [9]. Phenobarbital use has also been associated with reduced amplitude and spatial propagation of electrographic seizures, a phenomenon that may contribute to electroclinical uncoupling the dissociation between electrographic and clinically visible seizure activity [10]. As such, the persistence of brief rhythmic discharges in three of the four neonates despite polytherapy in two of them is consistent with the known limited efficacy of phenobarbital and, in Baby 4's case, with the clinically documented refractoriness of the seizures. This observation should nonetheless be interpreted with caution given the small sample size.

IV. Discussion

This article is the first report of the development of a video-EEG system for neonatal seizure detection and continuous neurological monitoring designed specifically for the NICU. Patient data presented here is preliminary with no statistical value as the clinical validation of our platform is currently on the way. The main objective of the NeuroSUS-RN is to provide a low-cost, easily deployable, and adaptable solution for neonatal neurological monitoring across the diverse landscape of NICUs in Brazil, with particular emphasis on resource-sensitive and geographically isolated healthcare settings. Unlike conventional neuromonitoring systems that often require specialized infrastructure, stable electrical conditions, and high-bandwidth data connectivity, our approach was designed to operate reliably under challenging clinical environments, minimizing susceptibility to electrical interference, unstable power conditions, and limited digital infrastructure. By incorporating robust signal acquisition strategies, local data processing, and flexible communication protocols, the platform aims to reduce dependence on external resources while maintaining clinically relevant monitoring capabilities. Furthermore, the system architecture was intentionally based on commercially available components with relative ease of acquisition in the Brazilian market, facilitating maintenance, scalability, and future implementation within the public healthcare system. This design philosophy supports the development of a sustainable technology pathway toward expanding access to advanced neonatal neuromonitoring beyond highly specialized centers. We estimated a cost of circa US$200 based on the commercial costs of components in Brazil, PCB design and assembly. To conform to ANVISA requirements (and INMETRO, ANATEL etc) costs could rise due to regulations on component traceability and the minute number of companies in Brazil that comply with the *good manufacturing practices* required for class II devices. Costs may also be lower for scaled production.

In the four neonates monitored in this preliminary clinical evaluation, the low-cost EEG acquisition system was able to capture electrographic traces of sufficient quality for clinical interpretation, allowing a neurophysiologist to identify brief rhythmic epileptiform discharges in three of the four recordings. Notably, two of these neonates subsequently underwent a conventional, gold-standard EEG examination, which confirmed the presence of epileptic seizure activity, corroborating the findings initially detected by the low-cost platform. The preliminary agreement between the low-cost system and conventional EEG supports the feasibility of the proposed platform for neonatal seizure monitoring, particularly in resource-limited settings such as low- and middle-income countries, where access to conventional EEG systems remains limited.

To further expand the platform, we are currently developing a multichannel functional near-infrared spectroscopy (fNIRS) module that will be fully integrated with the video-EEG system into a single multimodal neuromonitoring device. The platform also includes the development of hybrid EEG-fNIRS electrodes, enabling simultaneous acquisition of electrophysiological and cerebral hemodynamic signals from the same scalp locations. Because the optical emitters used in fNIRS induce photovoltaic (Becquerel effect) artifacts in EEG recordings [11] , the system employs temporally modulated light sources that generate predictable artifact patterns, enabling their suppression through dedicated signal-processing and embedded artificial intelligence algorithms [11]. Cerebral fNIRS has emerged as a valuable bedside neuromonitoring modality in the NICU by providing continuous, non-invasive

measurements of regional cerebral oxygenation and hemodynamic responses. When combined with EEG, fNIRS offers complementary information on neurovascular coupling, cerebral perfusion, and metabolic function, improving the detection and characterization of seizures, hypoxic-ischemic brain injury, and other neonatal neurological disorders [12, 13]. Integrating these complementary modalities into a low-cost embedded platform has the potential to deliver comprehensive multimodal neuromonitoring to NICUs that currently lack access to advanced neurodiagnostic technologies while enabling real-time bedside analysis through embedded AI. It is important to note that, unlike EEG amplifiers, there is no company that manufactures cerebral fNIRS devices in Brazil.

Beyond seizure monitoring, the platform will enable the establishment of a standardized Brazilian neonatal EEG database, providing a representative dataset for the development and validation of robust artificial intelligence models tailored to the Brazilian population. In addition, the microprocessor-based EEG acquisition units and intelligent camera modules will support the deployment of embedded AI models for real-time neonatal pose estimation and automated seizure detection directly at the bedside. Upon completion of the current study, a larger multicenter trial with systematic, simultaneous reference-standard EEG recordings will be conducted to establish the sensitivity and specificity of the platform for neonatal seizure detection and to further validate these embedded AI technologies.

The current patient data is preliminary and reflects only the initial usability assessments of our system. We plan to evaluate the video-EEG platform in a cohort of 90 high-risk neonates (sample size approved by the local ethics committee) admitted to the NICU of the Januário Cicco Maternity School Hospital (MEJC). Upon completion of the MEJC study, we intend to initiate a multicenter trial across NICUs of varying levels of complexity. This broader study will allow us to refine the system's design and propose standardized protocols for implementation within the SUS.

Acknowledgment

This study was supported by the Financiadora de Estudos e Projetos (FINEP) through the Centro de Neuroproteção Infantil project. The authors gratefully acknowledge the Sistema Único de Saúde (SUS) of Brazil for providing the clinical infrastructure and patient care that made this study possible. ***Abstract*—Open research ultrasound systems play a fundamental role in the development and validation of advanced biomedical imaging techniques by providing flexible access to radio-frequency (RF) signals, acquisition parameters, and signal processing algorithms. However, the increasing complexity of architectures and the diversity of electronic components make it difficult to compare the solutions reported in the literature. This paper presents a review of the state of the art in the electronic architecture of open research ultrasound platforms, covering the transmission, reception, signal conditioning, digitization, and digital processing stages. The main characteristics of high-voltage pulsers, multiplexers, T/R switches, analog front-end (AFE) circuits, and programmable logic devices are analyzed, focusing on operating voltage, channel density, operating frequency, integration level, and configuration flexibility. The analysis reveals a clear trend toward higher analog integration (multichannel AFEs with JESD204B/C interfaces), reduced use of discrete components, and the consolidation of hybrid FPGA/GPU/CPU architectures interconnected by high-speed buses (PCIe) for real-time reconstruction. The results provide a consolidated overview that serves as a reference guide for component selection and the design of new acquisition and imaging platforms.**

***Index Terms*—ultrasound imaging, open ultrasound systems, electronic components, analog front-end, beamforming**

I. Introdução

Os sistemas de ultrassom para diagnóstico não invasivo por imagem constituem uma das modalidades mais consolidadas de imageamento biomédico, combinando segurança, portabilidade e capacidade de fornecer informações anatômicas e funcionais de tecidos biológicos em tempo real. A contínua evolução desses sistemas é impulsionada pelo avanço de arquiteturas eletrônicas dedicadas, técnicas complexas de processamento de sinais e uma maior densidade de integração de componentes [1], [2].

A integração de eletrônica analógica de alta velocidade, aquisição multicanal e circuitos dedicados, como matrizes de portas programáveis em campo (*Field-Programmable Gate Array* – FPGA), pulsadores integrados de alta tensão e *analog front-ends* (AFEs), consolidou uma nova geração de plataformas de ultrassom para pesquisa altamente reconfiguráveis [3], [4]. Tais sistemas oferecem acesso direto aos dados brutos de radiofrequência (RF) e controle avançado dos parâmetros de excitação e amostragem, permitindo a validação de algoritmos customizados de *beamforming* na transmissão (Tx/T) e na recepção (Rx/R). No entanto, a consequente heterogeneidade das soluções desenvolvidas faz com que os detalhes de implementação e desempenho permaneçam dispersos na literatura, impondo barreiras para uma análise comparativa sistemática [5].

Este artigo apresenta uma revisão analítica e comparativa sobre a arquitetura eletrônica e os componentes empregados na construção de sistemas abertos de ultrassom para pesquisa. As principais contribuições deste trabalho incluem: (i) um panorama comparativo das plataformas abertas comerciais e acadêmicas consolidadas; (ii) uma análise detalhada dos circuitos TX, chaveamento T/R, AFEs e interfaces de comunicação; e (iii) a identificação das tendências tecnológicas de integração (como AFEs de alta densidade e RFSoCs) e os *trade-offs* entre flexibilidade, consumo energético e largura de banda.

II. Metodologia de Revisão e Critérios de Seleção

Esta revisão foi conduzida com o objetivo de sistematizar as principais arquiteturas eletrônicas e os componentes empregados em plataformas abertas de ultrassom destinadas à pesquisa e ao desenvolvimento de novas técnicas de imageamento. A revisão considerou tanto plataformas comerciais de pesquisa quanto sistemas acadêmicos e de código aberto que apresentassem informações técnicas suficientes para caracterizar sua arquitetura eletrônica. A busca bibliográfica foi realizada nas bases IEEE Xplore, ScienceDirect, PubMed, Scopus e Web of Science, complementada por buscas direcionadas nos sítios dos fabricantes para obtenção de folhas de dados e documentação técnica dos componentes. Foram considerados trabalhos publicados no período de 1990 a 2026. A estratégia de busca combinou termos relacionados à arquitetura de sistemas de ultrassom e aos principais blocos eletrônicos analisados. Foram empregados, individualmente ou em combinações, termos como “open ultrasound system”, “research ultrasound platform”, “programmable ultrasound”, “ultrasound front-end”, “ultrasound pulser”, “high-voltage multiplexer”, “T/R switch”, “ultrasound AFE”, “ultrasound FPGA”, “ultrasound RFSoC” e “ultrasound beamforming”. As buscas foram posteriormente refinadas de acordo com o bloco funcional analisado.

Foram incluídos estudos que apresentassem pelo menos uma das seguintes características: (i) descrição de uma plataforma de ultrassom reconfigurável ou destinada à pesquisa; (ii) descrição ou aplicação documentada de compo-

nentes eletrônicos utilizados em sistemas de ultrassom; (iii) apresentação de parâmetros elétricos ou arquiteturais suficientes para comparação; ou (iv) descrição de arquiteturas de aquisição e processamento relevantes para sistemas abertos de ultrassom. Foram excluídos trabalhos que (i) descrevessem exclusivamente equipamentos clínicos comerciais sem acesso ou flexibilidade para pesquisa; e (ii) não apresentassem informações técnicas suficientes para caracterizar a arquitetura analisada. A seleção das plataformas baseou-se na relevância para arquiteturas reconfiguráveis e no uso documentado na literatura. Para comparar os sistemas de forma holística, a análise relaciona as especificações de hardware extraídas (eletrônica e processamento) a parâmetros de desempenho, como fluxo de dados, escalabilidade, capacidade de aquisição, processamento e eficiência arquitetural, nas aplicações de ultrassom.

III. Arquitetura Geral de um Sistema de Ultrassom para Pesquisa

A cadeia de sinal de um sistema de ultrassom amostrado por canal é dividida em três domínios funcionais principais: transmissão dos sinais de excitação ao transdutor, recepção dos ecos provenientes dos tecidos e processamento digital para a formação e reconstrução das imagens [1], [6], [7].

Na etapa de transmissão, pulsadores de alta tensão geram os sinais elétricos aplicados aos elementos do transdutor para a emissão das ondas acústicas. Dependendo da arquitetura adotada, multiplexadores de alta tensão (*High-Voltage Multiplexers* – HV-MUXs) podem ser empregados para multiplexar múltiplos elementos em um número reduzido de canais eletrônicos, otimizando o custo e a complexidade do sistema [4], [8]. Durante a recepção, os ecos refletidos são direcionados ao circuito de aquisição por meio de uma chave T/R, que protege os circuitos sensíveis de recepção durante os pulsos de alta tensão de transmissão e encaminha os sinais de eco recebidos ao estágio de condicionamento analógico. Em seguida, os sinais são amplificados, filtrados e digitalizados para posterior reconstrução da imagem [9], [10]. Em muitas arquiteturas modernas, essas funções analógicas e de conversão são consolidadas em CIs AFE. Esses dispositivos multicanais reúnem amplificadores de baixo ruído (*Low-Noise Amplifiers* – LNAs), amplificadores de ganho variável (*Variable Gain Amplifiers* – VGAs) acoplados ao circuito de compensação de ganho no tempo (*Time Gain Compensation* – TGC), filtros passa-baixas (FPB) anti-aliasing (*Anti-Aliasing Filters* – AAFs) e conversores analógico-digitais (*Analog-to-Digital Converters* – ADCs) em dispositivos multicanais [11], [12]. Após a digitalização, os dados de RF são transferidos para unidades de processamento digital baseadas em FPGAs, unidades centrais de processamento (*Central Processing Units* – CPUs) e unidades de processamento gráfico (*Graphics Processing Units* – GPUs). Esses dispositivos são responsáveis pelo *beamforming* de recepção, incluindo as etapas de correção de atraso temporal, filtragem, somatório coerente, detecção de envelope, compressão logarítmica e execução de algoritmos avançados de reconstrução em tempo real [13], [14].

A. Plataformas Abertas para Pesquisa

As plataformas abertas variam substancialmente em poder computacional, número de canais e estratégia de Tx e Rx [3], [13], [15]–[17], [19]–[22]. A Tabela I apresenta uma síntese das principais características das plataformas comerciais, acadêmicas e de código aberto utilizadas pela comunidade científica. Observa-se que essas plataformas abrangem desde sistemas com 64 canais de recepção, como o us4R-lite, até arquiteturas com 1024 canais, como o SARUS, evidenciando a ampla variedade de soluções disponíveis para aplicações de pesquisa. Dentre as plataformas comerciais de maior porte, o Verasonics Vantage, que possui configurações de 128 e 256 canais, utiliza uma interface PCI Express de alta largura de banda para transferência dos dados ao computador hospedeiro com GPU, viabilizando aplicações como ultrassom ultrarrápido, elastografia e imageamento volumétrico [16], [17], [22], [23]. Em contrapartida, projetos portáteis e *open-source*, como o ULA-OP, utilizam arquiteturas modulares baseadas em FPGAs intermediárias e conectividade USB 2.0 ou 3.0, sacrificando a amostragem paralela massiva em prol do custo acessível e consumo reduzido [15], [20]. As características de processamento digital e armazenamento das plataformas apresentadas na Tabela I são complementadas pelos recursos de FPGA, memória e interfaces de comunicação resumidos na Tabela VI.

B. Transmissão Ultrassônica

A etapa de transmissão visa excitar os elementos piezoelétricos com pulsos de alta tensão (entre 10 e 200 Vpp) e frequências na faixa de 1 MHz a 50 MHz para gerar o campo acústico desejado no meio biológico [1], [7]. A seleção dos dispositivos de chaveamento e excitação depende de parâmetros críticos, tais como o número de canais, faixa de tensão de saída, capacidade de corrente e resistência no estado de condução (R_{ON}) da chave T/R integrada, analisados a seguir para os principais pulsadores integrados e multiplexadores de alta tensão disponíveis na literatura e no mercado.

1) Pulsadores para Sistema de Imagem por Ultrassom: Os pulsadores de alta tensão geram sinais de elevada amplitude e rápido tempo de subida para excitação dos elementos piezoelétricos [24]. As arquiteturas variam entre soluções unipolares, bipolares, multinível e geradores de formas de onda arbitrárias (*Arbitrary Waveform Generators* – AWGs) ou lineares [4], [7], [21], [25], frequentemente integrando *drivers* de potência, amortecimento ativo e retorno a zero (*Return to Zero* – RTZ) no mesmo encapsulamento para mitigar o *ringing* acústico [4], [15]. O mercado de circuitos integrados (CIs) para ultrassom médico é altamente especializado e vem evoluindo em direção a soluções de altíssima densidade. Diversas empresas consolidaram-se no fornecimento de CIs para aplicações de excitação ultrassônica. Esses dispositivos diferenciam-se quanto à excursão de tensão, resistência em condução (R_{ON}), número de canais, frequência máxima, capacidade de corrente e chave T/R integrada. A Tabela II sintetiza as principais características desses componentes.

Tabela I
CARACTERÍSTICAS DAS PRINCIPAIS PLATAFORMAS DE ULTRASSOM PARA PESQUISA DESCRITAS NA LITERATURA[1].

Plataforma	Referência	Número de canais (Tx/Rx)	Tensão Tx (V)	Forma de onda Tx	Faixa de freq. Tx (MHz)	Taxa de amostragem (MHz)
us4R-lite	[22]	256 / 64	±90	3 níveis	0,1 a 50	50
ULA-OP 128	[15]	128 / 128	±12	Linear	∼ 15	50
Verasonics Vantage 256	[16], [23]	256 / 256	±100	3 níveis	0,5 a 20	62,5
Cephasonics cQuest	[17], [18]	256 / 256	±100	3 ou 5 níveis	0,5 a 18	50
DIPhAS	[19]	256 / 256	±100	3 níveis	20	80
ULA-OP 256	[20]	256 / 256	±100	Linear	1 a 20	78,13
UARP	[21]	256 / 256	±100	5 níveis	0,5 a 15	80
SARUS	[13]	1024 / 1024	±100	3 níveis	1 a 30	70

[1]Os parâmetros apresentados foram obtidos a partir das referências bibliográficas e, quando disponíveis. Valores provenientes de diferentes fontes podem ter sido especificados sob condições de operação distintas e, portanto, não representam necessariamente uma comparação experimental direta.

Tabela II
PRINCIPAIS CARACTERÍSTICAS DOS PULSADORES DE ALTA TENSÃO EMPREGADOS EM SISTEMAS DE ULTRASSOM PARA PESQUISA.

Pulsador	Referência	Número de canais	Tensão de saída (V)	Corrente de saída (A)	Níveis do sinal	Freq. máx. (MHz)	Chave T/R int. ($R_{\mathbf{ON}}[\Omega]$)	Fabricante
HV7360	[29]	1	±100	±2,5	3	35	Não	Microchip
HV7361	[25], [29]	1	±100	±2,5	3	35	Sim (15)	Microchip
HV7321	[30]	4	±80	±2,5	5	20	Sim (8)	Microchip
STHV748S	[31]	4	±90	±2	3 / 5	20	Sim (13,5)	STMicroelectronics

TX7364	[41]	64	±100	±1	3	22	Sim (26)	Texas Instruments
STHVUP64	[42]	64	±100	±0,4 / ±0,2	3 / 5	20	Sim (45)	STMicroelectronics

2) Multiplexadores de Alta Tensão: Para reduzir a complexidade e o custo em sistemas em que o número de elementos do transdutor excede os canais físicos de amostragem, empregam-se matrizes de chaves multiplexadoras de alta tensão [4], [26]. Para aplicações em ultrassom, esses dispositivos devem suportar os elevados níveis de tensão gerados pelos pulsadores, conforme os parâmetros de tensão de alimentação positiva V_{PP} e negativa V_{NN}, respeitando o limite de tensão diferencial, apresentar baixa R_{ON}, capacitância parasita reduzida e tempos de comutação compatíveis com a frequência de operação do sistema [4], [24]. Além disso, devem garantir elevada isolação entre os estágios de transmissão e recepção, minimizando o acoplamento dos pulsos de alta tensão aos circuitos sensíveis de aquisição [24]. A Tabela III apresenta uma análise comparativa dos principais multiplexadores reportados na literatura. Entre os parâmetros de seleção, destaca-se o número de chaves (canais), que determina a quantidade de elementos do transdutor controlados por um único CI. Embora dispositivos com maior densidade de canais reduzam o número de componentes e simplifiquem o roteamento da placa de circuito impresso, eles podem aumentar efeitos parasitas, como capacitâncias internas e acoplamento entre canais (*crosstalk*), exigindo cuidados adicionais no projeto eletrônico. Como funcionalidade adicional, determinados modelos, como o MAX14803 e o HV2901, incorporam resistores de drenagem integrados (*bleed resistors*), que promovem a dissipação da carga residual acumulada nos elementos capacitivos do transdutor piezoelétrico, evitando variações indesejadas na tensão de *offset* [27], [28].

C. Recepção Ultrassônica

Os ecos ultrassônicos apresentam amplitudes muito baixas, da ordem de μV a mV, exigindo elevada sensibilidade na aquisição [1]. A arquitetura também deve garantir proteção e isolamento dos estágios de recepção contra os transientes de alta tensão da transmissão. Nesse contexto, observa-se a crescente substituição de componentes discretos por circuitos altamente integrados, como chaves T/R e AFEs comerciais.

1) Chaves T/R de proteção: Para proteger os amplificadores do caminho de recepção contra os pulsos de alta tensão da transmissão, uma chave T/R é posicionada entre o transdutor e o AFE. Seu desempenho influencia diretamente a sensibilidade, a faixa dinâmica e a integridade dos sinais adquiridos. Assim, são desejáveis baixa R_{ON}, baixa capacitância parasita, curto tempo de comutação e elevada isolação entre os caminhos de transmissão e recepção, além de capacidade para suportar os níveis de tensão e corrente da excitação sem introduzir distorções significativas [24]. Alguns dispositivos comerciais incorporam funções adicionais de proteção e condicionamento, contribuindo para arquiteturas mais compactas

e escaláveis [4]. A Tabela IV apresenta uma comparação entre algumas das principais chaves T/R utilizadas em sistemas de ultrassom para pesquisa. Entre essas soluções, destacam-se os dispositivos das famílias MD01xx e Tx810, frequentemente relatados na literatura.

De modo geral, dispositivos mais integrados reduzem a complexidade do hardware, enquanto soluções com baixa capacitância parasita e elevada largura de banda são particularmente adequadas para aplicações de alta frequência [24]. Observa-se, portanto, uma tendência de integração das funções de chaveamento T/R, proteção contra sobretensão e condicionamento analógico em um único CI.

2) Circuitos Analog Front-End: Os circuitos AFE fazem a interface entre o transdutor e o processamento digital, realizando o condicionamento dos sinais de eco antes da conversão. Como esses sinais apresentam baixa amplitude e ampla faixa dinâmica devido à atenuação durante a propagação nos tecidos, os AFEs integram múltiplos estágios analógicos de alta velocidade. Tipicamente, esses dispositivos possuem de 8 a 32 canais e integram LNA, VGA para TGC (0–40 dB), AAF e ADCs de alta velocidade, com resoluções de 10 a 16 bits. O consumo pode variar de aproximadamente 35 mW a 225 mW por canal, dependendo da arquitetura e das funcionalidades integradas [4]. A adoção de interfaces seriais de alta velocidade, como JESD204B/C, também reduz o número de conexões na PCB e favorece arquiteturas com elevada densidade de canais. Essa característica é particularmente relevante em aplicações como ultrassom ultrarrápido e imageamento 3D [64].

A Tabela V apresenta uma comparação entre AFEs comerciais utilizados em pesquisa. A integração de múltiplos canais em um único CI reduz a quantidade de componentes e favorece arquiteturas mais compactas. Os dispositivos analisados apresentam taxas de amostragem de dezenas a centenas de MSPS e resoluções de 10 a 16 bits, atendendo a diferentes requisitos de largura de banda e faixa dinâmica. A seleção de um AFE deve considerar o número de canais, a faixa de entrada, a taxa de amostragem, a resolução, a SNR, a interface digital, o consumo por canal e o desempenho de ruído [17]. AFEs com maior resolução e desempenho analógico são particularmente adequados para aplicações que exigem elevada sensibilidade e detecção de ecos de baixa amplitude [64], [65]. Alguns dispositivos também incorporam atenuadores, memória de configuração, filtros passa-alta (HPF) e demodulação digital I/Q para Doppler de onda contínua (CWD), aumentando a flexibilidade e reduzindo a necessidade de processamento externo. A família AFE58xx, da Texas Instruments, destaca-se entre os circuitos AFE empregados em sistemas experimentais de ultrassom devido à integração de múltiplos canais de recepção e recursos dedicados, como mixer CWD, demodulação digital I/Q (membros da família AFE58JD) e interfaces digitais de alta velocidade. Dispositivos como o AFE58JD28 e o AFE58JD48 ampliam essa capacidade ao oferecer maior resolução de conversão e suporte a interfaces como JESD204B, enquanto o AFE5832 e o AFE58JD32 representam soluções de maior densidade, com 32 canais de aquisição integrados. Por outro lado, embora a separação entre os estágios de transmissão (pulsadores) e recepção (AFEs) seja a abordagem predominante para reduzir o acoplamento de ruído de alta tensão, a literatura também apresenta transceptores monolíticos que integram ambos os caminhos em um único dispositivo. O MAX2082 integra, em um encapsulamento de 8 canais, pulsadores de alta tensão de 3 níveis, chaves T/R e uma cadeia completa de recepção e reduzindo a quantidade de componentes externos [66]. Já MAX2084 é um AFE com chaves T/R integradas, proporcionando maior densidade de integração e simplificação do *front-end* ultrassônico [67].

[1] Alguns dispositivos oferecem modos de baixo consumo e de alto desempenho, com diferentes níveis de consumo e ruído.

D. Dispositivos FPGA e Processamento Digital

Em plataformas abertas de pesquisa, a demanda por flexibilidade, elevada taxa de aquisição e processamento em tempo real consolidou o uso de arquiteturas híbridas compostas por FPGAs, CPUs e GPUs [17]. Após o condicionamento analógico e a digitalização no AFE, os sinais de RF ultrassônicos digitalizados são submetidos ao processamento digital, responsável pelo controle temporal da aquisição, *beamforming* e reconstrução da imagem final [4].

Entretanto, a taxa de dados gerada pelos ADCs em recepção simultânea representa o principal gargalo de processamento. Por exemplo, para 128 canais amostrados a 50 MSPS com 12 bits, a taxa contínua de dados atinge 128×50 MHz $\times$ 12 bits $\approx$ 76,8 Gbps ($\approx$ 9,6 GB/s), desconsiderando o *overhead* de protocolo. A transferência de dados entre os AFEs e o processador digital migrou das interfaces seriais LVDS paralelas tradicionais para os padrões seriais de ultra-alta velocidade JESD204B/C. O padrão JESD204 reduz drasticamente o número de linhas de sinal na PCB, simplificando o roteamento físico ao custo de exigir *transceivers* seriais dedicados na FPGA. As FPGAs desempenham papel fundamental no *front-end* digital devido à execução determinística, baixa latência e capacidade de processamento paralelo reconfigurável. Esses dispositivos são empregados no controle preciso dos tempos de disparo da transmissão, na sincronização multicanal, no pré-processamento dos dados de RF e na implementação inicial de algoritmos *beamforming* de recepção [13], [14], [61].

A Tabela VI apresenta os principais dispositivos lógicos programáveis e memórias (SRAM e DRAM) empregados nas plataformas de pesquisa, destacando a capacidade de armazenamento local necessária para acomodar o elevado fluxo de dados de RF antes da transferência para a unidade central de processamento [13], [15], [20], [21]. A integração entre os FPGAs responsáveis pela aquisição dos dados brutos RF ou IQ pré-filtrados e os processadores/GPUs do computador hospedeiro é realizada por meio de barramentos de alta velocidade e baixa latência, como o PCI Express (Gen3/Gen4 x4/x8), USB 2.0, USB 3.0 ou Thunderbolt 3 para o computador hospedeiro [16], [22]. No *back-end*, a elevada densidade de dados gerada por aplicações como o imageamento por ondas planas (*Plane-Wave Imaging* – PWI), o ultrassom ultrarrápido, a elastografia e o imageamento volumétrico (3D) impõe elevada carga computacional, podendo impor limitações de desempenho, dependendo da aplicação e do algoritmo empregado, a arquiteturas baseadas exclusivamente em CPUs ou FPGAs para a execução em tempo real desses algoritmos [16]. Nesse contexto, GPUs de propósito geral são amplamente empregadas na reconstrução intensiva de imagens. Em particular, dispositivos NVIDIA, utilizando a plataforma CUDA, permitem a execução em tempo real de algoritmos clássicos, como *Delay-and-Sum* (DAS) e reconstrução por síntese de Fourier baseada na Transformada Rápida de Fourier (FFT), bem como de métodos avançados de maior complexidade computacional, como *Delay-Multiply-and-Sum* (DMAS), *Filtered Delay-Multiply-and-Sum* (FDMAS) e estimadores de Mínima Variância (*Minimum Variance* – MV) [83].

IV. DISCUSSÃO

A análise das plataformas e componentes apresentados evidencia que a evolução dos sistemas abertos de ultrassom tem sido impulsionada pela maior integração dos circuitos eletrônicos e pelo avanço do processamento digital. Conforme discutido por Chen e Pertijs [4] e Lok e Li [5], o desenvolvimento de CIs específicos para ultrassom reduziu a complexidade da eletrônica analógica, aumentando a escalabilidade, modularidade e flexibilidade das plataformas experimentais.

Na transmissão, observa-se a evolução de pulsadores discretos para CIs multicanais que integram chaves T/R e recursos programáveis de excitação. Essa integração reduz a área da PCB, simplifica o roteamento e favorece plataformas compactas, como a us4R-lite [22]. Além disso, arquiteturas baseadas em AWGs ampliam a flexibilidade para técnicas como transmissão codificada, abertura sintética e formação de feixe adaptativa [7], [25]. Multiplexadores de alta tensão

Tabela VI
CARACTERÍSTICAS DOS DISPOSITIVOS FPGA, MEMÓRIA E INTERFACES DE COMUNICAÇÃO DAS PRINCIPAIS PLATAFORMAS DE ULTRASSOM PARA PESQUISA.

Plataforma	Ref.	FPGA	SRAM (por FPGA)	DRAM	Interface de comunicação
us4R-lite	[22]	Xilinx Kintex-7	34 Mbit	8 GB	PCIe Gen3 / Thunderbolt 3
ULA-OP 128	[15]	Altera Stratix II	4.8 Mbit/FPGA	1 GB	USB 2.0
Verasonics Vantage 256	[16], [23]	Altera Stratix V	45 Mbit	64 GB	PCIe Gen3 x8
Cephasonics cQuest	[17], [18]	Altera Cyclone IV	6.5 Mbit/FPGA	4 GB	PCIe / Gigabit Ethernet
DIPhAS	[19]	Xilinx Spartan-6	4.8 Mbit/FPGA	512 MB	PCIe / Gigabit Ethernet
ULA-OP 256	[20]	Arria V	19 Mbit/FPGA	80 GB	USB 3.0
UARP	[21]	Altera Stratix V	45 Mbit	256 MB/canal	PCIe Gen3 / USB 2.0
SARUS	[13]	Xilinx Virtex-6	19 Mbit/FPGA	2 GB/FPGA	PCIe Gen2 / Gigabit Ethernet

também permitem reduzir o número de canais eletrônicos necessários, sendo particularmente relevantes em transdutores matriciais para imageamento 2D e 3D [8], [26]. Entretanto, sua utilização envolve compromissos relacionados à resistência de condução, capacitâncias parasitas e acoplamento entre canais [24].

Na recepção, a integração de LNAs, VGAs, filtros, TGCs e ADCs em AFEs multicanais representa um dos principais avanços dos sistemas modernos. Essa abordagem reduz componentes externos, consumo e área, viabilizando sistemas com centenas de canais [11], [12], [14]. Interfaces digitais de alta velocidade, como LVDS e JESD204B, também aumentam a taxa de transferência e simplificam a comunicação com FPGAs [14], [65]. Outra tendência é a adoção de arquiteturas híbridas com FPGAs, CPUs e GPUs. Plataformas como SARUS [13], ULA-OP 256 [20], Verasonics Vantage [16] e us4R-lite [22] combinam a baixa latência e o processamento determinístico das FPGAs com o paralelismo das GPUs, permitindo aplicações computacionalmente intensivas, como ultrassom ultrarrápido, abertura sintética, elastografia e formação de feixe adaptativa [61].

Como evolução dessas arquiteturas, destaca-se a adoção de dispositivos SoC, como Xilinx Zynq UltraScale+ MPSoC, RFSoC, Intel Cyclone V SoC e Agilex, que integram processadores ARM e lógica programável, e, em alguns casos, ADCs e DACs de alta velocidade [64], [84]. Essa integração pode reduzir a latência, a área ocupada na placa e a necessidade de interconexões externas entre os blocos de conversão, processamento e memória, favorecendo o processamento em tempo real. Em conjunto, as plataformas analisadas apontam para uma convergência em direção a sistemas mais integrados, modulares, escaláveis e reconfiguráveis. A combinação de eletrônica analógica integrada, interfaces de alta velocidade e processamento paralelo possibilita maior número de canais, menor consumo e maior capacidade computacional [85]. Essas características são especialmente relevantes para a próxima geração de sistemas de pesquisa, incluindo aplicações de imageamento 3D, ultrassom portátil, dispositivos vestíveis e sistemas baseados em inteligência artificial [86]–[88].

V. CONCLUSÃO

Este trabalho apresentou uma revisão das principais arquiteturas eletrônicas e componentes empregados em plataformas abertas de ultrassom para pesquisa, abrangendo transmissão, multiplexação, proteção T/R, condicionamento analógico, conversão analógico-digital e processamento. A análise evidencia uma evolução em direção a sistemas com maior integração, densidade de canais e taxas de transferência. A seleção da arquitetura, entretanto, deve considerar conjuntamente número de canais, largura de banda, resolução dos ADCs, consumo, capacidade de processamento, complexidade de roteamento, flexibilidade e custo. Destaca-se também a crescente integração de conversores de alta velocidade, lógica programável e processadores em arquiteturas SoC e RFSoC, que podem reduzir latência, área e dependência de enlaces externos. Paralelamente, arquiteturas híbridas com FPGA, CPU e GPU permitem o processamento em tempo real de técnicas computacionalmente intensivas, como *beamforming* adaptativo, ultrassom ultrarrápido e reconstrução avançada de imagens. Espera-se que este estudo sirva como referência para o desenvolvimento e dimensionamento de novas plataformas experimentais, contribuindo para a seleção de componentes e arquiteturas adequados às diferentes aplicações. Essas tendências favorecem o avanço de sistemas portáteis, dispositivos *point-of-care* e plataformas de imageamento 3D e 4D [16], [26].

AGRADECIMENTOS

Os autores agradecem à Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), ao Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), à Fundação Araucária de Apoio ao Desenvolvimento Científico e Tecnológico do Estado do Paraná e à Secretaria da Ciência, Tecnologia e Ensino Superior do Paraná (SETI) pelo apoio concedido.

***Resumo*—A laserterapia tem sido investigada como recurso adjuvante para favorecer a cicatrização de lesões cutâneas em humanos, sobretudo por seus efeitos de fotobiomodulação, modulação inflamatória, analgesia, angiogênese e estímulo ao reparo tecidual. Este estudo teve como finalidade caracterizar os principais parâmetros técnicos e a eficácia clínica dos lasers utilizados nesse contexto, destacando a necessidade de padronização dos protocolos terapêuticos. Realizou-se uma revisão integrativa da literatura, orientada pela estratégia PICO, nas bases MEDLINE/PubMed, SciELO, BVS/LILACS e Cochrane Library, contemplando publicações até 2025. Foram incluídos artigos originais completos, em português, inglês ou espanhol, que avaliaram o uso de laser no tratamento de lesões cutâneas em humanos. O nível de evidência e a qualidade metodológica foram avaliados segundo critérios do Joanna Briggs Institute. Após a remoção de duplicidades, triagem por título e resumo e leitura integral, 33 estudos compuseram a amostra final. Desses, 22 estudos (66,7%) foram classificados como de alta eficácia, 5 (15,2%) como de eficácia média e 6 (18,2%) como de baixa eficácia. Os desfechos mais consistentes foram observados em úlceras diabéticas, deiscências cirúrgicas e feridas pós-operatórias. Os parâmetros mais associados a respostas positivas envolveram comprimentos de onda no vermelho visível (595–685 nm) e no infravermelho próximo (785–980 nm), com fluências frequentemente entre 1 e 5 J/cm^2; estudos recentes também reforçam a relevância de doses de 8 a 12 J/cm^2 em úlceras diabéticas. Conclui-se que a laserterapia apresenta potencial como recurso adjuvante na cicatrização de lesões cutâneas; entretanto, a heterogeneidade metodológica, a omissão de dados dosimétricos e a utilização de diferentes classes de laser ainda limitam a comparação direta entre estudos e a definição de protocolos clínicos universais.**

***Palavras-chave*—Laserterapia; fotobiomodulação; cicatrização de feridas; lesões cutâneas; parâmetros dosimétricos.**

I. Introdução

A cicatrização de feridas é um processo biológico complexo e essencial para a restauração da integridade tecidual. Esse fenômeno envolve eventos celulares, vasculares e moleculares organizados em fases parcialmente sobrepostas: inflamação, proliferação e remodelação. A compreensão dessas etapas é fundamental para o desenvolvimento de intervenções capazes de reduzir o tempo de reparo, prevenir complicações e melhorar a qualidade de vida de pacientes com lesões agudas ou crônicas. [1]–[4]

As feridas crônicas representam um problema relevante de saúde pública. Além do impacto funcional, estético e psicossocial, essas lesões estão associadas a elevada demanda assistencial, maior risco de infecção, internações prolongadas e aumento dos custos dos sistemas de saúde. Estimativas internacionais indicam que o tratamento de feridas crônicas gera gastos bilionários, evidenciando a necessidade de terapias adjuvantes seguras, acessíveis e clinicamente efetivas. [46], [48]

Nesse contexto, a laserterapia tem sido investigada como alternativa complementar ao tratamento convencional de lesões cutâneas. O termo laser deriva de Light Amplification by Stimulated Emission of Radiation e descreve uma fonte de luz coerente, monocromática e colimada, capaz de interagir com tecidos biológicos de forma controlada. Em baixas intensidades, essa interação não tem finalidade ablativa ou térmica, mas fotobiológica, sendo frequentemente descrita como terapia a laser de baixa intensidade ou fotobiomodulação. [5]–[12]

A fotobiomodulação está relacionada à absorção da luz por cromóforos celulares, especialmente pela citocromo c oxidase mitocondrial. Essa interação pode favorecer a produção de ATP, a liberação de óxido nítrico, a modulação de espécies reativas de oxigênio em níveis sinalizadores e a regulação de mediadores inflamatórios. Como consequência, pode ocorrer maior atividade de fibroblastos, síntese de colágeno, expressão de fatores pró-angiogênicos, como VEGF, formação de tecido de granulação e epitelização. Esses mecanismos ajudam a explicar a redução de dor, a melhora da microcirculação e a reorganização tecidual observadas em parte dos estudos clínicos. [7]–[12]

Entretanto, a resposta terapêutica depende diretamente de parâmetros físicos e clínicos, como comprimento de onda, potência, fluência, energia por ponto, área irradiada, modo

de emissão, frequência de aplicação, tempo de exposição, técnica de contato e características da lesão. A ausência de padronização dificulta a comparação entre estudos e pode explicar resultados divergentes, especialmente quando diferentes tipos de laser são agrupados em uma mesma análise.

Diante desse cenário, o objetivo deste estudo foi realizar uma revisão integrativa da literatura para caracterizar os parâmetros técnicos e a eficácia dos lasers utilizados no tratamento de lesões cutâneas em humanos, destacando os padrões mais associados a desfechos favoráveis e as limitações que ainda impedem a definição de protocolos clínicos universais.

II. Metodologia

O presente estudo foi desenvolvido como uma revisão integrativa da literatura, método adequado para reunir e discutir evidências provenientes de diferentes delineamentos metodológicos. A escolha dessa abordagem foi justificada pela grande heterogeneidade dos protocolos de laserterapia descritos nos estudos primários, o que inviabiliza uma metanálise quantitativa rigorosa sem padronização prévia das variáveis dosimétricas.

A revisão seguiu as etapas propostas para revisões integrativas: identificação do tema e da pergunta de pesquisa; busca sistematizada na literatura; definição dos critérios de seleção; categorização dos estudos; avaliação crítica das evidências; interpretação dos resultados; e síntese do conhecimento produzido. [13]

A pergunta norteadora foi estruturada pela estratégia PICO: pacientes humanos com lesões cutâneas; intervenção com laserterapia ou fotobiomodulação; comparação com tratamento convencional, placebo, outro comprimento de onda ou ausência de laser, quando disponível; e desfechos relacionados à cicatrização, como redução da área da ferida, tempo de fechamento, melhora do tecido de granulação, epitelização, dor, inflamação e complicações locais.

As buscas foram realizadas nas bases MEDLINE/PubMed, SciELO, BVS/LILACS e Cochrane Library, contemplando publicações disponíveis até 2025. A estratégia combinou descritores e palavras-chave em português, inglês e espanhol, usando principalmente os blocos: (“low-level laser therapy” OR “laser therapy” OR “photobiomodulation” OR “laserterapia”) AND (“wound healing” OR “skin wound” OR “diabetic foot ulcer” OR “pressure ulcer” OR “venous ulcer” OR “cicatrização de feridas”). A seleção manteve os mesmos critérios de elegibilidade para todos os anos avaliados, evitando distinção metodológica entre períodos de publicação.

Foram incluídos artigos originais completos, publicados até 2025, nos idiomas português, inglês ou espanhol, que avaliaram o uso de laser no tratamento de lesões cutâneas em humanos. Foram excluídos estudos exclusivamente in vitro ou em animais, revisões de literatura, protocolos sem resultados clínicos, estudos cujo desfecho principal não fosse cicatrização/reparação tecidual e publicações sem informações mínimas sobre a intervenção com laser.

Os registros encontrados foram organizados no EndNote para remoção de duplicatas. A seleção ocorreu em duas etapas: leitura de títulos e resumos, seguida de leitura integral dos textos potencialmente elegíveis. Dois pesquisadores realizaram a seleção e a extração de dados de forma independente, com resolução de divergências por consenso e discussão com um revisor adicional. [14]

Foram extraídas as seguintes informações: título, autores, país, ano, delineamento, nível de evidência, tipo de lesão, local de aplicação, fonte de luz, comprimento de onda, modo de emissão, potência, fluência, protocolo de aplicação, resultados clínicos, presença de grupo controle e classificação de eficácia. O processo de seleção foi documentado por fluxograma PRISMA, conforme apresentado na Fig. 1 [14]. A avaliação metodológica utilizou critérios do Joanna Briggs Institute, considerando o delineamento de cada estudo; os estudos não foram excluídos apenas por menor qualidade, mas essa condição foi incorporada à interpretação crítica dos achados. [15]

Para reduzir subjetividade, a eficácia foi classificada em três níveis: alta eficácia, quando houve melhora clínica robusta ou diferença estatisticamente significativa em relação ao controle; eficácia média, quando os resultados foram parciais, dependentes de um parâmetro específico ou sustentados por delineamentos com menor força de evidência; e baixa eficácia, quando não houve benefício significativo ou quando o laser não superou o tratamento convencional ou placebo.

III. Resultados e Discussão

Foram identificados 750 registros nas bases consultadas: 25 na SciELO, 387 no PubMed/MEDLINE, 128 na BVS/LILACS e 210 na Cochrane Library. Após a remoção de 38 duplicatas, 712 estudos foram avaliados por título e resumo; 574 foram excluídos por não responderem à pergunta de pesquisa ou por não atenderem aos critérios de inclusão. Em seguida, 138 textos completos foram avaliados, dos quais 105 foram excluídos após leitura integral, resultando em 33 artigos na amostra final.

O processo de seleção é apresentado na Fig. 1, com identificação, triagem, elegibilidade e inclusão final dos estudos.

A amostra incluiu estudos publicados entre 1994 e 2025, com predomínio de ensaios clínicos randomizados ou controlados. De acordo com a classificação do JBI, a maior parte dos estudos apresentou delineamento clínico controlado, embora relatos e séries de casos ainda componham parcela relevante da amostra. Essa distribuição demonstra que existe base clínica consistente, mas parte das evidências permanece limitada por tamanho amostral, controle incompleto, protocolos associados e heterogeneidade dosimétrica.

Em relação à origem das publicações, observou-se participação expressiva de estudos brasileiros, correspondendo a 40% da amostra. Essa presença é relevante por indicar interesse nacional na aplicação clínica da laserterapia, especialmente em feridas crônicas, úlceras por pressão, úlceras diabéticas e deiscências cirúrgicas. A literatura internacional complementou a amostra com estudos da Polônia, Holanda, Egito, Estados Unidos, Canadá, China, Índia, Coreia do Sul, Suíça, França, Indonésia, Irã, Colômbia e Malásia. A distribuição temporal

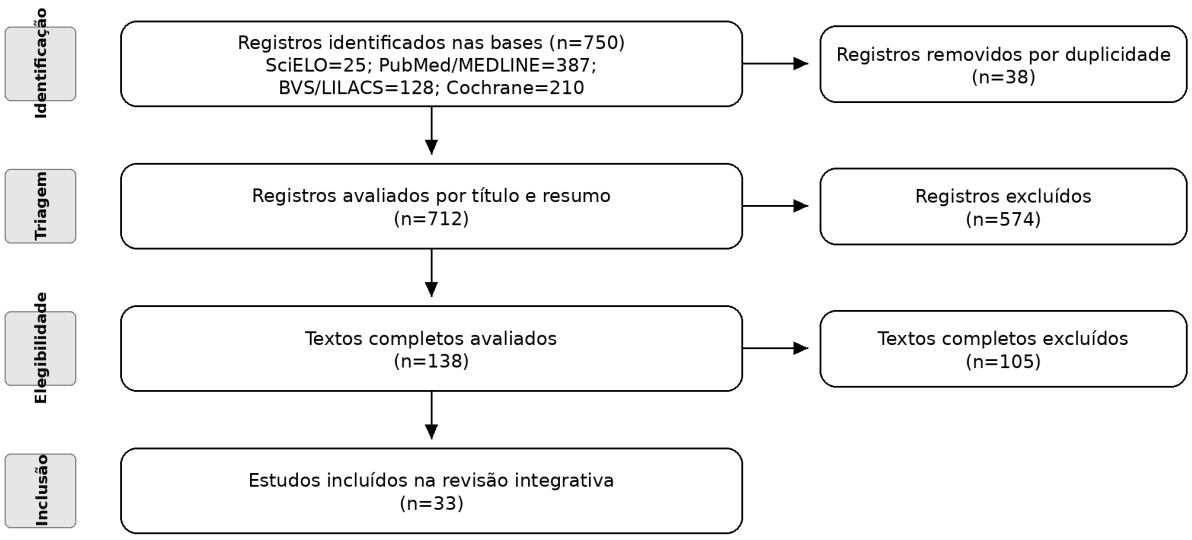

Fig. 1. Fluxograma PRISMA da seleção dos estudos.

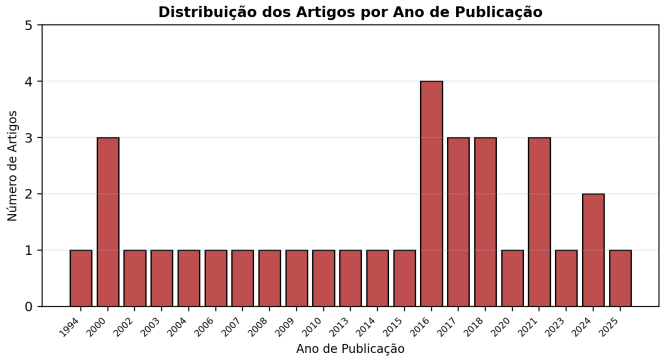

Fig. 2. Distribuição temporal dos artigos selecionados sobre laserterapia em lesões cutâneas.

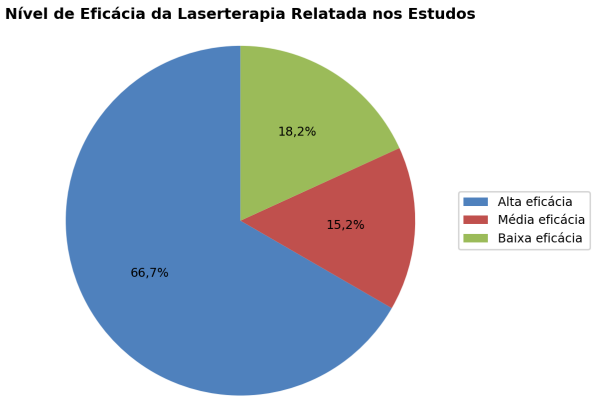

Fig. 3. Proporção do nível de eficácia clínica da laserterapia relatada nos estudos.

dos artigos incluídos é apresentada na Fig. 2, evidenciando continuidade da produção científica sobre laserterapia em lesões cutâneas entre 1994 e 2025.

A. Eficácia clínica relatada nos estudos

A análise por desfecho clínico indicou que 22 estudos (66,7%) relataram alta eficácia da laserterapia, 5 estudos (15,2%) apresentaram eficácia média e 6 estudos (18,2%) mostraram baixa eficácia, conforme sintetizado na Fig. 3. A predominância de resultados positivos sugere que o laser pode atuar como recurso adjuvante útil, mas a interpretação deve considerar o nível de evidência, o tamanho da amostra, a presença de grupo controle e a qualidade do relato dosimétrico.

Os resultados mais consistentes foram observados em úlceras diabéticas, deiscências cirúrgicas, feridas pós-operatórias e algumas feridas traumáticas. Nesses grupos, a laserterapia esteve associada à redução da área da lesão, aceleração da granulação, epitelização, diminuição de dor, menor inflamação e melhor qualidade do tecido cicatricial. Em contrapartida, os estudos com úlceras venosas e úlceras por pressão apresentaram maior heterogeneidade, incluindo resultados sem diferença significativa em relação ao controle.

Esse comportamento indica que a eficácia do laser não deve ser interpretada como propriedade universal da tecnologia, mas como resultado da interação entre o tipo de lesão, fase de cicatrização, profundidade tecidual, parâmetros físicos e frequência de aplicação. Assim, protocolos bem-sucedidos em lesões superficiais podem não gerar a mesma resposta em lesões profundas, crônicas, infectadas ou submetidas a pressão mecânica persistente.

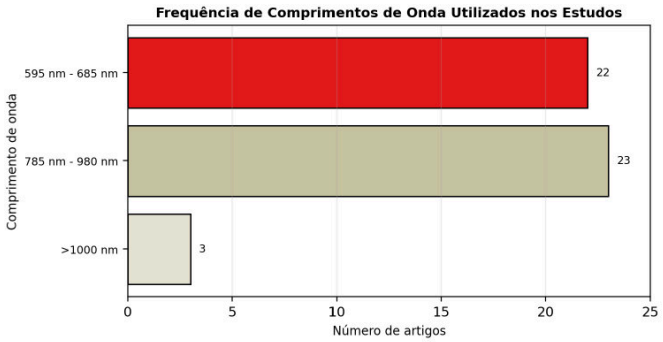

Fig. 4. Frequência das faixas de comprimentos de onda utilizadas nas intervenções com laser.

B. Comprimento de onda e profundidade de ação

O comprimento de onda foi um dos parâmetros mais relevantes para explicar as diferenças de resposta. A faixa vermelha visível, entre 595 e 685 nm, apareceu em 22 estudos e foi frequentemente associada a lesões superficiais, epitelização e modulação inflamatória local. Já o infravermelho próximo, entre 785 e 980 nm, apareceu em 23 estudos e foi utilizado especialmente em lesões mais profundas ou protocolos que buscavam maior penetração tecidual.

Apenas três estudos empregaram comprimentos de onda superiores a 1000 nm, geralmente associados a lasers de alta intensidade ou equipamentos dermatológicos específicos. Nesses casos, o mecanismo de ação pode diferir da fotobiomodulação clássica, razão pela qual a interpretação dos resultados exige cautela. Agrupar LLLT, PBM, HILT, PDL, Nd:YAG e lasers fracionados como se fossem uma única intervenção reduz a precisão científica da análise.

Os estudos comparativos indicaram que o comprimento de onda de 658 nm apresentou melhor desempenho em determinadas úlceras por pressão quando comparado aos comprimentos de 808 nm e 940 nm. Esse achado reforça que a seleção do comprimento de onda deve considerar a profundidade da lesão e os cromóforos-alvo, não apenas a disponibilidade do equipamento.

A contagem das faixas espectrais é apresentada na Fig. 4. Um mesmo estudo pôde ser contabilizado em mais de uma faixa quando utilizou múltiplos comprimentos de onda.

C. Fluência, dose e relato dosimétrico

Além do comprimento de onda, a fluência foi decisiva para a interpretação dos resultados. A maior parte dos protocolos com resposta favorável utilizou fluências entre 1 e 5 J/cm^2, embora alguns estudos tenham empregado valores menores ou muito superiores. Essa amplitude reforça a existência de uma janela terapêutica, na qual doses insuficientes podem não produzir efeito biológico relevante e doses excessivas podem gerar resposta inibitória ou efeito distinto do esperado.

Outro problema recorrente foi a omissão de informações dosimétricas completas. Em diferentes estudos, faltaram dados sobre área do spot, energia por ponto, irradiância, distância de aplicação, tempo total de exposição, número de pontos, intervalo entre sessões ou modo de emissão. Sem esses elementos, torna-se difícil reproduzir o protocolo e determinar se uma falha terapêutica ocorreu por inadequação da dose, refratariedade da lesão ou limitação metodológica do estudo.

Para fortalecer a área, futuros ensaios devem relatar, no mínimo: comprimento de onda, potência média e/ou de pico, energia por ponto, fluência, irradiância, área irradiada, modo de emissão, frequência de aplicação, número de sessões, técnica de contato ou varredura, distância do aplicador, características da ferida e terapia convencional associada.

D. Classe do laser e comparabilidade dos protocolos

Uma melhoria conceitual importante é separar os estudos por classe de laser. Os protocolos de baixa intensidade e fotobiomodulação têm como objetivo modular processos celulares sem dano térmico. Já os lasers de alta intensidade, como HILT, Nd:YAG ou sistemas Classe IV, podem combinar efeitos fotobiológicos, térmicos controlados e maior profundidade de penetração. Lasers dermatológicos, como PDL e laser fracionado não ablativo, possuem aplicação mais específica em cicatrizes e remodelação estética.

Essa separação é essencial porque protocolos com 660 nm e 4 J/cm^2 não são diretamente comparáveis a protocolos com 1064 nm, 25 J/cm^2 ou 80 J/cm^2. A ausência dessa distinção pode produzir conclusões excessivamente amplas. Portanto, a laserterapia deve ser discutida como um conjunto de modalidades ópticas, e não como uma intervenção única e homogênea.

Como síntese prática, sem propor protocolo universal, os achados indicam que lesões superficiais e fases de epitelização tendem a se beneficiar de luz vermelha, especialmente entre 660 e 685 nm, com fluências moderadas; úlceras diabéticas e lesões mais profundas aparecem com maior frequência em protocolos no infravermelho próximo, entre 785 e 980 nm; e feridas crônicas complexas exigem associação obrigatória com curativo adequado, controle de infecção, alívio de pressão, controle glicêmico, orientação do paciente e acompanhamento clínico. Assim, a laserterapia deve ser entendida como recurso adjuvante individualizado, e não como substituta do tratamento padrão.

E. Síntese dos estudos incluídos

A Tabela I apresenta a síntese dos 33 estudos incluídos, preservando autores, país, ano, nível de evidência, tipo de lesão, parâmetros técnicos e principais resultados clínicos. [16]–[45], [49]–[51]

IV. Limitações

Esta revisão apresenta limitações que devem ser consideradas. A primeira é a heterogeneidade dos estudos incluídos, que variaram quanto ao delineamento, tipo de lesão, parâmetros do laser, número de sessões e terapias associadas. A segunda é a presença de relatos e séries de casos, que são úteis para descrição clínica, mas possuem menor capacidade de generalização. A terceira é a ausência de relato dosimétrico

completo em parte da literatura, o que limita a replicabilidade dos achados.

Outra limitação é a impossibilidade de realizar metanálise quantitativa robusta, uma vez que os estudos não apresentaram padronização suficiente de parâmetros físicos e desfechos clínicos. Além disso, mesmo contemplando publicações até 2025, permanece o risco de perda de estudos publicados em bases não pesquisadas ou em literatura cinzenta. Por isso, os resultados devem ser interpretados como síntese integrativa e crítica da literatura disponível, e não como definição definitiva de protocolo terapêutico.

V. Conclusão

A laserterapia apresenta potencial como recurso adjuvante na cicatrização de lesões cutâneas em humanos, especialmente em úlceras diabéticas, deiscências cirúrgicas e feridas pós-operatórias. A maioria dos estudos analisados relatou melhora clínica, com predominância de protocolos que utilizaram comprimentos de onda no vermelho visível e no infravermelho próximo, frequentemente associados a fluências entre 1 e 5 J/cm^2.

Apesar dos resultados favoráveis, a evidência ainda é limitada pela heterogeneidade metodológica, pela inclusão de diferentes classes de laser e pela omissão de dados dosimétricos essenciais. Assim, não é adequado propor um protocolo universal a partir dos estudos disponíveis. Como síntese orientativa, os dados sustentam maior atenção aos protocolos de 660–685 nm para lesões superficiais e epitelização, e de 785–980 nm para úlceras diabéticas e lesões mais profundas, sempre como adjuvantes ao cuidado padrão. O uso clínico deve considerar tipo de lesão, profundidade, fase de cicatrização, características do paciente e parâmetros físicos do equipamento.

Recomenda-se que pesquisas futuras adotem ensaios clínicos randomizados bem controlados, com amostras maiores, descrição completa dos parâmetros ópticos e estratificação por tipo de lesão e tipo de laser. A padronização do relato técnico é condição necessária para transformar resultados promissores em protocolos seguros, reprodutíveis e baseados em evidências.

TABLE I: Apresentação dos artigos selecionados na revisão integrativa.

Artigo	Autores [ref.], país e ano	Nível	Lesão/local	Fonte de luz e parâmetros	Resultado principal
A1	Cárdenas Restrepo et al. [16], Colômbia, 1994	1.d	Queimaduras de 2^{o} e 3^{o} grau	GaAs 902 nm; modo pulsado; 292, 584 e 9344 Hz; 0,1-5 mW; 3 min/dia.	Redução clínica do tempo de hospitalização, granulação e epitelização, sem significância estatística robusta. Eficácia: baixa.
A2	Gonçalves et al. [17], Brasil, 2000	1.d	Úlceras hansênicas e não hansênicas	HeNe 632,8 nm; fluência 4 J/cm^2; potência descrita no original como 4,8 W.	Cicatrização total em 66,7% das úlceras hansênicas e 53,3% das não hansênicas; redução de dor, edema e exsudato. Eficácia: alta.
A3	Lucas et al. [18], Holanda, 2000	1.c	Úlceras de pressão estágio III	Cluster GaAl 904 nm; pulsado; 830 Hz; potência média 8 mW; 1 J/cm^2.	Sem diferença significativa em relação ao controle; o grupo controle apresentou maior redução mediana. Eficácia: baixa.
A4	Simunovic et al. [19], Suíça, 2000	1.c	Feridas cirúrgicas traumáticas em tecidos moles	GaAlAs 830 nm contínuo, 120 mW; HeNe 632,8 nm 10 mW + IR 904 nm pulsado.	Aceleração da cicatrização entre 25% e 35%, com alívio de dor e recuperação funcional precoce. Eficácia: alta.
A5	Franek et al. [20], Polônia, 2002	1.d	Úlcera crural venosa	GaAlAs 810 nm; contínuo; 65 mW; 4 J/cm^2.	Redução em todos os grupos, sem superioridade estatística do laser sobre placebo ou tratamento convencional. Eficácia: baixa.
A6	Lucas et al. [21], Holanda, 2003	1.c	Úlceras de pressão estágio III	GaAs 904 nm; pulsado 830 Hz; 12 diodos; 1 J/cm^2.	Não houve diferença significativa na redução absoluta ou relativa da ferida. Eficácia: baixa.
A7	Hopkins et al. [22], Estados Unidos, 2004	1.c	Abrasões superficiais padronizadas	Cluster multicomprimento: 820, 660, 950, 870, 880 e 940 nm; 700 Hz; 8 J/cm^2.	Contração significativamente maior nos dias 6, 8 e 10, inclusive com possível efeito sistêmico indireto. Eficácia: alta.
A8	Fernandes et al. [23], Brasil, 2007	4.d	Úlcera varicosa em paciente diabético	HeNe 632,8 nm; modo pontual; 4 min; 6 J/cm^2.	Redução aproximada de 50% da área em 5 dias, com melhora de edema e inflamação. Eficácia: média, por tratar-se de relato/caso limitado.
A9	Saltmarche [24], Canadá, 2008	4.c	Úlceras de pressão, diabéticas, venosas e feridas agudas/crônicas	MedX 1000; 785 nm; sonda 50 mW e clusters 80 mW; doses de 1-6 J conforme região.	Fechamento $\geq$50% em 61,9% das feridas e cicatrização completa em 42,9%. Eficácia: média.
A10	Stefanello e Hamerski [25], Brasil, 2006	4.d	Úlcera de pressão grau II	AsGa 904 nm; 45 mW; 6 J/cm^2; aplicação pontual nas margens e varredura no leito.	Cicatrização completa após 14 aplicações em 7 semanas. Eficácia: alta.
A11	Pinto et al. [26], Brasil, 2009	4.d	Deiscência aguda de safenectomia	Diodo 685 nm; 20 mW; 4,5 J/cm^2.	Cicatrização total na 9^{a} sessão e importante efeito analgésico desde as primeiras sessões. Eficácia: alta.
A12	Barreto e Salgado [27], Brasil, 2010	1.c	Úlceras em pacientes com sequelas de hanseníase	InGaIP 660 nm; contínuo; 40 mW; 4 J/ponto nas bordas e 2 J/cm^2 no leito.	Sem diferença significativa em área, profundidade ou escores de cicatrização. Eficácia: baixa.
A13	Taradaj et al. [28], Polônia, 2013	1.c	Úlceras de pressão estágios II e III	GaAlAs 940, 808 e 658 nm; contínuo; 50 mW; 4 J/cm^2.	O comprimento de onda de 658 nm foi superior; 808 e 940 nm não diferiram do placebo. Eficácia: média, dependente do comprimento de onda.
A14	Ha et al. [29], Coreia do Sul, 2014	4.c	Cicatrizes recentes de tireoidectomia	PDL 595 nm; NAFL 1550 nm; parâmetros específicos de pulso, fluência e densidade.	Melhora estética significativa com ambos os lasers, sem diferença entre as técnicas. Eficácia: alta.
A15	Palagi et al. [30], Brasil, 2015	4.d	Úlcera de pressão estágio III	AlGaInP 660 nm; emissão contínua/pulsada; 4 J/cm^2.	Redução de 7 x 6 cm para 1,5 x 1,1 cm em 5 semanas, com melhora do tecido de granulação. Eficácia: alta.
A16	Carvalho et al. [31], Brasil, 2016	1.c	Úlceras diabéticas	Laser HTM 658 nm; contínuo; 30 mW; 80 s/ponto; 4 J/cm^2.	Redução significativa da dor e da área da úlcera em comparação ao controle. Eficácia: alta.
A17	Mathur et al. [32], Índia, 2016	1.c	Úlceras diabéticas	Diodo 660 $\pm$ 20 nm; ~50 mW/cm^2; 60 s/ponto; 3 J/cm^2.	Redução média de 37% no grupo laser contra 15% no controle. Eficácia: alta.
A18	Ojea et al. [33], Brasil, 2016	1.c	Ferida cirúrgica após cirurgia bariátrica aberta	Diodo 808 nm; contínuo; 100 mW; 10 J/cm^2; 2 J/ponto.	Redução de seroma, dor, inflamação e melhor coaptação das bordas. Eficácia: alta.
A19	Piedade [34], Brasil, 2016	4.c	Úlceras crônicas diabéticas e de pressão	AsGa 904 nm; protocolos de 0,28 J/cm^2 e 4 J/cm^2 associados à drenagem linfática.	Ambos estimularam reparo; protocolo de 4 J/cm^2 foi substancialmente superior. Eficácia: média.
A20	Fialho et al. [35], Brasil, 2017	4.c	Úlceras por pressão estágios III e IV	HeNe 632,8 nm e AsGa 904 nm; 5 J/cm^2; 2 vezes/semana.	Dois pacientes cicatrizaram completamente; adesão e autocuidado influenciaram o resultado. Eficácia: alta.
A21	Srilestari et al. [36], Indonésia, 2017	1.c	Úlceras de pé diabético graus 1 e 2	Diodo 630 nm; 100 mW; laser-acupuntura e varredura sobre a úlcera.	Maior redução da área da úlcera em relação ao controle na 4^{a} semana. Eficácia: alta.
A22	Vitse et al. [37], França, 2017	1.c	Úlceras venosas crônicas	MLS 635 nm; 17,5 mW/diodo; 2,95 J/cm^2; 20 min; 2 vezes/semana.	Sem diferença na taxa de fechamento; redução tardia de dor. Eficácia: baixa.
A23	Kazemikhoo et al. [38], Irã, 2018	1.c	Deiscência de enxerto de pele pós-queimadura	650 nm contínuo, 150 mW, 2 J/cm^2; 808 nm contínuo, 4 J/cm^2.	Redução significativa da deiscência e melhora do prognóstico do enxerto. Eficácia: alta.
A24	Taradaj et al. [39], Polônia, 2018	1.c	Úlcera de pressão estágios II a IV	GaAlAs 940, 808 e 658 nm; contínuo; 4 J/cm^2; 5 vezes/semana.	Apenas 658 nm reduziu marcadores inflamatórios e estimulou angiogênese. Eficácia: média.
A25	Thabet et al. [40], Egito, 2018	1.c	Retardo de cicatrização em incisão de cesárea	Nd:YAG 1064 nm; pulsado; 3 kW de pico; 25 J/cm^2; 3 vezes/semana.	Redução altamente significativa do tamanho da ferida e melhora da aparência. Eficácia: alta.
A26	Pereira et al. [41], Brasil, 2020	4.c	Úlcera isquêmica iatrogênica pós-prótese total	Laser de alta potência 980 nm; contínuo; 10 W; 3,18 J/cm^2; feixe desfocado.	Granulação e redução considerável em lesão refratária à oxigenoterapia hiperbárica. Eficácia: alta.
A27	Breder et al. [42], Brasil, 2021	4.d	Deiscência de incisão de cesárea	Diodo 632,8 nm; 25 mW; 4 J/cm^2; associado a gel de barbatimão.	Cicatrização completa após 84 dias e cicatriz quase imperceptível. Eficácia: alta.
A28	Lu et al. [43], China, 2021	1.c	Feridas crônicas refratárias	Laser de alta intensidade BTL-6000; 1064 nm; contínuo; 8 W; 80 J/cm^2.	Redução significativa dos escores BWAT e PUSH em comparação ao curativo convencional. Eficácia: alta.
A29	Nair et al. [44], Malásia, 2021	4.d	Úlceras crônicas de diferentes etiologias	K-Laser Classe IV; 660, 800 e 970 nm; contínuo; 30 kJ em 3 min.	Quatro úlceras fecharam totalmente e as demais reduziram 68,2%-99% em 4 semanas. Eficácia: alta.
A30	Esmael et al. [45], Egito, 2023	1.c	Úlceras crônicas de pé diabético	Diodo Classe IV; 980, 915, 810 e 650 nm; até 24 W; até 20 kHz.	Modo sincronizado alcançou 60% de fechamento total contra 26,7% no modo separado e 6,7% no controle. Eficácia: alta.
A31	Torkaman et al. [49], Irã, 2024	1.c	Úlcera de pé diabético	GaAs 904 nm; 2 J/cm^2; 90 W; 3 vezes/semana; associado ao cuidado convencional.	Houve maior redução percentual da área da úlcera e modulação de marcadores angiogênicos relacionados a HIF-1α, VEGF e receptor específico. Eficácia: alta.
A32	Saura Cardoso et al. [50], Brasil, 2024	1.c	Úlceras de pé diabético não infectadas	GaAs 904 nm; densidades de 4, 8 e 10 J/cm^2; ensaio randomizado, duplo-cego e placebo-controlado.	Todas as doses ativas reduziram significativamente a área das úlceras; 10 J/cm^2 apresentou maior taxa de cicatrização completa e melhor resposta no seguimento. Eficácia: alta.
A33	Bezerra Miranda et al. [51], Brasil, 2025	1.c	Úlceras de pé diabético	Laser 660 nm com 4, 8 e 12 J/cm^2; comparação com infravermelho 904 nm a 10 J/cm^2; tratamento convencional associado.	As doses de 8–12 J/cm^2 em 660 nm e 10 J/cm^2 em 904 nm melhoraram significativamente a cicatrização em 10 semanas. Eficácia: alta.

AGRADECIMENTOS

Os autores agradecem à Fundação de Apoio à Pesquisa do Distrito Federal (FAPDF) pelo apoio financeiro ao projeto "Desenvolvimento e Construção de um Laser Sintonizável em Aplicações de Cicatrização da Pele" (2022–2024), que contribuiu para a infraestrutura e para o desenvolvimento científico relacionado a esta pesquisa.

***Abstract*— A 63-year-old man with acute anteroseptal ST-segment elevation myocardial infarction underwent primary percutaneous coronary intervention followed by adjunctive photobiostimulation (PBST), initiated 18 days after the ischemic event. PBST was delivered to the anterior thoracic region using a wearable 940-nm near-infrared light-emitting diode device. Serial echocardiography and myocardial perfusion SPECT were performed over one year. LVEF assessed by the biplane Simpson method increased from 46% at baseline to 61% at 120 days, with preserved systolic function on subsequent assessments. Global longitudinal strain was 23% at 120 days. Indexed LV end-diastolic volume remained stable (65.5 to 61.0 mL/m²), without progressive ventricular dilatation. Serial SPECT demonstrated a persistent fixed perfusion defect without reversible ischemia and preserved global ventricular function. Despite recognized risk factors for adverse remodeling, sustained functional recovery was observed. Although no causal relationship between PBST and ventricular recovery can be established from this single observation, these findings support further investigation of PBST as a potential adjunctive strategy after myocardial infarction.**

Keywords*— ST-segment elevation myocardial infarction; Photobiomodulation; Ventricular remodeling; Left ventricular function;*

I. INTRODUCTION

Acute myocardial infarction (MI) remains a major cause of cardiovascular morbidity and mortality. Myocardial injury resulting from ischemia may lead to left ventricular dysfunction, adverse ventricular remodeling, and subsequent heart failure [1]. Early reperfusion combined with antithrombotic therapy has significantly reduced both short- and long-term mortality following MI; however, mortality remains substantial, particularly during the acute phase and the first year after the event [2].

The myocardium has a high energy demand required to sustain specialized cellular processes and possesses a limited capacity to store substrates involved in glycolipid metabolism, mitochondrial oxidative phosphorylation, and adenosine triphosphate (ATP) production and utilization [3], [4]. Myocardial ischemia triggers a complex cascade of events, including alterations in energy metabolism, mitochondrial dysfunction, increased oxidative stress, dysregulation of intracellular calcium homeostasis, and activation of inflammatory and neurohumoral pathways involving the renin–angiotensin system [3], [5], [6]. These mechanisms contribute to apoptosis, fibrosis, and structural alterations in the myocardium, resulting in cardiac remodeling and directly affecting left ventricular function and clinical outcomes [7], [8].

Although early myocardial revascularization significantly reduces the extent of ischemia, ischemia-reperfusion (I/R) injury and persistent microvascular dysfunction can limit myocardial functional recovery, favoring adverse ventricular remodeling [3], [5], [9]. Consequently, adjunctive therapeutic strategies targeting inflammatory pathways, cellular bioenergetics, and preservation of myocardial viability have emerged as promising areas of investigation.

Photobiostimulation (PBST) involves the application of non-ionizing light, mainly in the red (λ = 650 nm) and near-infrared (NIR; λ = 700–1000 nm) spectral ranges, inducing photochemical responses that may subsequently lead to photobiomodulation (PBM) of cellular processes.

At the cellular level, PBST induces photochemical reactions that may modulate ATP production, reactive oxygen species (ROS) generation, inflammatory signaling pathways, nitric oxide (NO) release, and intracellular calcium (Ca^{2+}) homeostasis [10]. Experimental studies have suggested a cardioprotective role for PBST in ischemia–reperfusion injury, demonstrating reductions in infarct size and attenuation of pathological ventricular remodeling [6], [11]. These effects are thought to be mediated through improvements in mitochondrial function, cellular bioenergetics, and regulation of oxidative and inflammatory responses. However, clinical evidence supporting the use of PBST in patients following acute myocardial infarction remains limited and inconclusive.

Therefore, the present report aims to describe the longitudinal recovery of left ventricular function in a patient with acute myocardial infarction who received PBST as an adjunctive therapy to conventional treatment.

II. CASE REPORT

A 63-year-old man with a history of hypertension, dyslipidemia, chronic kidney disease, overweight, and prior smoking was admitted with an acute anteroseptal ST-segment elevation myocardial infarction (STEMI), confirmed by electrocardiographic findings and elevated cardiac biomarkers. Coronary angiography revealed multivessel coronary artery disease with thrombotic occlusion of the mid-left anterior descending artery (LAD). Primary percutaneous coronary intervention (PCI) with drug-eluting stent implantation was successfully performed, restoring TIMI grade 3 flow. A staged revascularization procedure was

subsequently completed for additional significant coronary lesions.

Transthoracic echocardiography performed within the first 24 hours demonstrated left ventricular systolic dysfunction, with a left ventricular ejection fraction (LVEF) of 46% by the biplane Simpson method, associated with regional wall motion abnormalities involving the anterior and anteroseptal segments. Right ventricular systolic function was preserved (TAPSE 21 mm).

The patient remained hemodynamically stable throughout hospitalization and was discharged on the eighth day, receiving guideline-directed medical therapy for secondary prevention after myocardial infarction.

A. Photobiostimulation Protocol

Photobiostimulation (PBST) was initiated 18 days after myocardial infarction as an adjunctive therapy to standard medical treatment. The protocol was developed based on experimental and clinical literature on photobiostimulation and near-infrared photobiomodulation [12], [13].

PBST was administered using a wearable vest-like device designed to cover the torso and deliver transcutaneous irradiation to the anterior thoracic region over a treatment area of 2088 cm² with dimensions of 58 × 36 cm. The device incorporated 300 uniformly distributed light-emitting diodes (LEDs) emitting near-infrared light at 940 nm. Treatment was delivered at a total nominal optical power of 6 W, corresponding to a calculated average surface irradiance of approximately 2.9 mW/cm². The radiant exposure (fluence) was 3.5 J/cm², corresponding to a total photonic energy of 7200 J per session. Each session lasted 20 minutes, and the system was powered by a low-voltage (12 V) power supply.

For transcutaneous thoracic irradiation with near-infrared light at 940 nm, a simplified optical propagation model is proposed. In this conceptual model, incident photons undergo multiple scattering events, resulting in three-dimensional redistribution of optical energy that may be approximated, for conceptual purposes, by a diffuse Lambertian model, together with absorption by tissue chromophores and molecular photoacceptors. Absorption of photonic energy by mitochondrial photoacceptors, including cytochrome c oxidase (CCO), may modulate respiratory chain activity, mitochondrial membrane potential, and the proton gradient, thereby favoring ATP synthesis. These initial photochemical events characterize photostimulation and may trigger downstream cellular signaling cascades, subsequently resulting in photobiomodulation (PBM) of cellular and metabolic processes. This model is conceptual and does not permit direct determination of photon distribution or the optical dose effectively delivered to the myocardium.

The treatment protocol initially consisted of daily sessions administered at 24-hour intervals. Beginning in the third month, treatment frequency was gradually reduced, reaching two sessions per week by the end of the fourth month. PBST was discontinued after completion of the four-month treatment protocol.

B. Ethical Aspects

This case report was approved by the Research Ethics Committee under CAAE No. 76100023.1.0000.5492, opinion No. 6.657.464. The study was conducted in accordance with the ethical principles of the Declaration of Helsinki and national standards for research involving human subjects.

III. CLINICAL EVOLUTION

Myocardial perfusion single-photon emission computed tomography (SPECT) with technetium-99m sestamibi (^99mTc-sestamibi) and dipyridamole stress was performed 54 days after myocardial infarction (36 days after initiation of PBST). Quantitative perfusion analysis yielded a summed stress score (SSS) of 10 and a summed rest score (SRS) of 10, reflecting perfusion abnormalities during stress and rest, respectively. The resulting summed difference score (SDS = SSS − SRS) was 0, indicating a fixed perfusion defect without a reversible ischemic component. Global left ventricular wall motion was preserved, although systolic thickening was reduced in the affected segments. Stress left ventricular ejection fraction (LVEF) was 53% (Fig. 1).

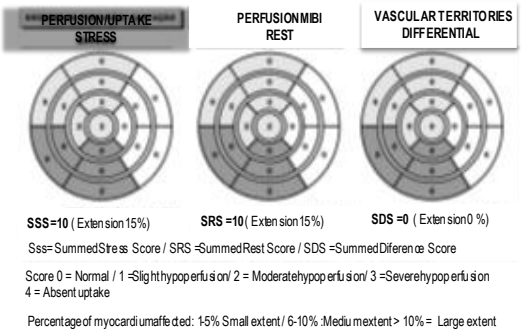

Fig. 1: Myocardial perfusion SPECT polar maps at rest and during pharmacological stress showing a persistent fixed perfusion defect involving approximately 15% of the LV myocardium (SSS=10, SRS=10, SDS=0), without reversible ischemia. Gated SPECT demonstrated preserved global LV systolic function.

Serial echocardiography demonstrated the recovery and subsequent preservation of left ventricular systolic function. LVEF assessed using the biplane Simpson method increased from 46% at baseline to 61% at 120 days. Subsequent assessments using other methods also demonstrated preserved systolic function, although values obtained using different techniques are not directly interchangeable. At 120 days, LV dimensions and regional wall motion were preserved, with a mean global longitudinal strain (GLS) magnitude of 23%. After one year, LV dimensions remained normal (LV end-diastolic diameter [LVEDD], 51 mm; LV end-systolic diameter [LVESD], 34 mm), with LVEF values of 62% by the Teichholz method and 70% by the cube method, and mild residual hypokinesis of the mid and apical anterior and septal segments. Indexed LV end-diastolic volume remained stable, from approximately 65.5 mL/m² at baseline to 61.0 mL/m² at one year, with no evidence of progressive LV dilatation. Baseline indexed LV end-systolic volume was unavailable, precluding serial comparison of this parameter.

At late follow-up, myocardial perfusion SPECT demonstrated persistent fixed perfusion abnormalities, with unchanged quantitative perfusion scores (SSS = 10, SRS = 10, SDS = 0; 15% extent) and no inducible ischemia. Global LV wall motion remained preserved, with reduced systolic thickening in the affected segments, while stress LVEF increased from 53% on the initial SPECT to >70% at follow-up. Thus, serial SPECT demonstrated an improved global functional response without a measurable change in perfusion defect burden.

During follow-up, serial imaging demonstrated recovery and sustained preservation of left ventricular systolic function, without evidence of significant reversible ischemia or progressive ventricular dilatation. These findings occurred in the context of optimized guideline-directed medical therapy with adjunctive PBST. Fig. 2 illustrates the temporal evolution of LVEF during follow-up, with values presented according to imaging modality and measurement method.

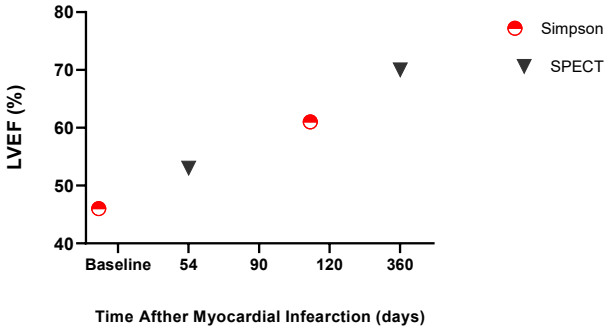

Fig. 2. Temporal evolution of left ventricular ejection fraction (LVEF) after acute myocardial infarction. Echocardiographic LVEF assessed by the biplane Simpson method increased from 46% at baseline to 61% at 120 days. Stress gated-SPECT LVEF was 53% at day 54 and >70% at follow-up.

IV. DISCUSSION

Patients with ST-segment elevation myocardial infarction (STEMI) experience substantial morbidity and mortality, frequently associated with the development of adverse ventricular remodeling. This process results from the activation of inflammatory and neurohumoral pathways triggered by the ischemic event. These pathways lead to alterations in gene expression and in molecular, cellular, and interstitial processes, ultimately resulting in structural and functional changes of the left ventricle. Many of these changes are closely linked to energy metabolism [14].

Post-infarction prognosis is influenced by multiple factors, including infarct size, time to reperfusion, multivessel coronary artery disease, and chronic kidney disease. In the present case, the patient presented a combination of characteristics recognized as major determinants of adverse ventricular remodeling and unfavorable clinical outcomes.

The inflammatory response triggered by myocardial ischemia develops predominantly during the first weeks following infarction, whereas neurohumoral activation may persist for up to six weeks after the acute event [15]. Although early reperfusion of the infarct-related artery is essential for preserving viable myocardium, restoration of epicardial coronary flow does not necessarily guarantee adequate microvascular perfusion. Consequently, microvascular obstruction and ischemia–reperfusion injury may occur despite successful revascularization [5], [9]. Microvascular obstruction may persist for up to three months after infarction, contributing to increased myocardial stiffness, reduced ventricular compliance, and impaired recovery of left ventricular function [16], and has been identified as an independent predictor of persistent ventricular dysfunction [17].

In the present report, photobiostimulation (PBST) was introduced as an adjunctive therapy during a phase characterized by intense inflammatory activity, tissue remodeling, and metabolic adaptation. From a pathophysiological perspective, PBST may modulate cellular bioenergetics, ATP production, oxidative stress, and inflammatory signaling pathways potentially relevant to post-infarction ventricular remodeling. In an experimental model, Feliciano et al. demonstrated that PBST modulated transcriptional and post-transcriptional pathways associated with post-infarction remodeling, including inflammation, apoptosis, myocardial hypertrophy, calcium handling, cellular metabolism, oxidative stress, and extracellular matrix regulation [6]. However, clinical evidence in acute myocardial infarction remains limited. A small clinical study reported lower troponin-T levels following adjunctive low-level laser therapy but no significant between-group difference in LVEF at 9 months [20].

The biological effects of PBST originate from the delivery of optical energy to biological tissues. Following photon absorption by intracellular photoacceptors, photophysical and photochemical events may modulate mitochondrial activity, cellular bioenergetics, redox signaling, and nitric oxide bioavailability. These responses may subsequently lead to photobiomodulation (PBM) of cellular processes and inflammatory pathways potentially relevant to post-infarction ventricular remodeling.

Longitudinal evaluation with serial imaging demonstrated recovery and sustained preservation of left ventricular systolic function. LVEF assessed using the same biplane Simpson method increased from 46% at baseline to 61% at 120 days. Subsequent assessments using other methods also demonstrated preserved systolic function, although values obtained by different techniques are not directly interchangeable. At 120 days, mean global longitudinal strain (GLS) magnitude was 23%, and ventricular dimensions remained preserved. Indexed LV end-diastolic volume remained stable, from approximately 65.5 mL/m² at baseline to 61.0 mL/m² at one year, supporting the absence of progressive ventricular dilatation.

Serial myocardial perfusion SPECT provided complementary functional and perfusion information. Quantitative perfusion abnormalities remained unchanged during follow-up (SSS = 10, SRS = 10, SDS = 0; 15% extent), indicating persistence of a fixed perfusion defect without a reversible ischemic component. Global ventricular function remained preserved, while stress LVEF increased from 53% on the initial study to >70% at late follow-up. These findings demonstrate an increased stress LVEF at late follow-up without a measurable change in fixed perfusion defect burden.

Post-infarction LVEF recovery is heterogeneous. Contemporary cohorts have reported median absolute LVEF improvements of approximately 6%–8%, with substantial interindividual variability [8], [18]. In the PREDICTS study, involving patients with more severe baseline systolic dysfunction, 26% recovered to an LVEF ≥50% at approximately 90 days after myocardial infarction, whereas the majority remained with persistent degrees of ventricular dysfunction [19]. Although these populations are not directly comparable with the present case, they provide clinical context for the magnitude of functional recovery observed.

Nevertheless, these findings should be interpreted in light of the limitations of a single-case observation. Recovery of ventricular function may reflect established mechanisms, including successful reperfusion, myocardial viability, recovery of stunned myocardium, and optimized guideline-directed medical therapy. Therefore, no causal relationship between PBST and ventricular recovery can be established. The sustained preservation of systolic function and stable ventricular dimensions observed during follow-up support further investigation of PBST as a potential adjunctive strategy after acute myocardial infarction.

V. CONCLUSION

This exploratory case report demonstrated sustained recovery of left ventricular function following acute myocardial infarction, with preserved ventricular dimensions and no evidence of progressive ventricular dilatation over one year of follow-up. Although no causal relationship between PBST and ventricular recovery can be established from a single observation, the favorable functional evolution observed supports further investigation of PBST as a potential adjunctive strategy for post-infarction ventricular recovery.

***Abstract*—Kinematic assessment of the upper limb is relevant in several neurological and musculoskeletal conditions, but in clinical settings it is generally restricted to laboratories, since it depends on marker-based camera systems and instrumented gloves, which are expensive and impractical for clinical routine. This paper proposes a new measure, the position of the hand and fingertips along the trajectory, obtained by an omnidirectional vision system, formed by a camera and a hyperbolic mirror, embedded in an instrumented replica of a water cup that captures images of the hand during grasping, and presents a qualitative and observational proof of concept of this measure. The measure recovers hand transport and finger aperture modulation throughout reach-to-grasp, whose synchronization is the most compromised after injuries, particularly neurological ones. In the qualitative evaluation of the proposal, we used data from experiments in which, together with the device images, data from a motion tracking system were collected; the markers of this system are projected onto the unrolled images of the device, through a registration between the coordinate systems followed by projection using the numerical model of the vision system obtained by calibration. The consistent overlap of the markers onto the corresponding regions of the hand allows a qualitative evaluation of the proposed measurement. The device also has an inertial measurement unit, which provides complementary measures of phase timing, smoothness, and tremor, acquired in synchrony with hand posture. The device thus offers potential as a portable alternative of reduced cost relative to laboratory systems to bring kinematic assessment of the upper limb to clinical settings outside major centers.**

I. Introduction

Drinking water is one of the activities of daily living (ADLs) most commonly used to assess and exercise upper-limb motor function, both in healthy adults [1] and typically developing children [2], as well as in individuals with a wide range of conditions, such as stroke [3], spinal cord injury [4], Parkinson's disease [5], cerebral palsy [6], chronic shoulder pain [7], and essential tremor [8]. In these conditions, upper-limb dysfunction compromises the performance of ADLs such as reaching for and grasping objects [9]. Two experimental protocols have been widely used to investigate these dysfunctions: *reach-to-grasp*, which analyzes the synchronization between hand transport toward the object and finger aperture for grasping [10], and *drinking from a glass*, which adds the transport of the cup to the mouth and the return to the initial position, constituting a complete functional task [3].

Kinematic assessment of these tasks provides quantitative variables that make it possible to understand the dysfunctions, that is, how each condition affects the upper limb, to track rehabilitation progress, and to support objective measures for research and scientific advancement. In stroke, for example, one of the most studied conditions, these variables reveal reduced peak velocity, longer movement time, lower trajectory smoothness, and loss of synchronization between hand transport and finger aperture, with maximum aperture tending to occur prematurely [10].

Acquiring these variables depends on marker-based optical tracking systems, which require a dedicated room with con-

trolled lighting, careful placement of markers on anatomical landmarks, and calibration. These requirements make frequent assessments and longitudinal follow-up unfeasible in clinical settings.

Beyond infrastructure requirements, optical tracking systems themselves present intrinsic technical limitations: occlusion of markers by body segments or by the manipulated object interrupts trajectories and requires interpolation, and label swapping between nearby markers introduces errors that are difficult to detect automatically. The hand is particularly poorly served, since the thumb joints, among the most affected in several neurological conditions, are among the least accessible to markers, and instrumented gloves, the usual alternative for the hand, are incompatible with severe spasticity. Together with infrastructure requirements, these limitations concentrate kinematic assessment in a few specialized centers and require patients and caregivers to travel for each session, imposing logistical and financial barriers that hinder and often prevent access, especially in remote and low-income regions.

Recent initiatives seek to overcome these limitations with portable, low-cost devices. Wearable inertial measurement units (IMUs) have been used to estimate clinical metrics and to characterize tremor and movement smoothness, counting movement units during the drinking task [11]. The smart cup of Bobin et al. [12] is a representative example: instrumented with inertial and pressure sensors, it monitors arm and hand activity during the drinking task, which is itself an ADL. However, isolated IMUs do not capture hand posture, and the metrics obtained with these systems still do not achieve full clinical reliability for use as reference values in rehabilitation [11].

A previously proposed device, named GULMN [2], [13], [14], integrates, in a single instrumented object, an omnidirectional vision system, formed by a camera and a hyperbolic mirror that captures images of the hand during grasping, and an IMU that provides kinematic data of the limb. Unlike wearable IMUs and the cup of Bobin et al., the embedded image provides, in synchrony with the inertial data, a direct observation of hand posture during grasping.

The objective of this paper is to present a new measure of the device, the position of the fingers and the palm of the hand along the trajectory, obtained from the omnidirectional images captured with the device, and also to carry out an observational proof of concept of this measure. Sections II and III describe the device and its measurement capabilities. Section IV proposes the new measure and Section V presents its proof of concept. Sections VI and VII discuss and conclude.

II. Device Design and Construction

The device is a replica of a transparent acrylic cylindrical cup, approximately 159.6 mm in height, 70 mm in diameter, and with a mass of approximately 250 g [14]. The cup is instrumented with two measurement subsystems, an omnidirectional vision system, formed by a camera and a hyperbolic mirror, that captures images of the hand during grasping, and an IMU. The hyperbolic mirror is mounted just below the cup's cap, above the transparent acrylic cylinder, and the base of the cup houses the camera, the mirror, and the IMU [14]. The camera and the IMU transmit their data by cable to an external computer, which performs acquisition and storage, at a sampling rate of 90 Hz [14]. All data are acquired synchronously (Fig. 1).

Figure 1. The instrumented cup and its measurement subsystems. Source: adapted from [14].

The most innovative measurement of the device is the omnidirectional image, obtained by a camera and a hyperbolic mirror, a configuration developed mainly in the context of mobile robotics [15], [16]. The camera, a BASLER acA1300-30gm with a resolution of 1280×960 pixels, is housed at the base of the cup and captures the image reflected by the mirror [14], with the requirement of obtaining the best possible resolution within the reduced dimensions of the cup. The mirror, made of aluminum, is machined on an ultra-precision lathe with a final finish by polishing with a synthetic diamond micro-tool, and is mounted just below the cap [14].

Through the image, the innovative data obtained in previous work is the posture of the hand while grasping the object [2], [13], [14]. The raw image captured by the camera is omnidirectional and maps the cylindrical surface around the cup onto a circular region of the sensor (Fig. 2). For the assessment of hand posture, this image is unrolled into a planar cylindrical panorama view, in which the angle around the cup and the height along it become orthogonal axes (Fig. 3). The reconstruction uses the calibrated geometry of the vision system to map each pixel to a direction in the scene: the calibration recovers the mapping between the radial position in the image and the height, or equivalently the inclination, over the cylindrical surface of the cup, while the azimuthal angle around the cup is preserved in the image [17].

An IMU embedded in the base of the cup (Bosch BNO055), with a triaxial gyroscope, accelerometer, and magnetometer, measures sagittal-plane acceleration and angular velocity dur-

ing the task and, by combining these signals, estimates the orientation and angular displacement of the limb, transmitted by cable at 90 Hz [14].

III. Measurement Capabilities

The capabilities reported here were established in previous work with the device, in which three groups of volunteers, namely typically developing children [2], healthy adults [14], and stroke survivors [13], [14], performed the drinking task. The study with typically developing children characterized grasp posture and spatiotemporal metrics across development [2]; the study with stroke survivors compared the more- and less-affected hands before and after rehabilitation [13]; and the doctoral thesis consolidated the methodology, bringing together temporal and spectral metrics, hand segmentation, and validation of the abduction angle [14]. The following observations are qualitative and are intended to illustrate the relevance of each measurement.

A. IMU-Based Measures

The IMU signals, acquired in synchrony with the grasping images, provide linear acceleration, angular velocity, and orientation of the limb throughout the task. The joint analysis of the resultant acceleration and sagittal-plane orientation locates the instants that delimit the movement, namely contact with the cup, movement onset, maximum amplitude near the mouth, contact with the table, and release, which define the accommodation, transport, and return phases (Fig. 4) [2], [13]. From this segmentation are derived the total duration and the duration of each phase, the hand accommodation time, mean and peak velocity parameters, the number of movement units, the straightness index, and the energy expenditure [2].

Orientation, angular velocity, and linear acceleration are well established in upper-limb biomechanics, including assessment after neurological injuries [3]. The measure proposed here is the temporal relationship between the grasping time, that is, the hand accommodation time, and the total task time. Stroke survivors showed a significantly longer grasping time in the more-affected hand, both in absolute and proportional terms, and a shorter total task time in the less-affected hand [13]; in longitudinal follow-up, this time decreased and correlated with standard assessments [14], suggesting its use for tracking grasp recovery.

Human movement has an average maximum frequency of approximately 2 Hz, and velocity oscillations above this value are identified as tremor. The device estimates trajectory smoothness by applying the fast Fourier transform to the angular velocity and relating the energy between 0 and 2 Hz, typical of healthy movement, to the energy between 2 and 6 Hz, typical of tremor. In the thesis that consolidated the methodology, the resulting spectral metric was consistently higher in the more-affected hand of stroke survivors than

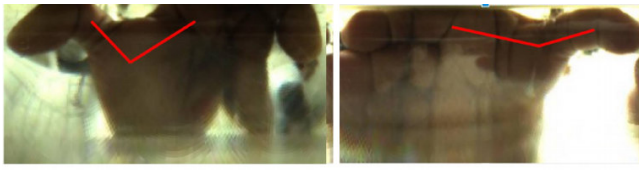

Figure 5. Grasping images of the more-affected (left) and less-affected (center) hand of a stroke survivor, with the thumb abduction angle indicated, and of a typical hand (right). Source: adapted from [13] and [2].

in the less-affected hand, correlated strongly with standard clinical tests, and tracked patient progress in the longitudinal experiments [14].

B. Hand Posture During Grasping from the Images

From the reconstructed images, the geometric analysis of posture provides thumb opposition, finger recruitment, and the abduction angle between the thumb and index finger [2], [14].

The main innovation of the device is the image of hand posture during grasping, particularly the abduction angle between the thumb and index finger (Fig. 5). The abduction angle is particularly promising for assessment, since the joints involving the thumb and index finger are among the most affected in several neurological conditions. The device also revealed the development of grasp posture in typically developing children, with the thumb opposing toward the palm in younger children and toward the index finger, closer to the adult pattern, in older children [2].

IV. Proposed New Measure: Directional Tracking of the Hand and Fingers

A. The Omnidirectional Vision System as a Directional Sensor

Omnidirectional vision systems formed by a camera and a hyperbolic mirror are widely used in mobile robotics for environment perception and motion estimation [16], [17]. In a catadioptric configuration, each pixel of the image corresponds to a viewing direction, defined by two angles, the azimuth around the symmetry axis of the vision system and the inclination angle. We propose exploring this property to locate, in spherical coordinates, any scene point tracked in the image.

In spherical coordinates (r, θ, φ), with origin at the focus of the mirror, where r is the radius, θ the inclination, and φ the azimuth, the two angles are obtained directly from the image. The azimuth φ is preserved by the image formation: the angular position of a point in the annular image, around the optical center, corresponds to the azimuth of its viewing direction around the axis of the cup. The inclination θ, in turn, results from the calibration of the vision system described in Section II, which associates the radial position of a point in the image with the elevation, or inclination, of its viewing direction [17].

From the azimuth and inclination thus obtained, it is possible to track the direction, frame by frame, of both the hand, taking the base of the palm as a reference, and the fingertips. Tracking the base of the palm describes hand transport toward the cup, while the relative tracking between the fingertips describes the modulation of hand aperture throughout the movement. The complete recovery of the three-dimensional position, including depth, is discussed in Section VI as a direction for future work. Even so, with a single embedded camera and without markers, the two components of reach-to-grasp, transport and finger aperture, are recovered.

B. Qualitative Experimental Validation

To qualitatively validate the proposed measure, we used data from experiments in which the device was employed together with a motion capture system taken as reference [14]. In this proof of concept, the positions of the hand and fingers are provided by the motion capture system's markers projected onto the images, which validates the geometric projection model; marker-free detection, directly in the images, is the next step.

Volunteer. One healthy individual participated, recruited from the local community, with no history of musculoskeletal injury of the upper limb. The intentional sample of a single participant is consistent with the observational nature of this proof of concept; expansion to larger samples, including individuals with motor impairment, is future work.

Ethical aspects. The data come from a study approved by the Human Research Ethics Committee of the Federal University of São Carlos, under approval report no. 2.495.168 (CAAE 79106017.0.0000.5504), in February 2018. All procedures followed the ethical guidelines in force, in accordance with Brazilian National Health Council (CNS) Resolution 466/12. The participant signed an informed consent form.

Procedure. The participant, seated with hip, knee, and ankle at 90° and without trunk support, performed the drinking task starting from a resting position on the table, with the device positioned at the height of the xiphoid process and at 80% of the upper-limb length. The task comprised reaching, transport to the mouth, return of the cup to the table, and return of the hand. After one familiarization trial, three repetitions were performed at self-selected speed, with the non-dominant limb [14]. For directional tracking, only the reach and transport phases were considered.

Acquisition and reference system. During the task, the device described in Section II recorded the omnidirectional images. In parallel, the movements were recorded by an optoelectronic Qualisys motion capture system (ProReflex, Qualisys Medical AB, Gothenburg, Sweden), with eight high-speed cameras at 120 Hz, taken as reference. Passive reflective markers were placed on the tips of the thumb and index finger and a marker on top of the cup, which allows comparing the trajectories estimated from the image with those of the reference system.

V. Results

A. Registration Between Reference Systems

The projection follows from a registration between the reference frame of the omnidirectional vision system, $\{V\}$, with origin at the focus of the mirror and axis z_V along the mirror's rotation axis, and the reference frame of the capture

system, $\{Q\}$. The Qualisys calibration aligns the axis z_Q with the vertical, that is, with the gravitational direction. It is then assumed, as a simplification, that the device is positioned with its rotation axis z_V also aligned with the vertical, so that the two z axes are parallel. As a consequence, the xy planes of the two systems are parallel to each other and to the horizontal, and the relative orientation is fully determined by a single rotation β about the vertical,

$$ {}^{Q}\mathbf{R}_V = \mathbf{R}_z(\beta) = \begin{bmatrix} \cos\beta & -\sin\beta & 0 \\ \sin\beta & \cos\beta & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{1} $$

The translation between the systems takes the origin of $\{Q\}$ to the viewpoint of $\{V\}$. The device has a fixed marker 14.5 mm above the focus of the mirror, which is taken as a reference: starting from its position $\mathbf{m}^Q$, a translation is performed along the vertical to the focus, preserving the orientation. The relative pose is thus described by the homogeneous transformation

$$ {}^{Q}\mathbf{T}_V = \begin{bmatrix} \mathbf{R}_z(\beta) & \mathbf{o}^Q \\ \mathbf{0}^\top & 1 \end{bmatrix}, \qquad \mathbf{o}^Q = \begin{bmatrix} A_x \\ A_y \\ h \end{bmatrix}, \tag{2} $$

where (A_x, A_y) is the center in the horizontal plane and h the height of the viewpoint, initialized at $\mathbf{m}^Q$ and at $m_z - 14.5$ mm and refined by the adjustment described next.

A marker at position $\mathbf{p}_i^Q$ in $\{Q\}$ is expressed in $\{V\}$ as $\mathbf{p}_i^V = {}^{Q}\mathbf{R}_V^\top(\mathbf{p}_i^Q - \mathbf{o}^Q)$. Since the z axes are parallel, the marker's azimuth in $\{V\}$ is the azimuth in $\{Q\}$ around the center, offset by β,

$$ \varphi_i = \operatorname{atan2}\big(p_{i,y}^Q - A_y,\ p_{i,x}^Q - A_x\big) - \beta. \tag{3} $$

The marker spheres are identified in the unrolled image of a single frame, chosen because it shows all hand markers visible. Each sphere provides an azimuth in the image, $\tilde{\varphi}_i$, obtained from its column position, since the unrolled image covers exactly 360° along its width. The registration then seeks the center and rotation that minimize the angular distance between the Qualisys-projected azimuths and those measured in the image,

$$ (A^*, \beta^*) = \arg\min_{A,\,\beta} \sum_i \operatorname{wrap}_\pi\big(\varphi_i - \tilde{\varphi}_i\big)^2, \tag{4} $$

where $\operatorname{wrap}_\pi(\cdot)$ normalizes the angular difference to the interval $(-\pi, \pi]$. The minimization is solved by nonlinear search, restarted from several initial rotations to avoid local minima.

With the orientation fixed, the height of each marker in the image is obtained from the calibration curve of the vision system, which converts the angular position in the spherical system into height on the reference cylinder of radius $\rho = 35$ mm adopted in the device calibration. By triangle similarity from the viewpoint, a marker at a horizontal distance $d_i = \|(A_x^*, A_y^*) - (p_{i,x}^Q, p_{i,y}^Q)\|$ and at a vertical offset Δz_i relative to the viewpoint is projected onto the reference cylinder at a height

$$ H_i = \rho\,\frac{\Delta z_i}{d_i}, \tag{5} $$

converted into an image row by the vertical scale of the unrolling. The height h is calibrated by best approximating, over the set of markers, the inclination read from the image, $\operatorname{atan2}(H_i, \rho)$, to the inclination computed from Qualisys, $\operatorname{atan2}(\Delta z_i, d_i)$. Once the registration is complete, the projection of each marker in any given frame is obtained by converting its azimuth φ_i into an image column and its height H_i into an image row, and on each frame of the reach and transport phases the markers and the segments connecting them are drawn.

B. Projection of the Markers onto the Reconstructed Images

The proof of concept of the measurement capability was carried out on the data from the device and the capture system, acquired in synchrony (Section IV). For each frame, the positions of the markers fixed at the thumb tip, the index fingertip, and the base of the palm, measured by the capture system, were projected onto the reconstructed image, using the calibrated catadioptric geometry of the vision system (Section II) and the registration between reference systems described above. The consistent overlap of the projected markers onto the corresponding parts of the hand in the image allows verification of the geometric projection model, a proof of concept of the proposed angular measurement capability.

The projected markers of the thumb, index finger, and palm fell consistently onto the corresponding parts of the hand in the reconstructed images, throughout the whole reach-to-grasp (Fig. 6). The trajectory of the palm-base marker describes hand transport toward the cup, while the relative motion between the thumb and index-finger markers describes the modulation of finger aperture throughout the movement. The joint projection of the transport and aperture trajectories, obtained from a single embedded camera, demonstrates the feasibility of the proposed measure and supports its future implementation without markers, through direct detection of the hand and fingers in the images.

VI. Discussion

The main result of this work is the visual verification of the correspondence between the two systems: based on the registration procedure and the device calibration, the thumb and index-finger markers, projected from the capture system, overlapped consistently with the hand in the reconstructed images, throughout the reach-to-grasp. This correspondence is a qualitative and observational proof of concept that omnidirectional vision carries the geometry needed to track hand transport and finger aperture modulation, and not a definitive quantitative validation of the proposed measure.

It remains to estimate depth, that is, the distance between the viewpoint of the vision system and the tracked point, which a single omnidirectional sensor does not provide directly. One

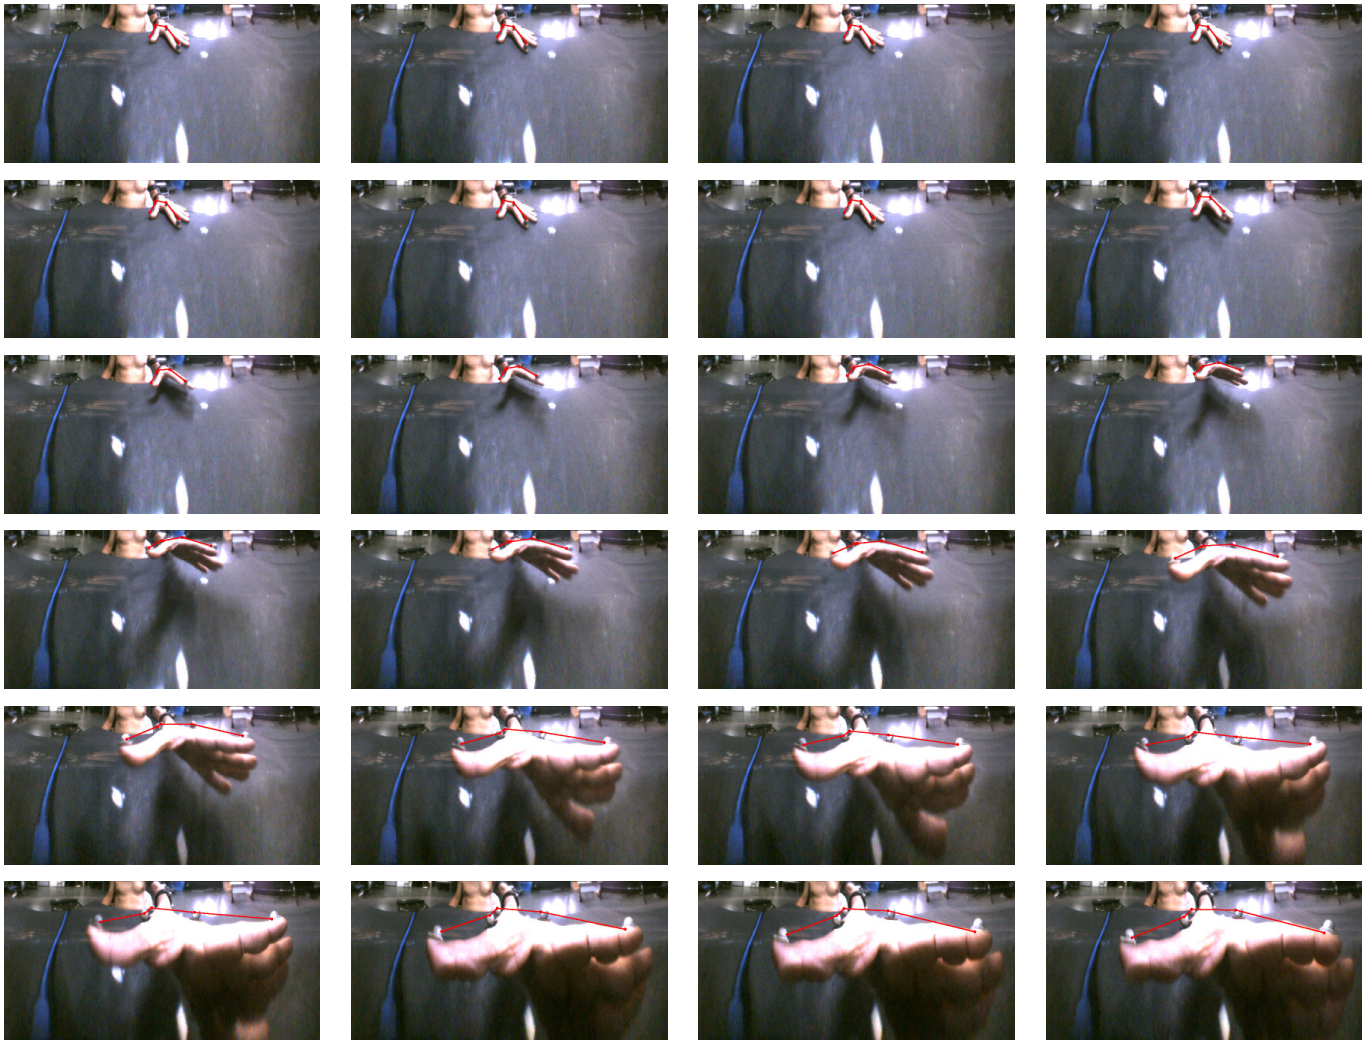

Figure 6. Projection of the capture system's markers onto the reconstructed images, for the thumb, index finger, and palm, along 24 equally spaced frames of the reach-to-grasp, for a healthy participant, arranged in 6 rows and 4 columns as in a video sequence.

possibility would be to estimate it from the ratio between the actual size of the hand, known from the cylindrical calibration of the vision system at the instant of grasping, and its apparent size in the image at each frame. This step has not yet been implemented or validated, and constitutes the main direction for future work to complete the three-dimensional tracking, recovering the three spherical coordinates of the position of the hand and fingertips, and not only their angular direction.

In addition to this result, the set of capabilities already established in previous work suggests that a single instrumented object of reduced cost relative to laboratory systems, with embedded sensing, can bring together findings that usually require laboratory motion capture and instrumented gloves, such as phase timing, hand posture during grasping, and movement smoothness. In particular, the abduction angle between the thumb and index finger, so far obtained by manual marking on the images, still does not allow conclusive results; its measurement connects directly to the three-dimensional tracking proposed in this paper, which could obtain it automatically and continuously throughout the movement, in synchrony with the other already-established IMU measures, allowing the correspondence between them to be studied in broader clinical contexts. Unlike wearable inertial sensors, which do not access hand posture, and the cup of Bobin et al. [12], which combines inertial and pressure sensors but does not image the hand, the device adds the omnidirectional image of grasping synchronized with the inertial data, with reliability and validity already indicated for the temporal and smoothness measures in the drinking task.

These measures, previously restricted to motion capture laboratories, could become accessible in a portable, marker-free cup of accessible cost relative to laboratory motion capture, which supports the argument for democratizing access to kinematic assessment. In clinical use, the device would have the potential to enable assessment and longitudinal follow-up of rehabilitation in primary care and smaller-scale services, without requiring patient travel, complementing the clinical instruments already established for upper-limb assessment,

such as the Fugl-Meyer Assessment [18], the ARAT [19], and the *Nine-Hole Peg Test* [20]. On a population scale, it would open the way for screening and monitoring upper-limb motor function in the various neurological and musculoskeletal conditions that compromise it, in regions far from major centers, addressing the scenario in which the concentration of assessment in a few centers contradicts the principles of universality and equity of Brazil's Unified Health System (SUS).

The main limitation of the current version is the cable that connects the cup to the external computer: according to reports from the volunteers and the team, it adds weight and resistance and restricts hand trajectory, which may bias the smoothness and tremor measures and reduce the ecological validity of the task, critical for use outside the laboratory. Added to this are the weight of the prototype and the cost of the hyperbolic mirror, whose manufacturing on an ultra-precision lathe, with a finish by polishing with a synthetic diamond micro-tool, is expensive and specialized. In addition, the geometry of the vision system occupies the interior of the cup and prevents it from holding water, so that the current version only mimics the drinking task. These points motivate an updated sensor design, wireless, lighter, with more affordable manufacturing for the mirror and, conveniently, with a water reservoir, conditions important to bring the task closer to the real activity and to realize the democratization potential discussed.

On the measurement side, the main directions for future work are: (i) quantitative validation of the geometric projection model, with metrics for angular error, agreement with the capture system, and repeatability across trials and participants; (ii) expansion of the sample to include individuals with motor impairment, such as stroke survivors and patients with Parkinson's disease, to verify discrimination between conditions and track longitudinal evolution; (iii) direct detection of the hand and fingers in the images, without external markers, the condition necessary to make the device independent of laboratory systems; and (iv) depth estimation, which would complete the tracking with three spherical coordinates, enabling, for example, automatic and continuous extraction of the abduction angle between the thumb and index finger. Together, these directions could convert posture metrics, today annotated manually, into continuous and automatic measurements throughout the movement, complementing or replacing external trackers and instrumented gloves with a single portable cup.

VII. Conclusion

This paper presented the device, an instrumented cup built as a replica of a water cup, for assessing the arm and hand in the various conditions that compromise the upper limb, such as stroke, Parkinson's disease, and spinal cord injury. We brought together its measurement capabilities already established in previous studies: the IMU signals, acquired in synchrony with the grasping images, from which phase timing, hand accommodation time, and smoothness and tremor by spectral analysis are derived; and hand posture during grasping from the images, including the abduction angle between the thumb and index finger.

As the main contribution, we proposed the use of the omnidirectional vision system as a directional angular sensor and presented a qualitative and observational proof of concept: the projection of the positions of the thumb, index finger, and palm onto the reconstructed images, which indicates that it is possible to recover hand transport and finger aperture modulation in reach-to-grasp, measured in synchrony with the other already-established measures of the device, precisely the components whose synchronization is most compromised after several neurological injuries. The projection of the markers confirmed that omnidirectional vision carries the geometry needed for this measure, and no comparable instrumented object simultaneously offers this possibility of spatial information of the hand and fingers during the functional task, which distinguishes the proposal in the state of the art of portable upper-limb assessment.

We also discussed its limitations, with emphasis on the cable of the current version and on depth, not yet estimated, which is necessary to complete the three-dimensional tracking.

By bringing together clinically relevant measures in a portable object of reduced cost relative to laboratory systems, the device points toward the democratization of upper-limb kinematic assessment, bringing it to rehabilitation settings outside major centers and aligning with the principles of universality and equity of Brazil's SUS. As directions with the greatest potential, we identify: quantitative validation of the geometric model, with angular error and agreement metrics; expansion of the sample to individuals with motor impairment; direct detection of the hand and fingers in the images, without external markers; depth estimation, necessary to complete three-dimensional tracking with three spherical coordinates; and a wireless, lighter version with more affordable mirror manufacturing.

***Abstract*— This study evaluated the safety of using *Viscum album* (*VA*) in both ultra-diluted (UD) and fermented (F) forms in healthy snakes at the Butantan Institute, using Raman spectroscopy combined with Principal Component Analysis (PCA). Fourteen snakes received monthly applications of *VA* according to the specific herbal formulation: UD (D3+D9) for six months and F (D3) for three months. Serum samples were collected and analyzed via Raman spectroscopy. The mean spectra for the UD and F groups exhibited the same set of bands as the control serum, with no bands unique to or missing from the control serum. Among the principal components, only PC4 and PC7 showed statistically significant differences (ANOVA, $p < 0.05$); these were linked to subtle variations in spectral regions associated with lipids, phenylalanine, and nucleic acids, a pattern that may be consistent with the reported immunomodulatory activity of the extract. The results indicate that Raman spectroscopy detected discrete biochemical modulation, with no spectroscopic evidence of toxicity under the conditions evaluated; complementary hematological, biochemical, and histopathological assessments are recommended to corroborate these findings.**

Keywords*— *Raman spectroscopy, serum, snake, Viscum album.

I. Introduction

The development of therapeutic alternatives with minimal side effects is a cornerstone of modern medicine and biomedical engineering. In this context, substances of natural origin, such as *Viscum album* (*VA*), have attracted growing scientific interest [1,2] due to their immunomodulatory properties and low toxicity, as well as their safety in both animal and human species, even at high doses [3].

VA is a perennial hemiparasitic plant that grows on host trees, such as oaks and apple trees [1,2]. Its main constituents include viscotoxins, lectins (ML1 to ML4) [3], flavonoids, and phenolic acids [1], which are responsible for antitumor and immunomodulatory effects [3].

Commercially, various formulations are available, notably fermented (F) and ultra-diluted (UD) extracts. Fermentation, as a biotechnological process, alters the extract's metabolomic profile and molecular organization, thereby modifying the availability of bioactive compounds. These changes can impact biological properties and structural stability, making molecular characterization essential before experimental application, particularly in animal models [1,3].

Herpetofauna, specifically snakes of the family Viperidae, play a significant role in biomedical research, being widely used in the production of antivenoms and in studies of venom composition and biological activity [4,5]. Increased longevity among these animals in research and conservation institutions has been accompanied by a higher incidence of chronic diseases, including neoplasms. However, studies evaluating the pharmacovigilance of new therapeutic approaches in this class remain scarce. Thus, the use of clinically healthy snakes represents a crucial step in investigating potential molecular alterations induced by compounds of interest, enabling estimation of their safety margin before application in diseased animals [3].

Among molecular characterization techniques, Raman spectroscopy is a rapid, non-destructive vibrational method capable of analyzing small sample quantities with minimal preparation and reduced animal handling. It relies on the interaction of light with molecular vibrations. It yields characteristic spectra in the 400–1800 cm^{-1} range, enabling the identification of biochemical changes, particularly in biological samples [6,7]. When combined with Principal Component Analysis (PCA), it becomes a powerful tool for detecting subtle spectral differences between experimental groups, thereby contributing to the assessment of the molecular stability of formulations [7,8].

Thus, the present study aims to investigate *VA* pharmacovigilance in healthy snakes using Raman spectroscopy.

II. Materials and Methods

A. Ethics and animals' selection

Healthy snakes (n=14) of the family Viperidae, belonging to the genus *Bothrops* sp., kept in captivity at the Butantan Institute's herpetology facilities in São Paulo, Brazil (CEUA No. 7991151220002256), participated in this study. All animals were adults of both sexes and were housed in a climate-controlled environment; they were fed monthly with mice bred and euthanized at the institution's own animal facility.

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

Blood samples were collected monthly from the caudal vein of healthy snakes, corresponding to approximately 1% of body weight. The samples were then packaged and stored at -20°C until shipment to the Laboratório de Espectroscopia Vibracional of the Center for Innovation, Technology and Education (CITÉ) in São José dos Campos, SP, Brazil, for analysis (Figure 1).

Fig. 1. Experimental assay with the snakes. (a) Snake restraint; (b) Collection via caudal of blood samples for serology; and (c) Samples processing for Raman spectroscopy.

The experimental setup involved a baseline assessment of all healthy snakes, followed by *VA* administration to the same individuals and subsequent sample collection. The animals were assigned to three groups: Control (Ctrl / zero) (n=14), Fermented (F) (n=4), and Ultra-diluted (UD) (n =10).

B. VA characterization

VA preparations were supplied by Injectcenter® (Injectcenter Manip Prod Farm Ltda., Ribeirão Preto, SP, Brazil) and were used in both UD and F formulations, packaged in 1.0 mL ampoules. The manufacturer provides preparations at different potencies (D2, D3, D6, D9, D12, D30, D60, and 200CH). According to the experimental protocol, the UD formulation consisted of a combination of the D3 and D9 potencies, administered at 0.5 mL of each potency per animal (1.0 mL total). In contrast, the F formulation consisted of the D3 potency at 0.5 mL per animal.

The phytotherapeutic agents were stored in their original ampoules; the ultra-diluted *VA* was kept at room temperature, while the fermented *VA* was refrigerated, in accordance with the manufacturer's guidelines. Upon opening, the contents of the ampoules were immediately administered to each animal in the respective group, via injection into the coelomic cavity, the standard parenteral administration site in snakes.

The treatments consisted of the monthly administration of the herbal *VA* preparation (one application per month), with UD-VA administered for 6 months and F-VA for 3 months. The applications were performed at times distinct from feeding and blood sample collection.

C. Raman spectroscopy

The blood sera underwent a single controlled thawing cycle at room temperature, ensuring batch homogeneity and minimizing artifacts resulting from protein degradation.

Aliquots of 80 µL from each sample were deposited onto an aluminum plate using a micropipette (mod. P200, Bio-Rad Laboratories Inc., Hercules, CA, USA) for subsequent reading. Analyses were performed using a dispersive Raman spectrometer (mod. Dimension P-1, Lambda Solutions Inc., Waltham, MA, USA) equipped with an 830 nm diode laser, 250 mW power, and a resolution of approximately 2 cm^{-1} in the 400–1800 cm^{-1} range; spectra were obtained through repeated collections and triplicate spectral acquisition.

Data were pre-processed using Chemoface (v. 1.75, UFLA, Lavras, MG, Brazil) [9], which involved fluorescence removal and baseline correction with a 7^{th}-order polynomial, followed by normalization to eliminate intensity variations.

Subsequently, the spectral mean for each group was calculated, allowing identification of differences in Raman spectral peak intensities and their correlation with the biochemical compositions described in the literature. The Raman spectra were then subjected to Principal Component Analysis (PCA) to identify relevant spectral variables.

This entire statistical procedure and the plotting of score graphs were carried out using MATLAB software (v. 2007a, The MathWorks, Inc., Natick, MA, USA). At the same time, analysis was performed using InStat software (v. 3.0, GraphPad Software Inc., San Diego, CA, USA), employing parametric one-way ANOVA and nonparametric comparisons (Kruskal-Wallis test with post hoc tests), followed by Tukey's test to compare all groups. The PCs were used to identify the groups in which these spectral differences were statistically significant ($p < 0.05$).

III. Results and Discussion

Raman spectra remained adequate for the 14 animals. They were used to calculate the mean Raman spectra for the Control (Ctrl: n=24), Fermented *VA* (F-VA: n=39), and Ultra-diluted VA (UD-VA: n=67) groups, which revealed a spectral profile with bands predominantly related to proteins, aromatic amino acids, and lipids [6,7,8,10,11] (Figure 2 and Table 1).

Spectra were obtained in triplicate at repeated monthly time points from the same 14 animals; therefore, spectra were treated as repeated measurements nested within each animal, and the reported statistical comparisons should be interpreted with this repeated-measures structure in mind.

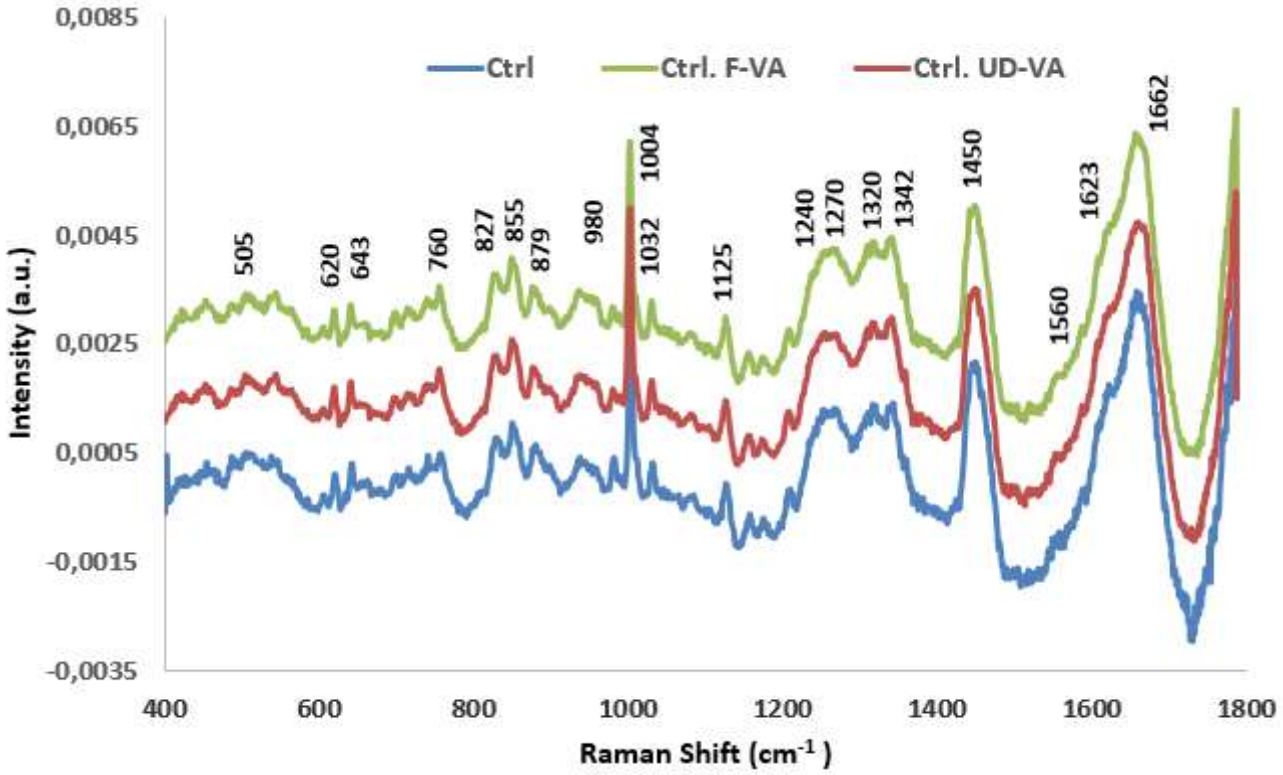

Fig. 2. Mean Raman spectra of the Control (Ctrl), F-VA and UD-VA Control groups.

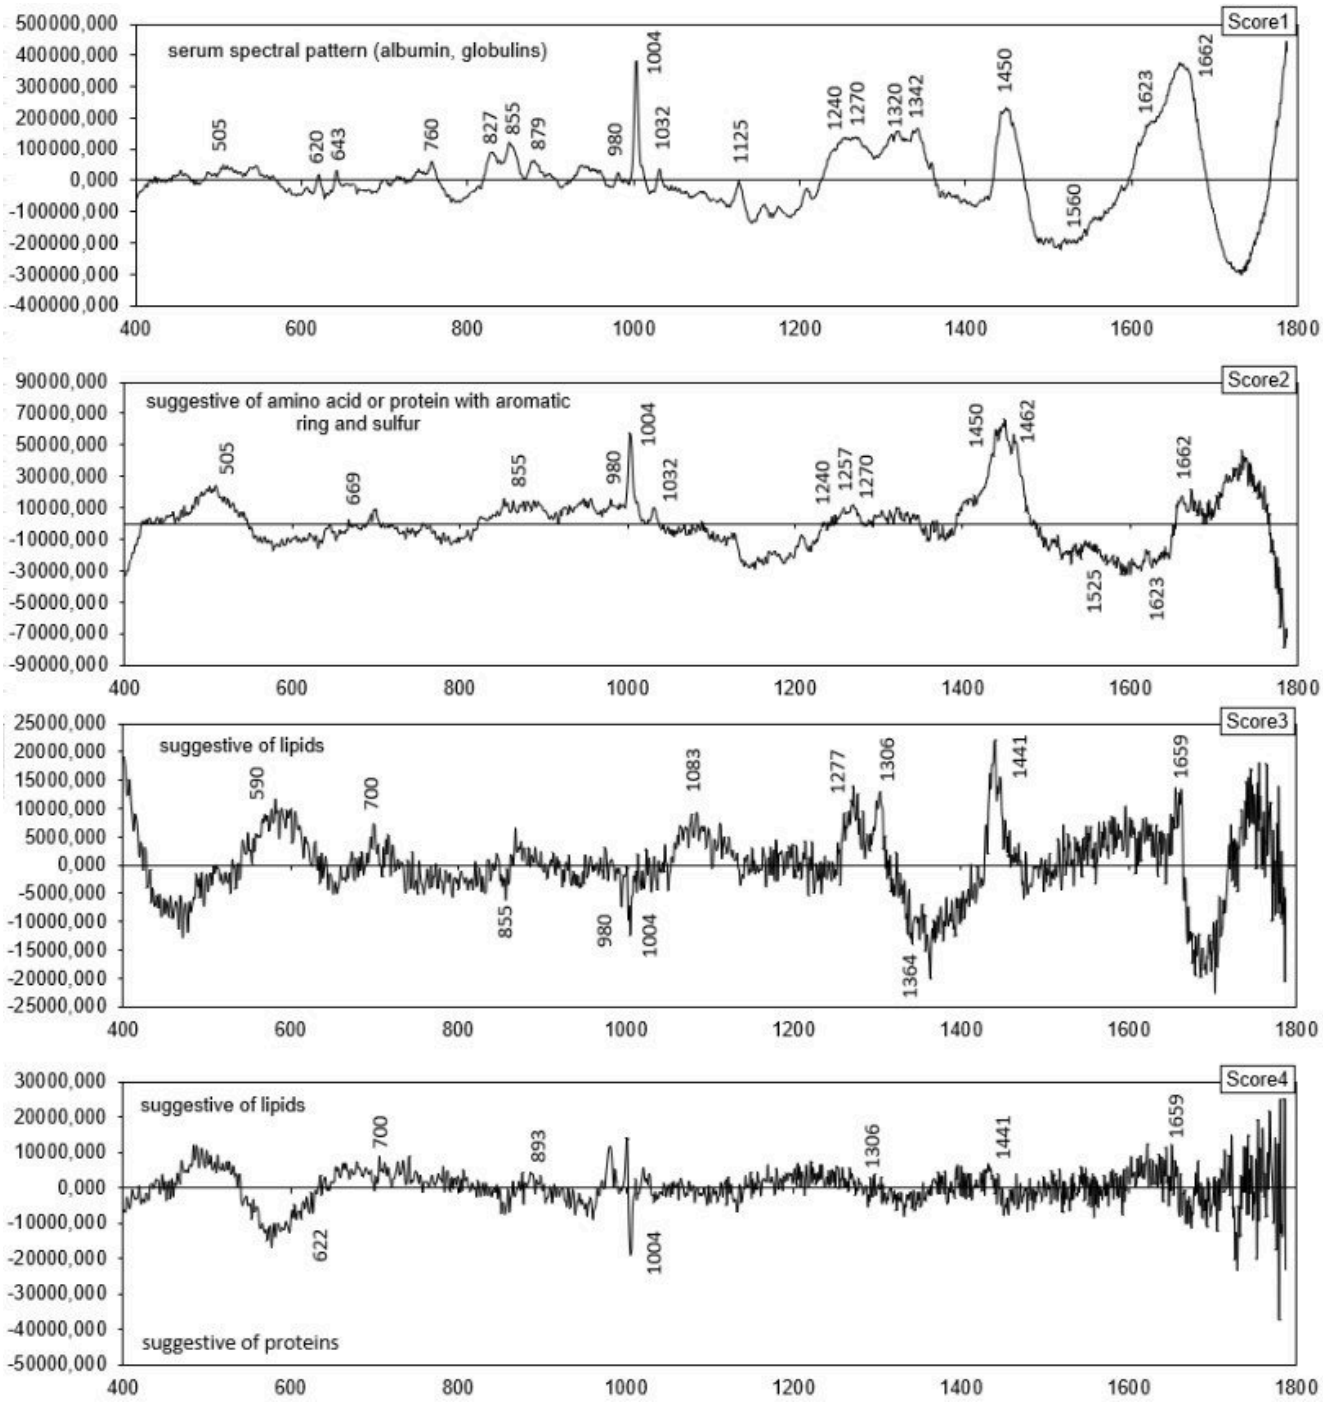
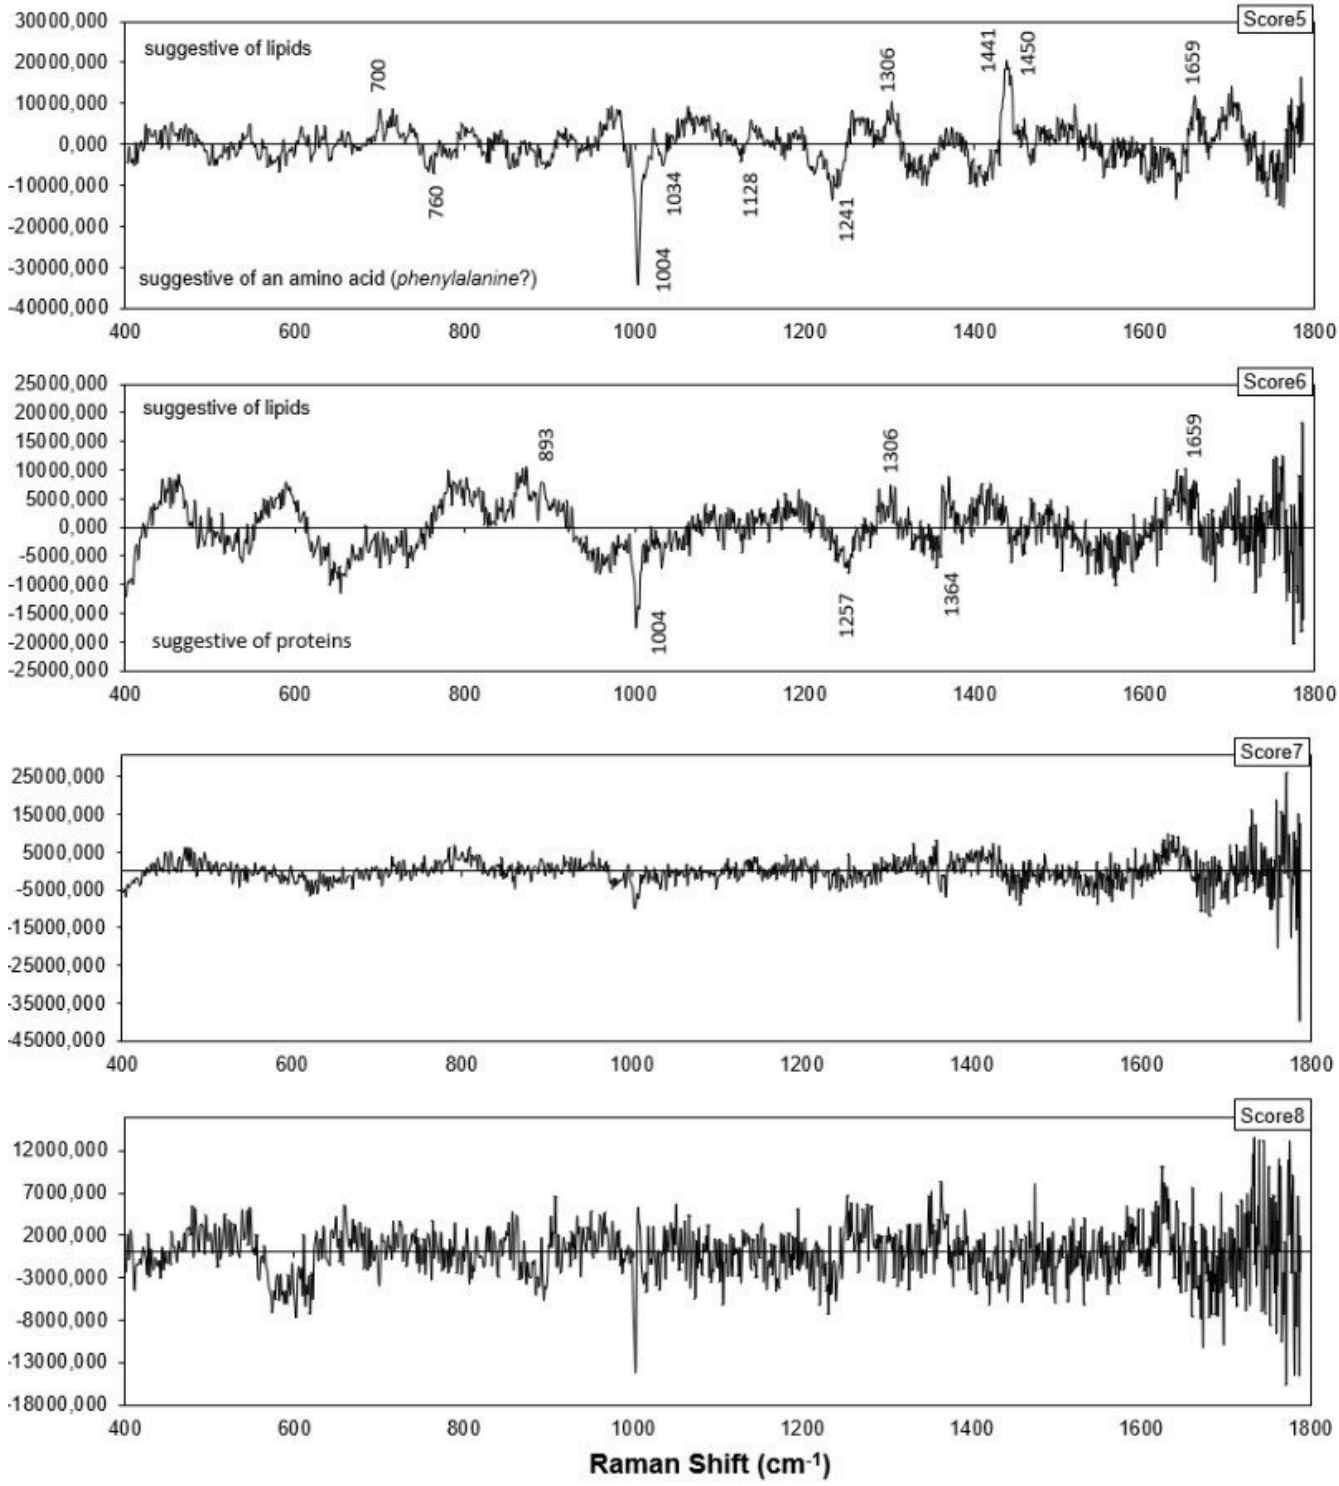
TABLE I. BIOCHEMICAL ASSIGNMENTS OF THE RAMAN BANDS IDENTIFIED IN THE SERUM SPECTRA OF HEALTHY SNAKES.



Peak (cm^{-1}) [*reference*]	**Assignment**
505 [10]	Disulfide bonds (S–S stretching), cysteine/cystine
620-643 [10, 13]	Phenylalanine and aromatic amino acids
760, 827 [10]	Tryptophan and indole ring
855, 879 [11]	Tyrosine and proteins (C–C stretching)
980 [10]	Symmetric stretching of proteins and phosphates
1004 [10]	Phenylalanine (aromatic ring)
1032 [11, 14]	Phenylalanine and proteins
1125 [11]	C–C stretching vibrations of lipids and proteins
1240-1270 [11, 15]	Amide III
1320, 1342 [10, 15]	Amide III and proteins
1450 [11, 16]	CH_2 deformation of lipids and proteins
1560, 1623 [10, 17]	Amide
1659-1662 [11, 17]	Amide I and lipids



A comparison of the mean Raman spectra across the control groups revealed neither group-specific bands nor the disappearance of bands from the snakes' physiological serum profile, suggesting that these variations are common among the groups, as observed in multivariate analyses of biofluids [12]. Most of the components evaluated (PC1, PC2, PC3, PC5, PC6, and PC8) are predominantly associated with the general albumin and globulin pattern and the serum lipid or protein fraction; no significant differences were observed between the groups (Figure 3).

This preservation of the spectral pattern provides an initial indication that *VA* use does not induce significant biochemical alterations in the animals' serum. PCA analysis demonstrated statistically significant differences only in PC4 and PC7 (ANOVA, $p < 0.05$).

In PC4, variations in relative intensity occurred in the 622 and 1004 cm^{-1} regions, bands assigned to protein- and lipid-related molecular vibrations, the control group was more specific to lipids. These variations suggest subtle relative changes in protein-associated spectral contributions without altering the fundamental physiological spectral profile. PC7 exhibited loading peaks in spectral regions similar to those observed for the other principal components, mainly corresponding to lipid- and protein-related bands.

This behavior indicates only an opposing contribution to the formation of the principal component and is not interpreted as an absolute reduction in the concentration of this metabolite. The observed increase in the fermented group's score compared with other experimental control groups further supports that the separation between groups occurred predominantly in PC4, indicating subtle biochemical modifications without a significant impact on the spectral profile organization (Figure 3).

Raman Shift (cm-1)

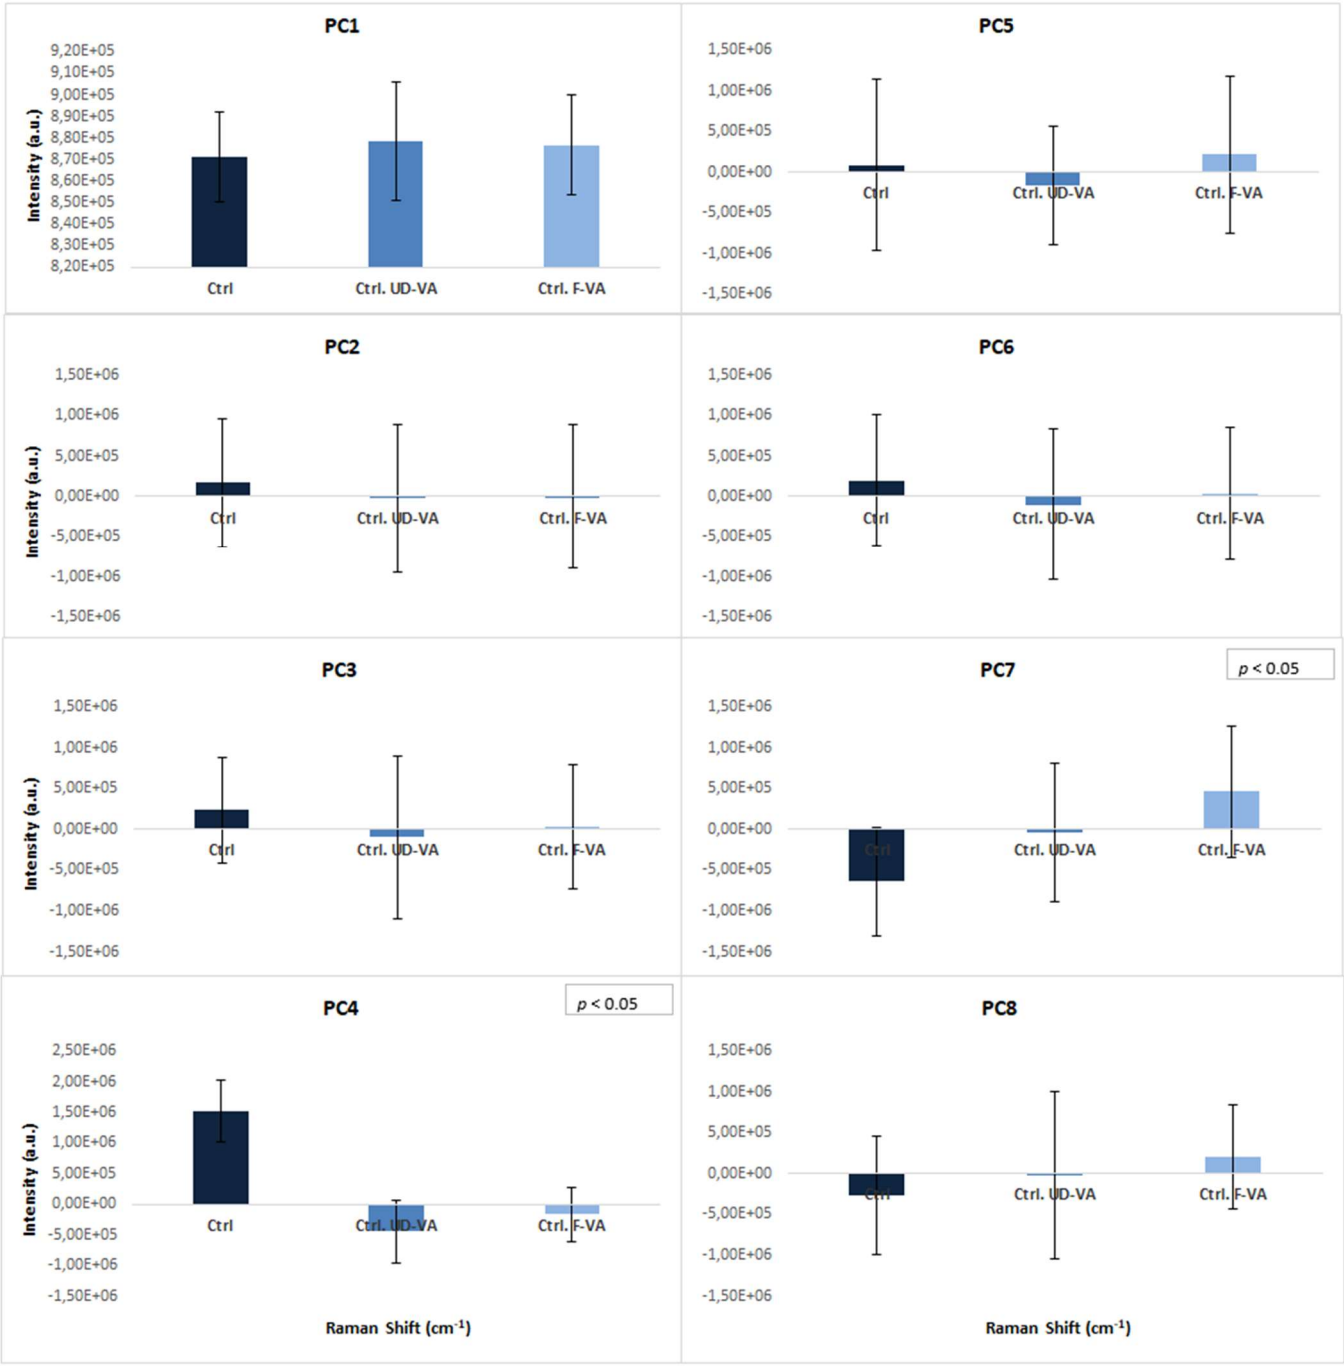

Fig.3. Loadings (intensity *vs*. Raman shift) and statistical comparison of the principal components (PC1–PC8) obtained via PCA of the Raman spectra from the Control (Ctrl), F-VA and UD-VA Control groups.

Taken together, the results indicate that both the UD and the F extract induced subtle biochemical changes detectable via Raman spectroscopy, while preserving the overall organization of the snake serum molecular profile.

The fact that statistical discrimination between groups occurred only in PC4 and PC7, components that typically capture less variance than the leading components (PC1 and PC2), demonstrates that higher-order principal components can contain biologically relevant information, even when representing a smaller portion of the data variability [7,8]. This suggests that the effect of the *VA* was limited to specific, subtle biochemical variations, without causing detectable global changes in the serum metabolic profile, within the sensitivity of the Raman approach employed. These results support the interpretation that using the extract, in either UD or F form, produces a biochemical modulation detectable by Raman spectroscopy without compromising the overall biochemical integrity of the animals' serum.

Therefore, the changes observed in PC4 and PC7 may reflect the action of compounds in the *VA* that can induce slight modifications in the snakes' serum metabolism, primarily involving proteins, aromatic amino acids, nucleic acids, and possibly lipids. This behavior is compatible with the extract's chemical composition: RIP-2 type lectins (viscumins) [18], which inactivate ribosomes and inhibit protein synthesis, could influence the availability of free amino acids such as phenylalanine (compatible with bands associated with aromatic amino acids), while phenolic

compounds and flavonoids [19] exhibit recognized antioxidant activity capable of influencing lipid peroxidation. Furthermore, the subtle contribution of bands associated with nucleic acids is compatible with a slight increase in cell turnover, potentially linked to the extract's immunomodulatory effect on immune cells [1,5]. It is important to emphasize that the PCA loadings support only spectral associations between these compound classes and the observed principal components; they do not, by themselves, provide evidence of metabolite concentration, protein synthesis rate, immune modulation, or cell turnover. While these biological properties have been described in the literature for *VA*, in the present study, they are interpreted as consistent with the spectroscopic findings; it is not yet possible to establish a direct causal link between these mechanisms and the observed alterations.

The spectral pattern observed in this study differs from that typically described in cases of actual tissue damage analyzed via Raman spectroscopy, patterns characterized by broad, widespread spectral changes, such as increased lipid content associated with catabolic products in liver damage [20] or the appearance of hemoglobin bands indicating hemolysis in systemic biocompatibility studies [21]. No broad, disseminated spectral change was detected in the present study; however, this preserved Raman profile, on its own, cannot establish the absence of toxicity, since clinical observation, hematology, serum biochemistry, and histopathology were not assessed in this work. Complementary evaluation via such methods is therefore advisable to corroborate the results obtained here.

IV. CONCLUSION

Raman spectroscopy combined with PCA proved useful for monitoring the effects of VA in healthy snakes. The detected changes were subtle and limited to specific components, with no spectroscopic evidence of toxicity under the conditions evaluated. Further clinical, hematological, biochemical, and histopathological analyses are recommended to confirm these results.

***Abstract*— Canine Visceral Leishmaniasis (CVL) is a chronic parasitic disease associated with systemic biochemical alterations, reinforcing the need for complementary diagnostic approaches. This study evaluated the ability of Raman spectroscopy to identify molecular signatures associated with different serological titers in dogs naturally infected with *Leishmania* spp. Serum samples from seronegative dogs and seropositive dogs with titers of 1/64 or ≥1/128 were analyzed. Raman spectra were preprocessed by baseline correction, smoothing, normalization, and Principal Component Analysis (PCA). Significant spectral differences were observed in bands assigned to phenylalanine (1003 cm^{-1}), tyrosine (829-853 cm^{-1}), proteins and lipids (1319-1449 cm^{-1}), and amide I (1659 cm^{-1}), indicating biochemical alterations associated with the host immune response. PCA revealed discrimination among the evaluated groups, with statistically significant differences for PC1 (p=0.017) and PC2 (p=0.0094). These findings indicate that Raman spectroscopy is sensitive to biochemical changes associated with CVL and may serve as a complementary tool for distinguishing different serological response profiles.**

***Keywords*— blood serum, dogs, Leishmania, Raman spectroscopy, titers.**

I. Introduction

Leishmaniasis comprises a complex of infectious diseases caused by obligate intracellular parasites of the genus *Leishmania* spp., which exhibit tropism for the mononuclear phagocyte system (MPS). Active transmission occurs via the blood meal of female phlebotomine sandflies of the genus *Lutzomyia* spp. Between 20 and 22 species of this parasite are known to cause disease in both humans and animals [1]. It is estimated that there are between 700,000 and 1 million cases worldwide [2]. It is classified as a neglected tropical disease based on the DALY (disability-adjusted life-year) indicator for morbidity [3].

Clinical classification varies according to the causative parasite species, manifesting as Cutaneous Leishmaniasis (CL), Mucocutaneous Leishmaniasis (MCL), and Visceral Leishmaniasis (VL). Domestic dogs play a significant epidemiological role in urban centers, serving as the primary reservoirs that maintain the transmission cycle. Therefore, monitoring infection in these animals is essential to prevent the spread of the disease to new geographic areas and to improve surveillance and diagnostic systems [1].

Since the disease presents with non-pathognomonic clinical signs and often requires differential diagnosis, there is a need to develop complementary methods that optimize diagnostic specificity and sensitivity while maintaining speed and low cost, particularly to serve remote endemic regions. Current diagnostic methods include parasitological methods; serological tests such as the Indirect Immunofluorescence Assay (IFA) and Enzyme-Linked Immunosorbent Assay (ELISA); the Dual-Path Platform (DPP) rapid test; and molecular methods such as the Polymerase Chain Reaction (PCR), which is considered the gold standard. However, these techniques require specialized laboratories, trained professionals, and careful interpretation by a veterinarian, considering the disease stage. Furthermore, fluctuations in the host's immunological status can lead to false-positive or false-negative results [1].

In this context, Raman spectroscopy has attracted interest in the medical field because it enables rapid, non-destructive molecular characterization of biological samples with minimal sample preparation. These characteristics have favored its application in the study of infectious diseases [4]. The Raman spectroscopy technique determines molecular structures by analyzing the vibrational frequencies of light scattered by the sample. This phenomenon is based on the interaction of light with matter, encompassing both elastic scattering (Rayleigh), which preserves the incident light's wavelength, and inelastic scattering (Raman) [4]. In the latter, scattered photons exhibit altered frequencies due to specific molecular vibrations, acting as a chemical fingerprint of the sample. This feature enables the identification of compounds such as carbohydrates, proteins, amino acids, lipids, and nucleic acids, thereby facilitating the monitoring of tissue differentiation [5]. Consequently, biochemical alterations preceding pathological manifestations can be identified in real-time during active infections.

The ability to distinguish among different serological levels, rather than simply classifying animals as seropositive or seronegative, is clinically relevant because it allows greater precision in assessing disease severity, monitoring the immune response over time, and informing therapeutic and epidemiological decisions. Given the diagnostic limitations of CVL, this study aims to evaluate the sensitivity and applicability of Raman spectroscopy as an innovative tool for differentiating serological levels in CVL diagnosis.

II. Materials and Methods

A. Sample collection and serological diagnosis

Blood serum samples from mixed-breed dogs in the

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

Serra do Cipó, MG, Brazil, (Ethics: CEUA 09001/2021) were collected and shipped under refrigeration to the animal clinical pathology laboratory. After processing, the serum samples (n = 57) were divided into two aliquots: one was used for diagnostic screening by IFA to determine titers, and the other was designated for Raman spectroscopy analysis.

B. Sample preparation and Raman spectroscopy acquisition

The aliquot designated for Raman spectroscopy was sent to the Vibrational Spectroscopy Laboratory of the Center for Innovation, Technology and Education (CITÉ) in São José dos Campos, SP, Brazil, for analysis.

Blood serum samples were stored frozen at -20°C and thawed once at room temperature, ensuring batch homogeneity and minimizing artifacts from protein degradation. Handling procedures were standardized across the evaluated groups to facilitate processing.

The 80 µL aliquots of each sample were deposited onto an aluminum plate using a micropipette (model P200, Bio-Rad Laboratories Inc., Hercules, CA, USA) for subsequent spectral acquisition. Raman spectra were collected using a dispersive Raman spectrometer (model Dimension P-1, Lambda Solutions Inc., Waltham, MA, USA) with an 830 nm excitation laser operating at 350 mW power, and a 30 s exposure time. The instrument was calibrated within the 400–1800 cm^{-1} range, and spectra were obtained in triplicate. Before analysis, the data were digitally processed to remove background fluorescence and correct the baseline using a 7^{th}-degree polynomial algorithm. Subsequently, the signals were normalized using L1 normalization (dividing each spectrum by the sum of its absolute values) to eliminate intensity variations due to minor differences in focus or droplet volume.

Next, the mean spectra for each animal group (low and high titers) were calculated, enabling the identification of differences in Raman peak intensities and their correlation with the biochemical compositions described in the literature.

Spectral analyses were conducted using statistical tools, specifically Principal Component Analysis (PCA), applied to the full set of triplicate spectra acquired for each animal rather than to group- or animal-level averages. This multivariate approach was employed to reduce data dimensionality and identify the main clusters based on the biochemical profiles of canine serum samples. All statistical processing and the generation of score plots were performed using MATLAB software (v. 2007a; The MathWorks, Inc., Natick, MA, USA).

III. Results and Discussion

Serological analysis of dogs enrolled in the CVL survey in the Serra do Cipó-MG by IFA method, identified healthy (seronegative) animals (n = 38) and animals infected (seropositive) with CVL (n = 17); the latter were subdivided based on titer levels into low-titer (IFA 1/64; n = 13) and high-titer (IFA ≥ 1/128; n = 4) groups. It should be noted that the high-titer group was considerably smaller than the other groups, a sample imbalance that reflects the natural distribution of serological titers in the surveyed population and represents a limitation inherent to this preliminary study.

Variations in the biochemical profiles of the canine sera evidenced diagnostic differentiation among the evaluated groups. These molecular changes reflect the systemic nature of CVL, a disease in which the complex interaction between parasite and host disrupts the balance of the Th1 and Th2 immune responses. While the Th1 profile correlates with resistance mechanisms that activate leishmanicidal macrophages, the Th2 response induces intense humoral activity and hyperglobulinemia. This immunological imbalance directly alters the concentrations and structures of serum proteins, lipids, and amino acids, underpinning the potential of Raman spectroscopy as a complementary diagnostic tool [1].

Figure 1 shows the mean Raman spectra obtained for the negative group (control) and for dogs testing positive with low titers (1/64) and high titers (≥ 1/128). A progressive increase in spectral intensity is observed in seropositive animals, most notably in the high-titer group (≥ 1/128), suggesting an association between the serological response and molecular alterations present in the serum. The most significant differences occurred in regions attributed to serum proteins, aromatic amino acids, and lipids. The peak at 1003 cm^{-1}, attributed to phenylalanine [6], increased progressively in infected dogs. This pattern suggests an increase in the serum protein fraction, resulting from the antigenic stimulation observed in CVL, a condition frequently associated with polyclonal hypergammaglobulinemia [1].

Alterations in the 829–853 cm^{-1} region, known as the tyrosine doublet [7], are frequently used as markers for conformational changes in proteins. The increased intensity of this doublet in seropositive animals suggests modifications consistent with intense immunological activation. Similarly, the bands between 1319 and 1342 cm^{-1} correspond to proteins and lipids [6] involved in metabolic responses to infection. The region between 1443 and 1449 cm^{-1}, attributed primarily to CH_2 and CH_3 vibrations of proteins and lipids [6], also showed higher intensity in infected animals, potentially reflecting changes resulting from the chronic inflammatory process.

Alterations in lipid metabolism have been reported in dogs with CVL, particularly in those with high parasite loads [8]. Another relevant result was observed in the 1659 cm^{-1} band, which predominantly corresponds to the amide I band [6]. The increase in this region reflects the contribution of serum proteins, particularly immunoglobulins, thereby mirroring the humoral activation characteristic of the infection [4].

Taken together, the alterations observed in the protein and lipid bands indicate that *Leishmania* sp. infection drives detectable biochemical changes in the serum of diseased dogs [4]. PCA confirmed the existence of spectral differences between the study groups. ANOVA of the scores showed statistical significance for PC1 (p = 0.017) and PC2 (p = 0.0094), whereas the remaining components yielded $p \geq 0.05$. These results indicate that the majority of the spectral variability associated with the infection is concentrated in the first two principal components, reinforcing that the differences between groups are not random but follow a biological pattern consistent with the pathophysiology of CVL (Fig. 2).

The distribution of the PCs suggests a separation between the negative and positive groups, as well as a tendency to distinguish between different serological titers. Although PCs 3 through 6 did not show statistical significance, possibly due to uneven sample sizes across groups, their spectral characteristics highlighted bands at 759, 855, 962, 1013, 1225, 1320, 1365, and 1375 cm^{-1}. These regions, associated with proteins, the amide group, carbohydrates, and phosphoproteins [6,9], suggest that multiple biochemical pathways are involved in the alterations observed in CVL.

Overall, the results indicate that the biochemical changes associated with CVL are reflected in spectral differences among the evaluated groups. However, these differences must be interpreted at the group level, as the limited number of animals and the uneven distribution of serological titers do not currently allow for the establishment of predictive capability for individual classification. For instance, supervised classification analyses would require a larger, more balanced dataset, as well as validation strategies that account for the origin of spectral replicates, thereby avoiding the use of spectra from the same animal for both model training and evaluation. Thus, the results presented should be considered exploratory and serve as a basis for future studies involving larger samples and individual-level validation.

IV – CONCLUSION

Raman spectroscopy identified spectral differences between seronegative and seropositive dogs, as well as among groups classified by serological titers. The progressive increase in the intensity of bands assigned to phenylalanine, proteins, and amide I in animals with higher titers demonstrates the technique's sensitivity to biochemical changes induced by the humoral response to CVL. Thus, Raman spectroscopy shows promise as a complementary tool for the biochemical characterization of CVL and the assessment of different serological profiles, offering additional support for the CVL diagnosis and monitoring.

***Abstract* — Chronic kidney disease (CKD) is associated with the retention of uremic solutes, with urea, creatinine and glucose being essential markers in clinical follow-up. This study evaluated the potential of Raman spectroscopy (RS) for identifying molecular patterns and quantifying these analytes in human serum. A total of 224 samples were analyzed and distributed into three groups: control (CTRL), diabetic and/or hypertensive (DIAB/SAH), and chronic kidney disease patients on hemodialysis (CKD). Spectra were obtained and pre-processed for fluorescence removal and normalization. Partial least squares (PLS) regression models were constructed for correlation with standard laboratory methods (photocolorimetry). Difference spectra revealed that the DIAB/SAH group had a profile associated with carbohydrates and lipoproteins, whereas the CKD group showed bands related to uremic retention. PLS regression demonstrated high predictive accuracy. RS, combined with multivariate analysis, enabled differentiation of molecular signatures and accurate quantification of biomarkers, being a promising complementary tool for the biochemical monitoring of patients with CKD.**

***Index Terms* — Raman spectroscopy, human serum, creatinine, urea, glucose, PLS**

I. Introduction

Chronic kidney disease (CKD) is associated with the retention of uremic solutes and metabolic and cardiovascular pathologies. Diabetes mellitus (DIAB) and systemic arterial hypertension (SAH) constitute underlying diseases that are determinant for the development and progression of renal injury, while creatinine, urea, and glucose are routine biochemical markers employed in the clinical-laboratory follow-up of these patients [1].

Raman spectroscopy (RS) is a vibrational technique based on the inelastic scattering of light (the Raman effect), capable of recording the molecular signature of proteins, lipids, carbohydrates, and low molecular weight metabolites without re-quiring the use of reagents, allowing rapid and non-destructive analysis of biological fluids and tissues. In human serum, the technique has already been employed to estimate clinically relevant analytes, including urea, creatinine, glucose, proteins, lipids, and lipoprotein fractions, especially when associated with multivariate methods [2-4].

In this study, RS of human serum from three clinical groups were analyzed, with the objective of identifying spectral patterns related to laboratory alterations in urea, creatinine and glucose and evaluating the potential of the technique for biochemical monitoring of patients with CKD undergoing renal replacement therapy.

II. Materials and Methods

This was an analytical, quantitative, and cross-sectional study, approved by the Research Ethics Committee of Alcides Carneiro University Hospital, Federal University of Campina Grande, under CAAE no. 65400422.0.0000.5182.

A total of 224 adults of both sexes were included and distributed into three groups: 1 – Control (CTRL), composed of 57 healthy individuals with urea, creatinine, and glucose within the normal range; 2 – Diabetic and/or hypertensive (DIAB/SAH), composed of 82 individuals with DIAB and/or SAH, with normal urea and creatinine and without renal insufficiency; and 3 – chronic kidney disease (CKD) patients,

composed of 85 individuals on hemodialysis, with elevated serum urea and creatinine and some hyperglycemic individuals.

Serum urea, creatinine, and glucose measurements were performed at the Centrallab laboratory (Cajazeiras, PB, Brazil) by photocolorimetry using an automated analyzer (model AU680, Beckman Coulter, Brea, CA, USA). Subsequently, the samples were sent to the Vibrational Spectroscopy laboratory of CITÉ /UAM (São José dos Campos, SP, Brazil) for spectral acquisition.

Raman spectra were collected using a dispersive spectrometer (model Dimension P1, Lambda Solutions Inc., Waltham, MA, USA), with excitation at 830 nm, power of 350 mW, a 1200 lines/mm diffraction grating, a cooled CCD detector, 2 cm^{-1} resolution and a spectral range from 400 to 1800 cm^{-1}. Three independent spectra were obtained per sample, totaling 672 spectra. The data were subjected to cosmic ray removal, fluorescence correction by polynomial fitting (7th order), normalization by the area under the curve, and calculation of the mean spectrum per sample, in a procedure compatible with protocols previously applied to Raman analysis of human serum [2, 5].

Exploratory data analysis included mean spectra of each sample and difference spectra between the CTRL, DIAB/SAH and CKD groups.

A partial least squares (PLS) regression model was developed for creatinine, urea, and glucose using Chemoface software (https://www.ufla.br/chemoface) from the Federal University of Lavras – UFLA. Raman spectral data (224 samples) in the 400–1800 cm^{-1} range were used as the X matrix, and serum concentrations of creatinine, urea, and glucose (mg/dL) obtained via the reference laboratory method as the Y matrix. The number of latent variables (LVs) was defined by the minimum root mean square error of cross-validation (RMSEcv), resulting in 4 LVs for creatinine, 5 for urea and 11 for glucose. Performance was evaluated by the coefficient of determination of cross-validation (R^2cv), RMSEcv, and the correlation coefficient of cross-validation (r) between measured and predicted values, following the internal validation strategy used in previous studies on the quantification of serum analytes by Raman spectroscopy [3, 5].

III. Results and Discussion

The mean Raman spectra of the CTRL, DIAB/SAH and CKD groups (Fig. 1A) showed spectral features of human serum, with greater contribution from the serum protein matrix, composed of albumin and globulins and other plasma proteins. The bands attributed to phenylalanine (1003 cm^{-1}), one of the main spectral markers of serum proteins [6], to CH^2/CH^3 deformations of proteins, phospholipids, and lipoproteins (1449 cm^{-1}) [7-9] and to the Amide I band, associated with the C=O vibrational mode of peptide groups (1660 cm^{-1}) [3, 8], corresponded to the main spectral contributions of the groups analyzed.

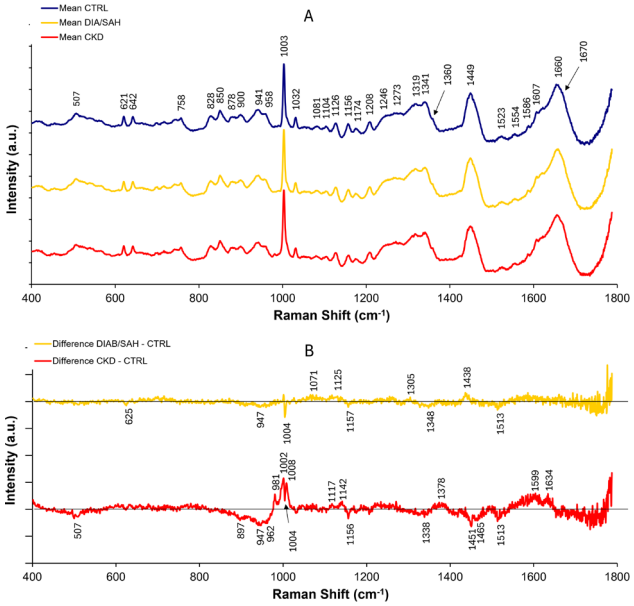

Fig. 1. Mean Raman spectra (A) and Raman difference spectra between the DIAB/SAH – CTRL and CKD – CTRL groups (B)

Bands attributed to aromatic amino acids, including tyrosine, phenylalanine, and carbohydrates (850 and 1032 cm^{-1}) [10-12]; C–C and C–N vibrational modes of proteins and serum metabolites (941 and 1126 cm^{-1}) [7, 13]; carotenoids (1156 cm^{-1}) [10, 11] and protein vibrations (1341 cm^{-1}) associated with nitrogenous compounds present in serum [8, 10] were also identified.

The spectral profile observed for the DIAB/SAH group suggested biochemical differences associated with glycemic and lipoprotein imbalance, characteristics directly related to the metabolic conditions present in diabetic and hypertensive individuals [8]. The contributions attributed to glycidic compounds and lipoproteins, with lower relative participation of serum proteins and carotenoids, showed agreement with alterations in the molecular composition of serum described in conditions of chronic hyperglycemia and metabolic dysfunction [8, 15].

In the Raman difference spectrum DIAB/SAH – CTRL (Fig. 1B), positive features showed contributions attributed to carbohydrates and glycidic compounds (1071 and 1125 cm^{-1}), compatible with C–O, C–O–C, and C–O–H vibrational modes of glucose and related metabolites [8]. Additional contributions were associated with lipids, phospholipids, and lipoproteins (1438 cm^{-1}) [14]. Negative features were identified in regions attributed to serum proteins and aromatic amino acids (947 and 1004 cm^{-1}) [7] and to carotenoids (1157 cm^{-1}) [14].

In the Raman difference spectrum CKD – CTRL (Fig. 1B), positive features occurred in regions attributed to phosphate vibrational modes (981 cm^{-1}) [16], spectral regions previously related to urea (1002 and 1008 cm^{-1}) [3, 13], compounds containing C–N and C–C bonds (1142 cm^{-1})

[17] and aromatic amino acids or protein structures (1599 cm^{-1}) [17]. Negative features were attributed to proteins and amino acids (947 cm-1) [10], carotenoids (1156 cm^{-1}) [15] and CH^2/CH^3 deformations of proteins, phospholipids, and lipoproteins (1451 cm^{-1}) [8]. The greater relative contribution of regions associated with urea, creatinine, phosphates, and nitrogenous compounds showed agreement with biochemical alterations described in patients with CKD undergoing renal replacement therapy, including retention of uremic solutes and disturbances of mineral metabolism resulting from reduced renal function [1, 2, 17].

Together, the mean spectra characterized the serum matrix common to the groups analyzed, whereas the difference spectra evidenced distinct biochemical patterns. The DIAB/SAH group showed a profile associated with glycidic and lipoprotein metabolism, whereas the CKD group showed a greater relationship with nitrogenous compounds, phosphates, and spectral markers compatible with uremic retention. Thus, Raman spectroscopy allowed differentiation of molecular signatures related to the clinical conditions evaluated.

Figure 2 presents the results obtained from the PLS regression model for creatinine (Fig. 2A), urea (Fig. 2B) and glucose (Fig. 2C).

For creatinine (Fig. 2A), the model presented a correlation coefficient r = 0.93 and R^2cv = 0.87. These values are highly consistent with previous studies, such as that of Almeida et al. (2016), which also obtained r = 0.93. The RMSEcv of 1.79 mg/dL is slightly lower (therefore, more accurate) than the error of 1.94 mg/dL. Giansante et al. (2022) showed the poorest correlation, with r = 0.64 and R2cv = 0.41, whereas Giana et al. (2025) exhibited r = 0.85 and R^2cv = 0.63.

In the urea assessment (Fig. 2B), performance was even more significant, with r = 0.97 and R^2cv = 0.98. The model's precision is evidenced by an RMSEcv = 10.3 mg/dL, result superior to those reported by Giana et al. (2025) (r = 0.89, R^2cv = 0.79) and Giansante et al. (2022) (r = 0.89, R^2cv = 0.8). The study by Almeida et al. (2016) showed the closest analytical correlation (r = 0.97) but yielded an RMSEcv of 17.6 mg/dL. Urea is the primary nitrogenous metabolite in serum and directly reflects the balance of catabolism.

Although showing slightly lower performance than creatinine and urea, PLS regression for glucose (Fig. 2C) presented a strong correlation between the methods, with r = 0.85, R^2cv = 0.72, and RMSEcv = 26 mg/dL. This study showed performance similar to that of the work of Silveira et al. (2017), in which r = 0.86, R^2cv = 0.74, and RMSEcv = 26.4 mg/dL were demonstrated. The model's performance in this research was superior to that reported by Giana et al. (2025) (r = 0.86 and R^2cv = 0.74) and Giansante et al. (2022) (r = 0.64 and R^2cv = 0.41).

The results obtained through the association between RS and PLS regression, presented in Fig. 2, demonstrate high potential for the quantification of serum metabolites indispensable for the evaluation of renal function. Analysis of the performance of the models for creatinine and urea reveals a high correlation between the values predicted by RS and those obtained by the reference laboratory methods.

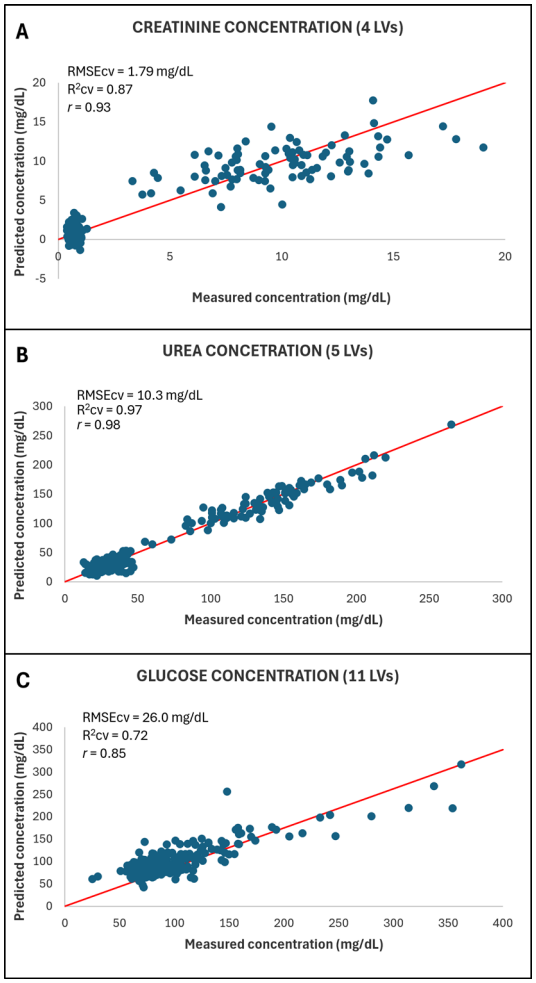

Fig. 2. Plot of the measured versus predicted concentration of the PLS regression and model performance (R^2cv = 0.87, r = 0.93 and RMSEcv = 1.79 mg/dL) for creatinine (A), (R^2cv = 0.97, r = 0.98 and RMSEcv = 10.3 mg/dL) urea (B), and (R^2cv = 0.72, r = 0.85 and RMSEcv = 26.0 mg/dL) glucose (C)

IV. Conclusion

Raman spectroscopy evidenced spectral differences among the CTRL, DIAB/SAH, and CKD groups, associated with distinct biochemical profiles of serum. Whereas the DIAB/SAH group showed contributions mainly related to glycidic, lipid, and lipoprotein compounds, the CKD group showed spectral contributions in regions associated with nitrogenous compounds, phosphates, and biomolecules compatible with alterations observed in chronic kidney disease. These findings demonstrated that Raman was capable of identifying differences in the molecular composition of serum among the clinical conditions evaluated.

When RS is integrated with multivariate spectral models such as PLS regression, it becomes a powerful tool for the biomolecular quantification of important markers in clinical

diagnosis and prognosis, as is the case of creatinine, urea, and glucose in the approach to CKD.

Because this is an exploratory and descriptive study, the results should be interpreted as preliminary evidence, reinforcing the potential of Raman spectroscopy as a complementary tool for biochemical investigation of human serum and encouraging future studies with a larger number of samples and independent clinical validation.

Abstract*—Efficient screening and early diagnosis of dermatological lesions remain significant clinical challenges due to visual overlap between malignant and benign categories and the high demand on specialized care. This paper presents SAD-DERM, a multi-platform clinical decision support system based on convolutional neural networks for the eight-class classification of skin lesions defined by the International Skin Imaging Collaboration (ISIC) 2019 taxonomy (AK, BCC, BKL, DF, MEL, NV, SCC, VASC). Three architectures (ResNet50, DenseNet121, and EfficientNetV2) were trained with transfer learning, focal loss, and mixup augmentation on a lesion-grouped 70/15/15 split of the ISIC 2019 archive, with a frozen test partition of 3,468 images never used during training, model selection, or calibration. The final configuration combined DenseNet121 and EfficientNetV2 through a weighted soft-voting ensemble (0.68/0.32) with Test-Time Augmentation and temperature scaling calibrated on the validation set. On the frozen test partition, the ensemble achieved a macro one-vs-rest area under the receiver operating characteristic curve (AUC) of 0.913 (95% confidence interval: 0.906–0.920), top-1 accuracy of 66.9%, and top-2 accuracy of 84.3%. Per-class analysis with bootstrap confidence intervals, specificity, and confusion analysis identified squamous cell carcinoma and basal cell carcinoma as the primary source of residual error, with bidirectional confusion within the malignant branch. A cascaded variant (malignancy gate + subtype classifiers) was implemented and did not improve SCC classification, suggesting a representation- or data-level rather than an architectural limitation. A threshold-based triage mode prioritizing melanoma recall achieved 91.0% melanoma sensitivity (95% bootstrap CI: [88.8%, 93.2%]) at the cost of reduced specificity in other classes. We conclude that SAD-DERM provides a technically feasible research-grade triage pipeline whose clinical utility must be established through external validation and reader studies. The software is registered at the Brazilian National Institute of Industrial Property (INPI) under process 512026004653-0 and approved by the institutional ethics committee (CAAE: 95092725.7.0000.5031).

I. Introduction

The skin acts as a protective barrier and sensory interface, but its integrity is frequently compromised by a vast array of clinical manifestations [1]. Dermatoses represent a substantial burden on healthcare systems, significantly affecting patients' quality of life and psychological well-being [2]. Timely diagnosis is often hindered by the shortage of specialists, resulting in dangerous care bottlenecks [3].

Among these lesions, non-melanoma skin cancers (NMSC), such as Basal Cell Carcinoma (BCC) and Squamous Cell Carcinoma (SCC), are the most common neoplasms in humans [4], with cumulative ultraviolet (UV) exposure as the primary etiological factor [5], [6]. Conversely, cutaneous melanoma, which originates in melanocytes, presents lower incidence but high lethality when diagnosis is delayed [7]. The precise clinical distinction between melanoma and benign lesions remains one of dermatology's greatest challenges due to visual mimicry and morphological overlap [8].

Pre-malignant and benign lesions act as confounding factors [1]. Actinic keratosis is an intraepithelial dysplasia and direct precursor to SCC [9]. Dermatofibroma and benign keratosis frequently mimic malignant lesions, complicating visual diagnosis [10], [11]. Vascular anomalies add further challenges, particularly in darker skin phototypes [12]. Traditionally, the gold standard requires dermatoscopic evaluation followed by invasive biopsies, overloading the diagnostic queue [4].

Convolutional Neural Networks (CNNs) have emerged as disruptive technologies in medical image interpretation [13]. Recent work achieved 80% accuracy using DenseNet on HAM10000 [14], while others reached 87.72% with custom detection systems [15]; systematic reviews confirm AI precision is often equivalent or superior to human specialists [16]. To bridge this gap, this paper presents SAD-DERM, a diagnostic support system focused on multi-class classification of eight dermatological categories, integrating deep learning into a practical multi-platform application. Unlike prior work

reporting aggregate accuracy on a single hold-out partition, we adopt a three-way lesion-grouped split with a frozen test partition, report per-class metrics with bootstrap confidence intervals, and analyze the confusion structure that dominates residual error. The system potentially assists healthcare professionals subject to the validation requirements discussed in Section VII [1], [3].

II. Theoretical Background and Clinical Categories

A. Convolutional Neural Networks (CNNs)

CNNs constitute a specialized class of deep learning architectures designed specifically for processing grid-topology data, such as digital images [13]. In contrast to conventional neural networks, CNNs employ local connectivity and weight sharing, providing exceptional efficiency in extracting spatial features and morphological patterns [13]. The architectural structure is outlined by convolutional layers that apply parameterizable filters (kernels) to generate feature maps, activation functions like ReLU for non-linearity, pooling layers for spatial dimensionality reduction, and fully connected layers for the final Softmax classification [13].

B. Dermatological Lesions Investigated

To ensure clinical applicability, the system considers eight mutually exclusive diagnostic categories encompassing benign, pre-malignant, and malignant lesions [17], [18]:

- **Actinic Keratosis (AK):** A pre-malignant condition associated with chronic sun exposure, presenting as rough, scaly areas with the potential to progress to SCC [17].
- **Basal Cell Carcinoma (BCC):** A slow-growing but locally invasive malignant neoplasm, often presenting as a pearly papule or ulcerated lesion [18].
- **Benign Keratosis (BKL):** Non-malignant lesions with a keratotic appearance, frequently associated with benign epidermal alterations [18].
- **Dermatofibroma (DF):** A benign cutaneous lesion of fibrohistiocytic origin, typically observed as a firm nodule, frequently located on the lower limbs [19].
- **Melanoma (MEL):** A highly malignant neoplasm originating from melanocytes, characterized by asymmetry, irregular borders, and multiple shades [18].
- **Melanocytic Nevus (NV):** A benign proliferation of melanocytes, being one of the most frequent pigmented lesions in clinical practice [20].
- **Squamous Cell Carcinoma (SCC):** A malignant neoplasm derived from keratinocytes, often presenting as an infiltrated or ulcerated lesion with significant metastatic potential [17].
- **Vascular Lesion (VASC):** Benign alterations associated with the proliferation or dilation of cutaneous vascular structures, including angiomas [18].

III. Materials and Methods

The research was conducted based on a supervised learning workflow for multi-class classification using the TensorFlow/Keras ecosystem. The dataset was sourced from the ISIC 2019 archive, comprising 25,331 images spanning the eight diagnostic categories above. The complete pipeline, from data preparation to deployment, is summarized in Figure 1.

A. Data Splitting and Evaluation Protocol

The ISIC 2019 archive was partitioned using a lesion-grouped stratified split into 70% training (15,821 images), 15% validation (3,861 images), and 15% test (3,468 images). Grouping was enforced at the lesion level: all images sharing the same `lesion_id` were assigned to a single partition, preventing cross-partition leakage through multiple acquisitions of the same lesion. Images with no clinical grouping metadata (2,084) were excluded, and near-duplicate detection via perceptual hashing removed an additional 97 images before splitting. Class distribution across partitions was verified to be proportional to the full cohort within each class.

Patient-level grouping was attempted but proved infeasible: the ISIC 2019 distribution does not publish patient identifiers, HAM10000 does not expose them [27], and the ISIC Archive API v2 does not return `patient_id` for BCN20000 or MSK images (verified through direct API queries; the coverage report is part of the project's reproducibility artifacts). This constraint is discussed further in Section VII.

The test partition was frozen before any model training and used only for final evaluation, after all architectural, calibration, and threshold decisions had been finalized on the validation set. No metric reported in this paper is computed on the validation set.

B. Preprocessing and Data Augmentation

The images underwent spatial resizing and normalization specific to each pre-trained architecture (224×224 for DenseNet121 and ResNet50; native resolution and preprocessing for EfficientNetV2). To mitigate class imbalance and prevent overfitting, medically-safe augmentations were applied during training: random horizontal and vertical flips, rotations within $\pm20^\circ$, small brightness and contrast jitter, and random zoom. The mixup technique [26] was employed during fine-tuning, generating synthetic training samples through linear interpolations between pairs of images and their labels.

C. Architectures and Training Methodology

Three ImageNet-pretrained backbones were evaluated: ResNet50 [21], DenseNet121 [22], and EfficientNetV2 [23]. Each was adapted with a classification head consisting of Global Average Pooling, BatchNorm, Dropout (0.3–0.5), a Dense(256) layer with GELU activation, and a final Dense(8) layer with softmax activation.

Training occurred in two phases: (i) head warm-up with a frozen feature extractor (AdamW, lr $= 10^{-3}$), and (ii) fine-tuning with layer-wise learning-rate decay and cosine schedule. Due to severe class imbalance, the Focal Loss function was employed [24]:

$$L_{FL} = -\alpha(1 - p_t)^{\gamma} \log(p_t), \tag{1}$$

where p_t is the probability assigned to the correct class, α is a per-class weight inversely proportional to the effective number

of training samples, and $\gamma = 2.0$ controls the penalization of easily classified examples. The AdamW optimizer was used with weight decay regularization. Mixed-precision training (`mixed_float16`) was used for hardware acceleration on the Radeon Open Compute (ROCm) platform.

D. Ensemble, Calibration, and Test-Time Augmentation

The final inference configuration, denoted **M4**, combines four components:

1) **Ensemble.** DenseNet121 and EfficientNetV2 softmax outputs were combined via weighted soft voting, with weights fitted on the validation set (DenseNet: 0.68, EfficientNetV2: 0.32).
2) **Temperature scaling.** The ensemble logits were calibrated with a single temperature parameter fitted on the validation set via negative log-likelihood minimization [25].
3) **Test-Time Augmentation.** Input images were transformed with horizontal flip, vertical flip, $\pm 10^{\circ}$ rotation, and center crop 90%, and the resulting softmax outputs were averaged. TTA is a well-established technique for reducing predictive variance under distribution shift [28].
4) **Argmax decision.** Final class assignment by argmax over the calibrated ensemble probabilities.

Ablation modes M1 (DenseNet121 alone), M2 (EfficientNetV2 alone), and M3 (ensemble without TTA or calibration) were also evaluated to isolate the contribution of each component.

E. Clinical Threshold Mode (M5)

A fifth decision mode, denoted **M5**, operates on the same calibrated ensemble probabilities as M4 but replaces argmax with a cost-sensitive rule that prioritizes melanoma recall. M5 does not introduce a new model; it changes only the mapping from calibrated probabilities to predicted labels. Let $p_c(x)$ denote the calibrated probability for class c on image x. M5 selects the predicted label by maximizing the expected utility:

$$\hat{y}(x) = \arg\max_{c} \; u_c \cdot p_c(x), \tag{2}$$

where $u \in \mathbb{R}^8$ assigns $u_{\text{MEL}} = 10$ and $u_c = 1$ otherwise. The factor of ten reflects a deliberate clinical design choice that penalizes melanoma false negatives tenfold, consistent with the clinical priority of melanoma detection [29]. It is not derived from a formal elicitation study, which is out of scope for this work. A grid search over per-class scaling factors was performed on the validation set. Because the rule is a deterministic argmax over utility-weighted probabilities, it inherits the same ranking structure as M4 and differs only in the decision boundary. Consequently, M5 and M4 share identical AUC; they differ only in threshold-dependent metrics (precision, recall, specificity, F1).

F. Metrics and Statistical Analysis

For each mode, per-class precision, recall (sensitivity), specificity, F1, and one-vs-rest area under the receiver operating characteristic curve (AUC) were computed on the frozen test partition, together with macro and weighted averages. All point estimates are accompanied by 95% stratified bootstrap confidence intervals (CIs; 1,000 resamples, stratified by true class; $n = 1{,}000$ follows standard practice for bootstrap CI estimation in medical imaging). Calibration was assessed with two complementary definitions of Expected Calibration Error (ECE): top-label ECE, which measures reliability of the argmax prediction, and macro ECE, which averages per-class one-vs-rest reliability. Brier scores are reported for both definitions. Two complementary error metrics are reported for malignant classes: *label-exact recall* (e.g., true SCC classified as SCC) and *branch-level retention* (e.g., true SCC classified as any of AK, BCC, MEL, SCC), the latter reflecting the clinically actionable distinction between referral and non-referral.

TABLE I
INFERENCE MODES ON THE FROZEN TEST PARTITION (3,468 IMAGES). POINT ESTIMATES WITH 95% STRATIFIED BOOTSTRAP CONFIDENCE INTERVALS (CIS).

Mode	Macro AUC	Top-1	Top-2	Macro F1
M1 (DenseNet)	0.904 [0.894, 0.912]	64.94%	83.68%	51.48%
M2 (EffNetV2)	0.891 [0.882, 0.899]	63.26%	81.81%	46.68%
M3 (Ensemble)	0.909 [0.901, 0.916]	66.06%	83.65%	52.16%
M4 (Ens+TTA+Cal)	**0.913 [0.906, 0.920]**	**66.90%**	**84.31%**	**53.22%**

G. Hardware and Infrastructure

The experimental development was executed on a Linux environment. The primary hardware comprised an AMD Ryzen 7 8700G processor, 64 GB of RAM, and an AMD Radeon RX 6800 XT GPU, utilizing TensorFlow-ROCm for hardware acceleration within a Docker container for reproducibility.

H. System Architecture and Implementation

The SAD-DERM system is deployed as a four-layer client-server application. The backend uses Python and the FastAPI framework, exposing REST endpoints for authentication (JWT), patient management, and inference. A PostgreSQL 15 database persists users, diagnoses, and patient records. The client is built in Flutter, providing a single codebase for mobile, web, and desktop, with clinical history tracking and a side-by-side view of AI predictions and specialist hypotheses. The entire backend is containerized with Docker for reproducibility. We note that the system-level architecture is presented for completeness; quantitative throughput, latency, and usability evaluations are outside the scope of this work.

IV. RESULTS

A. Ablation of Inference Components

Table I presents the four pre-specified inference modes evaluated on the frozen test partition. Each mode isolates the incremental contribution of a specific component.

The ensemble (M3) improved macro AUC by +0.018 over the better single backbone (M1), and TTA combined with calibration (M4) added +0.004, yielding 0.913. We note that non-overlapping confidence intervals do not constitute a formal test

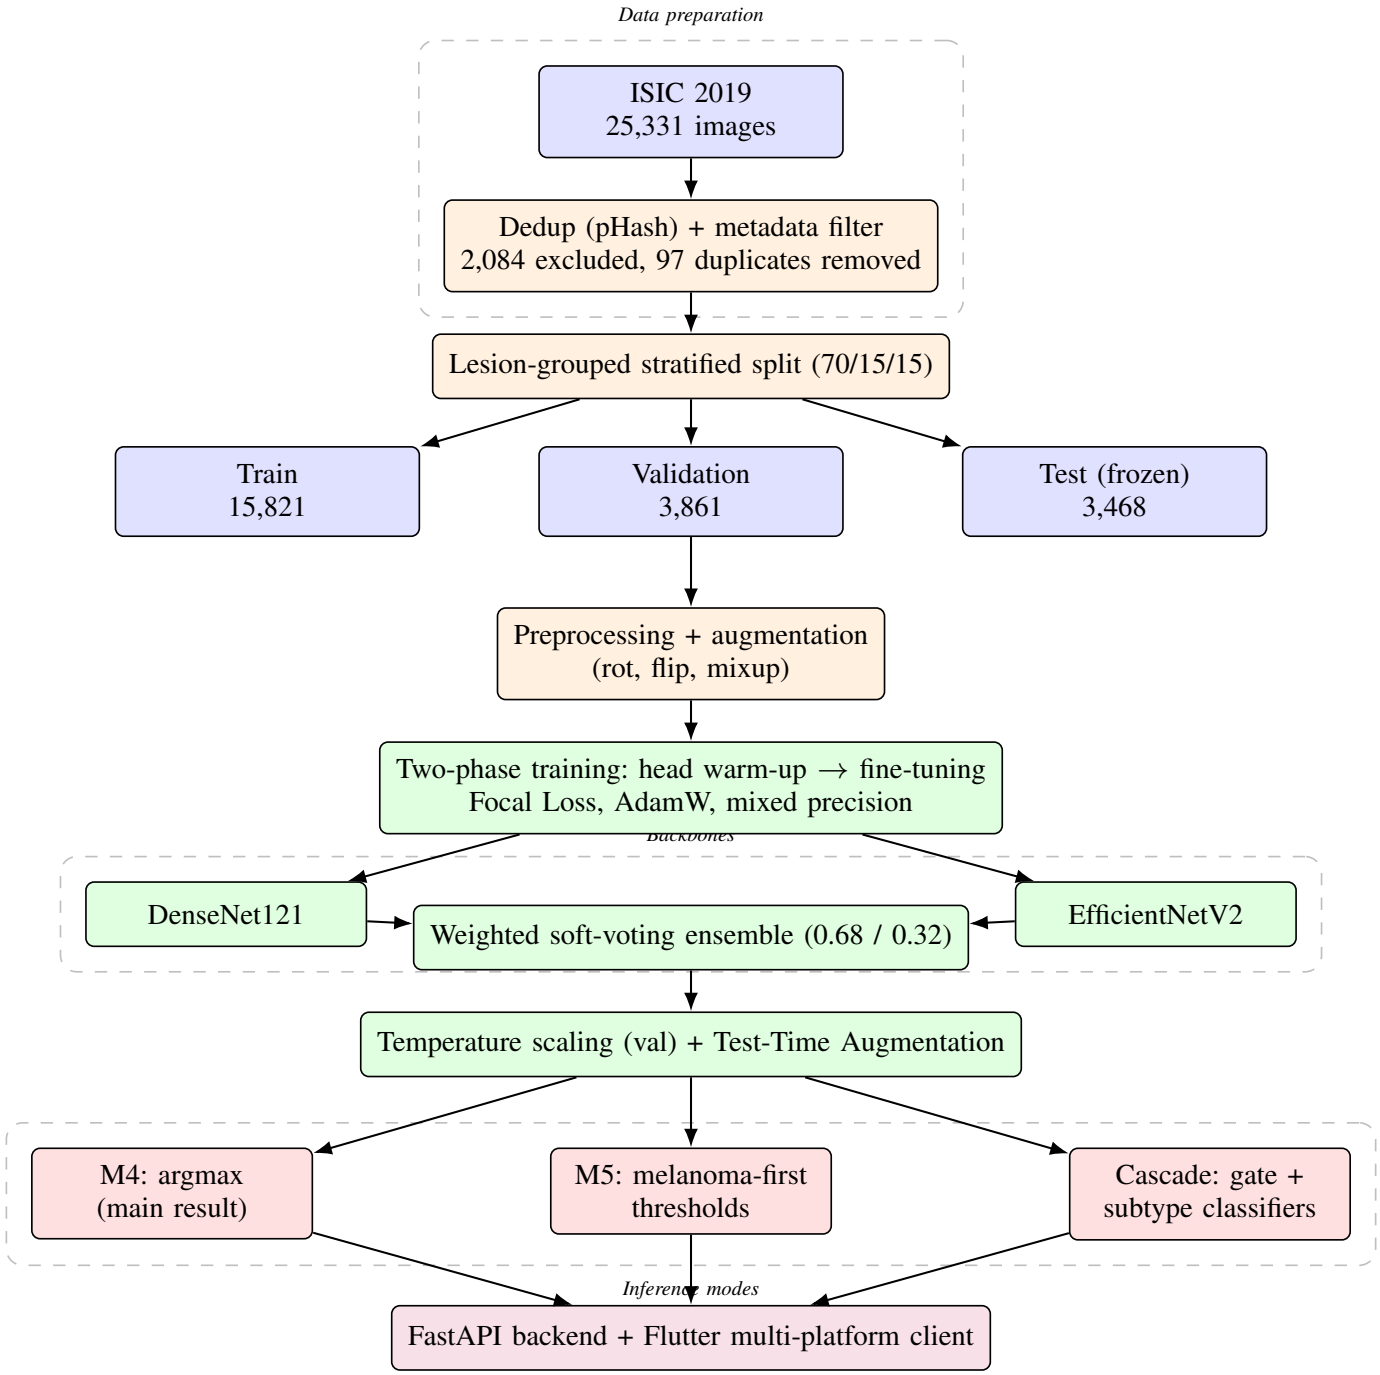

Fig. 1. End-to-end pipeline of SAD-DERM. Data flows from the ISIC 2019 archive through deduplication and lesion-grouped stratified splitting, followed by two-phase training of two backbones. The final inference configuration combines weighted soft-voting ensemble, temperature scaling, and Test-Time Augmentation. Three decision modes (M4 argmax, M5 melanoma-first thresholds, and the cascaded variant) share the same calibrated ensemble. Inference is served through a FastAPI backend to a Flutter multi-platform client.

of difference between correlated models; a paired bootstrap or DeLong-style test is left as future work.

B. Per-Class Performance

Table II reports per-class metrics for M4 on the frozen test partition. All point estimates are accompanied by 95% bootstrap CIs. The corresponding confusion matrix is shown in Figure 2.

Two observations are central (Figure 2). First, the historical concern from preliminary versions of this work — that apparent high recall in small classes might reflect leakage — is resolved by the frozen test partition: DF recall dropped from a leakage-suspect 1.00 to 47.9%, and VASC from 0.98

TABLE II
PER-CLASS FROZEN TEST METRICS FOR M4 (ENSEMBLE + TTA + CALIBRATION, ARGMAX DECISION).

Class	Supp.	Prec.	Recall	Spec.	F1	AUC
AK	110	23.4%	39.1%	95.8%	29.3%	0.920
BCC	497	68.6%	65.4%	95.0%	66.9%	0.950
BKL	362	42.9%	58.6%	90.9%	49.5%	0.867
DF	48	28.8%	47.9%	98.3%	35.9%	0.893
MEL	634	63.2%	50.6%	93.4%	56.2%	0.825
NV	1689	86.8%	78.0%	88.8%	82.2%	0.921
SCC	81	24.8%	43.2%	96.9%	31.5%	0.930
VASC	47	62.3%	91.5%	99.2%	74.1%	0.998

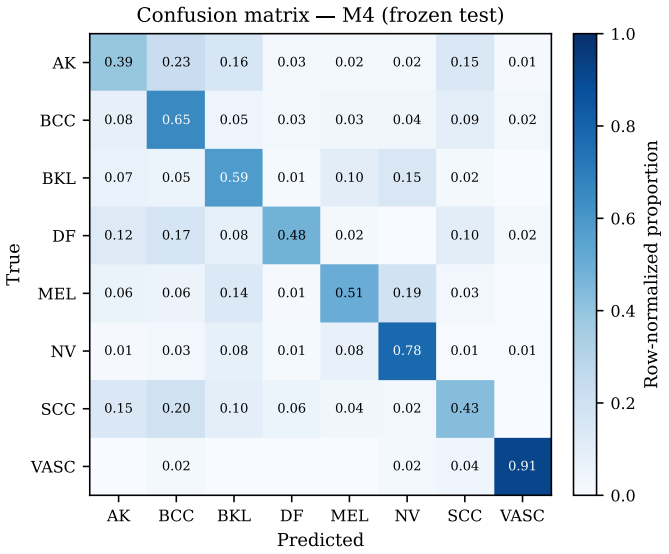

Fig. 2. Row-normalized confusion matrix for M4 on the frozen test partition. Diagonal cells correspond to label-exact recall. The off-diagonal mass in the SCC↔BCC block within the malignant branch is discussed in Section V.

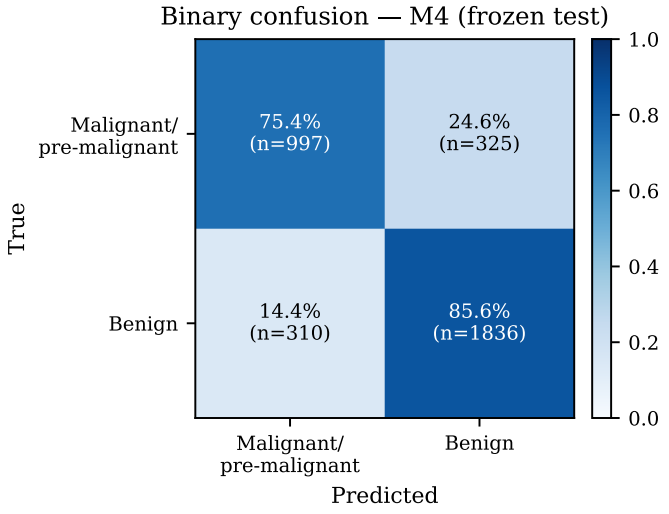

Fig. 3. Binary confusion matrix collapsing the eight classes into malignant/pre-malignant (AK, BCC, MEL, SCC) and benign (BKL, DF, NV, VASC). Values are row-normalized; raw counts in parentheses.

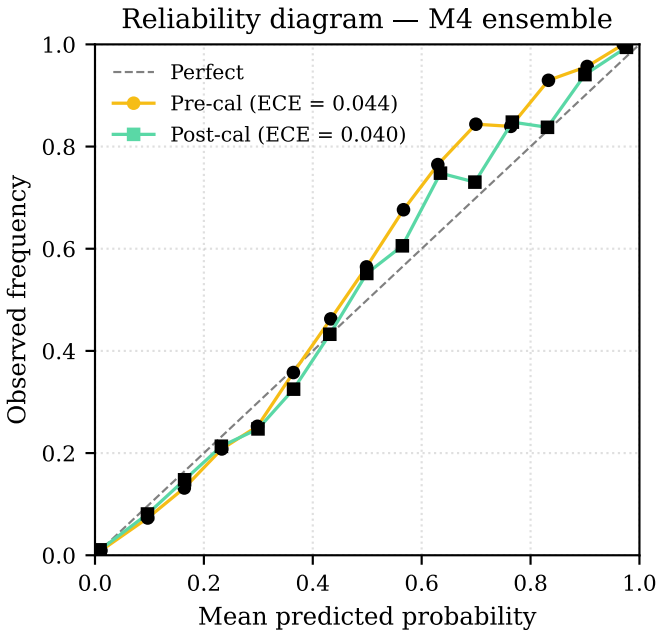

Fig. 4. Reliability diagram for the M4 ensemble before and after temperature scaling. Curves are macro-averaged across the eight one-vs-rest class probabilities. The ECE values shown in the legend (0.044 pre-calibration, 0.040 post-calibration) correspond to the macro-averaged definition. The top-label ECE reported in the text is defined differently and yields 0.076 → 0.042. The dashed diagonal indicates perfect calibration.

to 91.5%, both with wide confidence intervals reflecting their small supports. Second, the residual errors concentrate in specific class pairs: SCC (recall 43.2%), AK (39.1%), and DF (47.9%) exhibit the lowest label-exact recalls, whereas the dominant classes NV and BCC remain above 65% recall.

C. Calibration

Temperature scaling fitted on the validation set reduced the top-label Expected Calibration Error (ECE) on the frozen test from 0.076 to 0.042 (a 45% reduction). Under the macro-averaged per-class definition, the corresponding values were 0.044 and 0.040 (Figure 4). These two figures reflect different definitions of ECE (top-label versus macro-averaged) and are not in conflict. The multiclass Brier score moved from 0.457 to 0.452. Per-class ECE reductions were observed for six of the eight classes, with NV (the majority class) accounting for most of the residual miscalibration. The reduction in top-label ECE confirms that the ensemble probabilities, after calibration, are suitable inputs for downstream threshold-based decision modes.

V. ERROR ANALYSIS

A. Melanoma False Negatives

Under argmax decisions (M4), 313 of 634 melanoma images were not classified as MEL, corresponding to a label-exact melanoma recall of 50.6%. This figure is important context for the reviewer concern that "*three in ten melanomas would not be recovered*" in an earlier single-model configuration. In the

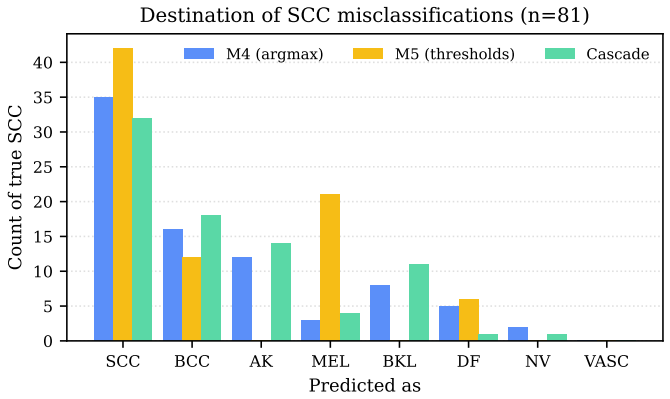

Fig. 5. Destination of SCC misclassifications on the frozen test partition (n=81 true SCC), comparing M4 (argmax), M5 (melanoma-first thresholds), and the cascaded variant. Malignant retention (SCC, BCC, MEL, AK) versus benign leakage (BKL, DF, NV, VASC) is reported in the text.

frozen test M4 configuration, the label-exact recall of 50.6% reflects the fact that many melanomas are classified as benign melanocytic nevi (NV), which is clinically the safest of the false-negative destinations.

To address the clinical priority of melanoma detection, we evaluated the threshold-based mode M5 (Section III-E). On the frozen test partition, M5 achieved a melanoma sensitivity of 91.0% (95% bootstrap CI: [88.8%, 93.2%]), reducing melanoma false negatives from 313 (M4) to 57 (M5) — an 82% reduction. This gain, however, comes at a substantial cost: melanoma specificity dropped from 93.4% (M4) to 49.2% (M5), and BCC false negatives increased from 172 to 239. M5 is therefore reported as a melanoma-first triage configuration, not as a general-purpose classifier.

Because M5 and M4 share identical calibrated probabilities and differ only in the decision rule, their one-vs-rest AUCs are identical; only threshold-dependent metrics change. This reinforces that M5 is an operational mode, not a different model.

B. SCC and BCC: Bidirectional Confusion

Analysis of the frozen test confusion matrix (Figure 2) reveals that SCC and BCC, the two most clinically consequential malignant classes after melanoma, form a bidirectional confusion zone within the malignant branch. The distribution of SCC misclassification destinations is shown in Figure 5, and the binary collapse is shown in Figure 3.

Bootstrap 95% CIs for malignant retention are [72.8%, 88.9%] (M4), [86.4%, 97.5%] (M5), and [76.5%, 91.4%] (cascade). The intervals overlap for all pairwise comparisons, so no difference in retention is statistically significant at the current test-set size (81 SCC images). We therefore avoid claiming superiority of any mode for SCC retention and report the point estimates with their uncertainty.

The confusion matrix also reveals that SCC misclassification is dominated by cross-class errors within the malignant branch: in M4, 16 SCCs were predicted as BCC, and 12 as AK. Both destinations result in a decision to refer the lesion for histopathological confirmation, since all three classes warrant biopsy under clinical guidelines. We emphasize that this does not imply clinical equivalence: SCC, BCC, and AK differ in prognosis, metastatic potential, and therapeutic planning, and the label-exact error remains clinically meaningful even when the referral decision is preserved. Only 15/81 (18.5%) of SCCs leaked into the benign branch, where triage would not refer the patient. In the cascade, benign leakage was 16.0%, and in the threshold-mode M5, 7.4%. These figures characterize SCC as primarily a *within-malignant* discrimination problem rather than a gate-failure problem.

Finally, the reverse direction is equally informative: 47 of 497 true BCC images (9.5%) were classified as SCC by M4, and 66 of 497 (13.3%) by the cascade. The bidirectional SCC↔BCC confusion, with substantial mass in both directions, suggests that the two classes share visual features that the current backbone cannot separate reliably — a hypothesis we tested directly with the cascaded architecture (Section V-C).

C. Cascaded Architecture Experiment

To test whether the SCC bottleneck could be resolved by architectural decomposition, we implemented a cascaded classifier consisting of (i) a binary malignancy gate (MEL, BCC, SCC, AK vs. BKL, NV, DF, VASC), (ii) a malignant subtype classifier over the four malignant classes, and (iii) a benign subtype classifier over the four benign classes. Each stage was trained with the same transfer-learning, focal-loss, and two-phase fine-tuning procedure as the flat models, and inference used soft-gating fusion of the three calibrated outputs.

The cascade failed the pre-registered SCC success criterion (39.5% vs. 58.2% target) while passing the criteria for melanoma recall (54.4% vs. 48.6% floor), BCC recall (68.8% vs. 63.4% floor), and macro AUC (0.919 vs. 0.903 floor). Critically, the benign leakage of SCC in the cascade (16.0%) was not statistically different from M4 (18.5%), and the bidirectional SCC↔BCC confusion *increased*: BCC→SCC errors rose from 9.5% (M4) to 13.3% (cascade). Removing BKL, NV, DF, and VASC from the subtype problem did not simplify it; instead, it isolated the hardest boundary (SCC vs. BCC) and forced the subtype classifier to make finer distinctions within the malignant branch that the backbone cannot support.

We interpret this result as consistent with a representation- or data-level limitation rather than a decision-boundary or architectural one, but we emphasize that this should be read as a hypothesis rather than a causal proof. The failure of a single cascaded configuration does not exclude the possibility that other causes — label ambiguity, class size, domain heterogeneity, resolution, or training strategy — contribute to the SCC bottleneck. The cascade result is reported as a negative finding with full metrics in the reproducibility artifacts; no further hyperparameter iteration was attempted after the pre-registered criteria were evaluated.

VI. Discussion

The SAD-DERM system demonstrates three contributions to the automated classification of dermatological lesions.

First, the ablation study (Table I) shows that the combination of ensemble learning, Test-Time Augmentation, and temperature scaling yields a macro AUC of 0.913 on a frozen test partition. The point estimates are consistent with a genuine contribution from each component, though we refrain from claiming statistical significance of the incremental gains without a paired test of differences.

Second, the per-class analysis with bootstrap CIs (Table II) reveals that the dramatic recalls reported in preliminary versions of this work (e.g., 1.00 for DF, 0.98 for VASC) were artifacts of leaky evaluation. The frozen test partition shows that small classes suffer wide uncertainty, and that SCC and AK remain the weakest categories by label-exact recall.

Third, the cascade experiment (Section V-C) provides a negative result: architectural decomposition does not resolve SCC misclassification and isolates rather than resolves the SCC↔BCC boundary. This has methodological implications: future work should report *branch-level retention* alongside *label-exact recall*, since only the latter reflects downstream clinical safety. In our test set, label-exact SCC recall was 43.2% (M4) and 39.5% (cascade), while branch-level retention was 81.5% and 84.0% respectively.

The threshold-based mode M5 illustrates the trade-off between sensitivity and specificity in a clinical triage setting. Prioritizing melanoma detection reduces melanoma false negatives from 313 to 57 on the frozen test partition, but at the cost of increasing BCC false negatives from 172 to 239 and reducing specificity across all non-melanoma classes. M5 is therefore positioned as a melanoma-first screening mode, applicable when the clinical cost of missing melanoma dominates the cost of unnecessary referrals, and not as a replacement for the argmax classifier. This trade-off is consistent with the broader literature on cost-sensitive classification in clinical decision support [29].

VII. Limitations

Our study has five limitations that should be considered when interpreting the results.

a) Lesion-level, not patient-level grouping.: The ISIC 2019 composite dataset does not publish patient identifiers in its official distribution. We attempted to recover `patient_id` by joining ISIC 2019 image IDs against the original HAM10000, BCN20000, and MSK metadata sources, and by querying the ISIC Archive API v2 directly. HAM10000 does not expose patient identifiers [27], and the ISIC Archive API v2 does not return `patient_id` for BCN20000 or MSK images. Consequently, our splits are grouped at the *lesion* level, with zero cross-partition lesion overlap. This is consistent with prior ISIC 2019 literature but does not exclude the possibility that images of the same patient appear in different partitions when the lesions are distinct; residual patient-level correlation between partitions cannot be fully excluded and is not quantified in this work. Patient-level validation would require the ISIC 2020 or ISIC 2024 cohorts, which publish patient identifiers but are binary (melanoma vs. rest) rather than eight-class.

b) No external validation.: All reported metrics are derived from a single frozen test partition of the ISIC 2019 dataset, which was curated from the same sources as the training data. Performance on images acquired under different conditions remains unknown. Prior work has shown that dermatological CAD systems degrade substantially under domain shift, and our macro AUC of 0.913 should not be interpreted as a predictor of clinical performance on external data.

c) No clinical reader study.: The current system was evaluated against histopathological ground-truth labels, not against dermatologist decisions. A proper clinical validation would compare model predictions to the decisions of board-certified dermatologists on the same images, ideally with a multi-reader multi-case design. Without such a study, our results characterize model-label agreement, not clinical utility.

d) Statistical power for small classes.: The frozen test set contains only 81 SCC, 48 DF, and 47 VASC images. Per-class differences between M4, M5, and the cascade do not reach statistical significance at 95% confidence for any of these classes, as bootstrap CIs overlap. Larger test partitions would be required to detect clinically meaningful differences in these categories. We report all per-class metrics with CIs and refrain from claiming superiority of any mode on small classes.

e) No formal paired test of model differences.: The reported confidence intervals are computed independently for each mode. Comparisons between modes (e.g., M1 vs. M4, or M4 vs. cascade) would ideally use a paired bootstrap of the metric differences, or a DeLong-style test for correlated AUCs. We report independent CIs and refrain from claiming statistical superiority of any single mode. A paired analysis is left as future work.

VIII. Conclusion

This study demonstrated the technical feasibility of a deep-learning-based decision support system for the automated screening of dermatological lesions across eight ISIC 2019 categories. On a frozen test partition of 3,468 images, the final configuration combining DenseNet121 and EfficientNetV2 with Test-Time Augmentation and temperature scaling achieved a macro one-vs-rest AUC of 0.913 (95% CI: 0.906–0.920), top-1 accuracy of 66.9%, and top-2 accuracy of 84.3%. A threshold-based melanoma-first triage mode achieved 91.0% melanoma sensitivity, at the cost of reduced specificity in non-melanoma classes. A cascaded architecture was implemented and produced a negative result, consistent with a representation- or data-level limitation rather than an architectural one.

The SAD-DERM system is consolidated as a research-grade support tool, integrating natively with clinical applications via a REST API and a Flutter multi-platform client. From the perspective of applied software engineering in health, the platform combines computational robustness with clinical usability. The research has its first functional version formally registered

at the National Institute of Industrial Property (INPI) under process number 512026004653-0, and is duly approved by the Ethics Committee (CAAE: 95092725.7.0000.5031). Future work will focus on (i) external validation on an independent dataset with patient identifiers, (ii) a reader study comparing model and dermatologist decisions, and (iii) refinement of the SCC/BCC discrimination through additional training data or auxiliary contrastive objectives.

ACKNOWLEDGMENT

The authors would like to thank the Postgraduate Program in Systems and Products Engineering (PPGESP) at the Federal Institute of Education, Science and Technology of Bahia (IFBA) for the academic support. This study was financed in part by the National Council for Scientific and Technological Development (CNPq) through the master's scholarship process 133298/2025-6.

Carta de Resposta aos Revisores

CBEB 2026 — Congresso Brasileiro de Engenharia Biomédica

Prezado(a) Editor(a) e Comitê Científico,

Agradecemos os comentários criteriosos dos dois revisores sobre o manuscrito "Simultaneous Quantification of Macronutrients in Commercial Milk Using Raman Spectroscopy and Partial Least Squares Regression". Reconhecemos a relevância de todos os pontos levantados. Dado o formato de artigo curto do CBEB e o prazo estabelecido para a versão final (camera-ready), nem todas as revisões sugeridas puderam ser implementadas nesta submissão; abaixo, detalhamos o que foi efetivamente revisado e justificamos os pontos que permanecem como direção explícita para a versão estendida deste trabalho.

Revisor 1

> *"Validar pelo menos um subconjunto das amostras por métodos analíticos independentes e utilizar esses valores na calibração, pois um modelo não pode demonstrar precisão superior à confiabilidade de sua própria referência."*

Resposta dos autores: Concordamos que esta é uma limitação real do estudo. Como a condução de novos ensaios de referência (Kjeldahl, Gerber/Soxhlet, HPLC) está fora do escopo temporal desta submissão, optamos por tornar essa limitação explícita no texto, em vez de mitigá-la sem novos dados. Incluímos na Conclusão a seguinte ressalva: *"the reference values used for calibration corresponded to the concentrations declared on the nutritional labels, rather than to independent reference analytical methods; therefore, the results presented here reflect the Raman-PLS model's agreement with the declared information, within the regulatory tolerance, rather than a validation of absolute analytical accuracy."* A validação com métodos de referência independentes está registrada como etapa necessária para a versão estendida deste trabalho.

> *"Também considero necessário esclarecer o número efetivo de amostras independentes e evitar tratar as 10 aquisições Raman de uma mesma amostra como observações independentes na validação. O leave-one-out deveria excluir conjuntamente todas as medições pertencentes ao mesmo produto/lote, evitando data leakage."*

Resposta dos autores: Este é um ponto metodológico importante que optamos por não alterar nesta versão, pois uma reanálise completa da validação cruzada agrupada por amostra (grouped leave-one-out) no Chemoface exigiria reprocessamento dos dados brutos, o que não foi possível concluir dentro do prazo da versão final do congresso.

> *"Apesar dos Rcv entre 0,784 e 0,861 e dos RMSEcv reportados, não existe um conjunto externo de teste; portanto, afirmar excelente capacidade preditiva apenas com validação cruzada é prematuro."*

Resposta dos autores: Atendido parcialmente. Na Conclusão, a linguagem foi ajustada de "robust/excellent predictive performance" para *"satisfactory predictive performance under leave-one-out cross-validation"*, e a ausência de validação absoluta foi explicitada (ver resposta ao ponto anterior).

Revisor 2

Resumo (Abstract)

> *"Reescrever o final do resumo acerca dos métodos tradicionais de controle de qualidade de leites em pó. Ficou um pouco genérico, uma vez que o trabalho carece de uma seção de trabalhos relacionados. Adicionar também resultados quantitativos mais significativos."*

Justificativa dos autores: Atendido parcialmente. A frase final do Resumo foi reescrita para substituir a afirmação genérica anterior por um resultado quantitativo concreto do próprio estudo: *"15 of 15 samples complied for total protein and casein, and 14 of 15 for both total fat and lactose, the exceptions being attributed toMie scattering-driven optical attenuation and a possible lactose labeling discrepancy, respectively."* A expressão "robust predictive performance" também foi ajustada para "satisfactory predictive performance", em linha com a resposta ao Revisor 1.

Objetivos

> *"Adicionar outros modelos de regressão, bem como um teste estatístico (Wilcoxon) para quantificar melhor os métodos avaliados."*

Justificativa dos autores: A comparação com modelos de regressão alternativos (PCR, MLR) e a aplicação formal de testes estatísticos (Wilcoxon) são adições valiosas, mas exigiriam espaço adicional incompatível com o limite de páginas do formato de artigo curto do CBEB. Optamos por não incluir esses elementos nesta versão para preservar a profundidade das demais seções, e os registramos como direção prioritária de expansão metodológica na versão de periódico.

Trabalhos relacionados

> *"Carece de uma seção específica para posicionar o trabalho na literatura, bem como as principais contribuições metodológicas."*

Justificativa dos autores: Concordamos com a necessidade de uma seção dedicada. Por restrição de espaço do formato de artigo curto, não foi possível inserir uma subseção específica nesta versão; a contextualização da contribuição do trabalho permanece distribuída ao longo da Introdução.

Metodologia

> *"Muito curta, é necessário aumentar os detalhes desde a aquisição até a metodologia de comparação e avaliação, os autores têm espaço para tal. Remodelar a figura do fluxograma metodológico para ficar mais clara. Além disso, esta é apenas citada na figura e não é descrita."*

Justificativa dos autores: Atendido. A seção de Metodologia foi expandida com subtítulos que espelham cada etapa da Fig. 1 (fontes de amostra, aquisição espectral, pré-processamento, modelagem multivariada, validação e figuras de mérito), de modo que o fluxograma passa a ser descrito em texto corrido, e não apenas citado. Foi também adicionado um parágrafo detalhando explicitamente o cálculo de conformidade com a tolerância ANVISA (limite inferior = valor do rótulo × 0,80; amostra considerada conforme quando a média prevista somada ao RMSEcv é maior ou igual a esse limite), etapa que antes aparecia apenas implicitamente nos Resultados. A Fig. 1 foi redesenhada com fontes maiores, cores diferenciando cada etapa do fluxo, espaçamento revisado entre as caixas e uma nova etapa explícita de "Regulatory Compliance Assessment (ANVISA ±20%)", alinhando a figura ao texto metodológico ampliado.

Resultados

> *"Rever todas as unidades das métricas de R2 e RMSE."*

Resposta dos autores: Revisamos as ocorrências dessas métricas no manuscrito e confirmamos que r_{cv} é reportado corretamente como adimensional e $RMSE_{cv}$ consistentemente em g/100 mL em todas as figuras e tabelas nenhuma inconsistência de unidade foi identificada nesta verificação.

Agradecemos novamente a avaliação do comitê e permanecemos à disposição para esclarecimentos adicionais.

Abstract*—The rise of bacterial resistance is a major threat to global public health due to recurrent therapeutic failures and the consequent increase in mortality. In this scenario, Raman spectroscopy stands out as a promising vibrational optical technique, as it enables the identification of cellular biochemical profiles. This study aimed to evaluate the spectral differences between clinical strains of Gram-negative bacteria (*Escherichia coli* and *Klebsiella pneumoniae*) presenting distinct susceptibility profiles (resistant and sensitive), correlating these spectral variations with the mechanisms of action of the antibiotics ciprofloxacin and ampicillin. A total of 121 clinical strains derived from biological samples (urine, cerebrospinal fluid and secretions) submitted for identification at the Municipal Laboratory of Jacareí (Jacareí, SP, Brazil) were used. Spectra were collected in quintuplicate using a dispersive Raman spectrometer (830 nm laser, 400 to 1800 cm^{-1} spectral range), totaling 605 spectra, which were preprocessed for background and noise removal. The results showed that, despite high intrinsic cellular biochemical similarity, the resistant strains exhibited variations in spectral intensity within similar ranges compared to the sensitive group. The results suggest that Raman spectroscopy proved to be an effective analytical tool to discriminate the antimicrobial resistance profile in clinical strains of *E. coli* and *K. pneumoniae.

Keywords—Antimicrobials, Gram-negative bacteria, microbial resistance, optical diagnosis, Raman spectroscopy.

I. INTRODUCTION

The emergence and rise of antimicrobial resistance over the years have consolidated as one of the primary threats to public health in the 21st century, impacting healthcare systems with high morbidity and mortality rates. This phenomenon directly affects medical practice by resulting in severe and difficult-to-manage infections, which prolong hospitalizations, extend treatments, and, consequently, lead to patient death [1]. The 2025 GLASS report [2] highlights that, between 2018 and 2023, antimicrobial resistance increased in 40% of the monitored pathogen-antibiotic combinations, with annual relative increases ranging from approximately 5% to 15%.

The overuse and misuse of antibiotics are currently considered a severe global public health crisis. Resistance reduces treatment efficacy, leading to therapeutic failures, increased mortality, and serious economic impacts [3]. This resistance occurs through a combination of biological mechanisms, including mutations in drug targets, the production of antibiotic-degrading enzymes (such as β-lactamases), or the overexpression of broad-specificity efflux pumps (e.g., AcrAB-TolC and MexAB-OprM), which extrude multiple antibiotic classes before they can reach their target [4].

Ampicillin is a broad-spectrum antibiotic belonging to the β-lactam class, frequently used in clinical practice and agriculture due to its low cost and good initial efficacy [3]. Its mechanism of action is based on interfering with cell wall biosynthesis in Gram-negative bacteria by cross-linking to penicillin-binding proteins (PBPs) during peptidoglycan synthesis, which inhibits essential reactions and weakens the bacterial structure [3]. Ampicillin resistance rates have become high, occurring through the acquisition of β-lactamase genes, mutations in target PBPs, and extrusion by efflux pumps [1, 4]. Furthermore, resistant strains adapt by reducing their metabolic growth and decreasing cell membrane permeability (e.g., porin downregulation), which physically restricts the amount of the compound penetrating the cell and prevents the drug from reaching optimal concentrations [5]. Ciprofloxacin, on the other hand, is a second-generation fluoroquinolone antibiotic introduced into clinical use in the 1980s and is structurally characterized by having a fluorine atom at the C6 position [4]. The drug primarily targets the essential bacterial enzymes DNA gyrase and topoisomerase IV, converting them into toxins that stabilize the cleavage complex, fragmenting the chromosome through DNA double-strand breaks and resulting in oxidative cell death pathways [7]. Despite its broad spectrum of activity against Gram-negative pathogens and good efficacy against Gram-positive ones, resistance to ciprofloxacin has grown considerably and encompasses multiple methods, such as mutations in the genes of the target enzymes themselves (such as gyrA and parC), overexpression of efflux pumps, and plasmid-mediated quinolone resistance (PMQR) [7]. The pathway through PMQR elements, in particular, includes both the production of Qnr family proteins (which physically protect gyrase) and variant enzymes such as AAC(6')-Ib-cr, which directly acetylates and inactivates the ciprofloxacin molecule, creating additional barriers to clinical treatment [8].

The ability of these pathogens to resist therapeutic treatments and survive in hostile environments is associated, among other factors, with the composition and architecture of their cell envelope [9]. The cell envelope of Gram-negative bacteria, such as *Escherichia coli* and *Klebsiella pneumoniae*, exhibits a structural composition organized in multiple layers (outer membrane, cell wall, and inner membrane) that protect the cell from hostile environments. The envelope consists of a system of molecular barriers and is primarily supported by carbohydrate complexes. In Gram-negative bacteria, this structure is formed by a thin peptidoglycan layer protected by an asymmetric outer

membrane rich in lipopolysaccharide (LPS) [9]. Hypervirulent pathogens, such as *K. pneumoniae*, possess capsular polysaccharide (CPS) as a defense mechanism, characterized as a glycan network that functions simultaneously as a shield and an attractant against host antimicrobial peptides [10]. Regarding proteins, their activity is related to controlling the chemical interface and metabolic flux. Integral membrane proteins, such as porins (beta-barrel channels like OmpK35 and OmpK36 in *K. pneumoniae*), have their expression suppressed under stress to restrict antibiotic influx, just as transmembrane protein complexes act as efflux pumps (such as the AcrAB and AcrAB-TolC systems). These biomechanical structures identify intracellular drugs and actively eject them into the extracellular medium, which is characteristic of multidrug resistance phenotypes [3,4]. Additionally, the selective permeability and combined efficacy of glycoprotein networks are associated with lipid diversity [9]. In fact, adaptive mechanisms allow microorganisms such as *E. coli* to reduce cell membrane permeability and restrict drug accumulation by downregulating dedicated transmembrane networks used for antibiotic passage, such as the OmpF porin system [5]. It is known that during the infectious process, the envelope undergoes active chemical remodeling; the bioconjugation of molecules such as palmitate or aminoarabinose directly to the lipid A moiety of LPS is the primary mechanism to neutralize the affinity for last-line antibiotics, such as colistin [10].

In Gram-negative bacteria, nucleic acids (DNA and RNA) are structured by continuous phosphodiester bonds that support the arrangement of nitrogenous bases. The DNA compartment encompasses the main chromosome and a dynamic genome, consisting of mobile genetic elements such as plasmids, transposons, and integrons, whereas the RNA fraction is predominantly organized as ribosomal RNA, highlighting the conserved 16S and 23S domains. The integrity and regulation of this genetic material depend on specific enzymes, such as DNA gyrase, topoisomerase IV, and RNA polymerase, which constitute direct therapeutic targets for clinical antimicrobians, such as fluoroquinolones and rifampicin. In addition to their physiological and structural role, intrinsic characteristics of these biopolymers, such as unmethylated CpG motifs and single- or double-stranded RNA chains, act as pathogen-associated molecular patterns (PAMPs). These components are recognized by intracellular receptors of the host's innate immune system, such as TLR9, acting as the primary triggers of the inflammatory response during the infectious process [9, 10].

Raman spectroscopy is a vibrational technique based on measuring the inelastic scattering of light from a laser by molecules and has stood out for being non-destructive and label-free, effective for chemotaxonomic identification and classification of a wide variety of microorganisms, including bacteria and fungi [11]. By measuring the vibrational energies of fundamental cellular constituents, such as proteins, lipids, carbohydrates, and nucleic acids, the technique can provide a biochemical and structural "spectral signature" for microorganisms [12-14]. Witkowska et al. (2016) [12] evaluated both isolated fungal cells and the main constituents of the cell wall of these fungi (chitin, galactomannan, and β-1,3-glucan). Furthermore, the authors successfully applied the technique to identify the fungus Trichophyton rubrum directly in clinical samples of infected human skin. Additionally, to handle data complexity and perform accurate taxonomic classification, Raman spectra are frequently combined with multivariate statistical analysis and machine learning methods, such as principal component analysis (PCA) and support vector machines (SVM) [11].

In the field of bacteriology, Raman spectroscopy has proven to be effective, enabling the identification and differentiation of bacterial species. Oliveira et al. (2012) [11] used the technique to discriminate seven species of pathogenic bacteria commonly causing urinary tract infections, being capable of identifying spectral differences linked to biochemical content. Subsequently, Oliveira et al. (2020) [13] deepened this study, by expanding the analysis to nine clinical species (three Gram-positive and six Gram-negative) and establishing correlations between statistically significant spectral peaks (ANOVA) and cellular biochemical components, such as peptidoglycans, proteins, and nucleic acids. Recently, the study by Oliveira et al. (2016) [15] evolved the application of the technique from a taxonomic focus to analyzing the problem of antimicrobial resistance, investigating four Gram-negative species (*E. coli*, *K. pneumoniae*, *Proteus mirabilis*, and *Enterobacter cloacae*); by analyzing spectral variations in regions of proteins, lipids, saccharides, and nucleotides. The study successfully discriminated resistant from sensitive strains, achieving a remarkable accuracy of 99.1% independently of the species. In another study, Singh et al. (2023) [16] evaluated sensitive and resistant clinical isolates of *E. coli*, *Acinetobacter baumannii*, and *Enterobacter* spp. by analyzing spectra collected with and without exposure to antibiotics with different mechanisms of action (ciprofloxacin, gentamicin, meropenem, and nitrofurantoin). The results demonstrated that sensitive strains exposed to ciprofloxacin and meropenem exhibited a reduction in the intensity of bands associated with DNA and proteins, accompanied by an increase in lipid bands; however, treatment with gentamicin and nitrofurantoin generated the opposite effect in these same sensitive strains, increasing the nucleic acid signal and reducing those of proteins and lipids.

Considering the relevance of identifying resistance profiles to guide antibiotic therapy, this study aims to evaluate the average spectral differences between clinical strains of Gram-negative bacteria (*E. coli* and *K. pneumoniae*) presenting distinct susceptibility profiles (resistant and sensitive). Additionally, it seeks to compare the obtained results with data already described in the relevant literature associated with the mechanism of action of the antibiotics.

II. Material and Methods

A. Samples

A total of 121 clinical strains, obtained from biological samples (such as urine, cerebrospinal fluid, and secretions), were sent to the Municipal Laboratory of Jacareí (Jacareí, SP, Brazil) for analysis. These bacteria were morphotinctorially identified using Gram staining and standardized biochemical tests for Gram-negative bacilli: EPM MILI (Probac do Brasil, São Paulo, Brazil; MS Registration: 10104030068) for *E. coli* strains and API 20E

(BioMérieux Brasil S.A., Rio de Janeiro, Brazil; MS Registration: 10158120563) for *K. pneumoniae* strains. Antimicrobial susceptibility testing (AST) was performed following two main protocols. First, the disk diffusion method (Kirby-Bauer) was conducted by exposing the bacterial strains cultured on Mueller-Hinton agar to filter paper disks impregnated with antimicrobial agents, including the antibiotics ampicillin and ciprofloxacin. After incubation at 35 ± 2 °C for a period of 16 to 18 h, susceptibility or resistance was characterized by the presence or absence of growth inhibition zones around the disks, verifying that strains exhibiting microbial growth up to the area of direct drug exposure were classified as resistant. Second, automated broth microdilution, using the MicroScan system (Beckman Coulter, São Paulo, SP, Brazil), was employed to determine the minimum inhibitory concentration (MIC) and to detect extended-spectrum β-lactamase (ESBL)-producing bacteria. The AST protocols and breakpoint interpretations were guided by established diagnostic standards, including the guidelines of the American Society for Microbiology (ASM), the Manual of Clinical Microbiology, and the criteria established by the Clinical and Laboratory Standards Institute (CLSI) or the Brazilian Committee on Antimicrobial Susceptibility Testing (BrCAST)/EUCAST.

For the Raman spectroscopy analysis, the bacterial strains were cultured on Mueller-Hinton agar, as this medium has been shown to cause less interference in bacterial Raman spectra, according to [11]. After the standard incubation of 16 to 18 h at 35 ± 2 °C, the plates were safely stored in biohazard boxes to ensure sample integrity and safety during transport. Subsequently, the plates were forwarded for spectral data collection. At the time of analysis, the biomass was carefully collected from the colonies present on the agar surface using a disposable 10-µL loop to avoid interferences, and the material was deposited onto a sheet of aluminum foil. Spectra were collected in quintuplicate, resulting in 605 measurements. After spectral acquisition, all samples were discarded following standard laboratory biosafety protocols. Table 1 describes the different bacterial species used in this study, which were selected due to their relevance in infectious conditions, along with the number of strains to represent the biological variation among the species.

TABLE I
SUSCEPTIBILITY AND RESISTANCE PROFILE OF THE STUDIED BACTERIAL STRAINS

Group		*Species*	
		E. coli	*K. pneumoniae*
Susceptible		30 strains	28 strains
Resistant	Ciprofloxacin	20 strains	17 strains
	Ampicillin	26 strains	–[a]

[a]"–" indicates strains not evaluated for the antibiotic in question.

B. Spectral Acquisition

Spectral data acquisition was performed using a dispersive Raman spectrometer (model Dimension P-1 HR, Lambda Solutions Inc., Waltham, MA, USA), equipped with an 830-nm diode laser as the excitation source. The radiation was delivered to the sample through a fiber-optic cable coupled to a probe (model Vector Probe, Lambda Solutions Inc.) with a focal length of 10 mm, generating a beam on the target with an approximate spatial resolution of 160 µm and ensuring an excitation of 300 mW. The inelastically scattered light was collected by the same probe and directed the detection system, which consisted of a spectrograph and a CCD camera detector. Spectra were collected covering the spectral range from 400 to 1800 cm^{-1} with a spectral resolution of approximately 4 cm^{-1}. To determine reproducibility, each bacterial sample was analyzed in five independent replicates. Acquisition parameters were fixed at an exposure time of 5 s and 10 accumulations per point (total time of 50 s per spectrum). System calibration was checked daily, and readings showing background saturation were discarded.

C. Preprocessing

Following the acquisition, the spectra were subjected to a preprocessing routine to remove equipment-inherent noise and isolate authentic vibrational information, eliminating interferences common in biological samples. Initially, a correction was performed for differences in the wavelength-dependent sensitivity of the spectrometer's optical components (probe, mirrors, diffraction grating, lenses, and CCD camera). Subsequently, the subtraction of the camera's dark signal, correction of potential detector reading defects (hot/cold pixels), and manual removal of spurious cosmic ray spikes were carried out. To eliminate background interference, the subtraction of a 7th-order polynomial fitted over the useful spectral range was applied. The selection of spectral regions of biochemical interest was determined based on domain-specific literature, corroborated by visual inspection of the spectral averages of the analyzed groups.

D. PLS Regression

In order to develop a predictive diagnostic model, the spectra were subjected to partial least squares discriminant analysis (PLS-DA). PLS-DA is a supervised method that establishes a linear relationship between the spectra (X) and the resistance profiles (Y), optimizing the covariance between them. The data were tabulated in spreadsheets and projected onto latent variables (LVs), allowing the identification of the spectral characteristics that discriminate the bacterial phenotypes. PLS-DA also allowed the construction of confusion matrices and the determination of the model's accuracy, sensitivity, and specificity for the differentiation of susceptible and resistant groups of *E. coli* and *K. pneumoniae*. The PLS-DA analyses were performed using the Chemoface software (Universidade Federal de Lavras, Lavras, MG, Brazil), as described by Nunes et al., 2012.

III. Results

A. Mean Raman Spectra of the Sensitive and Resistant Strains of Selected Bacteria Specie

Fig. 1 presents the mean Raman spectra of *E. coli* and *K. pneumoniae* groups in the range from 400 to 1800 cm⁻¹.

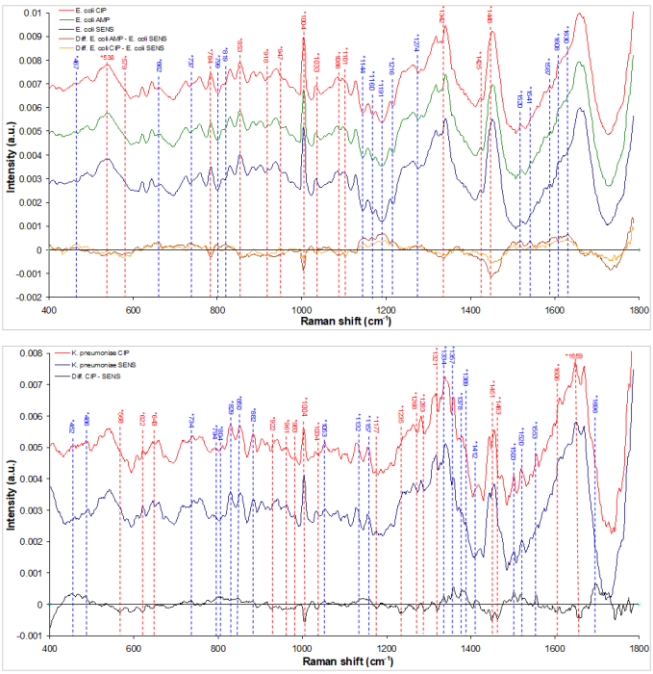

Fig. 1. Mean Raman spectra of *E. coli* and *K. pneumoniae* groups in the range from 400 to 1800 cm⁻¹.

Initially, a similarity was observed between the spectra of both susceptible and resistant strains of each species, which was expected and is justified by the common biochemical composition of this cell type, predominantly consisting of proteins, lipids, nucleic acids, and carbohydrates [5,6,8]. Despite the similarity between the spectra, it was possible to observe differences in the peak intensity pattern.

In Fig. 1, the spectra of the resistant *E. coli* groups (to both ampicillin and ciprofloxacin) showed higher intensity in the positive bands with peaks in the range of ~1520–1630 cm⁻¹, which can be assigned to proteins and amino acids, as well as the peaks at 1216 and 1274 cm⁻¹. Nucleotide bases were also observed at 737, 799, and 819 cm⁻¹, in addition to regions with collective contributions from multiple cellular constituents (~1144–1191 cm⁻¹). In contrast, the susceptible *E. coli* group showed higher intensity in the negative bands with peaks that can be assigned to LPS, such as 579 cm⁻¹, and the peaks in the range of ~853–1101 cm⁻¹, except for the peaks at 1004 and 1033 cm⁻¹, which correspond to aromatic amino acids (phenylalanine, tyrosine, tryptophan).

In the ciprofloxacin-resistant *K. pneumoniae* group, the spectra showed higher intensity in the positive band at peaks that can be assigned to proteins and amino acids, such as those at 829, 850, 1334, and 1357 cm⁻¹, in addition to the range of ~1503–1653 cm⁻¹, noting an approximate similarity with the profile of this latter range observed in the resistant *E. coli* group. The peaks in the range of ~734–804 cm⁻¹ can be assigned to nucleotide bases. The susceptible *K. pneumoniae* group showed higher intensity in the negative bands with peaks that can be assigned to proteins and amino acids in the ranges of ~622–643 cm⁻¹, ~1451–1463 cm⁻¹, and ~1606–1659 cm⁻¹, and to LPS at the peaks of 922 and 961 cm⁻¹.

When analyzing and comparing the susceptible and resistant strain groups of both species, the peak ranges with the highest intensity were found to be close. In the resistant *E. coli* groups, when observing the intensity in the mean difference plot, it was noted that the ampicillin-resistant group showed a higher intensity than the ciprofloxacin-resistant group. Indeed, these spectral variations may be related to the different phenotypic and adaptive mechanisms involved in surviving antimicrobial pressure.

B. Classification of Resistant Versus Sensitive Bacteria by PLS Regression

Table 2 presents the confusion matrix for the classification of spectra from resistant and sensitive strains of *E. coli* and *K. pneumoniae* species. Considering the 360 spectra obtained from the *E. coli* species, an accuracy of 84.4% was achieved. Analysis of the confusion matrix in Table 2 demonstrated that the technique correctly classified 205 out of 227 spectra from resistant strains (true positives) and 99 out of 133 spectra from sensitive strains (true negatives). The model presented only 22 false negatives (resistant strains incorrectly classified as sensitive) and 34 false positives (sensitive strains classified as resistant). With this distribution, the predictive validation achieved a sensitivity of 90.3% and a specificity of 74.4%. For the PLS-DA evaluation of *K. pneumoniae* strains, the model was also accurate. Based on the analysis of 140 spectra, the model achieved an accuracy of 88.6%, correctly classifying 79 out of 84 spectra from susceptible samples and 45 out of 56 from resistant samples. There were five false positives and 11 false negatives. From this distribution, the model demonstrated a sensitivity of 80.4% and a specificity of 94.0%. Furthermore, the PLS-DA analysis suggests that the classifiers may be capable of predicting unknown samples.

TABLE II
CONFUSION MATRIX FOR THE CLASSIFICATION OF THE SPECTRA FROM RESISTANT OR SENSITIVE STRAINS OF *E. coli* AND *K. pneumoniae*

E. coli	**Susceptible**	**Resistant**
Susceptible (*n* = 133)	99	34
Resistant (*n* = 227)	22	205
Sensitivity (%)	90.3%	
Specificity (%)	74.4%	
Accuracy (%)	84.4%	
K. pneumoniae	**Susceptible**	**Resistant**
Susceptible (*n* = 84)	79	5
Resistant (*n* = 56)	11	45
Sensitivity (%)	80.4%	
Specificity (%)	94.0%	
Accuracy (%)	88.6%	

IV. Discussion

The analysis of the difference spectra between the susceptible and resistant groups allowed a comparison of the intensity variations between the susceptibility and resistance of the strains, which may be related to the phenotypic mechanisms and adaptive survival strategies of each species.

Oliveira et al. (2012) [11] extended previous studies in order to differentiate pathogenic species using Raman spectroscopy, a capability later broadened by Oliveira et al. (2020) [13] to encompass a wider range of Gram-negative bacteria for differentiating pathogenic species using Raman spectroscopy, a capability further expanded by Oliveira et al. (2020) [13] to include a wider range of Gram-negative bacteria (*E. coli*, *K. pneumoniae*, *P. mirabilis*, and *E. cloacae*) based on their specific biochemical signatures. In another study, results demonstrated that metabolic changes can be associated with antimicrobial resistance, allowing spectral differences to be observed between resistance phenotypes, as well as interspecies variations [15]. In the current study, the resistant *E. coli* groups showed an increase in peak intensity for protein, amino acid, and nucleotide base assignments, as was also observed in the *K. pneumoniae* group. These findings may indicate phenotypic adaptations associated with cell envelope remodeling, particularly the downregulation or alteration of porins to reduce membrane permeability, a resistance strategy that restricts drug entry but often imposes a significant metabolic fitness cost [5]. In the ciprofloxacin-resistant groups, the spectral findings may be related to the drug's mechanism of action. As previously discussed, it acts by converting DNA gyrase and topoisomerase IV into toxic complexes that induce genome fragmentation and oxidative stress; thus, the concomitant higher intensity in protein and nucleic acid bands may suggest the activation of cellular protection mechanisms against chromosomal damage. This metabolic response observed in the spectra corroborates the hypothesis of PMQR [7]. Munita and Arias (2016) [1] and Reygaert (2018) [17] reported that clinical strains frequently harbor plasmid-mediated resistance determinants, such as the fluoroquinolone-modifying enzyme AAC(6')-Ib-cr or qnr genes, which encode proteins capable of physically shielding DNA gyrase against fluoroquinolones.

The susceptible *E. coli* and *K. pneumoniae* groups showed higher intensity peaks with characteristics mainly associated with lipoprotein assignments and aromatic amino acids, in addition to other protein ranges (which is expected, given the wide variety and types of proteins that compose the cell). The higher intensity peaks in these groups may be associated with the preservation of the structural integrity of cell envelope constituents, such as LPS and peptidoglycan, in bacteria that have not been subjected to adaptive stress. Indeed, the intensity in certain protein and aromatic amino acid peaks (such as phenylalanine, in the ~1004 cm^{-1} region) can be associated with the preserved expression of the species' porins, such as OmpK35 and OmpK36. Oliveira et al. (2026) [15] state that, from a baseline morphological and compositional standpoint, *E. coli* exhibits smaller global intensity variations in its spectra when compared to the other studied species. The results suggest that antibiotic resistance does not rely on an isolated molecular alteration.

Regarding the PLS-DA analysis, the study reinforced the clinical utility of Raman spectroscopy, which, when coupled with this discriminant analysis technique, can serve as a rapid diagnostic strategy, aligning with the global surveillance priorities outlined by the WHO [2] to combat antimicrobial resistance. The high sensitivity observed in the *E. coli* groups may reflect the model's ability to capture biochemical and structural alterations in the spectral signature associated with bacterial resistance mechanisms [1]. Indeed, exposure and resistance to β-lactam antibiotics, such as ampicillin, alter the composition and synthesis of bacterial cell wall structures [3], which is reflected in the electrophysical properties of the *E. coli* cell envelope [6]. These macromolecular changes are related to the vibrational modes of lipids and proteins in the Raman spectra, enabling the PLS-DA model to discriminate resistant phenotypes. The predictive variations between *E. coli* and *K. pneumoniae* highlight that different Gram-negative pathogens employ distinct envelope defense mechanisms [1], ranging from localized modifications in the outer membrane barrier [5] to alterations in intracellular targets, such as those protecting DNA gyrase against quinolones [7]. Ultimately, the chemometric analysis of the difference spectra between susceptible and resistant groups within the PLS-DA framework allowed for a direct comparison of intensity variations. This approach not only demonstrates significant predictive value for identifying resistance profiles in unknown clinical samples but also connects these spectral differences directly to the phenotypic mechanisms and adaptive survival strategies unique to each species.

V. Conclusion

This study reinforced that Raman spectroscopy can be a non-destructive and label-free analytical tool for differentiating the antimicrobial susceptibility profiles in clinical strains of Gram-negative bacteria, such as *E. coli* and *K. pneumoniae*. The results indicated that the spectral differences between susceptible and resistant strains may be associated with a set of structural changes, reflecting variations in lipid compounds, proteins, amino acids, and nucleotide bases. Despite the standardization challenges for direct clinical samples, spectral acquisition and the monitoring of biochemical characteristics support a promising path toward the development of rapid optical diagnostic systems, complementing conventional susceptibility testing in clinical environments. The precise distinction between susceptible and resistant strains occurred independently of the species analyzed, indicating that the spectral signatures of resistance override interspecies biological variations. Furthermore, the fact that the model achieved high accuracy using few latent variables (LVs) reveals that this phenotypic differentiation may present spectral bands from a restricted group of biochemical constituents involved in the resistance of these Gram-negative bacteria. Therefore, future studies are required to develop a database containing other bacterial species, both susceptible and resistant to antibiotics.

***Abstract*—Unstageable pressure injuries are covered by slough or eschar that obscures the wound bed and the depth of tissue damage. This study evaluated infrared thermography combined with seeded region growing to assess these injuries. A descriptive cross-sectional study was conducted on six injuries from three patients drawn from a database compiled from 30 patients admitted to a referral hospital in Curitiba. Images were acquired using a Fluke Ti32 camera, processed in SmartView, and segmented into the outer area, border, inner layers, and thermal islands using thresholds ranging from 0.05 to 0.50. The minimum, mean, and maximum temperatures of each region, the mean temperature by region type, and the thermal gradient between the outer area and the islands were determined. Thermal gradients ranged from 1.22 to 4.44 degrees Celsius, with the largest values observed in the two sacrococcygeal injuries of Patient B, while Patient A showed an irregular internal reheating pattern. The approach quantified spatial temperature variability and provided information complementary to clinical inspection. The small number of cases and the cross-sectional design limit the generalizability of the findings.**

***Index Terms*—thermography, pressure injury, thermal analysis, image segmentation.**

I. Introduction

Unstageable pressure injuries are characterized by the inability to determine the actual depth of tissue damage because slough or eschar obscures the wound bed [1]–[3].

These injuries pose a challenge in clinical practice because devitalized tissue prevents direct inspection of the wound bed and makes it difficult to estimate the extent of tissue involvement [4]–[7]. This limitation may delay treatment decisions and increase the complexity of care [8].

The limitations of visual assessment alone have encouraged the use of complementary methods to identify physiological alterations before clinically evident manifestations occur [9], [10]. Among these methods, infrared thermography enables the measurement of temperature variations associated with inflammation and blood perfusion [11]–[13].

However, interpretation based solely on the thermogram color palette is insufficient. Quantitative analysis of thermal data can improve characterization of the spatial temperature distribution and reduce assessment subjectivity.

Seeded Region Growing (SRG) is a segmentation method based on the similarity of adjacent pixels. Starting from a seed defined within the region of interest, the algorithm iteratively incorporates neighboring pixels that satisfy a homogeneity criterion. Growth ceases when the predefined threshold is no longer met, resulting in spatially connected and thermally similar regions [14].

Accordingly, this study aimed to evaluate infrared thermography combined with seeded region growing for assessing unstageable pressure injuries.

II. Methods

This descriptive cross-sectional study was approved by the Research Ethics Committee under protocol no. 5,651,212. Thermal data were obtained from hospitalized patients with limited mobility in the intensive care unit, medical clinic, and trauma wards of a referral hospital in Curitiba, Brazil. Unstageable pressure injuries were selected from a previously established database of 30 individuals, using the National Pressure Injury Advisory Panel classification [3]. Injuries covered by slough were excluded. The final sample comprised six injuries covered by eschar from three patients.

Thermal images were acquired using a Fluke Thermography Ti32 infrared camera and processed in SmartView software, version 4.3. Thermographic image acquisition was standardized, with temperature maintained at 22 ± 1°C and humidity between 45% and 55% using a digital thermo-hygrometer with a probe (SH112; J-Prolab, Brazil). Acclimatization lasted five minutes, during which the region to be imaged remained exposed and free from contact to avoid thermal imprinting. During image acquisition, participants were positioned in lateral recumbency. An approximate distance of 50 cm was maintained between the skin surface and the camera. The initial analysis used a blue-to-red color palette from the software accompanying the thermal camera to represent the minimum and maximum temperature ranges, with blue tones corresponding to lower temperatures and yellow and red tones to higher temperatures.

The data were exported in `.txt` format and transferred to the API software. Seeded region growing was then applied to segment the regions of interest [14]. Delineation began in the outer area and progressed toward the internal regions, forming successive layers and thermal islands.

Layer and island formation were stopped when the segmented region spanned the injury perimeter or reached the threshold defined between 0.05 and 0.50. The starting point for seed growth development was established as the point closest to the previously developed margin, ensuring no areas were left unanalyzed. The initial marking was made at the edge, followed by the outer area and subsequently the inner layers, until only small areas—designated as "islands"—remained. The colors for these strata were selected from the API's available palette to ensure contrast between the different layers and islands. A 200% zoom level was applied to better identify the seed growth starting points; the API allows for zooming up to 950% if necessary. For each region, the minimum, mean, and maximum temperatures, along with the number of pixels, were recorded to characterize the thermal distribution within each injury. For Patient B, the legend retained the same island indicators for the right and left lesions to ensure standardization, even though data were unavailable for Islands 2 and 3 in the right sacrococcygeal lesion. For Patient C, the seeded region growing procedure was repeated three times on the gluteal lesion to assess repeatability.

Descriptive statistics were calculated from the mean temperatures of the segmented regions. For each of the six injuries, the number of regions (N) and mean temperature were calculated by region type: outer area, border, layer, and island. The thermal gradient (ΔT) was defined as the mean temperature of the outer area minus the mean temperature of the islands.

III. Results and Discussion

Six unstageable pressure injuries from three patients were analyzed. This injury category was selected because the presence of eschar limits direct clinical assessment. Appropriate identification and classification are essential for reducing complications and guiding care [15].

Fig. 1 presents optical and thermal images of Patients A, B, and C, including one trochanteric injury, four sacrococcygeal regions analyzed separately, and one gluteal injury.

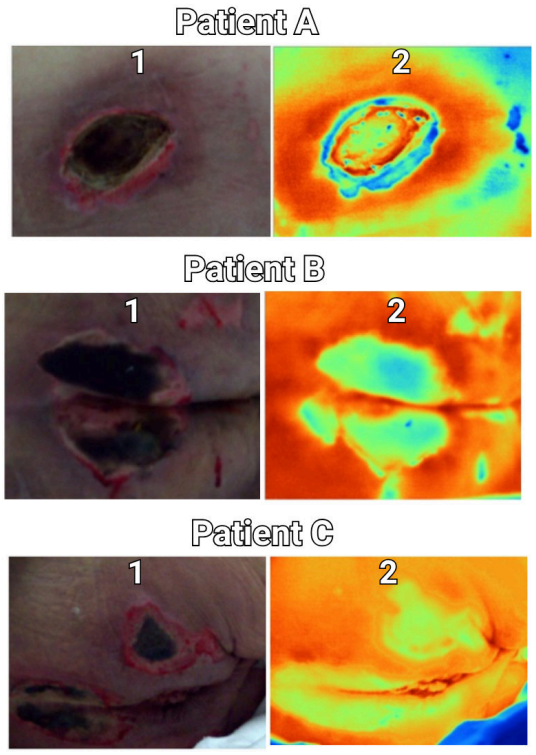
The optical images show eschar but do not provide direct information on thermal distribution or underlying perfusion. In the thermograms, orange and red regions correspond to higher temperatures, whereas blue tones indicate lower temperatures.

Siah et al. [16] observed that distinct thermal patterns in surgical wounds identified during the first postoperative days were associated with delayed healing. These findings indicate that thermography may contribute to monitoring perfusion and the inflammatory response.

Bates-Jensen et al. [17] demonstrated that objective skin temperature measurement improves early identification of pressure-injury-related erythema, particularly when visual inspection is limited by skin tone.

Collectively, this evidence indicates that thermal assessment provides physiological information complementary to visual inspection and may reveal microcirculatory alterations before clinically evident manifestations [16], [17].

After seeded region growing was applied, thermal layers and islands were identified, revealing an asymmetric and variable temperature distribution. These variations may reflect changes in blood perfusion and tissue metabolic activity [11], [18].



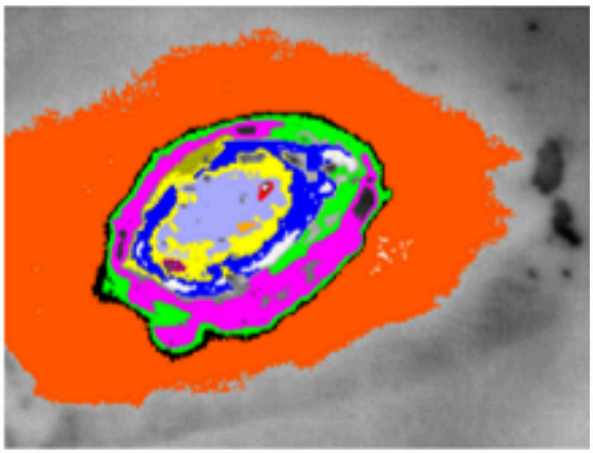


Figure 1. Optical and thermal images of the six unstageable pressure injuries from three patients. (1) Optical image; (2) thermal image using the blue-to-red palette.

Fig. 2 presents the segmented thermogram of the trochanteric injury in Patient A.

Island 2	37.78
Island 3	37.68
Island 4	37.32
Island 5	36.36

Figure 2. Segmented thermogram of the trochanteric injury in Patient A, with layers generated by seeded region growing.

The minimum, mean, and maximum temperatures of the segmented regions in Patient A are presented in Table I.

Table I
THERMAL DATA FOR THE INJURY IN PATIENT A

Areas	Min (°C)	Mean (°C)	Max (°C)
Outer area	38.4	38.74	39.3
Border	37.9	38.11	38.3
Inner layer 1	37.5	37.77	38.0
Inner layer 2	36.7	37.06	37.3
Inner layer 3	38.0	38.25	38.5
Inner layer 4	38.5	38.72	39.0
Inner layer 5	37.5	37.80	38.0
Island 1	37.0	37.31	37.5
Island 2	37.5	37.78	38.0
Island 3	37.4	37.68	37.9
Island 4	37.1	37.32	37.5
Island 5	36.2	36.36	36.5

The segmentation enables the identification of regions with similar thermal behavior and the establishment of boundaries between adjacent areas. This strategy supports quantitative analysis of temperature variations and improves thermogram interpretation [14], [19], [20].

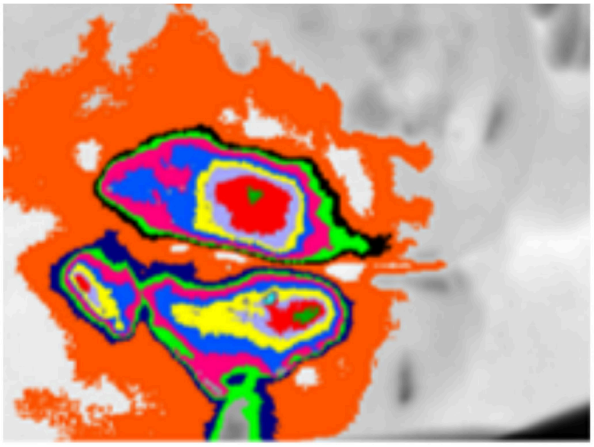

Fig. 3 presents the segmentation of the two sacrococcygeal injuries in Patient B. Although they share an outer area, the algorithm separated the right and left regions, which were analyzed independently in Tables II and III.

Table II
THERMAL DATA FOR THE RIGHT SACROCOCCYGEAL INJURY IN PATIENT B

Areas	Min (°C)	Mean (°C)	Max (°C)

Island 5	–	–	–

To assess the repeatability of the seeded region growing procedure, the gluteal injury in Patient C was segmented three times, as shown in Table VII.

Considering the mean temperature of corresponding regions, the maximum absolute difference among the three repetitions was 0.38 °C in Island 4, numerically corresponding to 1.13% of the three-repetition mean. The mean relative range across the evaluated regions was 0.57%, indicating low intra-image variation among the repeated segmentations.

Table VIII summarizes the descriptive statistics by region type and the thermal gradient for the six injuries.

Table VIII
DESCRIPTIVE STATISTICS AND THERMAL GRADIENTS FOR THE SIX INJURIES

Patient/injury	**Outer area**		**Border**		**Layer**		**Island**		ΔT (°C)*
	N	**Mean (°C)**	**N**	**Mean (°C)**	**N**	**Mean (°C)**	**N**	**Mean (°C)**	
Patient A	1	38.74	1	38.11	5	37.92	5	37.29	1.45
Patient B – right sacrococcygeal	1	37.90	1	37.12	6	35.17	1	33.75	4.15
Patient B – left sacrococcygeal	1	37.90	1	37.12	10	35.31	3	33.46	4.44
Patient C – right sacrococcygeal	1	35.01	2	34.47	2	34.09	2	33.79	1.22
Patient C – left sacrococcygeal	1	35.01	1	34.28	1	33.91	4	32.95	2.06
Patient C – gluteal	1	35.38	1	34.72	4	33.81	4	33.89	1.49

*ΔT = mean temperature of the outer area − mean temperature of the islands.

The largest gradients occurred in Patient B: 4.15 °C (right) and 4.44 °C (left). These values represent the largest thermal contrast between the outer area and the islands; however, they should not be interpreted in isolation as a measure of clinical severity. Lower temperatures in the central regions may be associated with reduced perfusion and heat transport and should be interpreted alongside absolute temperatures and clinical assessment [11], [18], [21].

Patient A had a gradient of 1.45 °C but showed reheating in inner layers 3 and 4, with mean temperatures of 38.25 °C and 38.72 °C, respectively. This pattern confirms that the difference between the outer area and the islands does not, by itself, describe the full pattern of regional temperature variation within the injury.

In Patient C, the gradients were 1.22 °C in the right sacrococcygeal injury, 2.06 °C in the left sacrococcygeal injury, and 1.49 °C in the gluteal injury. In the gluteal injury, Island 1 had a mean temperature of 35.32 °C, whereas the remaining islands ranged from 33.10 °C to 33.60 °C, demonstrating internal temperature variability that would be attenuated by using only the overall island mean.

Prolonged pressure can cause cell deformation, impaired microcirculation, hypoxia, inflammation, and ischemic damage [12], [22]. Because blood flow contributes to heat transport in tissues, changes in perfusion may alter local temperature [18]. However, inflammatory processes, environmental conditions, and individual characteristics also affect thermograms, requiring cautious interpretation.

Overall, the findings indicate that segmentation into layers and islands adds information to visual analysis by identifying central cooling and reheating patterns, as well as spatial temperature variability. Regional quantification may reduce subjectivity and support injury monitoring without replacing clinical assessment [11], [14], [21].

The main limitations were the small number of patients, the cross-sectional design, and the lack of longitudinal follow-up of clinical progression.

IV. CONCLUSION

Infrared thermography combined with seeded region growing quantified thermal differences in six unstageable pressure injuries and distinguished central cooling and internal reheating patterns that were not evident through visual inspection alone. The largest gradients occurred in the two sacrococcygeal injuries of Patient B, whereas the injuries in Patients A and C showed lower contrast and greater regional temperature variation. This approach has potential as a complementary tool for clinical assessment; however, studies with larger sample sizes and longitudinal follow-up are needed to better define its clinical applicability and limits of interpretation.

***Abstract* — De-epithelialized human amniotic membrane (HAM) shows better adhesion and proliferation of epithelial cells compared to its intact form. However, conventional de-epithelialization methods (EDTA, Dispase II, trypsin-EDTA) require prolonged exposure and may compromise the basement membrane. This study evaluated the effect of a single 15-minute exposure of HAM to ozone (O3) using a hydrodynamic system, through qualitative histological analysis (H&E) and optical profilometry (WYKO NT1100), in a sample obtained from a single donor. Histological analysis showed preservation of the internal structures of HAM after treatment, with discrete alterations restricted to the epithelial layer compared to the control group. Optical profilometry recorded a reduction in mean surface roughness (Ra), from 0.626 (± 0.116 µm) in the in natura group to 0.509 (± 0.132) in the treated group, with no statistically significant difference (p = 0.0835; unpaired t-test with Welch's correction). These preliminary findings suggest that O3 exposure may promote alterations in the HAM epithelial layer while preserving the basement membrane and stroma, which reinforces its potential as an alternative to conventional chemical and enzymatic methods.**

Keywords* — *human amniotic membrane, ozone, de-epithelialization, skin graft.

I. Introduction

Human Amniotic Membrane (HAM), also known as the amnion, is the innermost layer of the placenta that surrounds and protects the embryo, and is generally regarded as biological waste after delivery. Histologically, it is composed of three layers: an epithelial layer, a basement membrane, and a stroma.

The epithelial layer is formed by a single layer of epithelial cells with a columnar or cuboidal shape, supported by a basement membrane composed mainly of type IV collagen and laminin. Laminin plays a fundamental role in epithelial cell adhesion and also contributes to their proliferation, migration, and differentiation. Beneath it lies the stroma, composed of three layers: an inner compact layer, a fibroblast layer, and a spongy layer. The stromal extracellular matrix is largely composed of type I, III, V, and VI collagen, in addition to laminin and fibronectin [2].

Historically, HAM has been successfully used as a skin graft substitute in the treatment of burns and wounds for more than a century, and its application has expanded to several areas of regenerative medicine, such as dentistry, oncology, and urology. This wide range of applications is related to its low immunogenicity, which reduces the risk of rejection and inflammation, as well as its ability to accelerate epithelialization and reduce pain [1,3].

As a biological tissue, HAM must be disinfected or sterilized before use, since microbial contamination, mainly by bacteria, is one of the main causes of discard. Gamma radiation is considered the gold-standard method for tissue sterilization, generally applied at a dose of 25 kGy to ensure high microbiological safety. However, doses equal to or greater than 20 kGy can cause structural alterations in HAM, including damage to the basement membrane, degradation of collagen fibers, nuclear chromatin condensation, and reduction of growth factors and tissue inhibitors of metalloproteinases [4]. In this context, there has been growing interest in alternative low-temperature sterilization methods capable of better preserving the physicochemical

and biological properties of biomaterials, in addition to offering faster processing and lower environmental impact.

Ozone (O3) has been investigated as an effective alternative compared to conventional methods, owing to its high oxidative power. When this gas is dissolved in water, its molecular bonds are broken, generating reactive oxygen species that react with organic and inorganic compounds. This process increases the permeability of the cytoplasmic membrane and favors its interaction with the cytoplasm, resulting in cell dissolution [5].

Awoyama et al. [6] found that 15 minutes of ozonation using a hydrodynamic system with ozonated water was able to efficiently disinfect HAM samples experimentally contaminated with Staphylococcus aureus. The authors reported small morphological alterations in the epithelial layer, while the remaining internal structures remained preserved. Based on these findings, the present study aimed to evaluate the effect of exposing HAM to O3 for 15 minutes, using the same hydrodynamic system employed by Awoyama et al. [6], to assess alterations on the surface of the biomaterial. For this purpose, histological analysis was used to verify possible alterations in the epithelial layer and the preservation of the underlying structures. In addition, optical profilometry was employed to quantify roughness (Ra) and verify topographic alterations on the epithelial surface of HAM.

II. Materials and Methods

This study, approved by the Research Ethics Committee of Universidade Anhembi Morumbi (opinion No. 3.984.423; CAAE: 289370020.0.0000.5492) and conducted in accordance with ANVISA RDC No. 190/2003, used HAM obtained at Santa Casa de Misericórdia de Pindamonhangaba (SP, Brazil). The membrane was obtained from a cesarean delivery performed under aseptic conditions, from a donor aged between 28 and 30 years, presenting negative serology for syphilis, hepatitis B, toxoplasmosis, and HIV, following signature of the Free and Informed Consent Form. Samples were washed with sterile saline solution (0.9% NaCl) to remove biological residues and subsequently segmented for the experimental procedures.

Figure 1. Collection and separation of HAM.

A. Experimental procedure

The hydrodynamic system used in this study was developed based on the methodology described by Awoyama et al. (2022) [6], consisting of a closed circuit for ozone generation and dissolution in water, with components manufactured from materials resistant to the oxidative action of the gas. The ozonated water circulated continuously through the system to the head where the HAM samples were positioned, in a climate-controlled environment with controlled temperature. In this study, the exposure time was standardized at 15 minutes, which, according to Awoyama et al. (2022), was the time required for HAM disinfection [6]. This exposure condition was selected based on the previously reported disinfection protocol and was not intended to establish an optimal de-epithelialization exposure time.

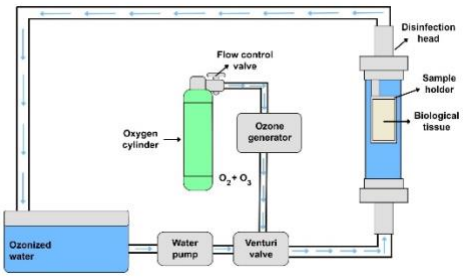

Figure 2. Schematic representation of the hydrodynamic system used for HAM de-epithelialization. Adapted from Souza et al. [8].

B. Histological analysis

For histological evaluation, HAM samples were fixed in 10% formalin solution and subjected to dehydration, clearing, infiltration, and paraffin embedding. Histological sections were obtained using a rotary microtome and stained with hematoxylin and eosin (H&E). Slide analysis was performed using an optical microscope (Opticam® Microscopy Technology), with image capture through T Capture® software. The histological assessment was primarily qualitative, focusing on the epithelial layer and preservation of the basement membrane and stroma.

C. Optical profilometry

Profilometric analysis was performed on a WYKO NT1100 instrument to evaluate possible alterations in the surface morphology of HAM after experimental processing. Samples were divided into a control group (in natura) and a group subjected to the hydrodynamic system with ozonated water for 15 minutes, with measurements taken in standardized central areas of each sample to ensure reproducibility, based on the methodology described in the study by Souza et al., 2026. The main parameter analyzed was mean roughness (Ra), determined from eight measurements (n = 8) obtained from samples derived from the same donor, and defined as the arithmetic mean of the absolute height deviations relative to the centerline of the evaluated profile. Ra means were compared using an unpaired t-test with Welch's correction (two-tailed), preceded by a Kolmogorov-Smirnov normality test ($p > 0.10$ for both groups), with significance set at $p < 0.05$.

III. Results and Discussion

Histological analysis of HAM showed preservation of the internal structures after treatment with O3 for 15 minutes (C

and D), with discrete alterations observed in the epithelial layer compared to the control group (A and B). These findings are consistent with the results reported by Awoyama et al. [6], who also described small morphological alterations in the epithelium after O3 exposure, without significant compromise of the structural integrity of the membrane. In addition, the basement membrane and stroma remained preserved after ozonation (Figure 3).

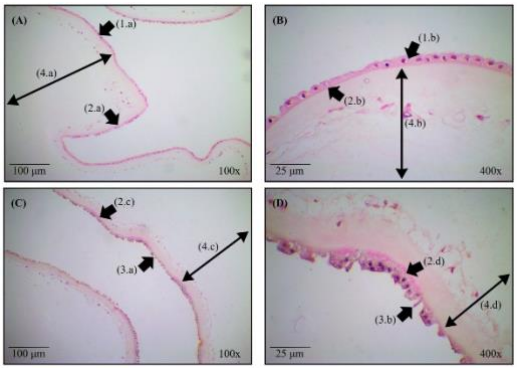

Figure 3. Histological images of HAM stained with H&E. Images (A and B) represent the in natura samples; (**C** and **D**) represent samples processed with O3 for 15 minutes. Arrows (**1.a**) and (**1.b**) indicate the epithelial layer; (**2.a**), (**2.b**), (**2.c**), and (**2.d**) indicate the basement membrane; (**3.a**) and (**3.b**) indicate the alterations observed in the epithelial layer of the treated group; (**4.a**), (**4.b**), (**4.c**), and (**4.d**) indicate the stroma.

In addition, optical profilometry analysis revealed differences in surface topography between the groups (Figure 4). The control group (I) showed a visually more irregular surface, observed both in the two-dimensional projection (I-A) and in the three-dimensional reconstruction (I-B), whereas the group treated with O3 for 15 minutes (II) showed an apparently more homogeneous surface, observed in the two-dimensional projection (II-A) and in the three-dimensional reconstruction (II-B).

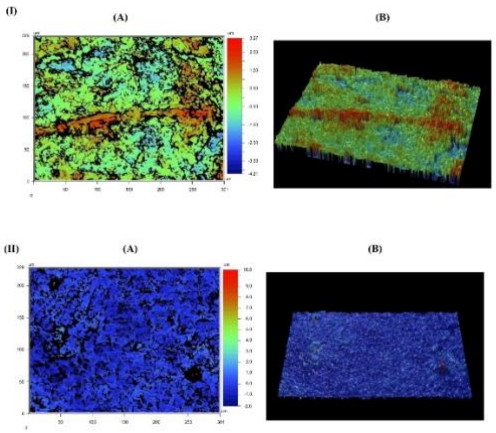

Figure 4. Optical profilometry of HAM: (**I**) in natura group and (**II**) group treated with O3 for 15 minutes; for each group, (**A**) two-dimensional projection and (**B**) three-dimensional reconstruction of the surface topography.

Table 1 presents the mean roughness (Ra) data for the epithelial face of HAM. The Ra value of the in natura sample was 0.626 (± 0.116 µm), while in the group treated with O3 the value was 0.509 (± 0.132 µm). However, this difference was not statistically significant ($p = 0.0835$), indicating only a trend toward reduced surface roughness after treatment. Together with the histological findings, these results suggest that the effects of O3 were mainly observed at the epithelial surface, without affecting the deeper layers of the membrane, with evidence of partial epithelial disorganization in the treated group. These data corroborate the study by Kawata et al. (2025), which used the same hydrodynamic system employed in this study, and reported that for significant alterations to occur in the HAM epithelium, higher O3 dosages are required, and consequently, longer exposure and ozonation times [7].

Tabela 1. Mean roughness (Ra) values obtained by optical profilometry in in natura samples and samples treated with O3 for 15 minutes (mean ± standard deviation). The significance level adopted was 5% ($p < 0.05$).

Parameter	in natura	O3	p-value
Ra (µm)	0,626 (± 0,116)	0,509 (± 0,132)	0,0835

IV. Conclusion

This study found that processing HAM for 15 minutes using a hydrodynamic system with ozonated water induced small alterations in the epithelial layer without affecting the deeper layers of HAM. Although a reduction in surface roughness was observed, the difference was not statistically significant. Therefore, under the conditions evaluated, the treatment resulted in epithelial alterations, but the findings are not sufficient to confirm effective de-epithelialization of the biomaterial. The use of samples from a single donor represents an additional limitation, and future studies should include a larger number of samples from different donors and evaluate different ozone exposure conditions to better assess the de-epithelialization potential of the method.

Abstract*—Skin aging has driven increasing demand for minimally invasive aesthetic procedures, highlighting the combined use of energy-based technologies, such as Microfocused Ultrasound (MFU), and collagen biostimulators, such as Calcium Hydroxyapatite (CaHA). Although the association of these therapies is clinically promising for treating skin laxity and improving dermal quality, current protocols generally recommend intervals between applications due to the theoretical risk of filler material degradation by the ultrasound. This study aimed to evaluate, *in vitro*, the morphological and structural integrity of CaHA crystals when immediately subjected to MFU application. A controlled *in vitro* experimental study was conducted using an ex vivo biological model (porcine skin, Sus scrofa domesticus) and an ultrasonic phantom to reproduce the attenuation of the ultrasonic wave by the human dermis. Synthetic, dry, and non-commercial CaHA samples were divided into a control group (untreated) and an experimental group (treated with MFU using transducers with 3.0- and 4.5-mm focal depths). Analyses were performed using Scanning Electron Microscopy (SEM) to identify the occurrence of fragmentation, cracks, or alterations in crystal porosity. The results demonstrated that no visible changes were detected between the control samples and the samples subjected to MFU. Additionally, no visible differences were observed between the samples covered with porcine skin and those covered with the phantom. In conclusion, under the specific conditions evaluated, the thermal and mechanical energy of MFU did not produce additional morphological changes detectable by SEM in dry synthetic CaHA crystals, regardless of the protocol's frequency or covering medium. These findings represent an *in vitro* proof of concept and do not constitute evidence of clinical safety for same-day combined protocols.

Keywords*—Calcium hydroxyapatite; Microfocused Ultrasound; Facial Rejuvenation; In vitro Study.

I. INTRODUCTION

Skin aging is a multifactorial biological process characterized by progressive structural and functional changes in the epidermis, dermis, and subcutaneous tissue, resulting in reduced dermal thickness, loss of elasticity, changes in tissue support, and redistribution of facial fat compartments. These modifications compromise both skin quality and facial contours, driving the development of minimally invasive therapies capable of promoting rejuvenation with a high safety profile and limited recovery time.

Among these therapies, Microfocused Ultrasound (MFU) has established itself as a key energy-based technology for treating specific skin laxity [1]. The method involves focusing ultrasonic waves at predetermined depths, creating small zones of thermal coagulation (Thermal Injury Zones—TIZs) at temperatures sufficient to cause localized denaturation of collagen fibers and subsequent tissue remodeling [2]. This process triggers immediate tissue contraction and stimulates a prolonged biological response of neocollagenesis, without compromising the integrity of the epidermal surface.

Concurrently, calcium hydroxyapatite (CaHA) stands as one of the most widely used dermal biostimulators in contemporary aesthetic medicine [3], [4]. Composed of synthetic calcium hydroxyapatite microspheres suspended in a biodegradable carrier gel, its action combines an initial volumizing effect with the progressive stimulation of type I and III collagen synthesis, thereby improving skin quality and restoring tissue structure [5], [6]. Initially introduced for the treatment of facial lipoatrophy, its use subsequently expanded to various facial and body rejuvenation protocols, making it

one of the most extensively studied biomaterials for dermal biostimulation [7], [8].

In recent years, several clinical studies have demonstrated that combining MFU and CaHA can enhance aesthetic outcomes compared to the use of either technology alone [9], [10], [11]. While MFU promotes collagen reorganization through the controlled deposition of thermal energy in deep tissue planes, CaHA acts as a scaffold for the deposition of new collagen around its particles; this creates complementary mechanisms of action capable of simultaneously addressing skin laxity, tissue support, and dermal quality [12], [13], [14].

Despite favorable clinical outcomes, a significant gap remains regarding the direct interaction between ultrasonic energy and the biomaterial following implantation. In clinical practice, various protocols recommend performing MFU prior to CaHA application or maintaining an interval of weeks or months between procedures; this approach is based on the hypothesis that the mechanical and thermal energy generated by ultrasound could alter the physical integrity of the biostimulator particles and compromise their biological performance [15]. However, this recommendation remains based predominantly on theoretical considerations and indirect clinical evidence, with a scarcity of experimental studies directly investigating potential morphological changes in calcium hydroxyapatite following immediate exposure to MFU.

From a biomedical engineering perspective, characterizing this interaction is of great scientific importance. Validating the structural stability of CaHA when exposed to microfocused ultrasound supports the development of safer clinical protocols and contributes to the creation of experimental models designed to evaluate the interaction between injectable biomaterials and energy-based therapeutic technologies. Furthermore, the use of ultrasonic phantoms with acoustic properties similar to those of human skin enables the controlled replication of ultrasound propagation conditions, thereby reducing reliance on animal models and enhancing experimental reproducibility.

Given the high physicochemical stability of calcium hydroxyapatite as a bioceramic, it was hypothesized that the energy delivered by MFU clinical protocols would be insufficient to produce detectable morphological changes in the material's crystalline structure.

Thus, this study aimed to evaluate—using Scanning Electron Microscopy (SEM)—potential morphological changes in synthetic calcium hydroxyapatite crystals immediately after exposure to microfocused ultrasound (MFU). To replicate the acoustic propagation conditions encountered in clinical practice, two experimental overlay models were used—porcine skin (*Sus scrofa domesticus*) and an ultrasonic phantom [16] previously characterized as having acoustic properties compatible with human skin—thereby allowing for an investigation into the influence of the propagation medium on the biomaterial's structural integrity.

To date, no studies have been identified in the literature that directly evaluated the morphological integrity of CaHA crystals exposed to MFU using Scanning Electron Microscopy (SEM)—an approach that enables direct visualization of the mineral surface at the micrometer scale and the detection of structural alterations such as fragmentation, fissures, and changes in surface porosity.

II. MATERIALS AND METHODS

A. Materials

The experiment utilized dried samples of non-commercial synthetic calcium hydroxyapatite crystals (0.12 mg); porcine skin strips; a graphite-loaded ultrasonic phantom; a Microfocused ultrasound device (Pixie Pen V3 – By MedSystems); a Leica EM SCD050 sputter coater for sample preparation; and a ZEISS AURIGA 40 for scanning electron microscopy.

B. Sample Organization

Initially, the samples were divided into two main groups of 6 samples each, totaling 12 samples. The first group consisted of samples treated with the SMP 4-4.5 tip (4 MHz frequency, 4.5 mm focal depth, 0.9 J energy, and a rate of 7 pulses per second), designed to target the SMAS region for facial lifting. The second group consisted of samples treated with the DDP 7-3.0 tip (7 MHz frequency, 3.0 mm focal depth, 0.6 J energy, and a rate of 7 pulses per second), intended to induce thermal denaturation in the deep dermis to restructure the skin's deep support and enhance firmness.

Each subgroup within these two divisions contained 3 samples (0.1 mg each), resulting in a total of four sample divisions (i.e., two main groups and two subgroups). Within each subgroup, the samples were individually placed on a smooth acetate sheet featuring a standardized 10 mm x 10 mm grid pattern—arranged in parallel and sequential rows—to form a total sample area of 30 mm x 10 mm.

C. MFU exposure protocol

In the first group, the first set of samples was covered with a layer of ultrasound phantom material, with an area corresponding to the acetate markings and a thickness of 4.5 mm (30 mm x 10 mm x 4.5 mm). The second set of samples was covered with porcine skin, also with dimensions corresponding to the acetate surface markings and a thickness of approximately 4.3 mm (30 mm x 10 mm x 4.3 mm); (Fig. 1).

Fig. 1. MFU pulse delivery using an SMP 4-4.5 tip (4 MHz, 0.9 J, 7 pulses per second, 4.5 mm focal depth) on a porcine skin overlay.

Both coverings aimed to simulate the physical characteristics and reproduce certain acoustic properties of a strip of human skin approximately 4.5 mm thick—matching the target depth of the facelift handpiece near the Superficial Musculo-Aponeurotic System (SMAS), a region where

CaHA biostimulators are also used for structural support, bone projection, and facial contouring to correct age-related loss of bony support. The first sample in each sequence served as a control and was not treated; subsequently, the remaining four samples received 100 ultrasound pulses each from the SMP 4-4.5 handpiece using the specified settings, creating duplicates for each subgroup. The thicknesses of both the phantom and the animal skin were measured using analog calipers and a thickness gauge.

In the second group, the first sequence of three samples was also covered with the ultrasonic phantom—sharing the same specifications and ultrasonic characteristics but with a thickness of 3.0 mm (30 mm x 10 mm x 3.0 mm). As in the first group, the second sequence was covered with a strip of porcine skin, also approximately 3.0 mm thick (30 mm x 10 mm x 3.0 mm). These coverings aimed to mimic the physical characteristics of a strip of human skin at the deep-dermis depth for which the DDP 7-3.0 handpiece was designed, as well as to replicate some of its ultrasonic properties (Fig. 2).

This region also represents a significant depth for biostimulators, as it is the primary dermal level for stimulating neocollagenesis to provide skin support and firmness. As with the first group, both thicknesses were measured using a caliper and an analog thickness gauge. Also as with the first group, the initial samples in each sequence were not treated—serving as the control group—while the remaining four samples received 100 ultrasound pulses each. Both groups underwent the procedure on the same day.

Each sample received 100 ultrasound pulses, applied to an area of approximately 1 cm² of porcine skin and phantom material. Radial movements around a central point were required to deliver the shots, as the device does not fire while the applicator is stationary for safety reasons. The small experimental application area resulted in a density of 100 ultrasound pulses/cm², a value exceeding the average densities of 5.0–6.7 shots/cm² (SMP 4-4.5) and 2.5–3.3 shots/cm² (DDP 7-3.0) observed in routine practice [15]. Thus, the experimental protocol represented a deliberately more severe acoustic exposure scenario, to establish a conservative condition for evaluating the morphological integrity of the CaHA crystals.

Fig. 2. MFU pulse delivery with DDP 7-3.0 tip, 7 MHz, 0.6 J, 7 pulses per second, 3.0 mm focal depth, on a porcine skin covering.

Although the treatment tips serve different purposes, they are similar in dimensions—particularly regarding their firing diameter, which is 1 cm in both cases. Nevertheless, thermal contraction effects were observed in the treated skin samples when compared to those not exposed to ultrasound (Fig. 3). The general classification and grouping of the samples are outlined in Table 1.

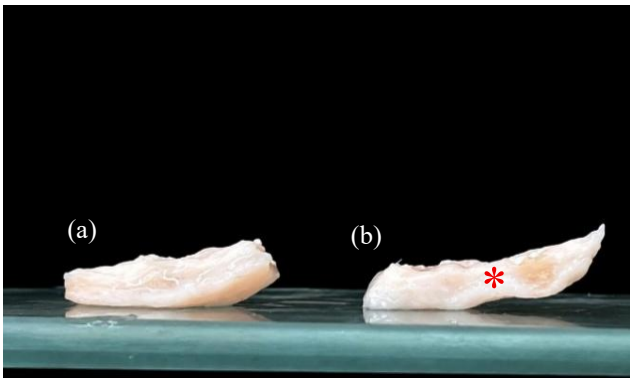

Fig. 3 Comparison of porcine skin samples: (a) sample not subjected to MFU firing; (b) sample subjected to firing with the SMP 4-4.5 transducer; (*) thermal contraction. In both samples, the epidermis faces downward, in contact with the glass surface.

TABLE I SAMPLE GROUPS

	Frequency [a]	*Coverage*	*Focus*	*Test group*	*Energy (J)*
1	4 MHz	phantom	4.5 mm	1	0.9 J
2	4 MHz	phantom	4.5 mm	1	0.9 J
3	7 MHz	phantom	3.0 mm	2	0.6 J
4	7 MHz	phantom	3.0 mm	2	0.6 J
5	4 MHz	skin	4.5 mm	1	0.9 J
6	4 MHz	skin	4.5 mm	1	0.9 J
7	7 MHz	skin	3.0 mm	2	0.6 J
8	7 MHz	skin	3.0 mm	2	0.6 J
9	-	phantom	-	1	-
10	-	phantom	-	1	-
11	-	skin	-	2	-
12	-	skin	-	2	-

[a] The pulse repetition rate was the same for all samples (7 PPS – pulses per second), as was the number of shots per sample (100 ultrasound pulses). The groups refer to the material coating the samples, and the subgroup refers to the focal spot of the tip used.

D. Characterization of the Ultrasound Phantom

The ultrasonic phantom used was developed by the Ultrasound Laboratory (LUS) at the Graduate School of Engineering of the Federal University of Rio de Janeiro (COPPE/UFRJ) and was originally designed to mimic the acoustic properties of human skin [16]. The model in question consists of 50 mL of Regular Plastic (plastic for making plastic worms; M-F Manufacturing Co., Inc., stock no. 2132LP, Fort Worth, Texas, USA)—polyvinyl chloride (PVC) monomers immersed in a plasticizer—and 1.0 g of graphite. Graphite was selected due to its high durability, physicochemical stability, resistance to biological degradation, and ease of handling—characteristics that make it a promising material for fabricating phantoms intended for biomedical ultrasound research. Additionally, the graphite acts as an ultrasonic wave scattering agent, allowing for the adjustment of the material's acoustic properties and producing behavior more similar to that observed in biological tissues [16].

The physical properties determined for the sample used were: thickness of 2.86 ± 0.29 mm, density of 0.94 ± 0.03 g/cm³, acoustic impedance of 1.40 ± 0.04 × 10^6 kg·m^{-2}·s^{-1}, attenuation coefficient of 1.11 ± 0.03 dB·cm^{-1}·MHz^{-1},

ultrasonic propagation speed of 1488.12 ± 0.01 m/s, specific heat of 1694.66 ± 6.90 $J \cdot kg^{-1} \cdot °C^{-1}$, and thermal conductivity of 0.24 ± 0.00 $W \cdot m^{-1} \cdot K^{-1}$ [16].

When compared to reference values described in the literature for human skin, the phantom demonstrated high similarity in acoustic parameters fundamental to ultrasonic wave propagation. The measured propagation speed (1488 m/s) was extremely close to the lower limit reported for human skin (1498–1624 m/s), while the attenuation coefficient (1.11 $dB \cdot cm^{-1} \cdot MHz^{-1}$) fell within the reference range described for this tissue (1.04–3.50 $dB \cdot cm^{-1} \cdot MHz^{-1}$). These results indicate that the material is capable of satisfactorily reproducing the interaction of the ultrasonic beam with the skin layer, particularly regarding phenomena such as absorption, scattering, and energy loss during propagation.

The use of ultrasonic phantoms in experimental studies is of great scientific importance, as it enables testing under controlled and reproducible conditions, free from the variability inherent in biological tissues. Furthermore, these materials allow for the standardization of experimental protocols, facilitating comparisons between different samples, equipment, and acquisition conditions. In the context of this study, the phantom served as a reference material for evaluating the behavior of measurements obtained from biological tissue.

The comparison between the phantom and the animal skin used in the *in vitro* experiments—specifically porcine skin—is particularly relevant because the skin represents the first interface encountered by ultrasonic waves upon entering the body. Consequently, its acoustic properties directly influence the transmission, reflection, absorption, and distribution of ultrasonic energy within the underlying tissues. Although porcine skin shares anatomical and physiological characteristics with human skin, variations in thickness, hydration, structural composition, and storage conditions can influence experimental results. In this regard, the use of a pre-characterized phantom provides a stable reference standard, making it possible to verify whether the responses observed in the biological tissue align with the expected behavior of a material that reproduces the acoustic properties of skin, as shown in the comparisons in Table II.

TABLE II COMPARATIVE VALUES BETWEEN THE ACOUSTIC PROPERTIES OF THE PHANTOM USED AND AVERAGE MEASUREMENTS OF HUMAN SKIN

Physical Property	***Unit***	***Phantom***	***Human Skin Reference Range***
Density (ρ)	g/cm^3	0.94 ± 0.03	1.09 – 1.20
Acoustic Impedance (Z)	$\times 10^6$ kg $\cdot m^{-2} \cdot s^{-1}$	1.40 ± 0.04	1.4-1.87
Propagation Velocity (c)	m/s	1488.12 ± 0.01	1498 - 1624
Attenuation Coefficient (α)	$dB \cdot cm^{-1} \cdot MHz^{-1}$	1.11 ± 0.03	1.04 – 3.5
Thermal Conductivity (k)	$W \cdot m^{-1} \cdot K^{-1}$	0.24 ± 0.00	0.23 – 0.50
Specific Heat (Cp)	$J \cdot kg^{-1} \cdot ° C^{-1}$	1694.66 ± 6.90[a]	3150 - 3660

[a] The specific heat of the phantom (1694.66 $J \cdot kg^{-1} \cdot K^{-1}$) falls within the range reported for dry human stratum corneum (1500–2200 $J \cdot kg^{-1} \cdot K^{-1}$) [20], [21]—the outermost layer of the epidermis, characterized by low water content—and is significantly lower than that of hydrated skin (3150–3660 $J \cdot kg^{-1} \cdot K^{-1}$).

E. Sample Processing

To enable microstructural characterization and reduce charging effects during microscopy analysis, the samples were subjected to a physical vapor deposition process via sputtering. The sputtering process aimed to deposit a thin gold layer onto the samples and was carried out using a Leica EM SCD050 automated coater equipped with an Adixen Pascal 2005 SD dual-stage mechanical pump. After positioning the sample holder inside the vacuum chamber, the system was evacuated until a safe residual pressure was reached.

Subsequently, the chamber was purged via 30 controlled injections of argon gas (analytical grade) using the "rinsing" function, with the aim of completely eliminating residual oxygen and stabilizing the working atmosphere.

Operational parameters were established by maintaining a constant pressure of 0.05 mbar and a fixed working distance of 50 mm between the metal target (Au) and the sample surface. Based on prior equipment optimization protocols designed to ensure film uniformity, the deposition process was conducted using a sputtering current of 40 mA for a total exposure time of 90 seconds. Upon completion of the programmed time, the plasma flow was interrupted by closing the shutter, and the reaction chamber was slowly pressurized to local atmospheric pressure prior to the removal of the metallized samples.

F. Scanning Electron Microscopy

Analysis of the surface morphology and dimensional assessment of the calcium hydroxyapatite crystals were performed using Field Emission Gun Scanning Electron Microscopy (FEG-SEM) with a ZEISS AURIGA dual-beam microscope (FIB-SEM CrossBeam; Carl Zeiss Microscopy GmbH, Germany). The analyses were conducted at the National Center for Structural Biology and Bioimaging (CENABIO/UFRJ).

Following gold coating, the sample stubs were mounted on the motorized stage and introduced into the high-vacuum analysis chamber. Images were acquired using an electron beam accelerating voltage (Electron High Tension – EHT) set to 2.00 kV and a working distance (WD) maintained between 4.8 mm and 5.2 mm, ensuring the necessary spatial resolution without causing thermal or structural damage to the material. Secondary electron detection for topographic mapping was performed using a conventional Everhart-Thornley (SE2) detector. Various magnification levels (ranging from 100x to 1.00 kX) were applied to obtain panoramic views of the distribution as well as to isolate and directly measure individual crystals/particles.

III. RESULTS

SEM images showed no visually detectable differences in the apparent morphology of the CaHA crystals, regardless of the experimental configuration tested. Among the 12 samples comprising the study cohort, the 8 samples subjected to MFU pulses showed no visually detectable differences compared with the 4 control samples. Consequently, no visually detectable evidence of immediate morphological degradation was observed.

A. Qualitative Characterization of the Control Group

Photomicrographs of control samples (samples 9, 10, 11, 12), which did not receive ultrasound shots, revealed that the CaHA crystals used as source have an intrinsically irregular and clastic (detrital) morphology. The presence of particles with varying dimensions and surfaces with pre-existing porosity and fragmentation was observed, characteristics inherent to the material in its dry state. Micrometric measurements confirmed the presence of crystals with major axes varying, for example, between 58.86 µm and 60.23 µm (Fig. 4). Observation of the conformation of the basal morphological profile was essential for comparison with the tested samples.

B. Evaluation of Experimental Groups

Samples subjected to 100 MFU shots were analyzed based on their technical classification into two subgroups defined by the frequency and focal depth of the ultrasonic transducer.

The subgroup subjected to 4 MHz shots (samples 1, 2, 5, and 6)—despite being exposed to a higher energy load (0.9 J) targeted at a depth of 4.5 mm (near the SMAS level)—showed no additional thermal or mechanical damage upon microscopic examination; furthermore, no new fissures, particle fusion, or microscopic patterns attributable to the ultrasonic beam were observed. Similarly, the subgroup subjected to 7 MHz shots (samples 3, 4, 7, and 8)—despite having a higher tissue attenuation rate in the deep dermis at 3.0 mm—also maintained apparent physical stability. The visual appearance of the crystals in these samples remained structurally indistinguishable from that of the control groups (Fig. 5).

C. Influence of Covering Media (Porcine Skin vs. Phantom)

No morphological or structural differences were detected between samples covered with porcine skin and those protected by the graphitized synthetic phantom. No morphological or structural differences were detected between samples covered with porcine skin and those protected by the graphitized synthetic phantom. The two covering media produced similar morphological outcomes under the experimental conditions evaluated; however, this similarity does not establish equivalence in the spatial distribution or dose of acoustic energy delivered to the crystals.

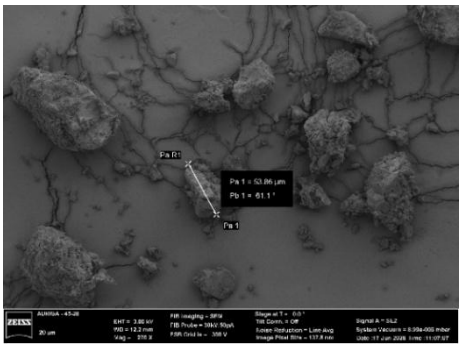

Fig. 4 Control sample (sample 10) at a 20-µm scale, with a reference particle measuring 53.86 µm, showing particles both smaller and larger than the reference particle in the same micrograph.

In summary, microscopy results confirmed that, regardless of the frequency used (4 MHz or 7 MHz), the applied energy density, or the covering material, the CaHA crystals maintained their apparent morphological integrity as assessed by surface SEM. No new fissures, fragmentation, or particle fusion were observed under the tested conditions. It should be noted, however, that the analysis is essentially qualitative and that the absence of visible changes via SEM does not imply clinical safety, as sub-micrometric or physicochemical alterations undetectable by this technique cannot be ruled out.

IV. DISCUSSION

The morphological integrity of CaHA crystals following exposure to MFU is a crucial factor for the validation of combined clinical protocols. SEM results demonstrated that, regardless of the frequency used or the covering material, there was no fragmentation, cracking, or alteration in the surface porosity of the crystals.

A. Thermal and Mechanical Stability of CaHA

The absence of structural damage can be explained by the intrinsic properties of CaHA as a bioceramic. While MFU operates by generating thermal injury zones (TIZs) with temperatures ranging from 65°C to 75°C to induce collagen denaturation and tissue contraction, the literature indicates that the thermal degradation of calcium hydroxyapatite occurs only at extremely high temperatures, with sintering points near 1000°C [2], [17].

Unlike other polymeric biostimulators such as poly-L-lactic acid (PLLA) or polycaprolactone (PCL)—which have glass transition temperatures close to the operating ranges of energy-based devices and may undergo deformation under thermal stress—CaHA exhibits superior thermal stability [17]. This serves as a benchmark for the intrinsic thermal stability of CaHA as a bioceramic. It is important to note, however, that the thermal effects of MFU are highly localized and transient, differing fundamentally from uniform bulk heating (bulk sintering). Therefore, the sintering temperature should not be interpreted as direct evidence of resistance to MFU, but rather as an indicator of the material's mineral robustness—which, combined with SEM findings, suggests that the energy delivered by MFU was insufficient to produce detectable morphological changes under the tested conditions.

B. Clinical Implications of the Order of Application.

Currently, there is a debate regarding the optimal treatment sequence: the application of MFU followed by CaHA on the same day is considered safe and effective for enhancing neocollagenesis [13]. The theoretical concern that ultrasound might fragment the biostimulator and accelerate its resorption in an unpredictable manner was not supported by the *in vitro* data presented here.

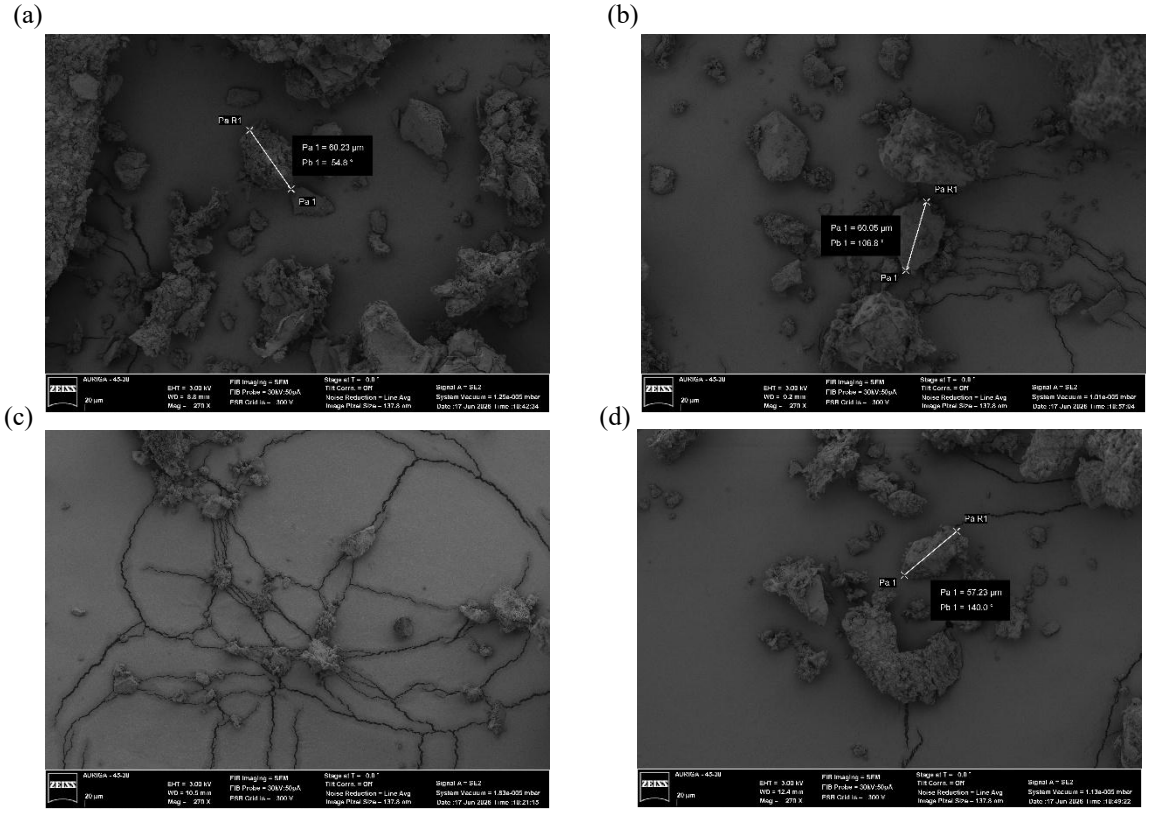

Fig. 5. (a) (sample 1) 20 µm scale with reference particle measured at 60.23 µm, 4.5 mm focal depth, 4 MHz, 0.9 J – Phantom covering. (b) (sample 5) 20 µm scale with reference particle measured at 60.05 µm, 4.5 mm focal depth, 4 MHz, 0.9 J – Phantom covering. (c) (sample 3) 20 µm scale, 3.0 mm focal depth, 7 MHz, 0.6 J – Animal skin covering. (d) (sample 7) 20 µm scale, reference particle measured at 57.23 µm, 3.0 mm focal depth, 7 MHz, 0.6 J – Animal skin covering.

Although some histological studies suggest that performing MFU first may "prime" the tissue and enhance subsequent interaction with CaHA particles, the present findings only indicate that direct MFU exposure did not produce additional morphological changes detectable by surface SEM under the tested conditions. Therefore, these results cannot be used to infer preservation of the biological function of CaHA particles after MFU exposure.

C. Validation of the Experimental Model and the Phantom

The phantom used showed an attenuation coefficient within the reported reference range for human skin, while its propagation speed was close to the lower limit of the reported range [16]. The attenuation coefficient is an important parameter influencing energy loss during propagation through the covering medium. Regarding this parameter, the phantom (1.11 $dB \cdot cm^{-1} \cdot MHz^{-1}$) fell within the reference range for human skin (1.04–3.50 $dB \cdot cm^{-1} \cdot MHz^{-1}$), indicating compatible attenuation. It should be noted, however, that other parameters—such as density, acoustic impedance, and specific heat—differ from the reference values for human skin (Table II); consequently, claims of complete equivalence to "*in vivo*" conditions are not supported by the available data.

It is important to note, however, that no homogeneous mimicking material can simultaneously reproduce all the characteristics of a stratified biological tissue like human skin [17], [18]. The suitability of a Tissue-Mimicking Material (TMM) is evaluated based on the specific application rather than an absolute match of all parameters [17], [18]. In this regard, the measured acoustic impedance (1.40×10^6 $kg \cdot m^{-2} \cdot s^{-1}$) falls within the range accepted for TMMs in the literature (1.4–1.7 MRayl) [17], [19], and the propagation speed (1488 m/s) differs by only 0.7% from the lower limit of the reference range, remaining within the ±5% tolerance reported in the literature [17], [18]. Regarding specific heat, the measured value (1694.66 $J \cdot kg^{-1} \cdot K^{-1}$) is consistent with the range reported for dry human stratum corneum (1500–2200 $J \cdot kg^{-1} \cdot K^{-1}$) [20], [21]—the outermost layer of the epidermis, characterized by low water content—and is lower than that of hydrated skin (3150–3660 $J \cdot kg^{-1} \cdot K^{-1}$). The phantom was therefore selected and validated based on its acoustic attenuation properties—the parameter most directly relevant to the energy reaching the crystals—without implying complete biological equivalence to *in vivo* human skin [22].

D. Crystal Morphology and Biological Response

It was observed that the CaHA samples used exhibited an irregular, clastic morphology rather than that of perfect microspheres. In the literature, commercial microspheres (such as Radiesse) feature smooth surfaces and diameters ranging from 25 to 45 µm to minimize chronic inflammatory reactions [23], [24], [25], [26]. The fact that crystals with more angular shapes withstood 100 ultrasound pulses without undergoing further fragmentation underscores the robustness of the mineral material. However, while it is tempting to infer those commercial microspheres—due to their more regular geometry and smooth surfaces—would offer an even greater margin of physical safety under the same MFU settings, this

inference remains speculative. Commercial CaHA/CMC microspheres differ from the crystals used in this study in terms of morphology, particle size distribution, and surface characteristics; therefore, direct studies using commercial formulations are required to validate this hypothesis.

E. Experimental Limitations

Despite the promising results, this study presents limitations inherent to the *in vitro* model. The use of dry, non-commercial crystals—while useful for observing the pure mineral structure—does not mimic, for example, the presence of a carrier gel (such as carboxymethylcellulose/CMC) found in some commercial products, or tissue hydration, both of which can influence thermal conduction [27]. Furthermore, the experiment focused on immediate physical integrity and did not evaluate potential long-term chemical changes or the biological inflammatory response following irradiation.

Moreover, as an *in vitro* model, the experiment does not account for the effect of blood perfusion, which plays a crucial role in heat distribution and dissipation within living tissues subjected to therapeutic or microfocused ultrasound.

V. CONCLUSION

Under the experimental conditions evaluated, immediate application of microfocused ultrasound did not produce additional morphological changes detectable by scanning electron microscopy in the dry synthetic calcium hydroxyapatite crystals. The 4- and 7-MHz MFU protocols were not associated with detectable additional fragmentation of the material under the tested conditions, regardless of whether the coating was of biological or synthetic origin.

These findings are consistent with the hypothesis regarding the physical feasibility of same-day combination protocols, indicating that, under the tested conditions the CaHA maintained its apparent morphological integrity. The validation of the ultrasonic phantom as a controlled experimental model contributes to future investigations into the interaction between energy-based technologies and injectable biomaterials.

The main takeaway from this study is that surface SEM, while adequate for detecting macroscopic morphological changes, is insufficient as a standalone method for characterizing subtle physicochemical modifications in mineral bioceramics. Key research gaps identified include: (1) studies using commercial CaHA/CMC formulations under hydrated and implanted conditions; (2) quantitative morphometric analysis combined with crystallographic (XRD) and spectroscopic (Raman, FTIR) characterization; (3) direct acoustic dosimetry of the energy delivered at the focal point in biological models; and (4) biological and in vivo validation of the safety of same-day combination protocols.

ACKNOWLEDGMENTS

The authors thank the Padrón Lins Multi-user Microscopy Unit at the Paulo de Góes Institute of Microbiology (UNIMICRO), located at the Health Sciences Center (CCS/UFRJ), for technical support and assistance with sample processing. We also thank the CENABIO team for their essential assistance with the microscopy analyses. Special thanks to Professor Marcelo Henrique Prado for providing the batch of calcium hydroxyapatite used in this study.

***Abstract*—β-metastable titanium alloys have emerged as promising alternatives to the most common titanium alloys used in medical devices, such as Ti-6Al-4V (Ti64), due to their lower toxicity, excellent corrosion resistance, and lower elastic modulus, more similar to cortical bone. This study aimed to evaluate the biological performance of the Ti-29Nb-13Ta-4.6Zr (TNTZ) alloy using Vero cells. The samples were characterized through direct contact cytotoxicity assays, extract cytotoxicity tests, cell viability assessment using the MTT assay, and scanning electron microscopy (SEM). The results demonstrated preservation of normal cell morphology, absence of cytotoxic effects, and cell viability above 70%. SEM analysis revealed satisfactory cell adhesion and spreading across the alloy surface. Overall, the findings indicate that the TNTZ alloy exhibits excellent biocompatibility and considerable potential for biomedical implant applications, representing a promising alternative to the conventional Ti64 alloy.**

***Index Terms*—Biomaterials; Bone tissue engineering; Cell adhesion; Metallic Biomaterials; Titanium; Titanium alloys.**

I. Introduction

By definition, biomaterials are materials designed to interact with biological systems for the purpose of evaluating, treating, augmenting, or replacing organs, tissues, or biological functions [1]. These materials must exhibit essential characteristics such as biocompatibility, ensuring that they do not induce significant adverse effects, including toxicity, inflammation, allergic reactions, or carcinogenicity [2]. These characteristics are essential to ensure a safe interaction with the host tissue and the long-term performance of medical devices. Furthermore, biomaterials should present suitable biodegradability or bioresorbability when required, be non-toxic, and possess surface characteristics compatible with their intended biomedical application. Therefore, the selection of an appropriate biomaterial is crucial to minimize undesirable physiological responses, such as local inflammation or infection, which may ultimately compromise systemic health [3], [4].

Bone tissue engineering has emerged as an effective strategy to restore skeletal function by promoting tissue regeneration while providing structural support and mechanical stability for the treatment of bone defects caused by trauma, tumors, infections, and congenital skeletal abnormalities, conditions that frequently require surgical intervention [5]. Metallic biomaterials play a fundamental role in stabilizing damaged bone structures and providing mechanical support, thereby reducing the risk of deformities, pain, and functional impairment. The chemical composition of these metallic devices can also be tailored according to patient-specific clinical requirements [5]. Commercially pure titanium (cp-Ti) and titanium alloys are among the most widely used metallic biomaterials for temporary and permanent implants because of their excellent mechanical performance, corrosion resistance, and biocompatibility. Moreover, there is the possibility of developing alloys with characteristics specifically optimized for each biomedical application [5]–[7], as modifications in alloy composition, thermomechanical treatments, and structural or chemical processing can significantly improve their intrinsic properties [4]–[6].

Among the recently developed β-type titanium alloys, Ti-29Nb-13Ta-4.6Zr (TNTZ) has attracted considerable attention because of its low elastic modulus, which reduces the stress-shielding effect while promoting osseointegration [6]. Furthermore, the alloying elements niobium (Nb), tantalum (Ta), and zirconium (Zr) provide excellent corrosion resistance and

Corresponding author: Andressa Francine Martins (andressa.francine@ufabc.edu.br)

exhibit high biological safety due to their non-toxic nature [6]. The development of this alloy addresses the need for an alternative to the conventional Ti-6Al-4V (Ti64) alloy, which contains aluminum and vanadium, elements that have been associated with potential long-term toxic effects [7]. Within this context, the present study aimed to evaluate the interaction between Vero cells and the β-metastable TNTZ titanium alloy to investigate its potential application as a biomaterial for bone tissue engineering and as a promising alternative to the commercially established Ti64 alloy.

II. Materials and methods

A. Sample Preparation

The TNTZ alloy was selected due to its non-toxic composition and its favorable mechanical and biocompatibility properties [6]. After forging, the samples were homogenized at 850 °C for 1 h under an argon atmosphere and subsequently water-quenched. The TNTZ specimens (8 mm in diameter and 30 mm in length) were then ground using silicon carbide (SiC) abrasive papers with grit sizes ranging from 120 to 3000, ultrasonically cleaned, and polished with a 0.6 μm silica suspension. Subsequently, the specimens were subjected to a single pass of Equal Channel Angular Pressing (ECAP) at 300 °C using Route A to refine the microstructure and enhance their mechanical properties [19].

B. Sample Sterilization

Prior to the in vitro experiments, the samples were washed with water and neutral detergent and sterilized. Moist heat sterilization was performed in an autoclave (Spencer) at 121 °C for 15 min [8].

C. Vero Cell Culture

Vero cells (São Paulo, Brazil; CCIAL-057) [9], an anchorage-dependent fibroblast-like cell line originally derived from the kidney epithelium of the African green monkey (*Cercopithecus aethiops*), were used. The cells were cultured in HAM-F10 medium (Sigma-Aldrich) supplemented with 10% fetal bovine serum (FBS; Cultilab), antibiotics (Cultilab), and maintained at 37 °C in a humidified atmosphere containing 5% CO_2 (Sanyo incubator). Cell morphology was routinely monitored using an inverted phase-contrast microscope (AxioVert A1, Zeiss). Trypan blue exclusion method was used before each cytotoxicity assay; only index with a minimum 90% viable cells were used in the subsequent experiments.

D. Direct Contact Cytotoxicity Assay

Direct contact cytotoxicity was an adapted protocol based on ISO 10993-5:2009, performed in triplicate. TNTZ alloy samples were evaluated; latex samples were used as the positive cytotoxic control, whereas Vero cells cultured under standard conditions served as the negative control. Vero cells were seeded in a 24-well culture plate at a density of 10^4 cells/mL directly onto the samples. After 24 h of incubation, cell morphology was examined using an inverted phase-contrast microscope (AxioVert A1, Zeiss).

E. Elution Cytotoxicity: morphology and MTT Assay

Elution media were prepared according to ISO 10993-12:2007, resulting in a surface area-to-volume ratio of 3 cm^2/mL for the TNTZ alloy samples, which were immersed in culture medium and incubated for 24 h at 37 °C. Simultaneously, Vero cells were seeded in 96-well plates at a density of 10^4 cells/mL and cultured until reaching confluence. Latex extracts were used as the positive cytotoxic control, while cells cultured under standard conditions without exposure to the biomaterial served as the negative control. All experiments were performed in triplicate. After 24 h, the culture medium was replaced with the previously prepared elution media, and the cells were incubated for an additional 24 h. Cell morphology was then evaluated using an inverted phase-contrast microscope (AxioVert A1, Zeiss). Subsequently, cell metabolic activity was assessed using the MTT assay. The elution media were removed, each well was washed with 100 μL of phosphate-buffered saline (PBS), and 100 μL of MTT solution (Sigma-Aldrich; 0.5 mg/mL) was added, followed by incubation for 2 h at 37 °C. The MTT solution was then discarded and replaced with 50 μL of dimethyl sulfoxide (DMSO; Synth). Absorbance was measured at 570 nm using a microplate reader (SpectraMax). The negative control was defined as representing 100% cell viability. Statistical analyses were performed using GraphPad Prism 5. Differences among experimental groups were analyzed using one-way analysis of variance (ANOVA) followed by Tukey's multiple comparison test, with statistical significance established at $p < 0.05$.

F. Scanning Electron Microscopy (SEM)

Samples intended for SEM were prepared according to previously established protocols. Cells interacting with TNTZ samples were fixed in 2.5% glutaraldehyde prepared in phosphate buffer. After rinsing with distilled water for 10 min, the samples were dehydrated in a graded ethanol series, dried using a critical point dryer (Leica EM CPD300), and sputter-coated with a 15-nm gold layer (Leica ACE200). Finally, the specimens were analyzed using a FEI Quanta 250 scanning electron microscope to evaluate cell adhesion, morphology, and spreading on the TNTZ alloy surface [11].

III. Results

A. Cytotoxicity Assessment

Cytotoxicity assays are performed to determine whether a biomaterial exerts toxic effects on living cells [12]. In the context of medical devices, such as the titanium alloy investigated in this study, these assays evaluate whether the material induces adverse cellular responses, including apoptosis or reduced cell viability, following the recommendations of ISO 10993-5 [13].

1) Direct Contact Cytotoxicity Assay: The direct contact cytotoxicity assay was carried out by culturing Vero cells directly on the surface of the TNTZ samples. Fig. 1 shows the morphology of Vero cells cultured under the positive control (latex) and negative control (standard culture conditions). As expected, the positive control exhibited a typical cytotoxic

response, characterized by severe morphological alterations and the absence of a continuous cell monolayer. In contrast, cells cultured under negative control conditions formed a confluent monolayer and maintained the characteristic fibroblast-like morphology of Vero cells, displaying an elongated shape with an oval nucleus [14]. Fig. 1 illustrates the morphology of Vero cells after 24 h of direct interaction with the TNTZ alloy; cells are attached to the material surface and preserved their characteristic morphology, showing no evidence of morphological damage or cytotoxic effects.

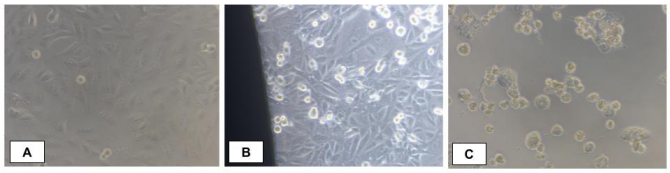

Fig. 1. Phase-contrast micrographs of Vero cells after 24 h of incubation with the control groups. (A) Negative control (standard culture conditions). (B) direct contact with TNTZ alloy. (C) Positive control (latex). Magnification: 400×.

2) Elution Cytotoxicity Assay: The elution cytotoxicity assay was performed to investigate the potential cytotoxic effects of soluble substances released from the TNTZ alloy. This method complements the direct contact assay. Vero cells after exposure to the elution media (Fig. 2) showed similar morphology to the direct contact assay; no morphological alterations were observed in cells exposed to the TNTZ elution media. The cell morphology closely resembled that of the negative control, whereas the positive control exhibited the expected cytotoxic characteristics.

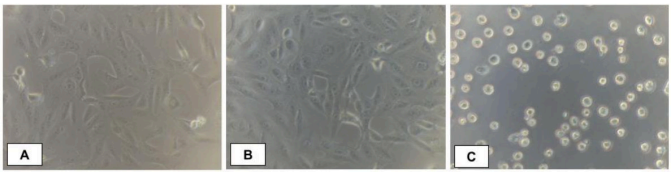

Fig. 2. Phase-contrast micrographs of Vero cells after exposure to TNTZ alloy extracts. (A) Negative control (standard culture conditions). (B) direct contact with TNTZ alloy. (C) Positive control (latex). Magnification: 400×.

a) MTT Assay: Cell metabolic activity was quantitatively evaluated by the MTT assay. Assuming normal data distribution and homogeneity of variances, the ANOVA generated an F-statistic comparing the variability among the TNTZ alloy, negative control, and positive control groups. No statistically significant differences were observed between the TNTZ alloy and the negative control ($p > 0.05$), indicating that exposure to the alloy did not negatively affect cellular metabolic activity. As shown in Fig. 3, cell viability remained above 70% relative to the negative control, satisfying the cytocompatibility criteria established by ISO 10993-5. The TNTZ alloy exhibited approximately 95% cell viability in comparison to the negative control, demonstrating the absence of cytotoxic effects and confirming its excellent *in vitro* biocompatibility, consistent with the morphological observations obtained in the cytotoxicity assays. The positive control presented 6.5% cell viability, statistically distinct from TNTZ alloy, and characteristic of cytotoxic response.

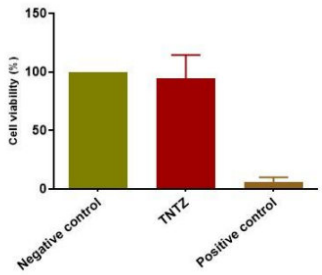

Fig. 3. Cell viability (%) determined by the MTT assay relative to the negative control.

B. Scanning Electron Microscopy (SEM)

SEM was performed to investigate the interaction between Vero cells and the surface of the β-metastable TNTZ alloy after 24 h of culture (Fig. 4). Cells were observed firmly attached to the alloy surface and distributed across the substrate. Their elongated and flattened morphology was consistent with the characteristic morphology of Vero cells. It was observed cytoplasmic extensions and intimate contact between the cells and the material surface, suggesting the establishment of early adhesion sites. Moreover, the cell spreading indicates favorable cell-material interactions, provided by the TNTZ surface for cellular attachment [15].

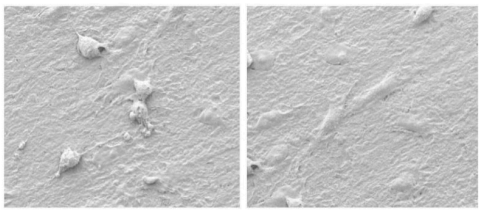

Fig. 4. Scanning electron micrographs showing the adhesion and spreading of Vero cells on the surface of TNTZ alloy specimens after 24 h of culture.

IV. Discussion

The development of novel titanium alloys for biomedical applications has been driven by the limitations of conventional alloys, particularly Ti64. Although Ti64 exhibits excellent mechanical strength and corrosion resistance, concerns regarding the long-term biological effects of aluminum and vanadium have stimulated the development of alternative titanium alloys

containing biologically safe alloying elements such as niobium, tantalum, and zirconium. In addition, β-type titanium alloys exhibit an elastic modulus closer to that of cortical bone, reducing the stress-shielding effect and promoting a more physiological distribution of mechanical loads at the bone–implant interface [10], [16].

The biological evaluation performed in this study demonstrated promising results for the β-metastable TNTZ alloy. The direct contact cytotoxicity assay showed that Vero cells maintained their characteristic fibroblast-like morphology, exhibited high confluence, and formed a continuous monolayer comparable to that observed in the negative control. In contrast, the positive control displayed severe morphological alterations and loss of monolayer formation, confirming the expected cytotoxic response. The preservation of normal cellular morphology following direct contact with the TNTZ alloy provides initial evidence of its biocompatibility.

The elution cytotoxicity assay further corroborated these findings. Exposure of Vero cells to the alloy extracts did not induce detectable morphological alterations, indicating that soluble/leachable released from the material did not exert adverse biological effects. This assay is particularly relevant because it simulates the release of metallic ions under physiological conditions, providing an indirect assessment of the chemical stability of the biomaterial. The absence of cytotoxic responses suggests that the TNTZ alloy remained chemically stable throughout the experimental period [17]. Quantitative evaluation by the MTT assay confirmed the qualitative observations obtained through optical microscopy. The TNTZ alloy exhibited approximately 95% cell viability, demonstrating that exposure to the material did not compromise mitochondrial metabolic activity. According to ISO 10993-5, materials exhibiting cell viability above 70% are considered non-cytotoxic. Therefore, the results obtained in the present study clearly demonstrate the excellent *in vitro* biocompatibility of the TNTZ alloy and reinforce its suitability for biomedical applications [15]. It is important to highlight that cytotoxicity was assessed using Vero cell lineage, a kidney epithelial cell with fibroblast-like morphology, and as such this initial biological evaluation screening does not provide information on the osteogenic behavior. Further analyses will be conducted in order to achieve a characterization of bone cells interacting with the materials.

Scanning electron microscopy provided additional evidence supporting the biological compatibility of the alloy. SEM images revealed numerous cells firmly adhered to the material surface, displaying an elongated and flattened morphology accompanied by extensive cytoplasmic projections. The presence of focal adhesion sites indicates the establishment of stable interactions between the cells and the biomaterial, representing an essential prerequisite for subsequent cellular proliferation and tissue integration [10]. The favorable cellular response observed in this study can be attributed to both the chemical composition and the microstructural characteristics of the TNTZ alloy. Previous studies have demonstrated that β-type titanium alloys containing niobium exhibit enhanced cell adhesion, proliferation, and metabolic activity compared with conventional titanium alloys, primarily because of their superior chemical stability and reduced release of potentially cytotoxic ions [15], [17].

Another important aspect concerns the thermomechanical processing of the alloy. The specimens evaluated in this study were subjected to ECAP followed by homogenization heat treatment. ECAP is well recognized for producing ultrafine-grained microstructures capable of improving both the mechanical and surface properties of metallic biomaterials. Although surface roughness and grain refinement were not directly investigated in the present work, these microstructural modifications may have contributed to the favorable biological behavior observed [10], [15], [19]. Overall, the present findings are consistent with recent literature identifying β-metastable titanium alloys as one of the most promising classes of materials for the next generation of metallic implants [17]. Their combination of excellent corrosion resistance, lower elastic modulus, and superior biological safety makes these alloys attractive alternatives to Ti-6Al-4V for orthopedic and dental applications [18]. Nevertheless, despite their intrinsic biocompatibility, further optimization of their surface properties through biofunctionalization or surface modification strategies may further enhance osseointegration and improve long-term clinical performance [10], [15], [17], [18].

V. Conclusions

The β-metastable TNTZ alloy demonstrated biological behavior consistent with the fundamental requirements for metallic biomaterials intended for medical device applications. Direct contact cytotoxicity, extract cytotoxicity, and MTT assays revealed no evidence of cytotoxic effects, while scanning electron microscopy confirmed satisfactory cell adhesion and spreading on the alloy surface. Furthermore, the results demonstrated that the TNTZ alloy maintains cellular metabolic activity and preserves the characteristic morphology of Vero cells, indicating excellent *in vitro* biocompatibility. The stable interaction established between the cells and the biomaterial suggests that the alloy provides a favorable surface for cellular attachment. The conclusions refer to data obtained with Vero cells assays; further analyses will be conducted with osteogenic cells.

***Resumo*— A membrana amniótica humana (MAH) é amplamente utilizada na medicina regenerativa devido às suas propriedades biológicas e terapêuticas. Entretanto, os efeitos do armazenamento sobre sua composição molecular ainda não são completamente compreendidos. O objetivo deste estudo foi avaliar a MAH por espectroscopia Raman após diferentes períodos de armazenamento em glicerol. Uma amostra de MAH foi analisada na condição *in natura* e após 2, 14, 35 e 68 dias de armazenamento em glicerol a −20 °C. Para cada condição experimental, foram adquiridos cinco espectros Raman em diferentes regiões da mesma amostra, os quais foram submetidos à correção da linha de base, normalização pela área sob a curva e cálculo do espectro médio. Observou-se similaridade entre os perfis espectrais da MAH *in natura* e após dois dias de armazenamento. Alterações espectrais tornaram-se evidentes após 14 dias, enquanto os espectros obtidos após 35 e 68 dias apresentaram características semelhantes entre si e distintas das demais condições experimentais, sugerindo a presença de um padrão espectral associado ao armazenamento prolongado. As principais bandas observadas foram compatíveis com os principais componentes da matriz extracelular da MAH e com as bandas Amida I e Amida III. Os resultados sugerem o potencial da espectroscopia Raman como ferramenta não destrutiva para o monitoramento de alterações espectrais na MAH durante o armazenamento em glicerol. Por se tratar de um estudo preliminar, análises quantitativas e multivariadas encontram-se em desenvolvimento para confirmação dos achados observados.**

Palavras-chave*— *membrana amniótica humana, espectroscopia Raman, armazenamento, glicerol.

I. INTRODUÇÃO

A membrana amniótica humana (MAH) é uma estrutura derivada da camada interna da placenta, composta por uma camada epitelial simples, lâmina basal e estroma rico em colágeno, elastina, fibronectina, laminina, ácido hialurônico, além de diversos fatores de crescimento [1-4]. Desempenha papel essencial durante a gestação, contribuindo para a troca de nutrientes, modulação da resposta imunológica e proteção mecânica durante o desenvolvimento embrionário e fetal. Devido à importância dessas funções, a MAH tem sido amplamente estudada na medicina regenerativa por suas propriedades anti-inflamatórias, antimicrobianas e de reparo tecidual. Diversos estudos demonstram sua eficácia biológica nas áreas de engenharia de tecidos, dermatologia e oftalmologia, sendo que, nesta última, seu uso terapêutico está consolidado [1-6]. Embora as propriedades terapêuticas da MAH sejam reconhecidas, seu armazenamento para uso posterior ainda representa um desafio. Um método comumente empregado para esta finalidade é a imersão em glicerol, pois segundo a literatura, este composto preserva suas características biológicas, estruturais e bioquímicas por um determinado período [7,8]. No entanto, apesar da ampla utilização deste método, sua eficácia ainda não está completamente elucidada. A Espectroscopia Raman se destaca como uma técnica promissora para a análise e caracterização da MAH, pois permite a investigação estrutural e química de materiais biológicos de forma não destrutiva, fornecendo informações detalhadas sobre sua composição

molecular [9-11]. Diante deste contexto, o objetivo do presente estudo foi avaliar a MAH por espectroscopia Raman após diferentes períodos de armazenamento em glicerol.

II. MATERIAIS E MÉTODOS

A. *Aspectos Éticos e Obtenção da MAH*

Uma amostra de MAH foi obtida de uma doadora que concordou em participar da pesquisa e assinou o Termo de Consentimento Livre e Esclarecido (TCLE). A voluntária foi submetida à cesariana na Santa Casa de Misericórdia de Pindamonhangaba, SP, Brasil, respeitando-se as normas técnicas para bancos de sangue de cordão umbilical e placentário, em conformidade com a Resolução RDC nº 190/2003 [12].

A amostra de MAH foi obtida assepticamente e de acordo com o protocolo aprovado pelo Comitê de Ética em Pesquisa da Universidade Anhembi Morumbi (Parecer nº 3.984.423; CAAE: 289370020.0.0000.5492). A doadora apresentou gestação sem intercorrências, sem antecedentes médicos ou sociais que contraindicassem a doação, além de sorologia negativa para HIV, hepatites B e C, HTLV, doença de Chagas, sífilis, citomegalovírus e toxoplasmose.

B. *Aquisição dos Espectros Raman e Armazenamento da Membrana*

A amostra de MAH foi lavada repetidas vezes com solução fisiológica de cloreto de sódio (NaCl) a 0,9% até completa remoção de resíduos sanguíneos [8]. Após a lavagem, um fragmento da amostra de MAH, na condição *in natura*, foi posicionado em um suporte de alumínio e submetido à aquisição de espectros Raman. Para esta finalidade, foi utilizado um Espectrômetro Raman Dispersivo (Dimension P-1, Lambda Solutions Inc, MA, EUA), com comprimento de onda de excitação de 830 nm e potência de saída de 350 mW. Para cada espectro, empregou-se tempo de integração de 4 segundos por *frame* e 10 acumulações, totalizando 40 segundos de aquisição. Em seguida, o restante da MAH foi armazenado em frasco de vidro contendo glicerol (Glicerina P.A ACS PM: 92,10 – Dinâmica®) sob refrigeração a −20 ºC. Após 2, 14, 35 e 68 dias, novos fragmentos foram obtidos, lavados 10 vezes com solução fisiológica de NaCl a 0,9% [13] para remoção do excesso de glicerol e submetidos à aquisição de espectros Raman para análise comparativa.

Para cada condição experimental, incluindo a condição *in natura*, foram adquiridos cinco espectros Raman. A cada aquisição, o suporte contendo o respectivo fragmento era reposicionado, de modo que os espectros fossem obtidos em regiões distintas. Esses espectros constituíram, portanto, medidas da mesma amostra de MAH e não replicatas biológicas independentes. Essas medidas foram utilizadas para a obtenção do espectro médio de cada condição experimental, tendo em vista a heterogeneidade natural do tecido.

C. *Processamento dos Espectros*

Os espectros obtidos foram exportados para o software MATLAB®, onde foram submetidos ao pré-processamento, incluindo correção da linha de base por ajuste polinomial de sexta ordem, seguida de normalização pela área sob a curva. Posteriormente, os espectros foram exportados para o software Microsoft Excel® onde foi calculado o espectro médio das cinco aquisições obtidas para cada período experimental, utilizado nas análises comparativas. As análises foram realizadas na faixa espectral de 400 a 1740 cm^{-1}.

III. RESULTADOS E DISCUSSÃO

A. *Análise Qualitativa dos Espectros Raman*

A Fig. 1 apresenta os espectros Raman médios da MAH *in natura* e após 2, 14, 35 e 68 dias de armazenamento em glicerol. Observa-se semelhança entre os perfis espectrais da MAH *in natura* e após dois dias de armazenamento, com manutenção das principais características espectrais. Após 14 dias, observam-se alterações no formato de algumas bandas e na intensidade relativa de determinadas regiões espectrais quando comparadas aos períodos anteriores, sugerindo alterações na composição molecular detectáveis por espectroscopia Raman. Nos períodos de 35 e 68 dias, os espectros apresentaram características similares entre si, indicando a manutenção de um perfil espectral semelhante entre esses períodos de armazenamento. Entretanto, observam-se diferenças em relação aos espectros obtidos *in natura* e após dois dias de armazenamento, principalmente quanto ao formato das bandas e à intensidade relativa de determinadas regiões espectrais.

As semelhanças e diferenças espectrais entre os diferentes períodos de estudo podem ser melhor visualizadas na Fig. 1(b), na qual foi aplicado deslocamento vertical dos espectros (*offset*).

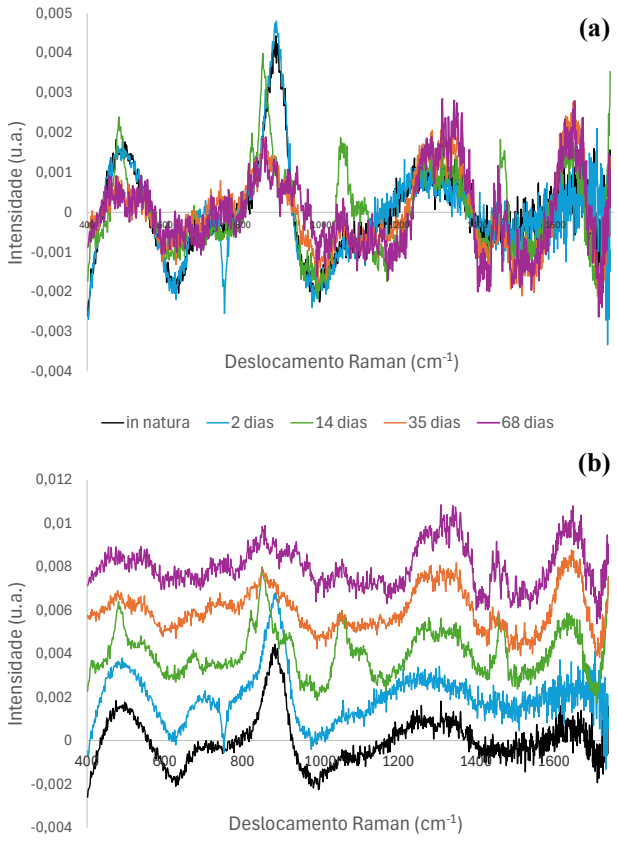

Fig. 1. Espectros Raman médios da membrana amniótica humana (MAH) *in natura* e após 2, 14, 35 e 68 dias de armazenamento em glicerol. (a) Espectros sobrepostos. (b) Espectros apresentados com deslocamento vertical (*offset*) para facilitar a visualização das diferenças espectrais. Os espectros foram submetidos à correção da linha de base e normalizados pela área sob a curva.

Esses resultados sugerem manutenção do perfil espectral nos dois primeiros dias de armazenamento, seguida por

mudanças espectrais detectáveis após 14 dias. Os espectros obtidos após 35 e 68 dias apresentaram características espectrais semelhantes entre si e distintas daquelas observadas na condição *in natura* e após 2 e 14 dias, sugerindo a presença de um padrão espectral distinto associado ao armazenamento prolongado, cuja confirmação requer análises quantitativas e/ou multivariadas, as quais estão atualmente em andamento.

A fim de explorar os componentes moleculares associados às alterações observadas, foi realizada a identificação das principais bandas Raman presentes nos espectros.

B. Identificação das Bandas Raman

A Tabela I apresenta as principais regiões espectrais observadas na análise dos espectros Raman da MAH.

TABELA I - PRINCIPAIS REGIÕES ESPECTRAIS OBSERVADAS NOS ESPECTROS DA MAH E SUAS POSSÍVEIS ATRIBUIÇÕES ESPECTRAIS COM BASE NA LITERATURA

Região observada na MAH	**Máximo aproximado**	**Possível atribuição espectral**	**Referência**
400 – 600 cm^{-1}	~490 cm^{-1}	Colágeno, elastina, fibronectina, ácido hialurônico.	Wang et al., 2023.
800 – 960 cm^{-1}	~890 cm^{-1}	Colágeno, elastina, ácido hialurônico; glicina presente no colágeno.	Wang et al., 2023; Cárcamo et al., 2012.
1200 – 1400 cm^{-1}	~1260 cm^{-1}	Amida III; colágeno, elastina	Bergholt et al., 2019; Wang et al., 2023; Milyudin et al., 2023; Cárcamo et al., 2012.
1540 – 1700 cm^{-1}	~1640 cm^{-1}	Amida I; colágeno, elastina, fibronectina, ácido hialurônico.	Bergholt et al., 2019; Wang et al., 2023; Milyudin et al., 2023; Cárcamo et al., 2012.

Foram observadas bandas nas regiões de aproximadamente 400 – 600 cm^{-1}, 800 – 960 cm^{-1}, 1200 – 1400 cm^{-1} e 1540 – 1700 cm^{-1}, com intensidades máximas em torno de 490 cm^{-1}, 890 cm^{-1}, 1260 cm^{-1} e 1640 cm^{-1}, respectivamente. Em espectros Raman obtidos de biomoléculas isoladas, bandas entre 530 e 560 cm^{-1} e entre 1640 e 1665 cm^{-1} foram associadas ao colágeno, elastina, fibronectina e ácido hialurônico, enquanto bandas entre 800 e 940 cm^{-1} e entre 1252 e 1260 cm^{-1} foram associadas principalmente ao colágeno e à elastina [11]. Essas regiões têm sido associadas a componentes da matriz extracelular e são compatíveis com a composição bioquímica da MAH.

De acordo com Bergholt et al. [10], as bandas observadas nas regiões de aproximadamente 1200 – 1400 cm^{-1} e 1540 – 1700 cm^{-1}, com intensidades máximas próximas de 1260 cm^{-1} e 1640 cm^{-1}, podem estar associadas às bandas Amida III (1230 – 1280 cm^{-1}) e Amida I (1650 – 1680 cm^{-1}), respectivamente. Essas bandas são frequentemente relacionadas à presença de componentes da matriz extracelular, incluindo colágeno, elastina, fibronectina e ácido hialurônico.

Os valores observados para as bandas com máximos próximos de 1260 cm^{-1} e 1640 cm^{-1} também são compatíveis com aqueles descritos por Milyudin et al. [14] para componentes da MAH, os quais foram atribuídos às bandas Amida III e Amida I, respectivamente. Essas bandas estão associadas a vibrações de ligações amida presentes em proteínas da matriz extracelular. Adicionalmente, bandas próximas de 879 cm^{-1}, 1247 – 1275 cm^{-1} e 1672 – 1678 cm^{-1} foram descritas em espectros Raman de colágeno tipos I e III, sendo atribuídas à glicina, Amida III e Amida I, respectivamente, compatíveis com os achados do presente estudo [9].

As interpretações realizadas neste estudo foram baseadas na comparação qualitativa e visual dos espectros Raman médios obtidos para cada condição experimental. Embora diferenças espectrais tenham sido observadas entre as condições avaliadas, análises quantitativas e multivariadas, como Análise de Componentes Principais (PCA), estão atualmente em fase de desenvolvimento. Dessa forma, os resultados devem ser interpretados como preliminares para as alterações espectrais associadas ao armazenamento da MAH em glicerol após diferentes períodos. Estudos futuros envolvendo maior número de doadoras, bem como análises quantitativas e multivariadas, serão necessários para confirmar os achados apresentados.

IV. CONCLUSÃO

A espectroscopia Raman permitiu detectar alterações no perfil espectral da membrana amniótica humana após armazenamento em glicerol. Observou-se manutenção do perfil espectral nos primeiros dois dias, alterações detectáveis após 14 dias e características espectrais distintas das anteriores após 35 e 68 dias. As principais regiões espectrais observadas foram compatíveis com os principais componentes da matriz extracelular e com bandas Amida I e Amida III. As alterações espectrais detectadas podem estar relacionadas a modificações em componentes proteicos específicos da matriz extracelular, entretanto, essa hipótese deverá ser confirmada por análises bioquímicas, estruturais e morfológicas complementares.

AGRADECIMENTOS

M. S. Melo agradece à Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) - Financing Code 001; Santa Casa de Misericórdia de Pindamonhangaba, SP, Brasil e Centro de Inovação, Tecnologia e Educação (CITÉ) / Universidade Anhembi Morumbi (UAM), São José dos Campos, SP, Brasil.

H. C. Carvalho agradece à Fundação Araucária (FA) e Superintendência de Ciência, Tecnologia e Ensino Superior (SETI), PR, Brasil, pelo auxílio à participação no congresso.

A. B. Fernandes, L. Silveira Júnior, R. A. Zângaro agradecem ao Instituto Ânima, Universidade Anhembi Morumbi, São Paulo, SP, Brasil.

A. B. Fernandes agradece ao CNPq (Conselho Nacional de Desenvolvimento Científico e Tecnológico) pela bolsa de produtividade (Processo No. 310708/2021-4).

***Abstract*— The development of printable biomaterials for bone tissue engineering requires formulations that combine easy extrusion with structural stability and rapid recovery after deposition. This study investigated the rheological behavior of a composite hydrogel of agarose, sodium alginate, gelatin, and β-tricalcium phosphate (β-TCP) as a candidate bioink for extrusion-based three-dimensional bioprinting. Rheological characterization included oscillatory strain and frequency sweeps, steady-shear viscosity measurements, oscillatory yield-stress determination, and a three-interval thixotropy test. The formulation exhibited a broad linear viscoelastic region, extending from approximately 0.01% to 13.3% strain, and predominantly elastic behavior, with the storage modulus remaining higher than the loss modulus throughout the tested frequency range. The oscillatory yield stress was approximately 1.02 kPa. Apparent viscosity decreased from 21,883 Pa·s at a shear rate of 0.01 s^{-1} to 0.203 Pa·s at 1,310 s^{-1}. Power-law fitting yielded a flow behavior index of 0.0098 and an R^2 of 0.991, confirming pronounced shear-thinning behavior. Following high-strain disruption, the hydrogel rapidly recovered its solid-like character, reaching 64.74% recovery of the storage modulus and 78.36% recovery of complex viscosity. Overall, the formulation combined resistance to deformation at rest, shear-dependent flow under extrusion-relevant conditions, and functionally relevant post-shear recovery. Direct printing further confirmed the rheological predictions, with printed grids maintaining their pore architecture and filament deflection remaining below 3.5% across unsupported spans of up to 5.63 mm. Overall, the formulation combined shear-dependent flow, structural recovery, and effective post-deposition shape retention, supporting its potential for extrusion-based 3D printing. Mechanical, degradation, and biological evaluations are still required to establish its suitability for bone tissue engineering applications.*

Keywords*— *Bone repair, Bioink, Rheology, 3D Bioprinting.

I. Introduction

Bone is among the most frequently transplanted tissues in clinical practice, and the repair of large defects arising from trauma, tumor resection, infection, or congenital malformation remains a persistent challenge in regenerative medicine [1,2]. Although bone possesses a notable intrinsic capacity for self-repair, defects exceeding a critical size do not heal spontaneously and require external intervention [2,3]. Autologous grafts are still regarded as the clinical gold standard, yet their use is constrained by donor-site morbidity, restricted donor availability, and the need for additional surgical procedures, whereas allografts and synthetic substitutes carry risks of immune rejection, disease transmission, and limited osteointegration [1,2]. In this context, bone tissue engineering has emerged as a promising strategy, combining three-dimensional scaffolds, cells, and bioactive signals to restore the structure and function of the native tissue [3,4].

Among the available scaffold fabrication technologies, three-dimensional (3D) bioprinting has attracted increasing attention because it enables the production of patient-specific constructs through the layer-by-layer placement of cells and biomaterials, with precise control over architecture and porosity [5,6]. Extrusion-based bioprinting, in particular, is the most widely adopted approach for bone applications, owing to its versatility, relatively low cost, and ability to process highly viscous formulations and elevated cell densities [6–8]. The success of this technique, however, depends critically on the bioink, which must simultaneously ensure adequate flow during extrusion, structural fidelity after deposition, and a biologically permissive environment, requirements that are often in conflict [5,9]. For bone-oriented applications, composite formulations that incorporate bioceramics such as β-tricalcium phosphate (β-TCP) into polymeric matrices are especially attractive, since the inorganic phase promotes new bone formation, increases the viscosity and mechanical strength of the construct, and contributes to its bioactivity and osteogenic potential [10–12].

The printability and post-printing stability of a bioink are largely governed by its rheological behavior, which makes rheological characterization an essential step prior to printing. Properties such as shear-thinning (pseudoplastic) flow, viscoelasticity expressed through the storage (G′) and loss (G″) moduli, yield stress, and the capacity for structural recovery after deformation (thixotropy) directly govern bioprintability [13]. An ideal bioink should flow readily under the shear imposed within the extrusion nozzle and rapidly recover its solid-like character once deposited, thereby preserving filament geometry and supporting the dimensional stability of multilayered constructs [7,14]. Assessing these parameters therefore provides a predictive basis for evaluating extrudability and shape fidelity before committing to printing trials [9,13].

In this work, the rheological behavior of a composite hydrogel based on agarose, sodium alginate, gelatin, and β-TCP was investigated as a candidate bioink for extrusion-based bone tissue engineering. The formulation was characterized through oscillatory strain and frequency sweeps, steady-state viscosity measurements, yield-stress determination, and three-interval thixotropy tests. Direct printing, grid shape-fidelity, and filament collapse tests were additionally performed to determine whether the rheological behavior translated into effective printability and post-deposition stability.

II. Materials and methods

A. Materials

Gelatin from porcine skin (Sigma-Aldrich, G1890); sodium alginate (Sigma-Aldrich, W201502); agarose (Kasvi, K9-9500); tribasic calcium phosphate, also referred to as β-tricalcium phosphate, with purity ≥96.0% (Sigma-Aldrich, 21218); and 10X phosphate-buffered saline (PBS 10X, Nova Biotecnologia, code 13-30262-05).

B. Preparation of the bioink

The hydrogel was prepared by adding 10 mL of PBS 1X to a 50 mL beaker under magnetic stirring at approximately 300 rpm and 80 °C. Agarose (0.2 g) was first added and dissolved until a translucent and homogeneous solution was obtained. Sodium alginate (0.4 g) was then gradually incorporated to avoid clump formation, followed by the addition of gelatin from porcine skin (0.5 g). At this step, the temperature was reduced to 50 °C, and the mixture was maintained under stirring until a uniform and slightly viscous solution was formed. Finally, β-tricalcium phosphate (β-TCP; 0.1 g) was gradually added and dispersed into the polymeric matrix. When magnetic stirring became inefficient due to increased viscosity, manual mixing with a spatula was performed to ensure homogeneity. The final formulation was visually assessed for homogeneity and absence of clumps.

C. Test Equipment and Conditions

The rheological assays were performed using an MCR 92 rotational rheometer (Anton Paar GmbH, Graz, Austria), equipped with a synchronous EC motor and air-bearing system, which enables torque measurements from 0.4 μNm with high sensitivity and no mechanical friction, making it particularly suitable for the structural characterization of low- to medium-consistency viscoelastic materials. A 25 mm parallel-plate geometry was used (PP25, Anton Paar), with a fixed gap of 1.0 mm. Temperature control was performed using a Peltier plate system, model P-PTD 200/AIR (Anton Paar), with an accuracy of ±0.1 °C, and all assays were conducted at 25 °C. Data acquisition and processing were carried out using RheoCompass™ software (Anton Paar).

D. Strain Sweep

The linear viscoelastic region (LVER) of the hydrogel was determined by an oscillatory strain sweep test. The samples were subjected to increasing strain values from 0.01% to 1000% on a logarithmic scale, while maintaining a fixed frequency of 1 Hz. During the assay, the storage modulus (G′), loss modulus (G″), and loss factor (tan δ = G″/G′) were recorded. The LVER was defined as the strain range in which G′ and G″ remained approximately constant, allowing a maximum variation of 10% relative to the initial plateau. The critical strain (γc) was defined as the strain corresponding to the onset of G′ decrease or to a measurable deviation from linear behavior. The strain used in subsequent oscillatory tests was selected within the LVER, preferably one order of magnitude below γc.

E. Frequency Sweep

The time scale-dependent viscoelastic behavior was evaluated by a frequency sweep test. The assay was performed at a fixed strain within the LVER, previously determined by the strain sweep test. The angular frequency (ω) was varied from 0.1 to 100 rad·s^{-1} on a logarithmic scale. The storage modulus (G′), loss modulus (G″), loss factor (tan δ), and complex viscosity were determined. The predominantly solid-like or liquid-like behavior was assessed based on the relationship between G′ and G″ over the frequency range. G′ values higher than G″ were interpreted as a predominance of elastic behavior, associated with shape retention after deposition. In contrast, G″ values higher than G′ would indicate predominantly viscous behavior. The frequency dependence of the moduli was used to infer the structural stability of the material at different time scales relevant to the extrusion process.

F. Viscosity Curve

The viscosity curve of hidrogel was evaluated using a steady-state rotational rheological test. The shear rate was varied from 0.01 to 1300 s^{-1} on a logarithmic scale, while the apparent viscosity and shear stress were recorded. The experimental data were fitted to the Ostwald–de Waele model, described by the following equation:

$$\eta = K\dot{\gamma}^{(n-1)} \quad (1)$$

where η is the apparent viscosity, $\dot{\gamma}$ is the shear rate, K is the consistency index, and n is the flow behavior index. For linearization, the model was expressed as:

$$\ln(\eta) = \ln(K) + (n-1)\ln(\dot{\gamma}) \quad (2)$$

Thus, the flow behavior index was calculated from the slope of the linear regression as n = slope + 1, while K was obtained from the exponential of the intercept. Values of n < 1 were considered indicative of shear-thinning behavior. The fitting quality was evaluated based on the coefficient of determination, residual analysis, and mean fitting error.

G. Yield Stress

The yield stress was determined using complementary methods, considering that structured semi-solid materials may exhibit protocol-dependent values. First, an oscillatory stress sweep was performed at a fixed frequency of 1 Hz. The stress was progressively increased on a logarithmic scale until disruption of the viscoelastic structure. The oscillatory yield stress was defined as the stress corresponding to the crossover point between G′ and G″, i.e., the point at which the viscous behavior begins to predominate over the elastic behavior. Additionally, the stress associated with the onset of G′ decrease was recorded and considered as the structural yield limit.

H. Thixotropy

The structural recovery capacity after intense deformation was evaluated using a three-interval oscillatory step-strain test at a fixed frequency of 1 Hz. In the first interval, the sample was subjected to 1% strain, within the LVER, for 120 s to record the initial structural state. In the second interval, the strain was increased to 200% for 120 s to induce structural disruption. In the third interval, the strain was returned to 1% for 300 s, allowing the recovery of G′ and G″ to be monitored over time.

Structural recovery was quantified as the ratio between the storage modulus after returning to low strain and the initial storage modulus, according to the following equation:

$$G' \text{ recovery } (\%) = (G't / G'0) \times 100 \quad (3)$$

where G′0 corresponds to the mean G′ value during the initial step, and G′t corresponds to the G′ value at defined time points after the high-strain step. Immediate recovery, in 10 s, final recovery, in 300 s, and the time required to recover 50% and 90% of the initial modulus were reported when applicable.

I. Filament Collapse Test

Post-deposition stability was evaluated using a filament collapse test with unsupported spans of 0.80, 1.60, 2.65, 3.67, 4.64, and 5.63 mm. A single filament was printed across the supports using the parameters shown in Table I. Images were acquired immediately after printing and analyzed using ImageJ/Fiji. Relative deflection was calculated as:

$$Relative\ deflection(\%) = \frac{\delta}{d} * 100 \quad (4)$$

where δ is the maximum perpendicular displacement of the filament relative to the straight line connecting the two supports, and d is the unsupported span length.

J. Direct Printing and Shape-Fidelity Assessment

The printability and shape fidelity of the bioink were evaluated by printing 30 × 30 mm square grids using a 0°/90° deposition pattern with three layers. The grid geometry was prepared using PrusaSlicer software, which was also used to define the printing parameters and generate the G-code. The bioprinter used was the BioEnder (BioEdTech, São Paulo, Brazil).

TABLE I. PRINTING PARAMETERS USED FOR SHAPE-FIDELITY ASSESSMENT.

Parameter	***Values***
Nozzle	0.6 mm
Speed	5 mm/s
Extrusion multiplier	0.5
Infill	20%
Layer height	0.5 mm
Printing temperature	25 ºC

Printing parameters (shown on Table I) were maintained constant for all samples. Immediately after printing, the constructs were photographed from the top with a millimeter scale and analyzed using ImageJ/Fiji. At least five internal pores per grid were evaluated by measuring their area (A) and perimeter (L). The printability parameter was calculated according to Ribeiro et al. [15] as:

$$Pr = \frac{L^2}{16A} \quad (5)$$

where values close to 1 indicate greater preservation of the designed square pore geometry.

K. Statistical Analysis

Rheological and printability data were expressed as mean ± standard deviation from at least three independent bioink preparations.

III. RESULTS AND DISCUSSION

The amplitude sweep analysis showed that the bioink exhibited a broad Linear Viscoelastic Region (LVER), extending from approximately 0.01% to 13.3% shear strain, as shown in Figure 1. Within this range, the storage modulus (G′) remained predominantly stable, with values close to 1,000 Pa at lower strain amplitudes, ranging from 1,002.59 ± 382.50 Pa to 1,008.37 ± 347.81 Pa. At the upper limit of the LVER, at γ = 13.3%, G′ was 927.34 ± 287.01 Pa, remaining within the stability criterion adopted for the linear region.

Throughout the LVER, the loss modulus (G″) remained lower than G′, with values ranging from 208.04 ± 55.63 Pa to 219.39 ± 43.19 Pa. This predominance of G′ confirms the mainly elastic behavior of the bioink under low-strain conditions, indicating that the three-dimensional network formed by interactions among agarose, alginate, gelatin, and β-TCP preserves its structural integrity within this range and behaves as a solid-like gel. The G′ values obtained are consistent with those reported for hydrogels applied to bone tissue engineering, which are generally within the range of hundreds to a few thousand Pa depending on polymer

composition, concentration, and the presence of inorganic phases [8,11].

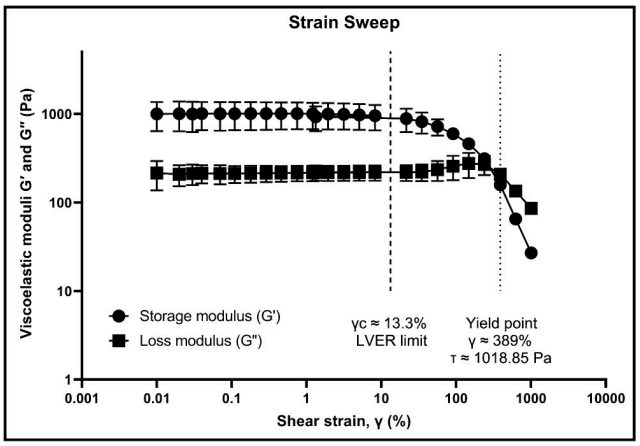

Fig. 1. Amplitude sweep analysis of the bioink showing the storage modulus (G′) and loss modulus (G″) as a function of shear strain. The dashed vertical line indicates the LVER limit/critical strain, while the dotted vertical line indicates the yield point/crossover between G′ and G″. Data are presented as mean ± standard deviation.

The amplitude sweep also allowed identification of two complementary structural thresholds. The first was the critical strain, observed at approximately 13.3%, corresponding to a shear stress of 127.10 ± 47.30 Pa. This point marks the onset of measurable G′ decrease and therefore indicates the beginning of nonlinear viscoelastic behavior. However, this should be interpreted as the initial structural yield limit rather than complete flow. The second threshold was the oscillatory yield stress, determined from the crossover between G′ and G″, as shown in Figure 2. This crossover occurred at approximately τy = 1,018.85 Pa, with a corresponding strain of about 389%. At the equivalent experimental point, the shear stress was 1,018.95 ± 49.96 Pa. The large separation between the onset of nonlinearity and the G′/G″ crossover indicates that the bioink begins to undergo structural rearrangement at moderate stress but only transitions to predominantly viscous behavior under substantially higher deformation.

This high oscillatory yield stress is a desirable characteristic for extrusion-based 3D bioprinting, since it indicates that the material has sufficient resistance to deformation before flowing. Such resistance contributes to shape retention after deposition, reducing the risk of immediate filament spreading or collapse of printed layers [14,15]. At the same time, the fact that the crossover occurs only at high strain supports the ability of the formulation to behave as a solid-like gel at rest while still becoming flowable under the stronger mechanical forces imposed during extrusion. Based on the identified LVER, a strain of 1% was selected for subsequent oscillatory tests, ensuring that the intrinsic viscoelastic properties of the bioink were evaluated without disrupting the network structure.

The frequency sweep further confirmed the stability of the bioink under oscillatory conditions within the LVER (Figure 3). Across the tested angular frequency range, G′ remained consistently higher than G″, with no crossover between the moduli. This indicates that the formulation maintained a predominantly elastic response over different time scales, reinforcing its solid-like gel behavior. G′ increased moderately with angular frequency, while G″ also increased at higher frequencies but remained below G′ throughout the test. This frequency-dependent increase in the moduli suggests that the polymeric-mineral network becomes more resistant to deformation at shorter time scales, while still preserving the dominance of the elastic component.

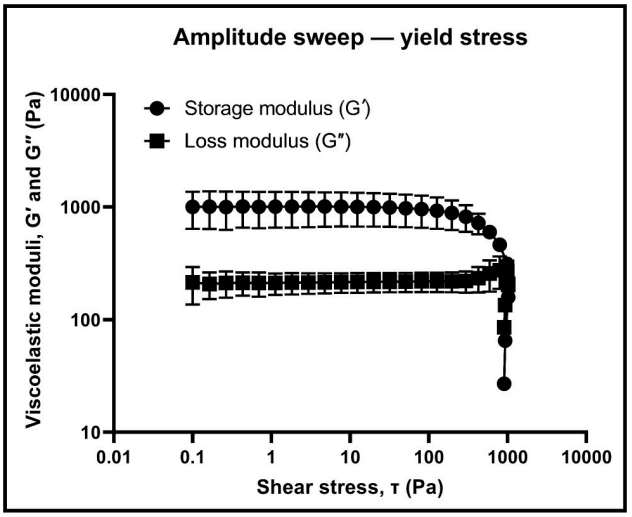

Fig. 2. Amplitude sweep for oscillatory yield stress determination. Storage modulus (G′) and loss modulus (G″) are shown as a function of shear stress. The yield stress was determined from the crossover between G′ and G″, corresponding to τy ≈ 1,018.85 Pa. Data are presented as mean ± standard deviation.

The absence of a G′/G″ crossover in the frequency sweep is particularly relevant for bioink performance, since it indicates that the material does not transition to a liquid-like state under the small-amplitude oscillatory conditions used to probe its structure. Similar behavior has been described for physically crosslinked and composite hydrogel bioinks, in which G′ > G″ over the frequency range is associated with a stable network, improved shape fidelity, and enhanced capacity to maintain filament geometry after deposition [9,11,13]. Therefore, the frequency sweep complements the amplitude sweep by showing that the bioink is not only stable at low strain, but also maintains its elastic character across the range of deformation time scales evaluated.

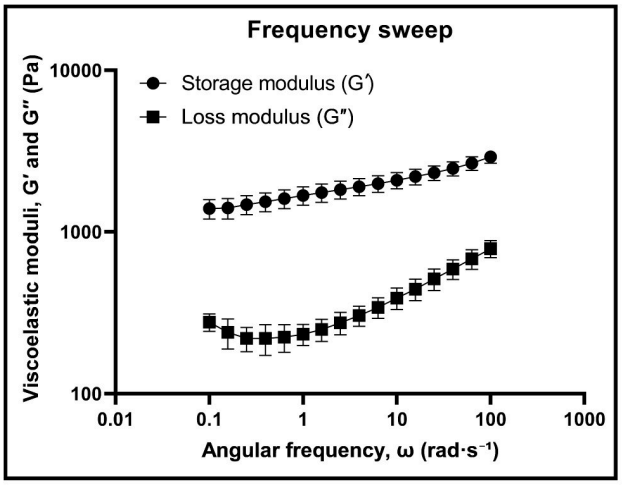

Fig. 3. Frequency sweep of the bioink. Storage modulus (G′) and loss modulus (G″) were evaluated as a function of angular frequency. G′ remained higher than G″ throughout the tested frequency range, indicating predominant elastic behavior and stability of the hydrogel network under oscillatory conditions. Data are presented as mean ± standard deviation.

The apparent viscosity of the bioink was evaluated as a function of shear rate and showed a marked reduction throughout the analyzed range, evidencing the pseudoplastic behavior characteristic of shear-thinning systems (Figure 4). The obtained slope was −0.9902, resulting in a flow behavior index of n = 0.0098, while the consistency index derived from the intercept corresponded to K = 474,473.24 mPa·s^n. The coefficient of determination was R^2 = 0.991, indicating a high-quality fit within the evaluated shear-rate range.

The apparent viscosity curve showed that, at a low shear rate of 0.010 s^{-1}, the bioink exhibited a viscosity of 21,883.00 ± 1,632.32 Pa·s. In contrast, at the highest evaluated shear rate, 1,310 s^{-1}, the viscosity decreased to 0.203 ± 0.115 Pa·s. This reduction of approximately five orders of magnitude confirms the strong dependence of viscosity on shear rate and demonstrates that the bioink becomes significantly less viscous under conditions of higher deformation. The flow index n ≈ 0.01, much lower than 1, confirms the strongly shear-thinning nature of the formulation. For comparison, Newtonian fluids present n = 1, whereas many bioinks described for soft tissue bioprinting exhibit n values between 0.2 and 0.6 (14,15). The exceptionally low n value obtained in this study indicates a highly pronounced pseudoplastic response, probably associated with the high density of entanglements and physical interactions among agarose, alginate, and gelatin, in addition to the contribution of β-TCP as a dispersed solid phase.

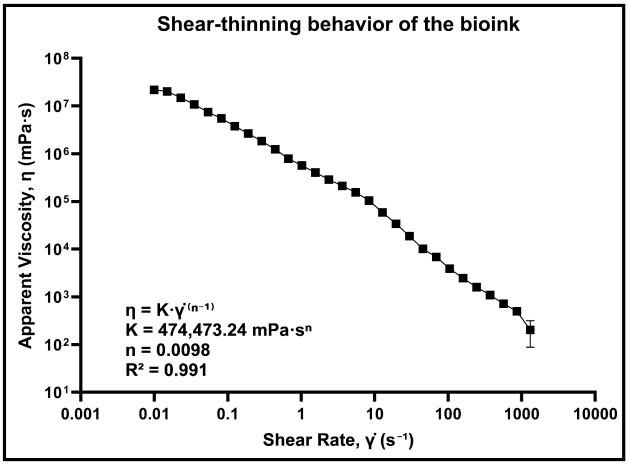

Fig 4. Apparent viscosity curve of the bioink as a function of shear rate. The data are presented as mean ± standard deviation in log-log scale. The marked decrease in viscosity with increasing shear rate confirms the shear-thinning behavior of the formulation. The apparent viscosity data were fitted using the power-law model, η = K·γ̇^(n−1), yielding K = 474,473.24 mPa·s^n, n = 0.0098, and R^2 = 0.991.

From the perspective of extrusion-based 3D bioprinting, this behavior is highly favorable. During passage through the extrusion nozzle, the increase in shear rate markedly reduces the viscosity of the bioink, facilitating flow and decreasing the need for excessive pressures, which could compromise cell viability. After deposition, when shear is removed, viscosity recovery contributes to filament shape retention and to the structural stability of the printed construct [7,8]. Together, the high consistency index, the strong shear-thinning behavior, and the elevated oscillatory yield stress indicate that the bioink can combine extrudability during printing with sufficient resistance to deformation after deposition. This balance is especially important for bone scaffold fabrication, in which geometric stability and controlled porosity are essential for the functional performance of the printed structure [4].

The thixotropy analysis was then performed to evaluate whether the bioink could recover its structure after a deformation event simulating extrusion. The three-interval oscillatory test consisted of an initial low-strain interval within the LVER, a high-strain interval to induce network disruption, and a final low-strain interval to monitor recovery. The results are summarized in Table II and illustrated in Figures 5 and 6.

TABLE II. SUMMARY OF RHEOLOGICAL PARAMETERS OBTAINED IN THE THREE INTERVALS OF THE THIXOTROPY TEST.

Parameter	***Interval 1 (Initial structure)***	***Interval 2 (Disruption)***	***Interval 3 (Recovery)***
G′ (Pa)	2,160 - 2,050	165 - 251	1,431 - 1,627
G″ (Pa)	373 - 348	358 - 412	455 - 304
η* (mPa·s)	348,91 - 330,4	62,769 - 76,852	239,01 - 263,3
G′ recovery (%)	—	—	64,74%
η* recovery (%)	—	—	78,36%

In the initial interval, the bioink exhibited predominantly elastic behavior, with G′ remaining higher than G″ throughout the entire period. The storage modulus remained close to 2.1 kPa, varying from approximately 2,160 Pa at the beginning to 2,050 Pa at the end of 120 s, indicating good network stability at rest. During the same interval, G″ remained around 350–370 Pa, confirming that the viscoelastic response of the formulation was dominated by the elastic component. The complex viscosity also showed only a slight decrease, from approximately 348,917 to 330,403 mPa·s, consistent with the maintenance of the internal structure under low deformation.

During the second interval, the application of high deformation promoted clear disruption of the viscoelastic network. G′ dropped abruptly to values close to 165 Pa at the beginning of the perturbation stage, while G″ remained within the range of approximately 358–412 Pa. Under this condition, G″ temporarily became higher than G′, indicating a transition of the material toward a more viscous behavior and confirming the breakdown of the elastic structure under intense deformation. The complex viscosity also decreased markedly, reaching values close to 62,769 mPa·s, further supporting the temporary loss of structural resistance. This behavior is consistent with the shear-thinning profile observed in the viscosity curve and confirms that the bioink

network can be disrupted under high deformation, allowing flow during extrusion.

After returning to low deformation in the third interval, the bioink showed rapid recovery of the viscoelastic moduli. G′ immediately increased to approximately 1,431 Pa within the first seconds and reached around 1,600 Pa in less than 15 s, stabilizing at a plateau close to 1,625 Pa until the end of the test. Although G′ did not fully return to its initial value, it again remained substantially higher than G″, which was maintained around 300 Pa at the end of the recovery stage. This result indicates that the bioink recovers its solid-like gel behavior after perturbation, an essential feature for maintaining filament shape after extrusion.

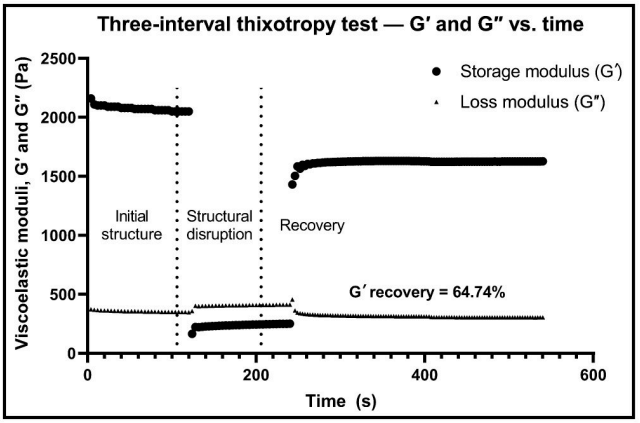

Fig. 5. Three-interval thixotropy test showing G′ and G″ over time. G′ decreased sharply during high strain and partially recovered after returning to low strain, reaching 64.74% recovery.

The structural recovery of G′, calculated from representative mean values of the initial and final intervals, was 64.74%. This value indicates partial but functionally relevant recovery of the viscoelastic network. The complex viscosity showed a similar response, increasing rapidly after removal of the high deformation and stabilizing around 263,000–264,000 mPa·s, with a recovery of 78.36%. The difference between G′ recovery and η* recovery suggests that different levels of structural organization within the bioink are restored at distinct time scales: interactions associated with resistance to flow may reorganize more rapidly, whereas full recovery of the elastic network depends on slower supramolecular rearrangements.

This profile of rapid recovery followed by stabilization is characteristic of hydrogels based on partially reversible physical networks. In the studied formulation, this behavior may be related to interactions among agarose, alginate, gelatin, and β-TCP. Agarose contributes to the formation of physical networks through hydrogen-bonding interactions, gelatin favors thermoreversible interactions and matrix cohesion, while alginate contributes to the viscosity and organization of the polymeric phase. In addition, β-TCP acts as a dispersed mineral phase that can increase the mechanical strength of the network and contribute to stability. The incomplete recovery of G′ within the 300 s window suggests that part of these interactions is not fully restored in the short term, a behavior also described for physical hydrogels and bioinks based on polysaccharides and proteins [11,16,17].

The filament collapse test demonstrated high post-deposition stability across all unsupported spans tested (0.80–5.63 mm). Relative deflection remained below 3.5%, ranging from approximately 0.5% to 3.2%. Even at the largest gap of 5.63 mm, the filament exhibited only ~1.9% deflection, indicating effective shape retention after extrusion.

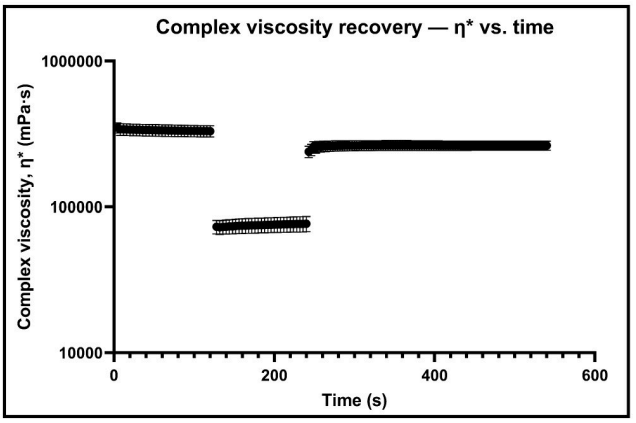

Fig. 6. Complex viscosity recovery during the thixotropy test. Complex viscosity (η*) decreased during the high-strain disruption interval and partially recovered after returning to low strain, indicating reorganization of the bioink network after shear-induced breakdown. Data are presented as mean ± standard deviation.

Overall, the low filament deflection demonstrates that the bioink can maintain its geometry after deposition, even across relatively large unsupported distances. These results confirm good post-printing stability and support the printability predicted by the rheological characterization.

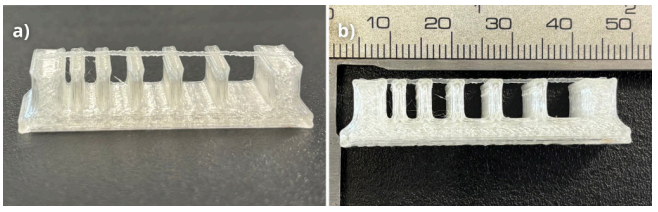

Fig. 7. Filament collapse test of the bioink across progressively increasing unsupported spans. (a) Oblique view and (b) perpendicular view showing preservation of filament continuity and minimal deformation after deposition.

Direct printing confirmed the ability of the bioink to form continuous filaments and preserve the designed grid architecture. The printed pores remained well defined, with a printability parameter of Pr = 1.15 ± 0.08, indicating good preservation of the square pore geometry.

Overall, the rheological results indicate that the agarose/alginate/gelatin/β-TCP bioink presents a favorable balance between flowability and structural stability. The amplitude sweep showed a broad LVER and high oscillatory yield stress, indicating resistance to deformation at rest. The frequency sweep confirmed that G′ remained higher than G″ across the tested frequency range, demonstrating the persistence of solid-like behavior under oscillatory conditions.

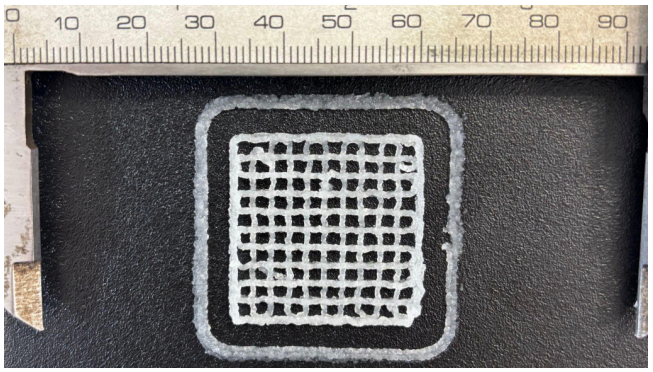

Fig. 8. Representative 30 × 30 mm grid printed with a 0°/90° deposition pattern, showing preservation of filament continuity and square pore geometry after deposition.

The viscosity curve showed pronounced shear-thinning behavior, supporting extrudability under high shear. Importantly, although G′ recovery was incomplete (64.74%), the direct printing results demonstrated that the recovered structure was sufficient to maintain filament geometry at the macroscopic scale after deposition. Together, these findings demonstrate a favorable balance between extrusion flowability and post-deposition stability, which are fundamental requirements for the fabrication of bone tissue engineering scaffolds with defined geometry and controlled porosity.

IV. Conclusion

The agarose/alginate/gelatin/β-TCP formulation exhibited rheological properties compatible with extrusion-based 3D bioprinting, including predominantly elastic behavior, pronounced shear-thinning, high oscillatory yield stress, and rapid partial structural recovery after deformation. Direct printing experiments further confirmed its printability, demonstrating preservation of grid geometry and low filament deflection across unsupported spans up to 5.63 mm. These results indicate that, despite the incomplete recovery of G′, the bioink provides sufficient post-deposition stability to maintain printed structures. Therefore, the formulation represents a promising candidate for the extrusion-based fabrication of scaffolds for bone tissue engineering. Further mechanical, degradation, and biological studies are still required to confirm its performance for bone regeneration applications.

Acknowledgment

The authors gratefully acknowledge Quantis Biotechnology for providing materials and laboratory infrastructure for the development of this study. The authors also thank Douglas Santos and Anton Paar for granting access to the rheometer and for their valuable technical assistance during the rheological characterization.

Abstract*—The development of bioinks with suitable rheological properties is essential for the successful application of extrusion-based 3D bioprinting in tissue engineering. In this context, whitlockite nanoparticles have attracted attention due to their bioactivity and piezoelectric behavior, making them promising candidates for developing piezoelectric bioinks for bone tissue engineering. This study aimed to investigate the influence of pure and zinc-doped whitlockite nanoparticles on the rheological properties of GelMA hydrogels intended for use as bioinks. GelMA was synthesized through glycidyl methacrylate functionalization and characterized by Nuclear Magnetic Resonance (NMR). Pure and zinc-doped whitlockite nanoparticles (0.5% and 1 mol% Zn) were synthesized using the sol–gel method and characterized by X-ray Diffraction (XRD). Hydrogels containing different nanoparticle concentrations (1 and 10 wt.%) were prepared and evaluated through rheological tests, including sol-gel transition temperature (Tsol−gel), viscosity, linear viscoelastic region (LVR), and structural recovery. The incorporation of whitlockite increased the sol-gel transition temperature and expanded the LVR, while all formulations maintained pseudoplastic behavior and structural recovery, properties that are desirable for extrusion-based 3D printing. The specific influence of zinc doping was less evident and depended on the nanoparticle concentration. Overall, the results indicate that incorporating zinc-doped whitlockite alters the rheological behavior of GelMA hydrogels, suggesting its potential for developing bioinks for tissue engineering applications.

I. Introduction

Bone regeneration is a widely discussed topic in the scientific community, since approximately two million bone grafting procedures are performed annually to repair bone defects [1]. Bone tissue has a highly complex structure due to its hierarchical arrangement of collagen fibers organized into seven layers [2], which makes it the stiffest tissue in the human body and confers high resistance to compressive forces. Thus, bones provide mobility and protect vital organs against mechanical shocks [3].

Another remarkable characteristic of bone tissue is its capacity for self-regeneration, which allows it to continuously remodel and replace itself, maintaining the individual's bone structure. This property facilitates the treatment of fractures and mild bone injuries, since the tissue itself is capable of regenerating [3]. However, in cases of severe tissue loss, the regeneration process depends on human intervention. This is a highly complex process because bone tissue is difficult to synthesize, and its regeneration depends on three factors: osteogenic cells, osteoinductive growth factors, and osteoconduction [4].

Therefore, biomaterials have become widely used in treatment. These components are studied within the interdisciplinary field of materials science, which investigates the relationships between the structure, properties, and processing of different materials. Within this field, biomaterials research focuses on cellular and tissue interactions at the molecular level. This area plays a crucial role in advancing medicine [5].

In this context, the evolution of bone repair strategies can be approached according to the different generations of biomaterials. The first generation aims to mimic biological bone components in an inert manner, without generating interactions, forming a bionic structure. The second generation involves the use of bioactive materials that integrate with the biological environment, albeit in an artificial manner. Furthermore, the third generation comprises bioactive and resorbable materials that are already used in tissue-engineering-based regenerative medicine [5].

Currently, a fourth generation of biomaterials has been proposed, with a focus on electrophysiological behavior [5]. In these materials, upon application of an external mechanical stimulus, surface charges form, creating electric fields with negative potential in compression regions and positive potential in tension regions. This polarization alters the

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

membrane potential of adjacent cells, promoting the opening of voltage-gated calcium channels and stimulating the migration and proliferation of bone-forming cells [6].

This behavior is explained by a chemical property shared by both structures: piezoelectricity, the ability to generate an electric field in response to mechanical stress. This occurs due to a transient deformation of the electric dipole in the crystalline material under mechanical loading, resulting in changes in atomic positions and a loss of the center of symmetry. Consequently, this dipole distribution leads to charge accumulation on the material surface, generating localized electric fields that interact with the electrical activity of surrounding cells. Therefore, by incorporating biomaterials with this characteristic, it is possible to establish an electrical interaction with bone tissue and stimulate regeneration [6].

In this context, to apply this therapeutic approach to bone regeneration, it is necessary to use a material that is both biocompatible and piezoelectric. One biomaterial that fits this proposal is the gelatin methacrylate (GelMA) scaffold, which provides structural support for regeneration by mimicking the extracellular matrix of bone tissue. Therefore, incorporating piezoelectric particles into this scaffold can increase the regeneration rate by electrically stimulating bone cells, promoting cell proliferation and migration.

Furthermore, another material that could be combined with the scaffold is the whitlockite nanoparticle (WK: $Ca_{18}Mg_2(HPO_4)_2(PO_4)_{12}$). Unlike hydroxyapatite, the most used calcium phosphate in bone scaffolds [7], WK exhibits intrinsic piezoelectric behavior, making it particularly suited to the electrical stimulation strategy described above. In addition, WK mimics the mineral composition of bone tissue and may stimulate osteogenic differentiation by suppressing osteoclastic activity while continuously releasing PO_4^{3-} and Mg^{2+} ions [8]. Moreover, zinc doping of this scaffold may also enhance bone regeneration by inhibiting bone resorption and consequently increasing the regeneration rate. In addition, zinc incorporation is biocompatible and does not produce undesirable reactions in the body [9].

Should the accelerated bone regeneration hypothesized for this piezoelectrically driven scaffold be confirmed in future studies, the potential clinical impact could include reducing hospital stay and hospital resource consumption. This would improve patients' quality of life, since severe bone fractures are not only debilitating but also reduce patients' autonomy and require long recovery periods. Furthermore, it could reduce hospital costs associated with this condition, making treatment more affordable and enabling greater investment in other healthcare sectors. Finally, since it is produced by 3D bioprinting, this treatment is more personalized and scalable, with the potential to reach not only large hospitals but also, in the future, the Brazilian Unified Health System (SUS).

As a first step toward the development of such a piezoelectrically-driven scaffold, the general objective of this study is to investigate the influence of incorporating pure and zinc-doped whitlockite nanoparticles into GelMA hydrogels on their rheological properties, with the aim of applying them as bioinks for 3D printing. Furthermore, the specific objectives are: (1) to synthesize zinc-doped whitlockite nanoparticles; (2) to characterize the rheological properties (sol-gel transition temperature, viscosity, LVR, and recovery) of GelMA hydrogels containing different concentrations of pure and zinc-doped whitlockite; and (3) to compare the effect of incorporating the different whitlockite formulations on the rheological behavior of the hydrogels. This study further aims to describe, on an exploratory basis, whether the incorporation of different whitlockite formulations is associated with changes in the rheological properties of GelMA hydrogels, based on the single-sample characterization performed for each formulation

II. METODOLOGY

A. Gelatin Methacryloyl (GelMA) Synthesis

To synthesize gelatin methacryloyl (GelMA), 10% (w/v) type A porcine skin gelatin was added to a bicarbonate buffer solution (pH 7.4) at 50 °C and mixed until complete dissolution. During stirring, 10% (w/v) glycidyl methacrylate (GMA) was added to the gelatin solution at 0.5 mL/min and maintained for 3 hours. Subsequently, the solution was dialyzed against distilled water using a dialysis membrane for one week, with daily water replacement, while kept at room temperature and protected from light, to remove unreacted glycidyl methacrylate and reaction by-products. Finally, the solution was lyophilized and stored at room temperature until further use.

To confirm the functionalization of the gelatin, the synthesized product was analyzed by Nuclear Magnetic Resonance (NMR). This technique is based on the spins of atomic nuclei, which selectively absorb radiofrequency energy, generating peaks corresponding to the contribution of protons in different chemical environments [10]. Thus, the analysis is based on evaluating the area under each peak by integrating it, thereby quantifying the proportions of different functional groups in the sample.

To determine the degree of functionalization of the gelatin methacryloyl, the NMR spectra were analyzed. First, the peak corresponding to the methacrylate protons of methacryloyl groups grafted onto lysine and hydroxylysine residues (6.1 ppm) was evaluated, as it indicates the functionalization of gelatin with methacrylamide groups, which is essential for hydrogel polymerization and formation. Next, the second peak analyzed corresponded to the methacrylate groups (5.75 ppm), which also play an important role in the functionalization and properties of the hydrogel. Finally, the peak corresponding to the non-functionalized amine groups (2.99 ppm) was analyzed. The degree of methacrylation was then calculated using the following equation:

$$DM(\%) = \frac{N_{functionalized}}{N_{amine}} \times 100 \quad (1)$$

B. Whitlockite Synthesis and Characterization

Whitlockite synthesis consists of mixing an acidic solution of H_3PO_4 at a concentration of 6.5 % (w/v) with an alkaline solution containing 5.7 % (w/v) $Ca(OH)_2$ and 1.35 % (w/v) $Mg(OH)_2$. The alkaline solution was prepared under stirring at 70 °C and maintained under these conditions for 1 hour. Subsequently, the acidic solution was added dropwise to the mixture at a rate of 12.5 mL/min. The reaction was then transferred to an autoclave and maintained at 70 °C for 48

hours. The resulting material was washed to remove residual unreacted acid and base, lyophilized to remove the remaining water, and finally calcined at 700 °C in a ceramic crucible using a muffle furnace for 1 hour.

For zinc-doped whitlockite, Mg^{2+} ions were partially substituted by Zn^{2+} ions. For this purpose, $Zn(NO_3)_2$ was added to the synthesis according to a molar proportionality between the compounds. The selected zinc doping levels were 0.5 and 1 mol %. Thus, during the preparation of the alkaline solution, the corresponding mass percentages of $Mg(OH)_2$ were replaced by $Zn(NO_3)_2$ while maintaining the stoichiometric proportion. The subsequent synthesis steps were carried out without further modifications. Finally, the three synthesized samples were characterized by X-ray Diffraction (XRD) to verify the formation of the whitlockite crystalline phase.

The formation of the whitlockite phase was confirmed by X-ray diffraction (XRD), validating the synthesis route employed prior to incorporation into the GelMA hydrogel. The diffractograms were compared with the reference standard for whitlockite.

C. *Hydrogel Synthesis*

The hydrogel was prepared by mixing 10% (w/v) gelatin methacryloyl (GelMA) with whitlockite nanoparticles at 35 °C until complete homogenization. Whitlockite concentrations of 1% (w/w) and 10% (w/w) were used in the hydrogel formulations. The final formulations analyzed in this study are presented in Table 1.

Sample	**Composition (in w/w %)**
Control	GelMA
WK1	GelMA + 1 % whitlockite
WK10	GelMA + 10 % whitlockite
WK1-Zn0.5	GelMA + 1 % Zn0.5-doped whitlockite
WK10-Zn0.5	GelMA + 10 % Zn0.5-doped whitlockite
WK1-Zn1	GelMA + 1% Zn1-doped whitlockite
WK10-Zn1	GelMA + 10% Zn1-doped whitlockite

Table 1. Composition of the hydrogel formulations.

D. *Rheological Characterization*

Rheological measurements were performed on uncrosslinked hydrogels using a HAAKE PCR rheometer (Thermo Scientific) with plate-plate geometry (diameter: 1.5 cm). Four tests were conducted: (i) oscillatory amplitude sweep to determine the linear viscoelastic region (LVR) and storage (G') and loss (G") moduli; (ii) flow curve (shear rate 20–100 s^{-1}) to evaluate viscosity and shear stress as a function of shear rate; (iii) temperature sweep (10–50 °C) to determine the sol-gel transition temperature (Tsol-gel); and (iv) three-interval thixotropy test (3ITT) to evaluate the structural recovery of the hydrogels after high shear deformation. All rheological measurements were performed on a single sample per formulation, without independent replicates; consequently, the results reported in this study are descriptive, and no inferential statistical analysis was performed.

III. RESULTS

Initial characterization confirmed WK formation during synthesis. The undoped WK was characterized in a previous work of our research group [11], while Zn-doped WK, analyzed post-calcination, also showed the whitlockite phase at 0.5 and 1 mol% doping (Fig. 1). XRD peaks matched ICDD card 00-070-2064, indicating successful synthesis. No secondary phases appeared in 1 mol% Zn-doped WK, suggesting high purity and Zn^{2+} incorporation into the crystal lattice, replacing Mg^{2+}, consistent with calcium phosphate doping reports [12]. The 0,5 mol% sample showed additional hydromagnesite and calcite phases, likely due to carbonate formation on calcium phosphate surfaces that interact with CO_2, especially under humid conditions [13]. Despite these secondary phases, Zn0.5-WK was used in rheological tests to study its effect on GelMA. Although calcite was an undesired phase, it is a bioactive biomaterial and has demonstrated promising biological applications in bone regeneration through both in vitro and in vivo studies [14].

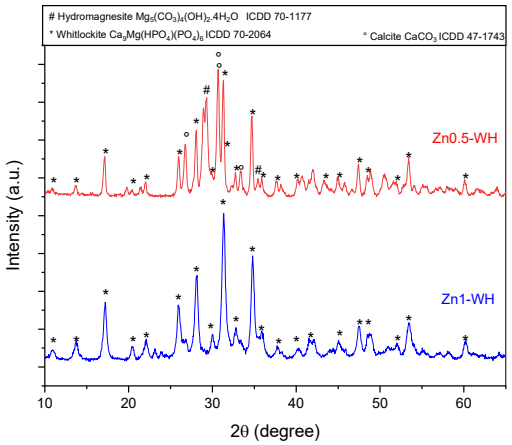

Fig. 1 – X-ray diffraction patters of the Zn-doped WK after calcination: results of the Zn1-WK in blue and Zn0.5-WK in red.

The produced hydrogels were characterized regarding their rheological properties in order to evaluate the influence of incorporating undoped and zinc-doped whitlockite nanoparticles in GelMA hydrogels. Initially, the sol-gel transition temperature ($T_{sol-gel}$) was evaluated. This parameter represents the critical temperature at which gelatin macromolecules, dispersed in an aqueous medium, adopt a random-coil conformation after losing their triple-helix structure. Since the triple-helix structures are crosslinked through intermolecular interactions, their loss leads to loss of physical entanglement, thereby resulting in loss of gel consistency [10]. This temperature is determined by the crossover between the storage modulus (G') and the loss modulus (G") during a heating ramp (Figure 2), indicating the temperature range in which the hydrogel remains in the gel state. The sol-gel transition temperature ranged from 34.02 °C to 37.17 °C, and the addition of whitlockite increased it relative to the control groups across all analyzed formulations.

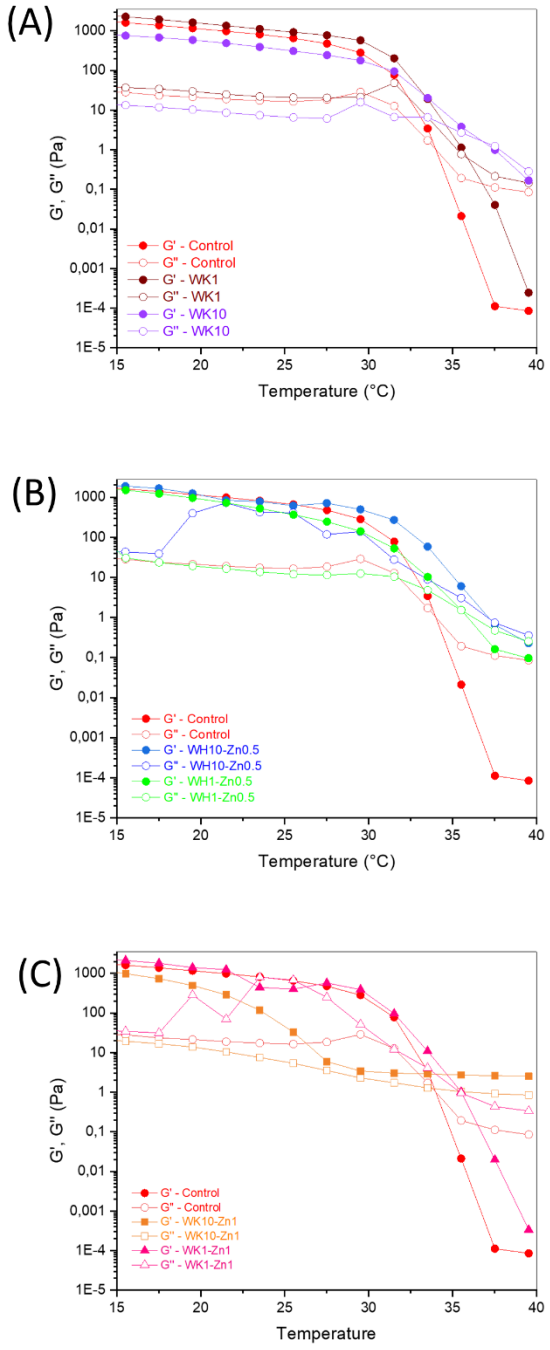

Fig. 2. Determination of the sol-gel transition temperature ($T_{sol-gel}$) of the different GelMA hydrogel formulations through the crossover between the storage modulus (G') and the loss modulus (G''). The panels show: (A) control and non-doped whitlockite formulations; (B) control and 0.5% zinc-doped whitlockite formulations; and (C) control and 1% zinc-doped whitlockite formulations

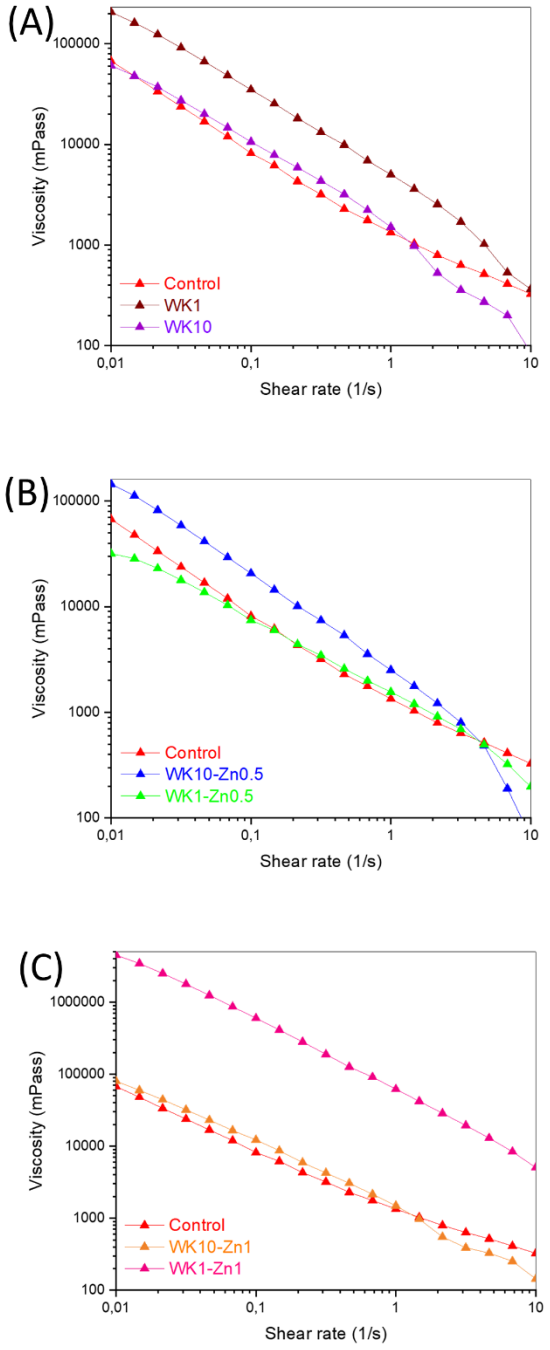

Fig. 3. Viscosity as a function of shear rate for the different GelMA hydrogel formulations.The panels show: (A) control and non-doped whitlockite formulations; (B) control and 0.5% zinc-doped whitlockite formulations; and (C) control and 1% zinc-doped whitlockite formulations

The viscosity of the hydrogels was measured as a function of shear rate to assess whether they behave as pseudoplastic fluids, and the results are shown in Figure 3. All formulations exhibited pseudoplastic behavior, characterized by a decrease in viscosity as the applied shear rate increased.

The flow curve test, which measures the shear stress as a function of shear rate, was also performed to evaluate complementary data regarding fluid behavior, and is shown in Figure 4. All formulations exhibited a local maximum in shear stress (stress overshoot) at shear rates between 37.31 s^{-1} (WK10) and 68.06 s^{-1} (WK10-Zn0.5), followed by a progressive decrease in shear stress. All formulations

containing 1% undoped or doped whitlockite exhibited the highest yield shear stress, followed by hydrogels with 10% whitlockite, whereas the control sample showed the lowest peak stress. The maximum shear stress reached approximately 1549.9 Pa (WK1-Zn1) and the minimum 561.86 Pa (Control).

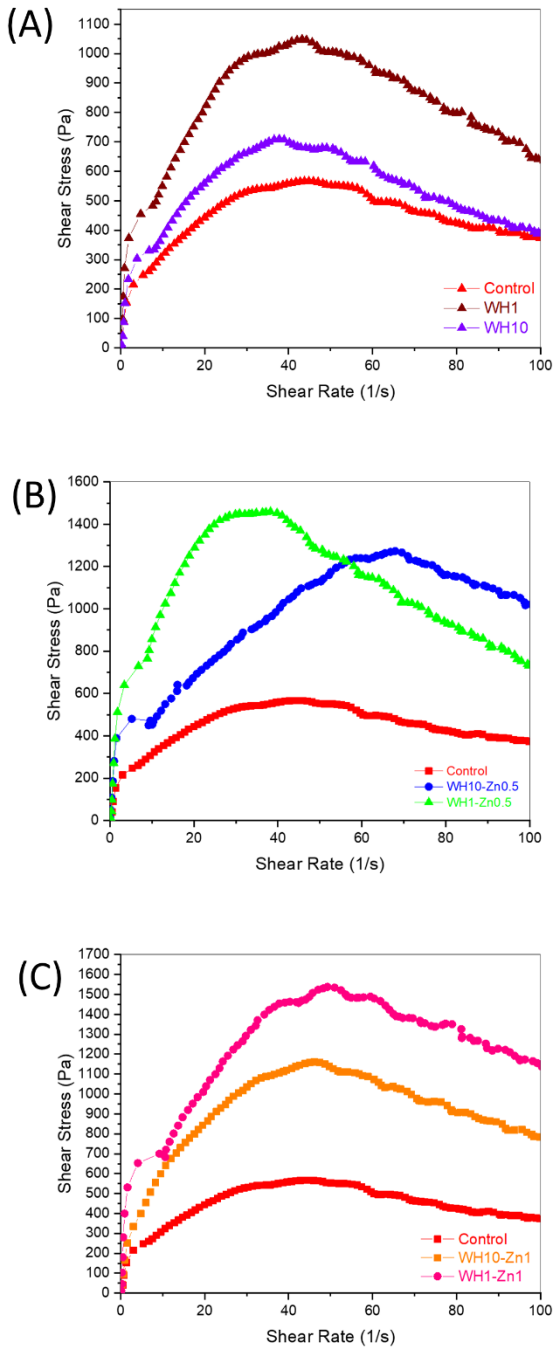

Fig. 4. Shear stress as a function of shear rate (flow curve) for the different GelMA hydrogel formulations. The panels show: (A) control and non-doped whitlockite formulations; (B) control and 0.5% zinc-doped whitlockite formulations; and (C) control and 1% zinc-doped whitlockite formulations

The linear viscoelastic region (LVR) was determined by shear strain sweep tests, and the results are shown in Figure 5. This analysis identifies the critical deformation limit at which changes in the internal structure of the hydrogel occur, corresponding to the crossover between G' and G". The LVR values ranged from 3.02 to 8.01, with the addition of undoped or Zn-doped whitlockite increasing this LVR region compared with the control group in all analyzed formulations.

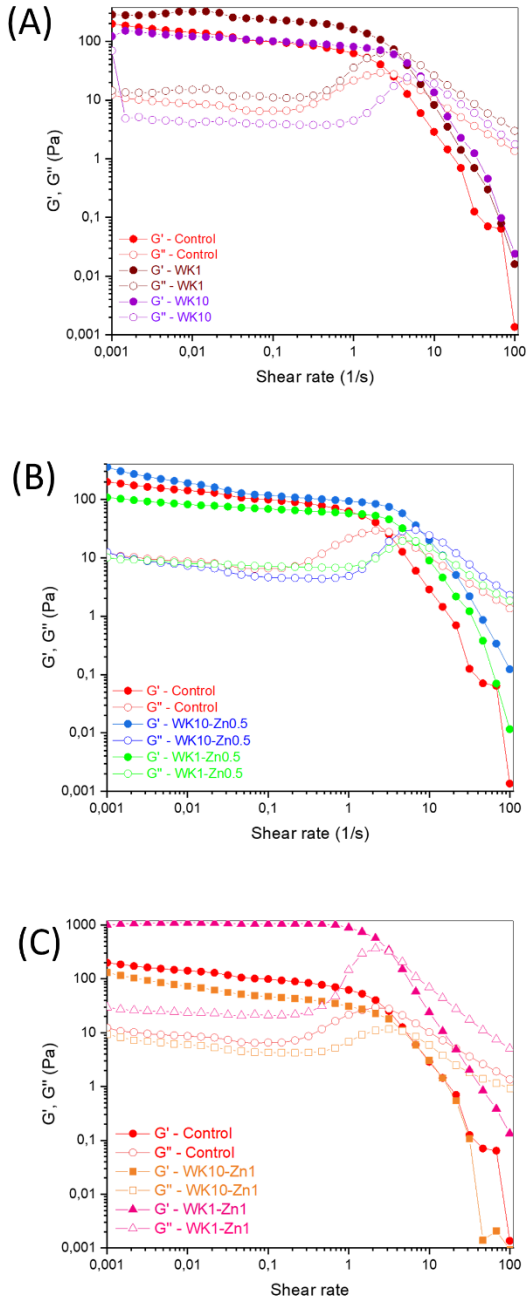

Fig. 5. Determination of the linear viscoelastic region (LVR) of the different GelMA hydrogel formulations by strain sweep analysis. The panels show: (A) control and non-doped whitlockite formulations; (B) control and 0.5% zinc-doped whitlockite formulations; and (C) control and 1% zinc-doped whitlockite formulations

Finally, the structural recovery capacity of the hydrogels was evaluated using a three-interval thixotropy test, in which the material was initially deformed within its linear viscoelastic region (LVR), then beyond its critical limit (outside the LVR), and finally returned to its initial condition. The test showed viscosity recovery values ranging from 55.56% to 90.81% (Figure 6).

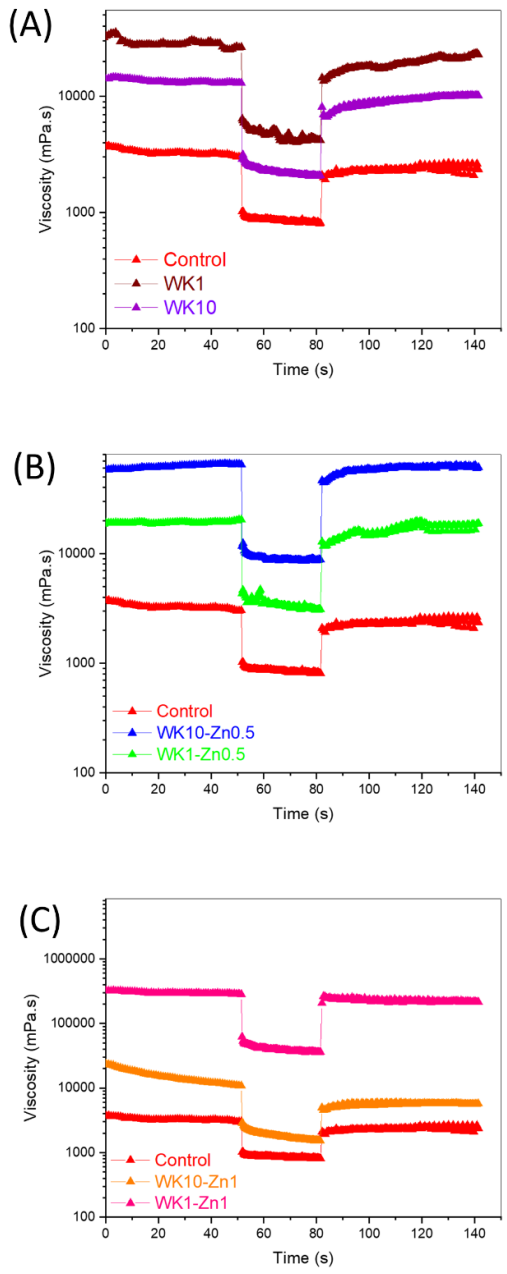

Fig. 6. Three-interval thixotropy test showing the structural recovery of the different GelMA hydrogel formulations after high shear deformation. The panels show: (A) control and non-doped whitlockite formulations; (B) control and 0.5% zinc-doped whitlockite formulations; and (C) control and 1% zinc-doped whitlockite formulations

The results obtained from the rheological tests described above are summarized in Table 2 to facilitate data visualization.

Table 2. Summary of the rheological properties of the synthesized GelMA hydrogels.

Sample	Tsol_gel (°C)	LVR	Recovery
Control	34.02	3.02	71.60%
WK1	35.85	3.52	73.23%
WK10	36.77	7.40	73.00%
WK1-Zn0.5	35.31	6.76	91.15%
WK10-Zn0.5	37.17	8.01	90.81%
WK1-Zn1	35.58	3.38	79.10%
WK10-Zn1	36.15	4.56	55.56%

IV. DISCUSSION

Rheological properties play a central role in the application of hydrogels as bioinks for 3D printing, since they determine both the material's ability to be extruded through the printing nozzle and its structural stability after deposition [9]. Gelatin methacryloyl (GelMA) exhibits thermoresponsive behavior: at low temperatures, its polymer chains adopt a triple-helix conformation, promoting physical crosslinking and increasing viscosity, whereas heating disrupts these interactions. This conformational change characterizes the sol-gel transition. Therefore, maintaining hydrogels below the critical transition temperature, in the region where G' > G", is important for shape fidelity and structural stability during 3D printing.

In this scenario, the increase in $T_{sol-gel}$ (Table 2) observed in the formulations containing undoped or Zn-doped whitlockite is consistent with previous reports, since ceramic nanoparticles have been described as reinforcing agents in hydrogels by creating intermolecular interactions with the polymeric chains that improve structural stability and resistance to deformation [15]. Furthermore, the slight increase in the sol-gel transition was mainly attributed to the ceramic charge, whereas zinc doping did not affect this property. At both whitlockite concentrations (1% and 10%), no apparent difference in transition temperature was observed between doped and undoped formulations. Moreover, all formulations exhibited $T_{sol-gel}$ above 34°C, which is favorable from a processing standpoint, as the material remains in the gel state at room temperature, facilitating its handling as a bioink.

Furthermore, pseudoplastic behavior was observed across all formulations (Figure 3), consistent with the expected behavior of hydrogels before chemical crosslinking. This property allows the material to be extruded through the printing needle by reducing its viscosity under shear stress, while recovering its viscosity at rest, thereby preventing excessive spreading or deformation of the deposited filament [16]. The classification as pseudoplastic fluids is also supported by the ascending branch of the flow curves (Figure 4), which shows the characteristic nonlinear, concave shear stress–shear rate relationship of a pseudoplastic fluid, with a characteristic yield stress [16]. Below the yield stress, the

physical entanglement of the polymeric network can be elastically deformed; above it, physical entanglement within the triple helix and intermolecular interactions cannot accommodate the deformations, and the fluid deforms plastically. The yield point increased with increasing amounts of doped or undoped WK in the hydrogels, suggesting that the ceramic powder interacts with the GelMA polymeric chains, thereby contributing to energy storage via intermolecular interactions under mechanical deformation. The formulation WK10-Zn0.5 exhibited anomalous behavior compared with Zn1-doped WH or undoped WH-containing hydrogels, which may be attributed to secondary phases formed during synthesis. The WK10-Zn0.5 formulation exhibited greater deformation at the yield point, suggesting strong interactions between the carbonate phases and the GelMA network. These results are interesting because they indicate that WK does not affect physicochemical interactions between the ceramic and the polymeric matrix, whereas carbonate phases may cause significant physicochemical interactions at high concentrations (10 wt.%). More studies are needed to determine whether this behavior extends to other calcium phosphate ceramics beyond WK.

Regarding the linear viscoelastic region (LVR), LVR values increased for formulations containing higher concentrations of whitlockite, particularly WK10 and WK10-Zn0.5 (Figure 5). This behavior indicates that these hydrogels withstand greater deformation before their internal structure is compromised, another characteristic that, together with pseudoplastic behavior, is essential for bioink printability, ensuring structural integrity and dimensional fidelity.

Finally, the structural recovery test is consistent with the predominantly physical (non-covalent) nature of the interactions sustaining the hydrogel network. Under high deformation, these junctions are disrupted, allowing the material to flow and reorganize once the mechanical stimulus is removed, restoring a large portion of the original viscosity. The highest recovery was observed for WK1-Zn0.5 (91.15%), closely followed by WK10-Zn0.5 (90.81%), suggesting a network with a greater capacity for physical reorganization after deformation, possibly favored by stronger mineral-polymer interactions. These results are consistent with those found in the flow curves (Figure 4), where the secondary phases found in the Zn0.5-WK ceramic were associated with stronger interactions with the GelMA chains.

Overall, the rheological results indicate that the incorporation of whitlockite, but not its zinc doping, modulates both the operating temperature of the hydrogel and its resistance to deformation and recovery capacity. Besdies, secondary carbonate phases showed stronger interactions with the GelMA network than the WK phases. These characteristics are relevant to applications involving material handling, injection, or 3D printing prior to crosslinking. However, the rheological characterization was performed using a single sample per formulation, without independent replicates; therefore, the differences observed among formulations should be interpreted as descriptive trends.

Although the present study focused exclusively on rheological characterization, incorporating whitlockite may support the future development of bioinks with piezoelectric potential, as it has been reported to exhibit piezoelectric behavior. This study does not directly demonstrate actual printability, mechanical performance, piezoelectric response, biological performance, or osteogenic effects. These aspects should be evaluated in future studies to further assess the suitability of the formulations for tissue engineering and their potential for regenerative applications.

V. CONCLUSION

The results of this study show that incorporating pure and zinc-doped whitlockite nanoparticles modifies the rheological properties of GelMA hydrogels, influencing parameters relevant to their application as bioinks. Overall, an increase in the sol-gel transition temperature ($T_{sol-gel}$) and in the linear viscoelastic region (LVR) was observed, while all formulations maintained pseudoplastic behavior and structural recovery capacity, which are relevant characteristics for 3D printing processes. Although it was found that zinc doping in the WK ceramics did not lead to significant changes in the properties of the formulations, the results indicate that the incorporation, in terms of mass fraction, of whitlockite represents a promising strategy for the development of biomaterials for tissue engineering, with piezoelectric functionality — reported for whitlockite in the literature — to be experimentally explored in future studies. *Additionally, the interaction between GelMA and carbonate phases must be further explored, as these phases strongly modulate GelMA properties.* Future studies involving independent experimental replicates, 3D printing assays, mechanical characterization, piezoelectric measurements, and biological evaluation will be necessary to further assess the suitability of these formulations for tissue engineering and their potential for regenerative applications.

***Resumo*—A retinopatia diabética (RD) é uma das principais causas de perda de visão evitável no mundo e se manifesta, em seus estágios iniciais, por lesões de fundo de olho como microaneurismas, exsudatos duros, exsudatos moles e hemorragias. Sua detecção automatizada é desafiadora, pois as imagens têm alta resolução e as lesões ocupam pouquíssimos *pixels*, sendo os microaneurismas, sinal mais precoce da doença, os mais difíceis. Este trabalho investiga, de forma controlada e estratificada por tipo de lesão, se a inferência assistida por fracionamento de imagem *Slicing Aided Hyper Inference* (SAHI) melhora a detecção de lesões de RD quando aplicada a um detector YOLO moderno, no conjunto de dados público DDR. Sob validação cruzada repetida e estratificada por lesão (5 *folds* $\times$ 3 repetições) e protocolo unificado de avaliação (*mean Average Precision*, mAP, a IoU 0,1 e 0,5), comparam-se três configurações: (A) treino e inferência em imagem cheia; (B) SAHI apenas na inferência; e (C) SAHI também no ajuste fino. A Config. B *reduziu* significativamente o desempenho global em relação ao *baseline* YOLOv8m ($p < 0{,}01$, Wilcoxon pareado), enquanto a Config. C aproximou o mAP global do *baseline*, sem diferença detectável sob o teste corrigido para a não-independência dos *folds*. O ganho concentrou-se nos microaneurismas: a Config. C elevou significativamente o AP@0,1 ($p_{\mathrm{Holm}} = 0{,}009$; $r = 0{,}82$) e aumentou o AP@0,5 de 0,059 para 0,111, ao custo de piora nas lesões maiores e difusas. Conclui-se que, para detectores YOLO modernos em alta resolução, o ganho do SAHI é localizado: não melhora o mAP global, mostra-se eficaz na detecção de microaneurismas no DDR.**

***Palavras-chave*—retinopatia diabética, detecção de lesões, YOLO, SAHI.**

I. Introdução

A retinopatia diabética (RD) é uma complicação microvascular da retina e uma das principais causas de perda irreversível de visão em pessoas com diabetes [1], [2]. No Brasil, mais de 13 milhões de pessoas vivem com diabetes, cerca de 6,9% da população [3], e a RD atinge entre 24% e 39% desse grupo [4]. Quando diagnosticada e tratada precocemente, o risco de cegueira pode ser reduzido para menos de 5% [4].

A RD pode ser caracterizada pela presença de determinados tipos de lesões na retina, tais como exsudatos duros (EX), exsudatos moles ou algodonosos (SE), microaneurismas (MA) e hemorragias (HE) [2]. Os microaneurismas, em particular, costumam ser as primeiras alterações visíveis associadas à doença e, ao mesmo tempo, as mais difíceis de detectar, por ocuparem pouquíssimos *pixels* nas imagens de fundo de olho. A identificação dessas lesões em fases iniciais é essencial para prevenir a progressão da doença a estágios mais graves e a consequente perda de visão.

Os exames que identificam essas lesões dependem de médicos especializados, cuja disponibilidade é limitada, o que pode retardar o diagnóstico, sobretudo em regiões remotas e de difícil acesso [5]. A análise humana está ainda sujeita a fatores subjetivos, como cansaço e nível de experiência do especialista [6], o que compromete a precisão justamente nos estágios iniciais, quando as alterações são sutis. Nesse cenário, a detecção automática por aprendizado profundo tem sido proposta como ferramenta de apoio ao especialista: detectar e classificar cada lesão, e não apenas graduar a imagem, oferece informação para o diagnóstico precoce, de forma mais rápida e menos suscetível à subjetividade do avaliador.

Automatizar essa tarefa, contudo, permanece um problema em aberto. No conjunto de dados público DDR (*Dataset for Diabetic Retinopathy*) [1], um dos maiores *benchmarks* da área, os detectores genéricos avaliados pelos próprios autores obtiveram mAP inferior a $0{,}01$ a IoU 0,5, com AP de microaneurismas abaixo de 1% [1], [7]. Esse desempenho reduzido decorre do tamanho e do formato das lesões, do ruído e do contraste das imagens, do reduzido número de exemplos anotados e da dificuldade dos algoritmos de aprendizado profundo em detectar objetos muito pequenos [5].

Para mitigar o problema dos objetos minúsculos, a literatura recente tem explorado estratégias diversas: realçar seletivamente as regiões mais informativas da imagem [8], [9], ampliar artificialmente sua resolução [10] ou modelar relações entre regiões distantes, em vez de apenas vizinhanças locais [11]. Uma alternativa independente da arquitetura do detector consiste em fracionar a imagem em janelas sobrepostas (*tiling*/*slicing*), de modo que cada janela seja processada em resolução efetiva mais alta. O *framework* SAHI (*Slicing Aided Hyper Inference*) [12] implementa essa ideia de forma

Os autores agradecem ao Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), sob o Processo nº 315447/2023-0, e à Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) — Código de Financiamento 001, pelo apoio a esta pesquisa.

genérica, aplicável na inferência e, opcionalmente, também no ajuste fino do detector. No contexto do DDR, trabalhos anteriores demonstraram que o fracionamento eleva o desempenho da detecção de lesões, seja por *tiling* convencional [5], seja pelo SAHI [7]. Entretanto, esses estudos empregaram arquiteturas YOLO de gerações anteriores (YOLOv4/v5, YOLOR-CSP), permanecendo uma lacuna de investigação do SAHI combinado a detectores YOLO mais recentes, sob um protocolo de comparação controlado e com análise estratificada por tipo de lesão.

Diante dessa lacuna, este trabalho avalia, de forma controlada e estratificada por tipo de lesão, se o SAHI melhora a detecção de lesões de RD quando aplicado a um detector YOLO moderno (YOLOv8m), em comparação com a inferência em imagem completa, utilizando o conjunto de dados DDR. As principais contribuições deste trabalho são:

- o emprego de um detector YOLO moderno (YOLOv8m) combinado ao SAHI no DDR;
- uma comparação *controlada* entre YOLO e YOLO+SAHI sob um protocolo unificado de pré-processamento, resolução, validação cruzada e avaliação, que isola o efeito do *slicing* (mesmo detector, mesmos *folds*);
- uma análise *estratificada por classe* de lesão (MA, EX, SE e HE), com teste estatístico pareado, que evidencia o *trade-off* do *slicing*, ganho nas menores lesões (microaneurismas) e perda nas maiores e mais difusas (exsudatos moles e hemorragias), demonstrando que seu benefício sobre um YOLO moderno em alta resolução é condicional à classe de lesão e ao regime de treino.

O restante do artigo apresenta a fundamentação teórica (Seção II), os trabalhos relacionados (Seção III), os materiais e métodos (Seção IV), os resultados e a discussão (Seção V) e as considerações finais (Seção VI).

II. Fundamentação Teórica

A. Detecção de objetos

A detecção de objetos consiste em delimitar cada instância presente na imagem por uma *bounding box* (caixa retangular que circunscreve o objeto) e atribuir-lhe uma classe [13]. Os detectores baseados em aprendizado profundo dividem-se em detectores de dois estágios, que primeiro propõem regiões de interesse e depois as classificam, como o Faster R-CNN [14], e detectores de estágio único, que tratam a detecção como um problema de regressão e predizem simultaneamente as caixas e as probabilidades de classe sobre a imagem completa, como o SSD [15] e a família YOLO (*You Only Look Once*) [16]. A principal vantagem dos detectores de estágio único é a velocidade de inferência, o que os torna adequados a aplicações em tempo real e a *hardware* de menor custo.

B. A arquitetura YOLOv8

Neste trabalho adota-se o YOLOv8 [17], na variante `m` (*medium*). Trata-se de um detector *anchor-free* com *backbone* do tipo CSPDarknet, *neck* PAN-FPN e cabeça de detecção desacoplada, que realiza a predição em três escalas (P3/P4/P5) com cabeças especializadas em objetos pequenos, médios e grandes, característica relevante para a detecção de lesões de tamanhos variados na retina. A variante `m` equilibra capacidade e custo computacional, sendo compatível com o treino em uma única GPU.

C. Slicing Aided Hyper Inference (SAHI)

O SAHI, proposto por Akyon *et al.* [12], é uma solução de código aberto que fornece um processo genérico de inferência e ajuste fino auxiliado por fracionamento. A imagem de entrada é dividida em janelas (*tiles*) sobrepostas; a detecção é realizada em cada janela e as predições são reagrupadas na imagem original por pós-processamento (por exemplo, supressão não máxima gulosa, *GREEDYNMM*). Ao processar regiões menores em resolução efetiva mais alta, o método amplia a visibilidade de objetos pequenos, sendo promissor para o problema dos microaneurismas. Pode ser aplicado apenas na inferência (*sliced inference*) ou também no treinamento (*slicing-aided fine-tuning*), regime no qual a literatura reporta ganhos maiores [12].

III. Trabalhos Relacionados

A. Evolução da família YOLO

A família YOLO evoluiu por sucessivas versões (YOLOv3, YOLOv4, YOLOv5, YOLOR, YOLOv7, YOLOv8, YOLOv11, entre outras), incorporando aprimoramentos de *backbone*, *neck* e *head*, além de técnicas de aumento de dados e funções de perda mais robustas. Essa evolução importa aqui porque os trabalhos que aplicaram *slicing* à detecção de lesões de RD empregaram gerações anteriores da família [5], [7], cujas limitações na detecção de objetos pequenos podem ter sido atenuadas nas versões recentes.

B. Detecção de lesões de RD no DDR

No estudo que apresentou o conjunto de dados, Li *et al.* [1] avaliaram detectores genéricos (SSD, YOLO e Faster R-CNN) e demonstraram a dificuldade central da tarefa: enquanto a classificação alcançou acurácia da ordem de 0,83 com a arquitetura SE-BN-Inception, os modelos de segmentação e de detecção tiveram desempenho fraco, com AP de microaneurismas abaixo de 1%, o que evidencia a necessidade de aprimorar o reconhecimento de microlesões para viabilizar a aplicação clínica. Alyoubi *et al.* [18] combinaram uma rede de classificação (CNN512) a um YOLOv3 para localização de lesões, obtendo mAP de 0,216 na detecção no DDR.

Uma linha de trabalhos correlatos explorou progressivamente a família YOLO nessa base. Santos *et al.* [19] propuseram uma abordagem baseada em YOLOv4 e, depois [5], um método baseado em YOLOv5 com pré-processamento, aumento de dados e *Tiling*, alcançando mAP de 0,2630 na validação e 0,1540 no teste do DDR (IoU 0,5). Em seguida, Pereira *et al.* [7] combinaram a arquitetura YOLOR-CSP ao *framework* SAHI, atingindo mAP de 0,3808 na *validação* do DDR (IoU 0,5), mas de apenas 0,2225 no *teste*; essa diferença de 0,16 no mesmo modelo ilustra o quanto números de um único *split* de validação podem ser otimistas.

C. Lacuna de pesquisa

Como a combinação YOLO+SAHI já foi aplicada ao DDR [7], a comparação direta "YOLO vs. YOLO+SAHI" não constitui, por si só, uma novidade. O que permanece em aberto, e é o objeto deste trabalho, é saber se o ganho atribuído ao *slicing* persiste sobre um detector YOLO moderno, quando medido sob protocolo unificado, sem o viés de *split* único e de forma estratificada por tipo de lesão.

IV. Materiais e Métodos

A. Visão geral do método

O fluxo experimental é ilustrado na Fig. 1. Não há aquisição própria de imagens: utilizam-se as 757 imagens do conjunto público DDR [1] que possuem anotações de lesão em nível de *bounding box* (Seção IV-B). Essas anotações, distribuídas em formato Pascal VOC, são convertidas para o formato YOLO, com deduplicação das caixas repetidas e unificação dos três *splits* oficiais em um único *pool* (Seção IV-C), sobre o qual se aplica validação cruzada repetida e estratificada pelo vetor de presença de lesão, tendo a imagem como unidade de divisão (Seção IV-E). Em cada *fold*, o mesmo detector YOLOv8m é treinado sob dois domínios de entrada, imagem completa em alta resolução (Configs. A e B) e *tiles* de 512×512 (Config. C, *slicing-aided fine-tuning*), com hiperparâmetros fixos, de modo que a única variável experimental seja o fracionamento (Seção IV-F). A inferência ocorre sobre a imagem completa (Config. A) ou de forma fracionada com o SAHI (Configs. B e C), caso em que as predições de cada *tile* são reagrupadas nas coordenadas da imagem original por supressão não máxima gulosa. Por fim, as predições são confrontadas com o *Ground Truth* pelo avaliador COCO, calculando-se o mAP a IoU 0,1 e 0,5, global e por classe (Seção IV-G); como as três configurações compartilham os mesmos *folds*, os resultados são pareados e comparados por testes estatísticos pareados (Seção IV-H).

B. Conjunto de dados

Os experimentos utilizam o conjunto de dados público DDR [1], também chamado OIA-DDR, composto por 13.673 imagens de fundo de olho de 9.598 pacientes, coletadas em 147 hospitais de 23 províncias da China; destas, apenas 757 possuem anotações de detecção em nível de *bounding box*, sendo este o subconjunto empregado neste trabalho. As quatro classes consideradas são microaneurismas (MA), exsudatos duros (EX), exsudatos moles (SE) e hemorragias (HE). As imagens têm alta resolução e tamanhos variáveis (da ordem de 1088×1920 a 3456×5184 *pixels*), enquanto as lesões ocupam regiões diminutas, o que constitui a principal motivação para investigar o *slicing*. As anotações são bastante desbalanceadas, com SE presente em apenas 239 imagens e 1.293 instâncias, contra 23.659 instâncias de EX, conforme resumido na Tabela I. A densidade das microlesões e a grade de *tiles* do SAHI são ilustradas, sobre uma imagem real do DDR, na Fig. 2.

Tabela I
Distribuição das anotações de detecção do DDR (subconjunto de 757 imagens anotadas), após a deduplicação descrita na Seção IV-C.

Lesão	Imagens com a lesão	Instâncias	% instâncias
MA (microaneurismas)	570	10.380	21,7%
EX (exsudatos duros)	486	23.659	49,4%
SE (exsudatos moles)	239	1.293	2,7%
HE (hemorragias)	601	12.538	26,2%
Total	757	47.870	100%

Tabela II
Configurações experimentais avaliadas.

Config.	Treino	Inferência	Propósito
A	imagem cheia	imagem cheia	*baseline* sem *slicing*
B	imagem cheia	*sliced* (SAHI)	efeito do *slicing* só na inferência
C	*tiles* (*slicing-aided FT*)	*sliced* (SAHI)	regime completo de *slicing*

C. Conversão de anotações para o formato YOLO

O DDR fornece as *bounding boxes* oficiais em arquivos Pascal VOC (XML), organizadas nos *splits* `train`/`valid`/`test`. A conversão adotada parseia esses XML e escreve as caixas no formato YOLO (`classe cx cy w h`, com coordenadas normalizadas em $[0, 1]$), unindo os três *splits* em um único *pool* de 757 imagens, de modo que a divisão entre treino, validação e teste passa a ser feita pela validação cruzada (Seção IV-E). Verificou-se que os XML contêm caixas duplicadas exatas (fator próximo de $1{,}7\times$); aplica-se, portanto, deduplicação por caixa, resultando nas 47.870 instâncias da Tabela I. Após a conversão, as caixas foram validadas visualmente sobre uma amostra de imagens, para descartar erros de eixo ou de normalização. Na avaliação, adotou-se um lado mínimo de caixa de 2 *pixels*, o que evita áreas nulas no reagrupamento geométrico do SAHI.

D. Arquitetura de experimentos

Para isolar o efeito do *slicing*, três configurações são avaliadas sob o mesmo protocolo, conforme a Tabela II.

A configuração A é o *baseline* (sem *slicing*); a B isola o efeito do SAHI aplicado apenas na inferência, sobre o *mesmo* modelo treinado em imagem completa; e a C corresponde ao regime completo, em que o modelo também é treinado sobre *tiles*. As Configs. A e B derivam de um *único* treino por *fold*, avaliado de duas formas (imagem cheia e SAHI), o que torna a comparação A vs. B um teste exato do efeito da inferência fracionada.

E. Validação cruzada

Adota-se validação cruzada repetida e estratificada, com a imagem como unidade de divisão (as 757 anotadas), de modo que uma mesma imagem nunca apareça em mais de um

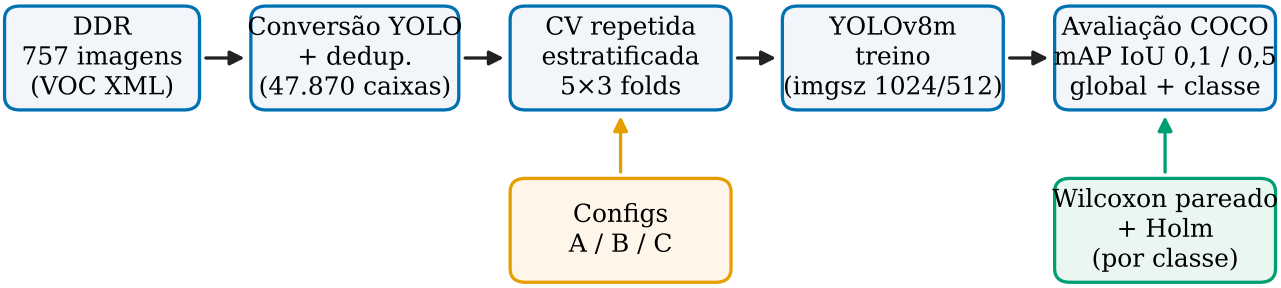

Figura 1. Visão geral do *pipeline* proposto: conversão das anotações VOC do DDR para o formato YOLO (com deduplicação), validação cruzada repetida e estratificada por lesão, treino do YOLOv8m, avaliação COCO (mAP a IoU 0,1 e 0,5, global e por classe) e teste estatístico pareado. As três configurações (A/B/C) compartilham os mesmos *folds*.

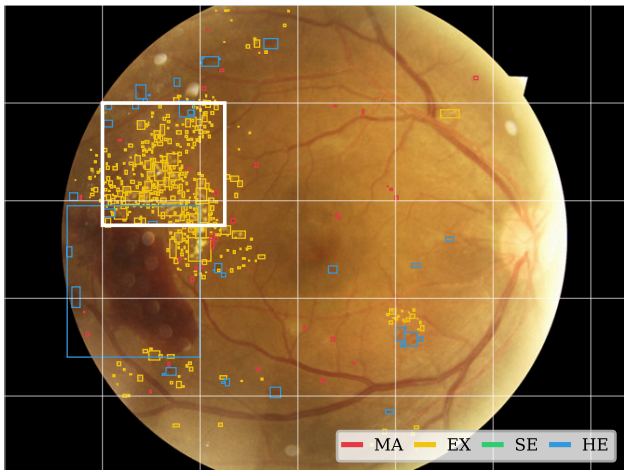

Figura 2. Imagem do DDR com as *bounding boxes* do *Ground Truth* (cores por classe) e a grade de *tiles* do SAHI (512 × 512, sobreposição 0,2); em destaque, um *tile*. A alta densidade de microlesões diminutas, muitas menores que a espessura da linha das caixas, motiva a inferência assistida por fracionamento.

subconjunto, evitando vazamento de dados. Como o DDR não disponibiliza identificadores de paciente para o subconjunto anotado, a partição é por imagem, não por paciente: imagens de um mesmo paciente podem, em princípio, ocorrer em *folds* distintos. Estimativas de partição única são instáveis em conjuntos pequenos, e a repetição reduz essa variância ao promediar múltiplas partições [20], [21]; no próprio DDR, Pereira *et al.* [7] reportam diferença de 0,16 de mAP entre validação e teste para o mesmo modelo, magnitude superior a qualquer efeito que se pretenda medir entre configurações.

Utiliza-se `RepeatedMultilabelStratifiedKFold` (5 *folds* × 3 repetições = 15 avaliações), estratificado pelo vetor binário de presença de lesão (tem MA / tem EX / tem SE / tem HE) de cada imagem [22]. Essa estratégia é essencial dado o desbalanceamento, sobretudo para SE, presente em 239 das 757 imagens: sob partição aleatória, os *folds* teriam contagens díspares dessa classe, inflando a variância de seu AP. Em cada *fold* externo, o conjunto de treino é novamente dividido de forma estratificada, reservando-se 80% para o ajuste dos pesos e 20% para a validação interna do *early-stopping*.

Como detector, hiperparâmetros (Tabela III), *seed*, *folds* e protocolo de avaliação são compartilhados, qualquer diferença entre A, B e C é atribuível ao fracionamento. O desempenho é reportado como média ± desvio-padrão do mAP entre os 15 *folds*.

F. Modelos e hiperparâmetros

O detector YOLOv8m foi implementado com a biblioteca `ultralytics` e o *slicing* com a biblioteca `sahi`, em Python. No *baseline* (Configs. A/B), as imagens são processadas em resolução elevada (lado maior redimensionado para 1024), a fim de preservar as lesões pequenas; nas inferências com SAHI, utilizam-se *tiles* de 512 × 512 com sobreposição de 0,2. Na Config. C, o modelo é treinado diretamente sobre *tiles* de 512 *px*, com *batch* maior, dado o menor consumo de memória por *tile*; treino e validação interna operam no domínio de *tiles*, para que o *early-stopping* reflita o mesmo domínio da inferência SAHI. Para preservar a morfologia das microlesões, emprega-se aumento de dados moderado e desativa-se o *mosaic*, que tende a prejudicar objetos minúsculos. A Tabela III lista os hiperparâmetros finais.

G. Métricas e protocolo de avaliação

Para comparar os modelos utiliza-se a *Intersection over Union* (IoU), que mede a sobreposição entre a *bounding box* predita e a do *Ground Truth*, conforme a Eq. (1):

$$\mathrm{IoU} = \frac{\mathrm{Area}\,(gt \cap pd)}{\mathrm{Area}\,(gt \cup pd)}, \tag{1}$$

em que gt é a caixa do *Ground Truth* e pd a caixa predita. A *Average Precision* (AP) é a área sob a curva de Precisão×Revocação de cada classe, e o *mean Average Precision* (mAP), a média das AP entre as classes, conforme a Eq. (2):

Tabela III
HIPERPARÂMETROS FIXOS (IDÊNTICOS ENTRE CONFIGURAÇÕES, SALVO OS *overrides* DE TREINO DA CONFIG. C).

Parâmetro	**Valor**
Detector / variante	YOLOv8m (`ultralytics`)
Otimizador / lr_0	SGD / 0,01
Resolução de treino (A/B)	1024 (lado maior)
Resolução de treino (C)	*tiles* 512
Batch (A/B | C)	8 | 16
Épocas (teto) / *patience*	100 / 20 (*early-stopping*)
Mosaic	desativado
SAHI *tile* / *overlap*	512×512 / 0,2
SAHI pós-proc. / *conf*	*GREEDYNMM* / 0,1
Seed	42

Tabela IV
DESEMPENHO GLOBAL (MAP, MÉDIA $\pm$ DESVIO ENTRE OS 15 *folds*) E TESTES PAREADOS. p_{Holm}: WILCOXON COM CORREÇÃO DE HOLM; r: TAMANHO DE EFEITO; p_{NB}: TESTE-T CORRIGIDO DE NADEAU–BENGIO. MELHOR VALOR EM **NEGRITO**.

Config.	**mAP@0,1**	**mAP@0,5**
A (*baseline*)	**0,300 $\pm$ 0,019**	**0,189 $\pm$ 0,015**
B (SAHI na inferência)	0,245 $\pm$ 0,033	0,095 $\pm$ 0,019
C (SAHI + *fine-tuning*)	0,290 $\pm$ 0,016	0,159 $\pm$ 0,012
Comparações pareadas (mAP@0,1):		
A vs. B	A>B; p_{Holm}=0,002, r=0,88, p_{NB}=0,001	
A vs. C	A>C; p_{Holm}=0,005, r=0,72, p_{NB}=0,125	
B vs. C	C>B; p_{Holm}=0,002, r=0,87, p_{NB}=0,013	

$$\mathrm{mAP} = \frac{1}{N}\sum_{i=1}^{N} \mathrm{AP}_i. \tag{2}$$

O mAP é calculado com o avaliador COCO (`pycocotools`) a IoU 0,1, compatível com o protocolo de Li *et al.* [1], e também a IoU 0,5, de forma global e por classe, sempre sobre o mesmo conjunto de teste de cada *fold*; dado o grande número de lesões por imagem, o limite de detecções por imagem foi ampliado (*maxDets* até 1000). Classes ausentes do *Ground Truth* de um *fold* são excluídas da média daquele *fold*, seguindo o padrão COCO.

H. Análise estatística

As três configurações são comparadas duas a duas, nos pares A vs. B, A vs. C e B vs. C, sob a hipótese nula bilateral de ausência de diferença de desempenho. A unidade de observação é o *fold*: como as três configurações são avaliadas exatamente sobre os mesmos 15 conjuntos de teste, cada uma produz um vetor de 15 valores, pareados elemento a elemento. Para um par (X, Y), define-se o vetor de diferenças

$$d_i = m_i^X - m_i^Y, \qquad i = 1, \ldots, 15, \tag{3}$$

em que m_i é a métrica obtida no *fold* i. O pareamento elimina a variabilidade atribuível à partição, isolando o efeito do *slicing*. O procedimento é aplicado ao mAP global (três comparações) e ao AP de cada lesão (doze comparações: 3 pares $\times$ 4 classes), sempre sobre o desempenho a IoU 0,1.

Cada vetor de diferenças é submetido a dois testes complementares. O primeiro é o de Wilcoxon pareado (*signed-rank*) [23], escolhido por não pressupor normalidade das diferenças, suposição pouco verificável com apenas 15 observações; dele se reporta o valor-p e o tamanho de efeito $r = |Z|/\sqrt{N}$, com $N = 15$. Esse teste, contudo, pressupõe observações independentes, condição que a validação cruzada repetida não satisfaz, pois *folds* de repetições distintas compartilham as mesmas imagens. Tal dependência subestima a variância das diferenças e tende a produzir valores-p artificialmente baixos, e não existe variante de Wilcoxon que a corrija. Aplica-se, por isso, um segundo teste: o teste-t pareado com a correção de variância de Nadeau–Bengio [24], que adiciona ao erro-padrão um termo proporcional à razão $n_{\mathrm{teste}}/n_{\mathrm{treino}} = 0{,}25$ de cada *fold*.

Os testes cumprem papéis distintos: Wilcoxon dispensa a normalidade, mas ignora a dependência entre *folds*; Nadeau–Bengio corrige essa dependência, ao custo de assumir diferenças aproximadamente normais. Considera-se robusta apenas a diferença em que ambos concordam; quando divergem, adota-se a conclusão do teste mais conservador, situação que ocorre em A vs. C (Seção V-A). Como análise complementar, dado o poder estatístico limitado de $n = 15$, a comparação é repetida tendo a imagem como unidade de observação: o AP é calculado por imagem e, como cada uma das 757 compõe o conjunto de teste exatamente uma vez por repetição, obtêm-se 757 observações pareadas, submetidas ao mesmo teste de Wilcoxon. Por fim, aplica-se a correção de Holm–Bonferroni separadamente em cada família de hipóteses, com $\alpha = 0{,}05$, denotando-se por p_{Holm} o valor-p corrigido.

V. RESULTADOS E DISCUSSÃO

A. Desempenho global

O desempenho global das três configurações, expresso pelo mAP médio entre os 15 *folds*, é apresentado na Tabela IV e na Fig. 3. O *baseline* em imagem completa (Config. A) obteve os maiores valores em ambos os limiares. A aplicação do SAHI restrita à inferência (Config. B) resultou em desempenho inferior, contrariando os ganhos reportados na literatura para arquiteturas anteriores [7], [12]. O regime completo, com ajuste fino no domínio de *tiles* (Config. C), atenuou essa degradação e aproximou-se do *baseline* a IoU 0,1, embora permanecesse abaixo dele a IoU 0,5.

Os testes pareados sustentam essa leitura. A diferença entre as Configs. A e B é significativa e com tamanho de efeito elevado ($p_{\mathrm{Holm}} = 0{,}002$; $r = 0{,}88$), resultado corroborado pela análise complementar por imagem ($p_{\mathrm{Holm}} = 0{,}003$) e pelo teste de Nadeau–Bengio ($p_{\mathrm{NB}} = 0{,}001$): a inferência fracionada, aplicada isoladamente sobre um modelo treinado em imagem completa, degrada o desempenho global. A diferença entre as Configs. B e C também é significativa ($p_{\mathrm{Holm}} = 0{,}002$; $p_{\mathrm{NB}} = 0{,}013$), o que evidencia que o ajuste fino no domínio de *tiles* é condição necessária para compensar essa perda.

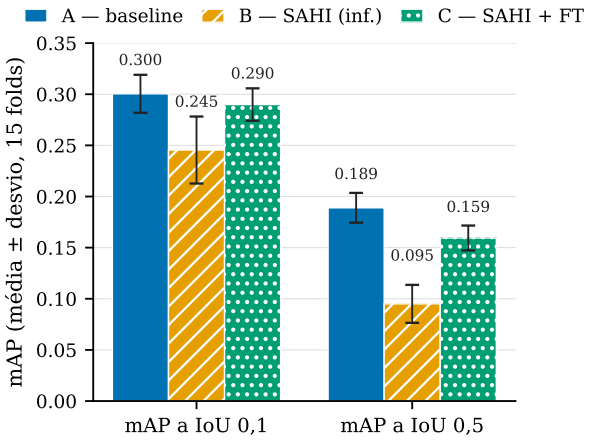

Figura 3. mAP global por configuração a IoU 0,1 e 0,5 (média ± desvio entre os 15 *folds*).

Já a comparação entre as Configs. A e C depende do teste adotado: a diferença é significativa sob Wilcoxon ($p_{\text{Holm}} = 0{,}005$), mas não sob Nadeau–Bengio ($p_{\text{NB}} = 0{,}125$), que ajusta a variância para a não-independência entre os *folds*. Pelo critério mais conservador, não há evidência suficiente para rejeitar a hipótese de ausência de diferença de mAP global entre elas. O *slicing* não produziu, portanto, nesta configuração experimental, o ganho global descrito em trabalhos com gerações anteriores de YOLO [5], [7].

B. Desempenho por classe

A estratificação por tipo de lesão revela comportamento distinto do agregado: os efeitos do *slicing* têm sinal e magnitude dependentes da classe, sendo positivos nas lesões de menor extensão espacial, conforme a Tabela V e as Figs. 4 e 5.

Os microaneurismas constituem a única classe em que uma configuração com *slicing* supera o *baseline* de forma estatisticamente significativa. A Config. C elevou o AP@0,1 de 0,177 para 0,216, incremento absoluto de 0,039 e relativo de 22% ($p_{\text{Holm}} = 0{,}009$; $r = 0{,}82$), e, a IoU 0,5, de 0,059 para 0,111. A Config. B também superou o *baseline* nessa classe (0,189 a IoU 0,1), sem atingir significância após a correção de Holm–Bonferroni. O efeito é consistente entre partições: a Config. C supera o *baseline* em 13 dos 15 *folds* (Fig. 6).

Nos exsudatos duros, o maior AP@0,1 coube à Config. B (0,404 contra 0,348 do *baseline*; $p_{\text{Holm}} = 0{,}008$); a IoU 0,5, porém, o *baseline* mantém-se superior (0,181 contra 0,108), o que sugere que o fracionamento aumenta a taxa de detecção dessa classe em detrimento da precisão de localização das caixas. Exsudatos moles e hemorragias apresentaram redução de AP sob ambas as configurações com *slicing*, comportamento analisado na Seção V-C.

C. O trade-off do slicing

A contrapartida do ganho nos microaneurismas é a perda nas lesões maiores e difusas. Exsudatos moles (SE) e hemorragias (HE), que frequentemente excedem ou cruzam as dimensões de um *tile* de 512 *px*, são fragmentados, e o reagrupamento por pós-processamento não os reconstrói integralmente. A inspeção qualitativa das predições corrobora o mecanismo, com caixas espúrias e fragmentadas concentradas nas junções dos *tiles*. O efeito é acentuado na Config. B: o AP@0,1 de SE cai de 0,354 para 0,178 ($\Delta = -0{,}176$) e o de HE cai 0,112, o que explica isoladamente a queda do mAP global dessa configuração. O ajuste fino da Config. C atenua o dano (SE recupera para 0,329; HE para 0,255), pois o modelo aprende a operar no domínio de *tiles*, mas ainda não iguala o *baseline* nessas classes (Fig. 5).

Esse *trade-off* explica por que o SAHI não melhora o mAP *global*: sendo uma média entre classes, o mAP dilui o ganho nos microaneurismas na perda em SE e HE. Na prática, o valor do *slicing* depende da métrica priorizada: quando o AP de microaneurismas é o critério de interesse, a Config. C supera o *baseline*; para uma detecção equilibrada das quatro classes, o *baseline* em alta resolução é mais robusto, um achado metodológico, não uma recomendação clínica, que exigiria validação adicional.

Em análise exploratória *post-hoc* (fora do protocolo predefinido e sem teste estatístico), a reavaliação dos pesos da Config. C com fusão IOU (em vez da IOS, padrão do SAHI) no *GREEDYNMM* eleva o mAP@0,5 de 0,159 para 0,183, próximo do *baseline* (0,189), preservando o AP@0,5 de MA ($\approx$ 0,11), indício de que a fusão imperfeita de caixas nas junções, mais que erros de detecção, responde por parte da perda a IoU alto.

O *slicing* também tem custo de inferência: cronometrado o teste de um *fold* (145 imagens; em média 34,9 *tiles* por imagem a 512/0,2), a Config. B custa 11,4× e a C 5,0× o *baseline*; a diferença entre ambas decorre da resolução de entrada herdada do treino (1024 vs. 512 *px*). Como tempos absolutos dependem do *hardware*, importam as razões: um sobrecusto de cerca de uma ordem de grandeza, a ponderar na viabilidade de rastreamento em larga escala.

D. Comparação com a literatura

Os resultados são posicionados frente à literatura do DDR na Tabela VI, com todos os valores a IoU 0,5. A comparação direta exige cautela: os trabalhos anteriores reportam um único

Tabela V
AP POR CLASSE (MÉDIA ENTRE OS 15 *folds*), A IOU 0,1 E 0,5. EM **NEGRITO**, O MELHOR VALOR POR CLASSE/IOU. †: DIFERENÇA SIGNIFICATIVA VS. A ($p_{\text{Holm}} < 0{,}05$, WILCOXON NA FAMÍLIA POR CLASSE). OS TESTES DE SIGNIFICÂNCIA FORAM CONDUZIDOS SOBRE O AP A IOU 0,1.

IoU	Config.	MA	EX	SE	HE
0,1	A	0,177	0,348	**0,354**	**0,323**
	B	0,189	**0,404**†	0,178†	0,210†
	C	**0,216**†	0,360	0,329†	0,255†
0,5	A	0,059	**0,181**	**0,308**	**0,208**
	B	0,032	0,108	0,150	0,091
	C	**0,111**	0,132	0,258	0,137

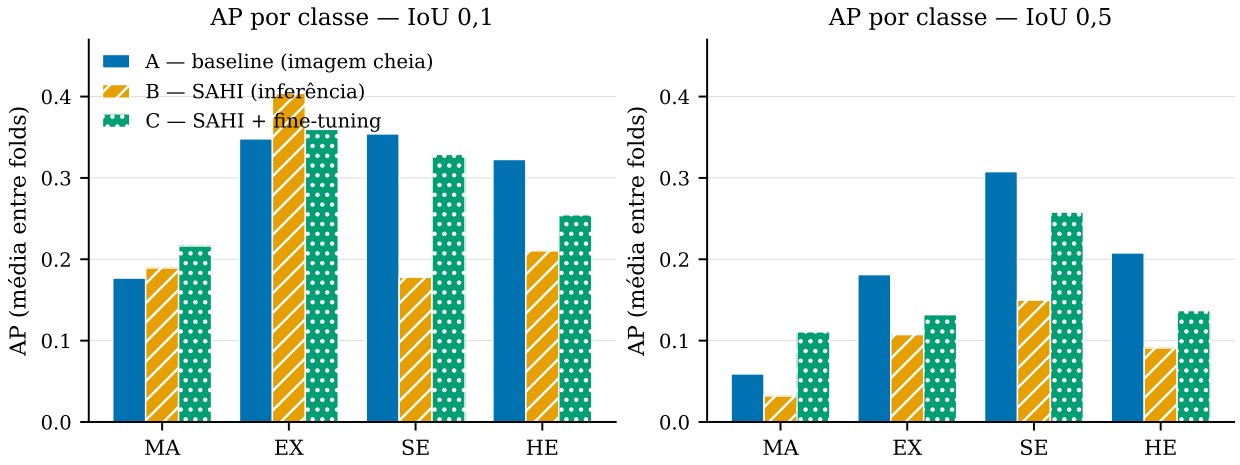

Figura 4. AP por classe de lesão (média entre os 15 *folds*), a IoU 0,1 (esquerda) e 0,5 (direita). O *slicing* beneficia os microaneurismas (MA) e, na inferência, os exsudatos duros (EX), mas prejudica os exsudatos moles (SE) e as hemorragias (HE), que são lesões maiores e mais difusas.

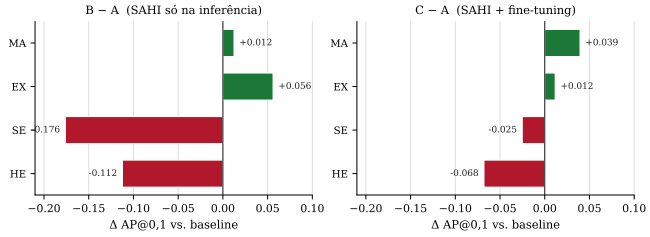

Figura 5. Ganho de AP@0,1 de cada configuração de *slicing* em relação ao *baseline* (A), por classe. Verde: ganho; vermelho: perda.

Tabela VI
COMPARAÇÃO COM A LITERATURA NO DDR (MAP A IOU 0,5). "VAL."/"TESTE" INDICAM O SUBCONJUNTO; "CV" INDICA VALIDAÇÃO CRUZADA REPETIDA (MÉDIA DE 15 *folds*). PROTOCOLOS, RESOLUÇÕES E ARTIFÍCIOS DE TREINO DIFEREM ENTRE ESTUDOS E NÃO SÃO DIRETAMENTE COMPARÁVEIS.

Trabalho / método	**Protocolo**	**mAP@0,5**
Li *et al.* [1] (SSD/YOLO)	teste	$< 0{,}01$
Alyoubi *et al.* [18] (CNN512+YOLOv3)	n. i.	0,216
Santos *et al.* [5] (YOLOv5+*Tiling*)	val.	0,263
Santos *et al.* [5] (YOLOv5+*Tiling*)	teste	0,154
Pereira *et al.* [7] (YOLOR-CSP+SAHI)	val.	0,381
Pereira *et al.* [7] (YOLOR-CSP+SAHI)	teste	0,222
Este trabalho, A (*baseline*)	CV	0,189
Este trabalho, C (SAHI+FT)	CV	0,159
Este trabalho, A (*split* oficial)	teste	0,113

split (tipicamente a *validação*), enquanto aqui se reporta a média de uma validação cruzada repetida, protocolo mais conservador. Para uma comparação justa, avaliou-se também a Config. A no *split* oficial do DDR (383/149/225), o mesmo usado por [5], [7]: nele o *baseline* obtém mAP@0,5 de 0,113, valor coerente com a faixa de teste dos trabalhos correlatos (0,154 e 0,222).

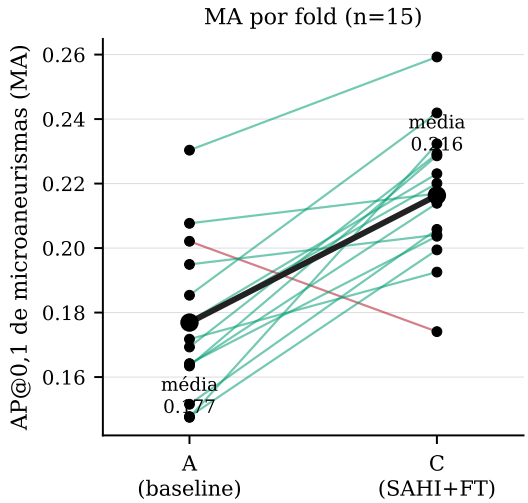

Figura 6. AP@0,1 de microaneurismas (MA), por *fold* ($n = 15$): *baseline* (A) vs. Config. C. As linhas verdes indicam *folds* em que a Config. C supera o *baseline* (13 de 15); a linha preta liga as médias (0,177 → 0,216).

Não se pretende, aqui, competir por desempenho absoluto: os métodos da literatura empregam artifícios adicionais (recorte do fundo, pré-treino em COCO, milhares de épocas, ajuste de âncoras, aumento de dados agressivo) que este estudo deliberadamente evita para *isolar* o efeito do *slicing*. O ponto é metodológico: a diferença entre validação e teste observada em [7] (0,381 vs. 0,222) reforça que números de *split* único devem ser lidos com cautela, e que a validação cruzada oferece estimativa mais fiel do desempenho esperado.

E. Limitações

Este estudo apresenta limitações. Primeiro, os hiperparâmetros foram fixados (sem busca), privilegiando a comparabilidade sobre o desempenho absoluto; uma busca dedicada poderia alterar as magnitudes, mas dificilmente inverteria o

trade-off por classe, de natureza geométrica. Segundo, avaliou-se um único detector (YOLOv8m) e uma única configuração de fracionamento (512/0,2); *tiles* menores poderiam favorecer os microaneurismas ao custo de agravar a fragmentação, e a extensão do *trade-off* a outras arquiteturas (YOLO recentes, *Transformers*) permanece em aberto. Terceiro, a avaliação restringe-se ao DDR, com generalização a outras bases, equipamentos e populações (por exemplo, IDRiD [25]) a verificar; e, sem identificadores de paciente, a partição é por imagem (Seção IV-E). Por fim, o escopo é a acurácia de detecção: desfechos em nível de paciente (graduação de RD, sensibilidade de triagem) não foram avaliados.

VI. Considerações Finais

Este trabalho avaliou, de forma controlada e estratificada por lesão, se a inferência assistida por SAHI melhora a detecção de lesões de RD no DDR quando aplicada a um detector YOLO moderno (YOLOv8m). A resposta é matizada. *Globalmente*, o SAHI não melhora o mAP: a inferência fracionada sobre um modelo treinado em imagem cheia (Config. B) degrada significativamente o desempenho, e mesmo o regime completo com ajuste fino (Config. C) não apresenta diferença detectável em relação ao *baseline*. *Por classe*, entretanto, o *slicing* cumpre sua promessa exatamente na lesão mais precoce e crítica: a Config. C melhora de forma significativa e consistente a detecção de microaneurismas, ao custo de piora nos exsudatos moles e nas hemorragias, que o fracionamento tende a fragmentar, *trade-off* que o mAP, por ser uma média entre classes, oculta.

A principal mensagem é que, em detectores YOLO modernos operando em alta resolução, o benefício do SAHI é *condicional*: localizado nas menores lesões e dependente de ajuste fino em *tiles*, e não o ganho global sugerido por trabalhos com arquiteturas anteriores. O resultado deve ser lido como evidência metodológica sobre o detector no DDR; uma recomendação clínica exigiria validação externa e desfechos em nível de paciente, fora do escopo deste estudo.

Como trabalhos futuros, pretende-se: (i) varrer o tamanho de *tile* e a sobreposição, buscando o equilíbrio do *trade-off*; (ii) explorar estratégias de fusão de caixas nas bordas dos *tiles* para reduzir a perda em lesões grandes; (iii) validar *cross-dataset*, treinando no DDR e avaliando em IDRiD [25] e em bases brasileiras; (iv) contrastar o *slicing* com arquiteturas mais recentes de YOLO e com *Transformers* de detecção; (v) aprofundar a análise dos modos de falha com técnicas de explicabilidade; e (vi) integrar a detecção a um *pipeline* de triagem com desfechos em nível de paciente.

***Abstract*—Increased life expectancy has raised the prevalence of bone disorders, increasing demand for biomaterials that promote bone regeneration. In this study, strontium oxide nanoparticles (SrO-NPs) were synthesized via green synthesis using pecan (*Carya illinoinensis*) shell extract as a reducing and stabilizing agent. The nanoparticles were characterized by X-ray diffraction (XRD), Fourier-transform infrared spectroscopy (FTIR), and N_2 porosimetry. XRD confirmed a cubic SrO phase with an average crystallite size of 45.26 nm, coexisting with an orthorhombic $SrCO_3$ phase. EDX indicated residual chlorine, demonstrating that the material was an SrO/$SrCO_3$ composite with precursor residues rather than pure SrO. FTIR identified characteristic O–H, C=O, C–O, and Sr–O vibrations, while N_2 adsorption–desorption indicated a mesoporous structure. *In vitro* assays using OFCOL II osteoblasts showed no cytotoxicity, elevated ROS, or dsDNA release. These findings support an *in vitro* safety profile and justify further investigation of osteogenic performance and *in vivo* response.**

I. Introduction

Population aging represents one of the most significant demographic transformations of the 21st century. Advances in health care, sanitation, and medical technologies have contributed to a steady increase in global life expectancy, with Brazil reaching an average life expectancy of 76.8 years in 2026 [1]. However, increased longevity has also been accompanied by a higher prevalence of chronic non-communicable diseases and age-related musculoskeletal disorders, particularly bone fragility and femoral fractures [2], [3]. Consequently, the demand for biomaterials for bone repair has grown substantially, encompassing various classes of materials, including metals, ceramics, polymers, and composites [4].

Femoral fractures constitute a major public health problem owing to their high morbidity, mortality, and the substantial economic burden they impose on health care systems. Between 2020 and 2025, approximately 630,687 hospital admissions for femoral fractures were recorded in Brazil, resulting in an estimated health care expenditure of R$1.42 billion [5]. These data highlight the urgent need for effective therapeutic

strategies to promote bone repair. In this context, tissue engineering has emerged as a promising approach for the development of three-dimensional scaffolds that support bone regeneration [6]. However, currently available biomaterials still present important limitations, including susceptibility to bacterial colonization, inadequate mechanical properties, and limited capacity to mimic the native bone extracellular matrix [7]. Thus, nanotechnology offers a promising strategy for overcoming these challenges through the development of nanostructured systems with enhanced bioactivity and surface properties [8].

Among the nanomaterials currently under investigation for bone tissue engineering, strontium oxide nanoparticles (SrO-NPs) have attracted considerable attention owing to the ability of strontium to stimulate osteoblastic activity, inhibit osteoclast differentiation, and promote bone formation [9], [10]. In addition, green nanotechnology has become established as a sustainable alternative to conventional synthesis methods, replacing toxic chemical reagents with biologically derived reducing and stabilizing agents obtained from plant extracts [11], [12].

Pecan (*Carya illinoinensis*) shells constitute an abundant agro-industrial byproduct in southern Brazil and are rich in phenolic compounds with high antioxidant activity [13]. Previous studies have demonstrated the potential of pecan shell extract for the green synthesis of silver nanoparticles with antimicrobial activity [14]. In this context, plant extracts have stood out as sustainable reducing and stabilizing agents owing to their rich phytochemical composition, including polyphenols and flavonoids, which enable the environmentally friendly synthesis of metallic and metal oxide nanoparticles [15]–[17]. Thus, the use of this biomass as a reducing and stabilizing agent in the synthesis of SrO-NPs adds value to a regional agro-industrial byproduct while promoting environmental sustainability.

This approach is aligned with the principles of green chemistry and the United Nations Sustainable Development Goals (SDGs), particularly SDG 3 (Good Health and Well-Being), SDG 9 (Industry, Innovation, and Infrastructure), and SDG 12 (Responsible Consumption and Production) [18]. Given the above, the present study aimed to synthesize and characterize SrO-NPs obtained through green synthesis using pecan shell extract and to evaluate their *in vitro* safety profile in OFCOL II osteoblastic cells, providing preliminary scientific evidence for their potential application as a bioactive nanomaterial in bone regeneration.

II. Materials and Methods

A. Green synthesis of SrO-NPs

Pecan shells were obtained from a local agro-industry in southern Brazil. The extract was prepared by the infusion method [19], in which 10 g of pecan shells were cleaned and dried at 40 $\pm$ 2 °C for 72 hours, followed by mixing with 500 mL of distilled water under magnetic stirring (300 rpm, 10 min, 85 $\pm$ 2 °C). The extract was then stored in an amber flask at 4 $\pm$ 2 °C.

SrO-NPs were synthesized by the hydrothermal method [20], [21]. Briefly, the pecan shell extract was mixed with a strontium chloride hexahydrate solution ($SrCl_2{\cdot}6H_2O$, Synth, $> 99\%$) (0.1 mol L^{-1}) under magnetic stirring (200 rpm, 25 $\pm$ 2 °C), promoting the reduction and nucleation steps. The mixture was then transferred to a stainless-steel autoclave with an internal polytetrafluoroethylene liner and subjected to hydrothermal treatment (160 °C, 480 min, 5 °C min^{-1}), followed by calcination (850 °C, 120 min, 30 °C min^{-1}) to promote stabilization of the SrO-NPs.to promote the stabilization of the SrO-NPs.

B. Characterization techniques

Crystalline phases were identified by X-ray diffraction (XRD) using a Bruker D2 Advance diffractometer with Cu Kα radiation (λ = 0.15418 nm), over a 2θ range of 20° to 80°, operated at 30 kV and 10 mA. The average crystallite size (d_c) was calculated using the Scherrer equation, as shown in (1).

$$d_c = \frac{K * \lambda_{\mathrm{CuK}\alpha}}{\beta * \cos(2\theta)} \tag{1}$$

Functional groups were analyzed by Fourier-transform infrared spectroscopy (FTIR) using an IRPrestige-21 spectrometer (Shimadzu) in transmittance mode, over the range of 4000 to 450 cm^{-1}.

Nitrogen physisorption measurements were performed on an ASAP 2020 system (Micromeritics) at 77 K. Adsorption–desorption isotherms were used to determine the specific surface area (SSA), pore volume (V_p), pore diameter (D_p), and pore size distribution [22].

A field-emission scanning electron microscope (FEG-SEM) TESCAN MIRA3 was used to evaluate morphological properties [23]. In addition, an Oxford EDX system coupled to the FEG-SEM TESCAN MIRA3 was employed to determine elemental composition, with 400$\times$ magnification and backscattered electrons. Samples were prepared by depositing the solids on double-sided adhesive tape fixed to aluminum stubs [24]. Data were collected in different modes: bulk, at specific points, and along a trend line.

C. In vitro safety profile

The *in vitro* safety profile was evaluated using OFCOL II osteoblasts (BCRJ-0192). Cells were cultured in RPMI medium supplemented with 10% fetal bovine serum, at 37 °C in a 5% CO_2 atmosphere. SrO-NPs were tested at concentrations of 12.5, 25, 50, and 100% of the stock solution (2000 μg/mL).

Cell viability and proliferation were assessed by the MTT assay (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) after 24, 48, and 72 hours of exposure [25]. Absorbance was recorded at 570 nm using a Synergy HTX microplate reader (BioTek). Nitric oxide (NO) production was determined by the Griess reaction, measuring nitrite (NO_2^-) and nitrate (NO_3^-) levels in the culture supernatant at 540 nm [26]. Generation of reactive oxygen species (ROS) in cells was measured using the DCFH-DA probe (2′,7′-dichlorodihydrofluorescein diacetate), with fluorescence

recorded at 480/520 nm (excitation/emission) [25]. Release of extracellular double-stranded DNA (dsDNA) was evaluated using the Quant-iT PicoGreen reagent, with fluorescence recorded at 480/520 nm (excitation/emission), as a punctual indicator of membrane integrity [25]. It should be noted that, in isolation, this assay does not allow inferences regarding genotoxicity, apoptosis, or mutagenesis, which would require additional specific assays (e.g., comet assay or micronucleus test). Untreated cells served as the negative control (NC), while hydrogen peroxide (H_2O_2, 200 μmol L^{-1}) was used as the positive control in all biological assays.

D. Statistical analysis

All experiments were performed in triplicate. Results are presented as a percentage relative to the untreated control (mean $\pm$ standard deviation). Statistical analyses were performed by one-way analysis of variance (ANOVA), followed by Tukey's post hoc test. Statistical significance was defined as $p < 0.05$, $p < 0.01$, $p < 0.001$, and $p < 0.0001$.

III. Results and Discussion

A. Characterization of the SrO-NPs

Figure 1 presents the X-ray diffractogram of the strontium oxide nanoparticles obtained by green synthesis (SrO-NPs), in which diffraction peaks characteristic of the cubic SrO phase were observed at 2θ = 27.5° (110), 29.1° (112), 35.6° (202), 42.9° (114), 49.0° (222), 49.6° (213), 52.6° (310), 56.7° (312), 60.1° (114), 61.4° (114), 66.3° (312), and 78.5° (013), in agreement with ICDD card no. 96-900-7717 [27]. In addition, diffraction peaks corresponding to the $SrCO_3$ phase were identified at 2θ = 22.1° (110), 25.2° (111), 31.5° (002), 33.7° (121), 39.1° (201), 40.8° (220), and 45.7° (221), in agreement with JCPDS card no. 00-005-0418 [28]. The coexistence of the two crystalline phases indicated that the synthesized material is not pure, being composed of SrO and $SrCO_3$. This heterogeneous composition should be taken into account when interpreting future assays.

The crystallite size, calculated using the Scherrer equation ($K = 0.94$) from the (202) diffraction peak, was 45.26 nm, a value consistent with data reported in the literature for SrO nanoparticles obtained by green synthesis [20], [29].

The FTIR spectrum (Figure 2) revealed the characteristic vibrational bands of the SrO-NPs. A broad band between 3600 and 3200 cm^{-1} was attributed to O–H stretching vibrations of water molecules adsorbed on the nanoparticle surface [22]. The band at 1650 cm^{-1} corresponds to C=O carbonyl stretching, likely originating from residual organic compounds present in the pecan shell extract [20]. At 713 cm^{-1}, the band was attributed to asymmetric stretching and out-of-plane bending vibrations of C–O bonds, related to the presence of carbonate species ($SrCO_3$) [30]. At 482 cm^{-1}, the band corresponded to a metal–oxygen (Sr–O) stretching vibration, possibly arising from the formation of SrO [22], [31]. These results corroborated the XRD findings and confirmed the coexistence of the SrO and $SrCO_3$ phases.

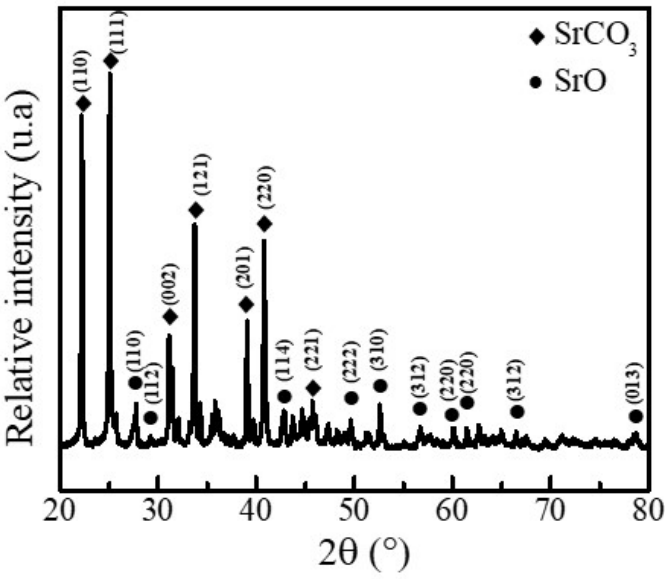

Fig. 1. XRD diffractogram of the SrO-NPs from *Carya illinoinensis* extract.

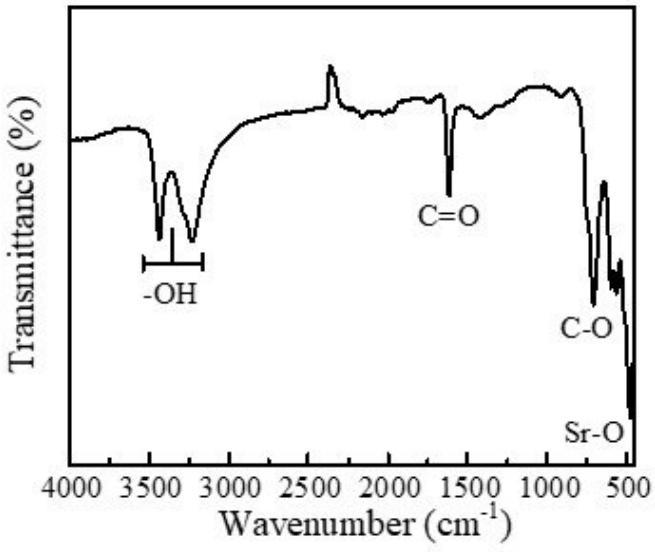

Fig. 2. FTIR spectrum of the SrO-NPs from *Carya illinoinensis* extract.

N_2 porosimetry of the material (Figure 3) exhibited a type IV(a) isotherm profile with an H3 hysteresis loop, according to the IUPAC classification [32]. This type of isotherm is characteristic of mesoporous materials, while H3-type hysteresis is associated with slit-shaped pores formed by aggregates. The specific surface area was approximately 45.79 $\pm$ 0.14 m^2 g^{-1}, with a pore diameter of 42.31 $\pm$ 0.14 nm and a pore volume of 0.044 $\pm$ 0.01 cm^3 g^{-1}, confirming the mesoporous nature of the material. Literature studies on SrO-based nanomaterials have reported similar textural properties, with low surface areas attributed to high-temperature calcination (600 °C to 800 °C), which promotes particle sintering and grain growth [27], [22].

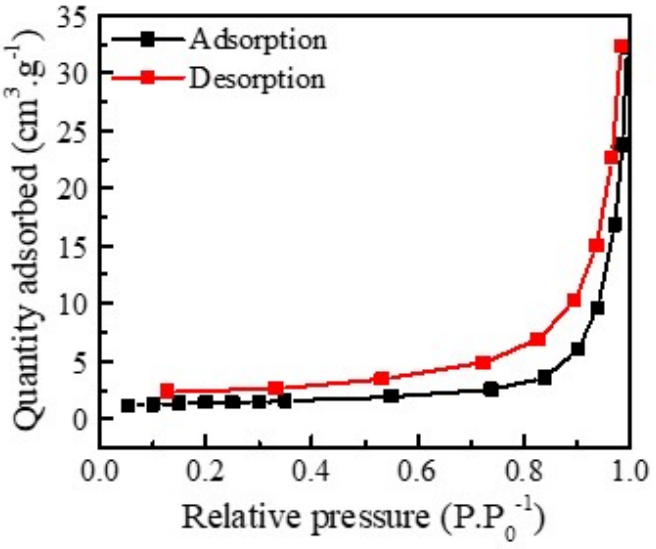

Fig. 3. N_2 adsorption–desorption isotherm of the SrO-NPs from *Carya illinoinensis* extract.

Morphological characterization of the green SrO-NPs was performed by high-resolution FEG-SEM combined with elemental analysis by EDX. The high-resolution micrograph of the SrO-NPs (Figure 4) revealed a heterogeneous and porous morphology, with small agglomerations attributable to the thermal treatment [20]. Elemental mapping by EDX (Figure 5) indicated a homogeneous dispersion of elements on the material surface, with a predominant presence of strontium (Sr, 33.6 wt%), in addition to chlorine (Cl, 22.8 wt%), attributed to the metal precursor used, suggesting that it was not completely consumed or removed during the synthesis or calcination process [22]. The residual chlorine content, together with the presence of the $SrCO_3$ phase demonstrated by XRD and FTIR characterization, indicates that the final material is composed of SrO and $SrCO_3$, with residues from the $SrCl_2{\cdot}6H_2O$ precursor.

B. In vitro safety profile

Figure 6 presents the results of the *in vitro* safety profile of the SrO-NPs. Cell viability and proliferation assays performed using the MTT method did not reveal any cytotoxic effects at the concentrations tested when compared with the control group. A statistically significant increase in cell viability was observed only at the 12.5% concentration after 48 hours of incubation. These results indicate that, under the tested conditions, SrO-NPs demonstrate a favorable biocompatibility profile, with no evidence of significant cellular toxicity. In bone regeneration applications, disordered cell growth can lead to fibrosis or, in extreme cases, osteosarcomas (bone tumors). In this sense, the observed profile suggested that osteoblasts maintained their basal physiological behavior, with no evidence of an exacerbated proliferative response [10].

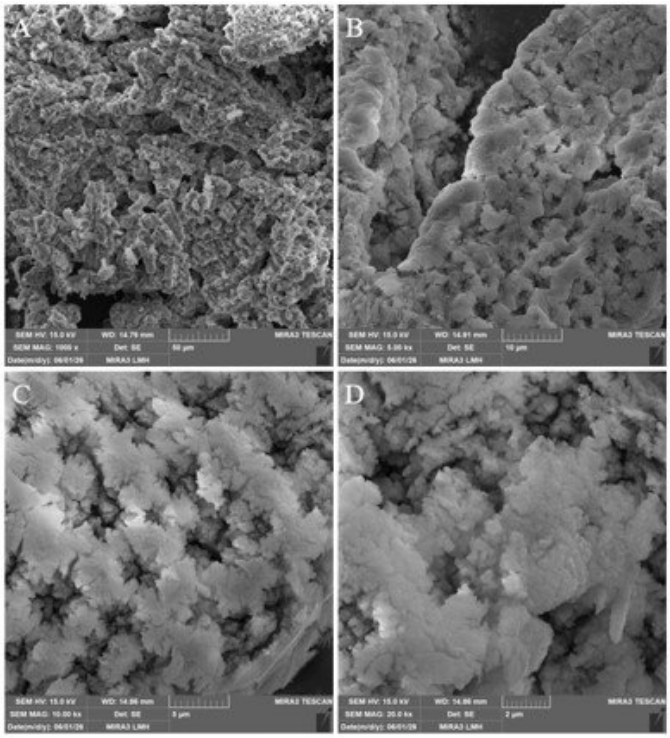

Fig. 4. High-resolution micrographs of green SrO-NPs at different magnifications: (a) 1 kx, (b) 5 kx, (c) 10 kx, and (d) 20 kx.

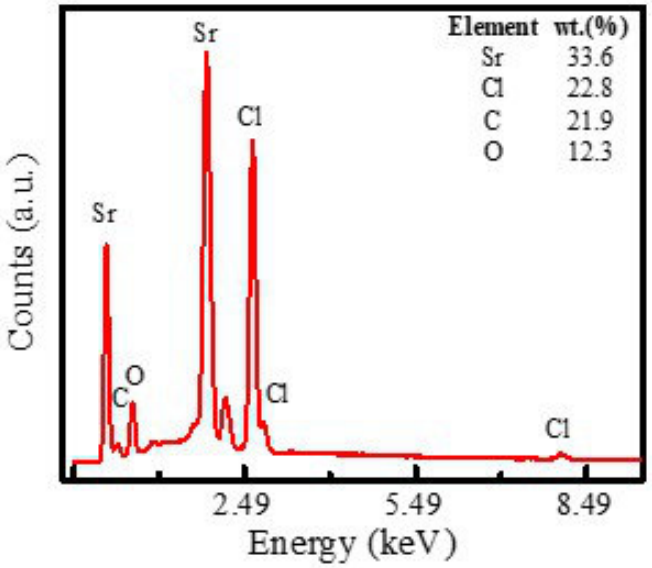

Fig. 5. Element distribution histogram of green SrO-NPs obtained from FEG-SEM micrographs.

Evaluation of nitric oxide (NO) showed that levels remained equivalent to the negative control (100%) at all concentrations and time points tested. This baseline performance indicated a possible absence of an acute pro-inflammatory response induced by the material [10], with additional tests being necessary to demonstrate anti-inflammatory activity. Regarding oxidative stress, the material did not cause an increase in

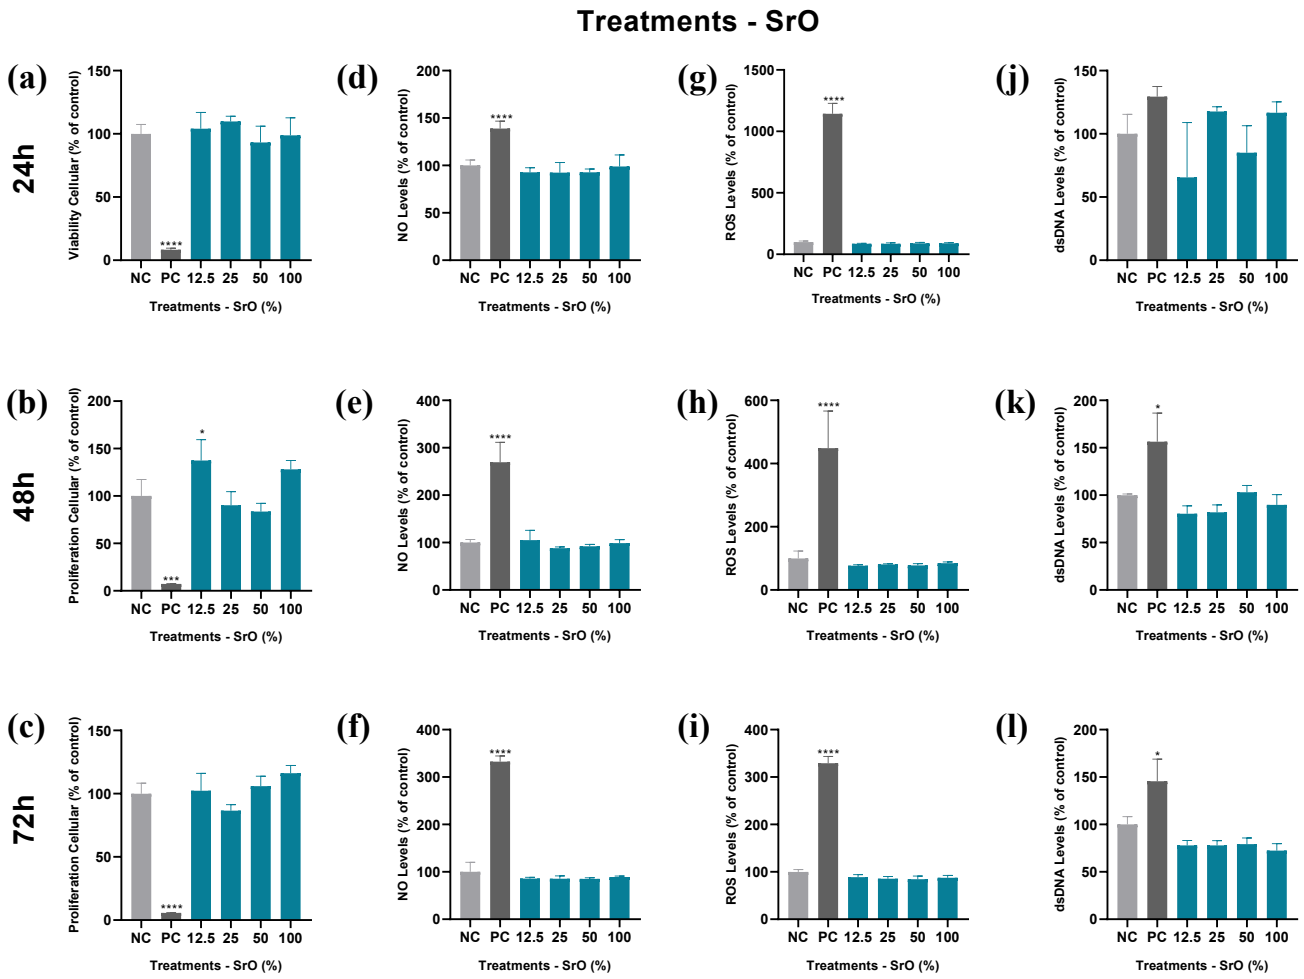

Fig. 6. *In vitro* safety profile of green SrO-NPs evaluated by MTT assay (a–c), nitric oxide (NO) production (d–f), reactive oxygen species (ROS) generation (g–i), and double-stranded DNA (dsDNA) quantification (j–l) after 24, 48, and 72 hours of exposure.

ROS levels relative to the control. Furthermore, the dsDNA assay showed that none of the concentrations used in the experiment promoted significant dsDNA release. These findings demonstrated preservation of membrane integrity under the tested conditions; however, this assay alone does not allow the conclusion that the material does not cause genotoxicity, apoptosis, or mutagenesis, requiring additional specific assays not performed in this study.

Taken together, the *in vitro* results demonstrate that the material obtained by green synthesis presented a favorable safety profile in terms of cell viability, without inducing inflammatory responses or oxidative stress detectable by the assays employed, even in the presence of other compounds such as $SrCO_3$ and residual chlorine from the synthesis. Similar *in vitro* safety conditions for $SrCO_3$ reported in the literature have shown neither toxicity nor stimulation in osteoblastic cells [33]. The residual chloride did not exert a cytotoxic effect or an adverse modulatory effect on the osteoblastic cells tested, likely still being bound to the metal precursor, reflecting its high percentage in the EDX analysis; however, the effect of chloride reported in the literature is characterized by the mimicry of calcium in bone stimulation [34]. This *in vitro* safety profile falls within the parameters of the ISO 10993-5 standard for cytotoxicity evaluation of biomedical materials [25], making the material a possible candidate for application in tissue engineering.

IV. Conclusion

SrO-NPs were successfully synthesized from pecan shell extract by means of an environmentally friendly approach, resulting in a crystalline, mesoporous material composed of SrO and $SrCO_3$ with residues of the chlorinated precursor, presenting textural and structural properties consistent with those reported in the literature for green-synthesized SrO nanostructures. The *in vitro* safety evaluation in OFCOL II osteoblasts indicated the absence of cytotoxicity, oxidative stress elevation, and significant dsDNA release, in agreement with ISO 10993-5, outlining a favorable scenario for the

biocompatibility of the synthesized material, although this remains to be confirmed through additional specific assays.

It should be noted that osteogenic performance, extracellular matrix mineralization, and the *in vivo* biological response were not evaluated in this study, so that any application in bone regeneration remains a perspective to be investigated and not a conclusion established by the present results; in this sense, the material is regarded as a potential nanoreinforcement for polymeric nanocomposites intended for future application in bone regeneration, rather than a biomaterial in itself. In addition, the valorization of pecan shells as an agro-industrial by-product reinforces the sustainability of this approach, and future investigations focused on osteogenic differentiation, *in vivo* biological response, and long-term biosafety will be essential for the consolidation of these nanoparticles as a candidate for bone tissue engineering applications.

ACKNOWLEDGMENT

The authors thank the Graduate Program in Nanosciences (PPGNano) and the Applied Nanomaterials Research Group (GPNAp) of Universidade Franciscana (UFN) for support in carrying out this work. This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior–Brasil (CAPES)–Finance Code 001.

CONFLICT OF INTEREST

The authors declare that they have no known financial conflicts of interest or personal relationships that could have influenced the work reported in this article.

***Abstract*—We compare droplet generation performance across three flow-focusing geometries fabricated via masked stereolithography (MSLA) 3D printing using an Elegoo Saturn 4 Ultra and Anycubic High Clear photopolymer resin. The geometries investigated are: (FF-I) symmetric cross-junction, (FF-II) tapered-entry diverging nozzle, and (FF-III) straight-entry diverging nozzle. All devices were post-processed with a two-cycle resin glazing protocol to restore optical transparency. Mineral oil with 2 wt% Span 80 was used as the continuous phase and a 10 mmol/L methylene blue aqueous solution as the dispersed phase. Droplet diameter, shape and frequency were characterized as a function of the flow-rate ratio $\phi = Q_d/Q_c$ for each geometry. Across all three geometries at fixed $Q_d = 20\,\mu$L/min and $Q_c = 200$–$800\,\mu$L/min, droplet generation was monodisperse ($\mathrm{CV}_d < 4.1\%$) throughout the dripping regime, producing near-circular droplets smaller than the channel outlet width. Mean droplet diameter and generation frequency each followed clear power laws in the flow-rate ratio ϕ, with near-identical exponents across the three designs ($m \approx 0.52$ for diameter, above the mass-conservation value of $4/9$, and $m \approx -1.4$ for frequency, matching the theoretical $-4/3$), while FF-II produced droplets $\approx 1.4\times$ larger than FF-I and FF-III. The measured frequency exponents closely matched a mass-conservation scaling model derived from T-junction theory, while the diameter exponents lay slightly above the theoretical prediction. The MSLA fabrication workflow produces functional devices in under 2 h 30 min print time, making rapid geometry iteration feasible on a single working day.**

***Index Terms*—droplet microfluidics, flow-focusing, power-law scaling, 3D printing**

I. Introduction

Flow-focusing (FF) is among the most widely used geometries for generating monodisperse water-in-oil (W/O) droplets in microfluidic devices. In the canonical symmetric FF design, two streams of continuous phase squeeze a central stream of dispersed phase through a narrow orifice, driving periodic pinch-off [2]. The resulting droplet diameter and generation frequency are controlled by the capillary number $Ca = \mu_c v/\gamma$, where μ_c is the continuous-phase viscosity, v a characteristic velocity, and γ the interfacial tension, and the flow-rate ratio $\phi = Q_d/Q_c$, where Q_d and Q_c are the dispersed- and continuous-phase volumetric flow rates, respectively [3]. Modifications to the basic geometry, such as introducing an asymmetric constriction or altering the focusing-entry geometry, can extend the accessible droplet-size range, improve monodispersity, or stabilize the dripping regime at higher throughput [1].

The ability to generate thousands of size-controlled aqueous droplets per hour makes droplet microfluidics a powerful tool in biomedical research. Because each droplet acts as an isolated microreactor, W/O emulsions produced by FF devices have been applied to tumor spheroid formation, organoid culture, high-throughput drug screening, and cell encapsulation for tissue engineering and cell therapy [1], [18]–[20]. In these applications, droplet size uniformity is not merely a physical metric: it directly governs the homogeneity of the encapsulated cell aggregate, since droplet volume sets the initial cell density and the resulting gradients of oxygen and nutrients that drive three-dimensional tissue-like organization [11], [18]. Achieving monodisperse generation, typically $\mathrm{CV} < 5\%$, across a wide range of droplet volumes therefore underpins the translational relevance of any FF platform.

Conventional fabrication of FF devices relies on soft lithography in poly(dimethylsiloxane) (PDMS), which requires a photolithographic master and clean-room infrastructure [4]. Masked stereolithography (MSLA) 3D printing offers a geometry-agnostic, rapid-prototyping alternative: all three device variants investigated here can be printed simultaneously on a single build plate in under 2 h 30 min with no tooling change. The broader landscape of 3D printing strategies for microfluidics has been reviewed by Su et al. [5]. Within droplet microfluidics specifically, 3D-printed modular devices have generated single and double emulsions using T-junction and co-flow geometries with active pneumatic control [6].

LCD-based vat photopolymerisation printers have achieved lateral features below 100 µm and embedded microchannels down to $170 \times 220\,\mu\mathrm{m}^2$ on low-cost Elegoo Saturn machines [14]; the Elegoo Saturn 4 Ultra specifically has been validated for transparent microfluidic devices [13] and as a PDMS master [15]. A comparison of an $18,000 DLP and a $380 LCD printer found LCD dimensional accuracy for open microchannels within 2.5% of nominal with optimized

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior — Brasil (CAPES) — Finance Code 001, and by CNPq (National Council for Scientific and Technological Development, Process 405055/2023-4).

exposure [7], while custom resins and post-processing push channel dimensions and optical clarity further [8]–[10].

The three geometries investigated here, a symmetric cross-junction (FF-I), a tapered-entry diverging nozzle (FF-II), and a straight-entry diverging nozzle (FF-III), represent three canonical flow-focusing classes [1]–[3], each imposing a distinct pinch-off mechanism: orifice-driven squeezing (FF-I), shear-dominated elongation along a gradual convergence (FF-II), and abrupt-constriction focusing followed by nozzle expansion (FF-III). The central hypothesis is that these mechanistic differences produce distinct droplet sizes and generation frequencies over the same ϕ window.

This paper presents a systematic comparison of droplet generation behavior across three MSLA-printed FF geometries, characterized by droplet diameter d, coefficient of variation CV, and generation frequency f as a function of ϕ.

II. Device Design

Three flow-focusing variants were designed (Fig. 1) and printed simultaneously on a single build plate. All devices share the same body footprint ($\approx 35 \times 35 \times 5$ mm), a uniform channel height of 1.0 mm, and a 2 mm port diameter; they differ only in the geometry of the focusing junction and the downstream channel. The three designs were chosen to represent distinct pinch-off mechanisms while keeping fabrication conditions identical, isolating the effect of junction geometry on droplet formation. Key cross-sectional dimensions are summarized in Table I.

TABLE I
Geometry Parameters

Parameter	**FF-I**	**FF-II**	**FF-III**
Channel dimensions (mm)			
Continuous channel width	0.8	1.0	1.0
Dispersed inlet width	1.0	0.8	0.8
Junction / orifice width	0.5	0.6	0.6
Outlet / exit width	1.5	1.5	1.5
Nozzle length	0.5	9.0	9.0
Channel height	1.0	1.0	1.0
Nozzle half-angle	–	2.9°	2.9°
Focusing entry type	concave	tapered	straight
Derived quantities			
A_{or} at junction (mm^2)	0.50	0.60	0.60

FF-I is a symmetric cross-junction with a concave-wall orifice, adapted from the flow-focusing geometry reported by Lee et al. [11]. Two lateral continuous-phase channels (0.8 mm wide) flank a 1.0 mm dispersed-phase inlet. The orifice is defined by symmetric concave cutouts in the lateral walls (inner radius $R = 0.25$ mm), forming a 0.5 mm constriction ($A_{or} = 0.50\,\text{mm}^2$) that squeezes the dispersed thread. The short orifice and abrupt confinement place this design in the classic squeezing-dominated regime.

FF-II is a tapered-entry diverging-nozzle geometry adapted from the Fluigent EZ Drop device [12]. Two lateral continuous-phase channels (1.0 mm wide) converge through symmetric trapezoidal walls (base 3.2 mm, height 0.9 mm) onto a 0.8 mm dispersed-phase inlet, meeting at a 0.6 mm orifice ($A_{or} = 0.60\,\text{mm}^2$). Downstream, the channel expands gradually along a 9 mm nozzle (half-angle $\approx 2.9°$) to a 1.5 mm exit. The progressive convergence of the continuous phase establishes a smooth velocity gradient at the orifice, favoring shear-driven thread elongation before pinch-off.

FF-III shares the orifice and nozzle of FF-II but replaces the tapered focusing walls with straight rectangular continuous-phase channels (1.0 mm wide) that meet the 0.8 mm dispersed-phase inlet at an abrupt 0.6 mm constriction ($A_{or} = 0.60\,\text{mm}^2$). Because A_{or} and the downstream nozzle are identical to FF-II, any difference in droplet behavior can be attributed solely to the entry geometry: the abrupt constriction concentrates the velocity discontinuity at the orifice plane, which is expected to trigger earlier thread instability and alter the pinch-off dynamics relative to the gradual entry of FF-II.

III. Fabrication

A. Printing

STL files for all three geometries were imported into Chitubox v1.1.0 (CBD-Tech, Shenzhen, China), arranged on a single build plate, and rotated 15° about the X-axis so that channel cross-sections were exposed transversely to the build platform. This orientation preserves the rectangular channel profile (avoiding staircase artifacts), prevents resin pooling inside the channel, and distributes peel forces to minimize warpage. Because each layer slice then intersects the channel perpendicularly, every newly exposed wall layer rests on cured resin from the previous layer, so no internal supports are required; auto-generated supports (Chitubox *Adaptive*, *Middle* density) were placed on the external device surfaces only.

Devices were printed on an Elegoo Saturn 4 Ultra 16K mono-LCD printer, with 14 × 19 µm pixel size and 405 nm wavelength (Elegoo, Shenzhen, China), using Anycubic High Clear resin (Anycubic, Shenzhen, China), following print parameters consistent with prior MSLA microfluidic work on the same platform [13], [15]: layer thickness 0.05 mm, normal layer exposure 2.0 s, bottom layer exposure 40 s (8 layers). All three devices were printed simultaneously; total print time was 2 h 26 min 11 s.

B. Resin Glazing for Optical Transparency

After printing, green-state devices were post-processed as follows (Fig. 2). First, parts were agitated for 5 min in isopropyl alcohol (≥99.5%) in the Anycubic Wash & Cure 3 station to remove uncured resin, then UV-cured for 5 min in the same station to consolidate the washed part before glazing. Next, a thin layer of Anycubic High Clear resin was applied to all surfaces with a flat nylon brush (7 mm × 10 mm) to fill the ∼50 µm layer-line corrugations and ∼19 µm pixel steps that scatter visible light and render the part opaque. The coated part was then UV-cured for 2 min; a thin IPA film was immediately applied and a second 2 min cure was performed under wet surface conditions to suppress oxygen inhibition of radical polymerization at the resin–air interface [16]. This glazing cycle was repeated a second time to further reduce residual

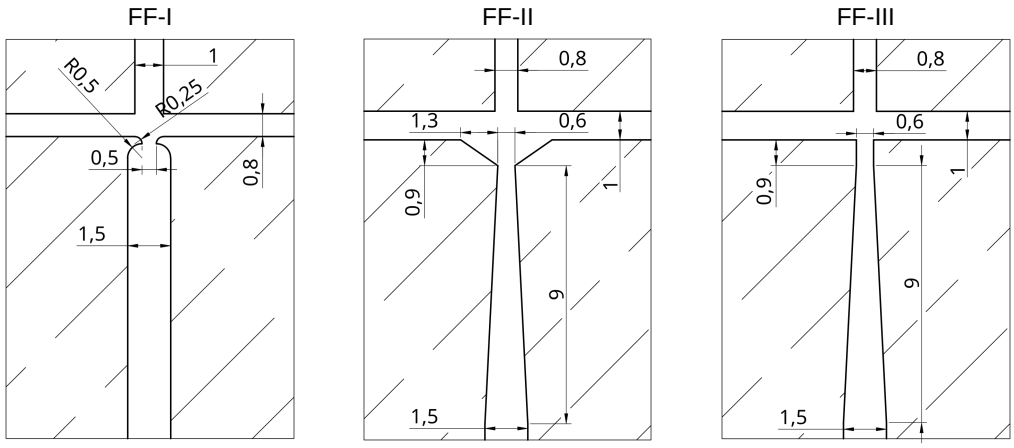

Fig. 1. CAD drawings of the three flow-focusing geometries (dimensions in mm): (a) FF-I symmetric cross-junction with concave-wall orifice, (b) FF-II tapered-entry diverging nozzle, and (c) FF-III straight-entry diverging nozzle. Key cross-sectional dimensions are listed in Table I.

haze, followed by a final 3 min dry UV cure to consolidate the glaze. Glazing was applied to the externally brushed faces required for imaging; the internal channel walls, which the brush cannot reach, retain the as-printed layer-line corrugation. After this protocol devices were visually transparent.

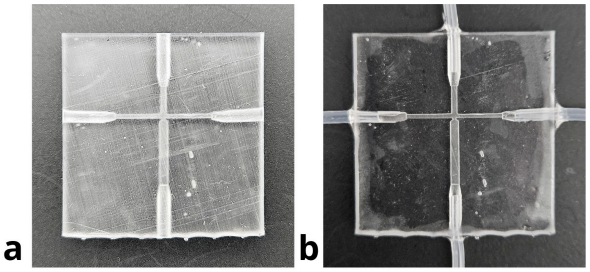

Fig. 2. Effect of resin glazing on optical transparency (black background). (a) FF-I device before glazing ; (b) same device after two-cycle glazing.

C. Tubing Bonding

Four silicone tubes (ID 1 mm, OD 2 mm, length 300 mm) were inserted 7 mm deep into lateral port holes (diameter 2.25 mm) on each of the four side faces of the device, producing an interference fit of 0.25 mm that retains the tube mechanically prior to bonding. Uncured Anycubic High Clear resin was applied around each tube–port interface and cured for 2 min under the UV station. This same-material bond avoids the adhesion incompatibilities observed with cyanoacrylate or epoxy on photopolymer substrates, and was leak-free at the operating pressures of this study. The tube-to-pump connections were made with blunt-tip dispensing needles (18 G $\times$ 12 mm) inserted into the silicone tubing and coupled to Luer-Lock syringes: a single 1 mL syringe for the dispersed phase and two 3 mL syringes for the continuous phase, one feeding each of the two lateral continuous-phase inlets.

IV. Experimental Setup

A. Syringe Pump

Flow was driven by an in-house syringe pump built around a bipolar stepper motor (6.7 Ω, 24 VDC, 0.6 A/phase; Sumtor Electric Co., Wuxi, China) mounted on a T-type linear rail (50 mm stroke, T6 trapezoidal lead-screw, nominal pitch 1 mm/rev), driven by a TB6600 microstepping driver (1/16 microstepping) and controlled by an Arduino microcontroller (AccelStepper firmware). The lead-screw pitch was calibrated to $L = 0.995$ mm/rev by commanding a 3 mm advance and measuring the actual carriage displacement with a dial indicator. The syringe carriage was fabricated by FDM 3D printing in PLA on a Creality Ender 3 V2 printer (Shenzhen, China), and accepts syringes of different diameters; the plunger diameter d_p was configured at runtime via the Arduino Serial Monitor for each syringe model. The pump accepts flow-rate commands in µL/min via the Arduino Serial Monitor and converts them to stepper pulse sequences via:

$$v_p = \frac{Q}{\pi d_p^2/4}, \qquad f = v_p \, \frac{N}{L} \tag{1}$$

where Q is the commanded flow rate, v_p is the corresponding linear plunger velocity, and f is the resulting stepper pulse frequency, set by the lead-screw pitch L (0.995 mm/rev) and the motor resolution N (6400 steps/rev). The smallest volume increment the pump can deliver is set by a single microstep and is given by

$$\Delta V = \frac{\pi d_p^2}{4} \, \frac{L}{N}, \tag{2}$$

i.e. the plunger cross-sectional area multiplied by the linear displacement per microstep (L/N), which defines the volumetric resolution of the pump for a given syringe. The two Luer-Lock syringe models used in this work (1 mL and 3 mL), together with their nominal plunger diameters d_p and the corresponding volumetric resolutions ΔV, are summarized in Table II.

TABLE II
VOLUMETRIC RESOLUTION PER SYRINGE

Syringe	d_p (mm)	ΔV (nL/microstep)
1 mL	4.78	2.79
3 mL	8.66	9.16

B. Fluids

The continuous phase was white mineral oil USP (Auros Química, São Paulo, Brazil) with 2 wt% Span 80 (sorbitan monooleate; Sigma-Aldrich, USA) dissolved by vortex mixing. The dispersed phase was a 10 mmol/L aqueous solution of methylene blue (Exodo Científica, São Paulo, Brazil) prepared in bi-distilled water. The methylene blue dyes the aqueous phase, providing the optical contrast needed to visualize and track the droplets against the surrounding oil under reflected-light illumination.

C. Imaging and Measurement

Devices were imaged using a custom reflected-light microscope assembled in-house on a CVI Melles Griot vibration-isolation optical breadboard (Fig. 3). The optical head consists of a 130× C-mount zoom lens coupled to a colour USB global-shutter camera (OV9782, Shenzhen Times Kangcheng Technology Co., Shenzhen, China). Illumination was provided by a ring LED lamp mounted on the front of the C-mount lens, directing light onto the device surface (reflected-light illumination); optical contrast between the aqueous droplets and the surrounding oil phase was enhanced by the methylene blue.

The camera–lens assembly was held on a magnetic-base post clamped directly to the CVI Melles Griot optical breadboard, providing a rigid, vibration-damped mount and defining the fixed imaging axis. Sample positioning was decoupled from the camera: each device was bonded with double-sided tape to a standard microscope slide along a short ($\approx$ 9 mm) strip at its upstream edge, near the dispersed-phase inlet, leaving the remainder of the device and the outlet tubing free of the chariot. The slide was mounted on the chariot, an XY positioning stage fixed via a 3D-printed adapter (double-sided tape) to a 100 mm × 100 mm granite block. The block rested on the table and was held in place by its own weight, allowing the whole sample assembly to be repositioned while its mass damped residual vibration. A Petri dish placed alongside the device collected waste fluid during operation, and a laptop was used both for video acquisition from the USB camera and for sending flow-rate commands to the Arduino-controlled syringe pump.

Videos were acquired at a resolution of 640 × 480 pixels and 180 fps using AMCap v3.0.9 (Microsoft, Redmond, USA). Droplets were detected using a YOLOv8 model trained on a dataset generated with the semi-automatic annotation pipeline described in [17]. To expose the detector to the full range of droplet morphologies, training frames were extracted from FF-I videos acquired at the two extreme generation regimes, the slowest (Q_d = 20 µL/min, Q_c = 200 µL/min) and the fastest (Q_d = 20 µL/min, Q_c = 400 µL/min), so that both the large, low-frequency plugs and the small, high-frequency droplets were represented in the dataset. Model training was performed inside a Docker container built from the official Ultralytics image (tag: 8.4.82). The trained model reached a detection performance of $\mathrm{mAP}_{50\text{-}95} = 0.95$ on the validation set, providing reliable localization for the subsequent tracking and sizing stages.

The detected droplets were subsequently processed using the droplet tracking, counting, and sizing pipeline described in [17], implemented in Python 3.12, to estimate the equivalent circular diameter (d) from the projected droplet area and the droplet generation frequency (f) from droplet passage events over time. For each operating condition (Q_c, Q_d), a 30 s video segment was analyzed. The coefficient of variation was calculated as $\mathrm{CV} = (\sigma_d/\bar{d}) \times 100\%$, where $\bar{d}$ and σ_d are the mean and standard deviation of the droplet diameter distribution, respectively.

V. RESULTS AND DISCUSSION

All three geometries generated monodisperse droplets in the dripping regime across the full flow-rate window tested (Q_d = 20 µL/min, Q_c = 200–800 µL/min), with droplet diameter, generation frequency, and their coefficients of variation summarized in Table III. Figure 4 shows a representative device (FF-III) in operation together with the automated droplet detection used to extract these quantities.

A. Theoretical Scaling Prediction from Mass Conservation

To provide a quantitative benchmark for the scaling exponents measured across the three geometries, we derived the expected dependence of droplet diameter d and generation frequency f on the flow-rate ratio ϕ, starting from mass conservation of the dispersed phase. In steady state, all fluid injected at rate Q_d must leave as droplets, so

$$f \cdot V = Q_d, \tag{3}$$

where V is the volume of an individual droplet.

Christopher et al. [21] reported, for T-junction geometries at low viscosity ratio, the empirical power-law scalings:

$$f \propto Ca^{4/3}, \qquad V \propto Ca^{-1/3}, \tag{4}$$

which were independently measured but mutually consistent with Eq. (3): combining them gives $f \cdot V \propto Ca^{4/3} \cdot Ca^{-1/3} = Ca \propto Q_c$, consistent with $f \cdot V = Q_d$ at fixed ϕ, where $Q_d \propto Q_c$.

To express these relations in terms of ϕ rather than Ca alone, we note that the capillary number scales with the continuous-phase flow rate, $Ca \propto Q_c$, and that $Q_d = \phi Q_c$. Substituting $Q_c = Q_d/\phi$ and holding Q_d fixed (as in the present experiments), Eq. (4) for the frequency becomes

$$f \propto Ca^{4/3} \propto Q_c^{4/3} = \left(\frac{Q_d}{\phi}\right)^{4/3} \propto \phi^{-4/3}. \tag{5}$$

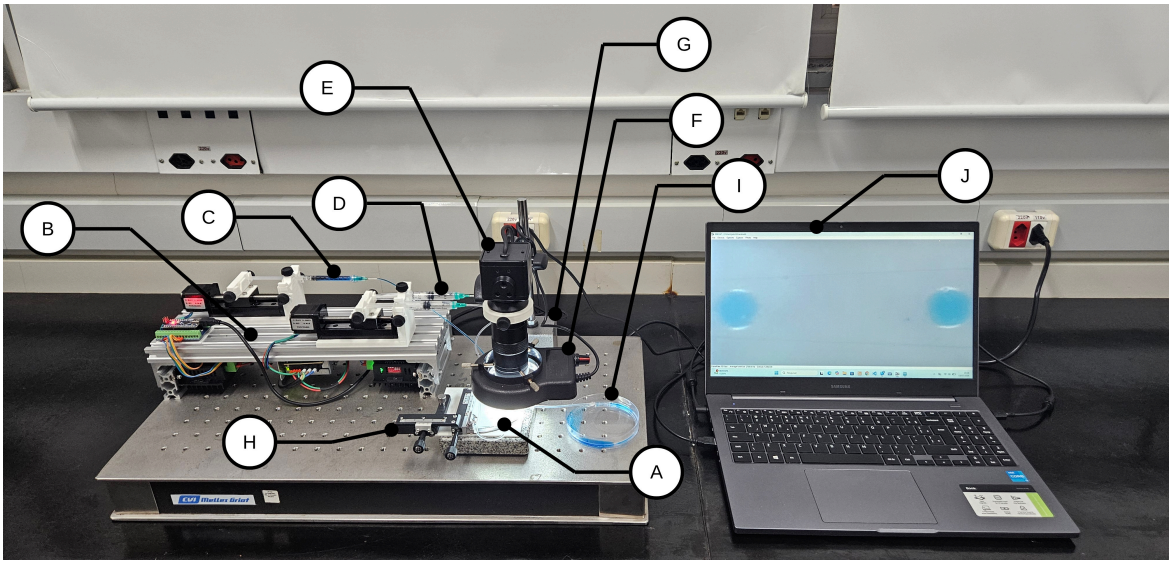

Fig. 3. Experimental setup mounted on the CVI Melles Griot vibration-isolation optical breadboard. (A) Microfluidic device; (B) syringe pump; (C) dispersed-phase syringe (aqueous methylene blue solution); (D) continuous-phase syringe (mineral oil); (E) camera; (F) ring light; (G) magnetic base clamped to the optical breadboard; (H) chariot for device positioning; (I) Petri dish for waste collection; (J) computer for video acquisition and syringe-pump control.

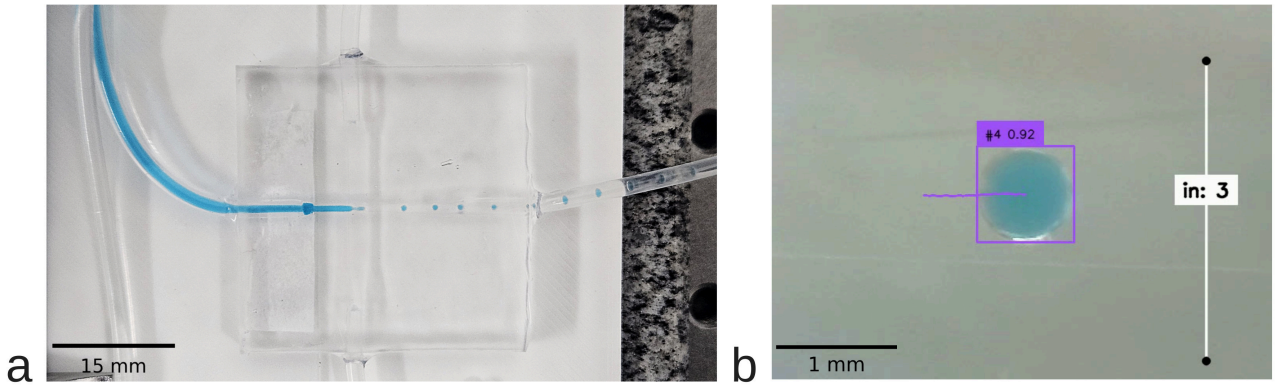

Fig. 4. Droplet generation and automated detection in the MSLA-printed FF-III device operating in the dripping regime ($Q_d = 20\,\mu$L/min, $Q_c = 200\,\mu$L/min; $\phi = 0.1$). (a) Transparent device in operation: the dispersed aqueous phase (methylene blue) enters from the right and breaks into a train of monodisperse droplets carried along the channel, with the outlet tubing running freely off the chariot. (b) Acquired video frame showing a droplet localized by the YOLOv8 detector (bounding box, track ID #4, detection confidence 0.92) and the crossing-count line used to estimate generation frequency (cumulative count: 3).

For the droplet volume, care must be taken because the empirical relation $V \propto Ca^{-1/3}$ in Eq. (4) was reported at fixed ϕ; the full dependence on both Ca and ϕ follows directly from mass conservation, $V = Q_d/f \propto Q_d \cdot Ca^{-4/3}$. Using $Q_d = \phi Q_c \propto \phi\, Ca$,

$$V \propto \phi\, Ca \cdot Ca^{-4/3} = \phi\, Ca^{-1/3} \propto \phi \left(\frac{Q_d}{\phi}\right)^{-1/3} \propto \phi^{4/3}, \tag{6}$$

at fixed Q_d. Assuming approximately spherical droplets ($V \propto d^3$), this yields

$$d \propto V^{1/3} \propto \phi^{4/9} \approx \phi^{0.444}. \tag{7}$$

Table IV summarizes the theoretical exponents predicted by Eqs. (5) and (7) alongside the exponents fitted from the present dataset (Sections V-B and V-D). While the frequency scaling exponents agreed closely with the T-junction prediction, the fitted diameter exponents lie slightly above the theoretical value across all three geometries. As discussed below, this offset is small relative to the uncertainty of a four-point power-law fit, and its near-identical magnitude across three geometrically distinct orifices argues against a junction-specific origin; we therefore anchor the quantitative comparison with theory on the directly counted frequency rather than on the diameter.

B. Droplet Size Distribution and Scaling with Flow-Rate Ratio

For all three geometries, droplet size distributions were narrow ($\mathrm{CV}_d < 4.1\%$ across all conditions), confirming stable, monodisperse generation over the entire flow-rate window tested. Fig. 5(a) shows the diameter distributions grouped by Q_c for each device. As expected, d decreases monotonically

TABLE III
DROPLET CHARACTERISATION SUMMARY

Geom.	Q_c (µL/min)	ϕ	d (µm)	CV$_d$ (%)	f (Hz)	CV$_f$ (%)
FF-I	200	0.100	814.5 ± 7.0	0.9	0.90 ± 0.04	4.4
	400	0.050	616.6 ± 10.8	1.7	1.81 ± 0.09	5.0

TABLE IV
THEORETICAL VS. MEASURED SCALING EXPONENTS ($\propto \phi^m$)

		Measured		
Quantity	**Theory**†	**FF-I**	**FF-II**	**FF-III**
f	$-4/3 \approx -1.333$	-1.39	-1.40	-1.41
d	$4/9 \approx 0.444$	0.52	0.52	0.53

†Derived from the scaling model of [21].

with increasing Q_c at fixed Q_d for all geometries, consistent with the shear-driven pinch-off mechanism of the dripping regime [2]. Notably, FF-I and FF-III produce droplets of nearly identical size at every condition tested (e.g. 814.5 ± 7.0 vs. 818.5 ± 7.5 µm at $Q_c = 200$ µL/min), despite their different orifice widths (0.5 vs. 0.6 mm). FF-II, in contrast, produces systematically larger droplets than both other geometries at every Q_c investigated, by a factor of 1.3–1.5× (e.g. 1131.1 ± 11.7 µm vs. 814–819 µm at $Q_c = 200$ µL/min). Since FF-II and FF-III share an identical orifice area ($A_{or} = 0.60\,\text{mm}^2$) and downstream nozzle, this difference can be attributed entirely to the entry geometry: the gradual convergence of the tapered walls in FF-II appears to sustain a longer dispersed-phase thread before the confined pressure build-up required for pinch-off is reached, delaying breakup relative to the abrupt constriction of FF-III.

The scaling of mean diameter with the flow-rate ratio ϕ is shown in Fig. 6(a) on logarithmic axes. All three geometries follow a clear power-law relationship, $\bar{d} \propto \phi^m$, with fitted exponents $m = 0.52$ (FF-I, $R^2 = 0.983$), $m = 0.52$ (FF-II, $R^2 = 0.934$), and $m = 0.53$ (FF-III, $R^2 = 0.974$). The near-identical exponents across all three geometries indicate that, while the absolute droplet volume is geometry-dependent (governed by orifice width and entry angle), the underlying scaling mechanism relating droplet size to the flow-rate ratio is conserved across all three junction designs.

The measured exponents ($m \approx 0.52$–0.53) lie slightly above the mass-conservation value $m_{\text{theory}} = 4/9 \approx 0.444$ (Table IV; Section V-A). Since Q_d is held fixed here, the $V \propto Ca^{-1/3}$ scaling cannot be verified from diameter data alone; the small residual offset is within the combined uncertainty of the four-point fit and the spherical approximation $d \propto V^{1/3}$.

C. Droplet Shape

Droplet aspect ratio, $\Psi = \min(w,h)/\max(w,h)$ (with $\Psi = 1$ corresponding to a perfectly circular projected shape), was evaluated to assess deviations from sphericity across the four Q_c values (Fig. 5(b)). All three geometries produced predominantly near-circular droplets ($\Psi > 0.89$ in all conditions), consistent with operation in the dripping regime. FF-II consistently exhibited the lowest median Ψ among the three geometries, most pronounced at $Q_c = 600$ µL/min (median $\Psi \approx 0.925$, vs. ≈ 0.98 for FF-I and FF-III), indicating more elongated droplets. Two contributions to this elongation are plausible and cannot be separated with the present dataset: (i) greater shear-driven stretching of the larger-volume FF-II droplets along the flow direction, and (ii) drag and contact-line pinning at the channel top and bottom surfaces — which retain the layer-line corrugation of the MSLA print orientation — since only the FF-II droplets grow comparable to the 1.0 mm channel height and can contact these walls. The smaller droplets produced by FF-I and FF-III remain near-circular across all conditions.

D. Generation Frequency

Fig. 5(c) shows the generation frequency distributions (computed over non-overlapping windows of $N = 3$ consecutive droplet crossing events, $f = (N-1)/\Delta t$; the number of windows per condition ranged from 5 at the lowest flow rate to 69 at the highest) grouped by Q_c. Frequency increased monotonically with Q_c for all geometries (Table III). Consistent with its larger droplet volume, FF-II generated droplets at a systematically lower frequency than FF-I and FF-III at every Q_c tested (e.g. 0.51 ± 0.02 vs. 0.90 ± 0.04 and 0.88 ± 0.02 Hz at $Q_c = 200$ µL/min).

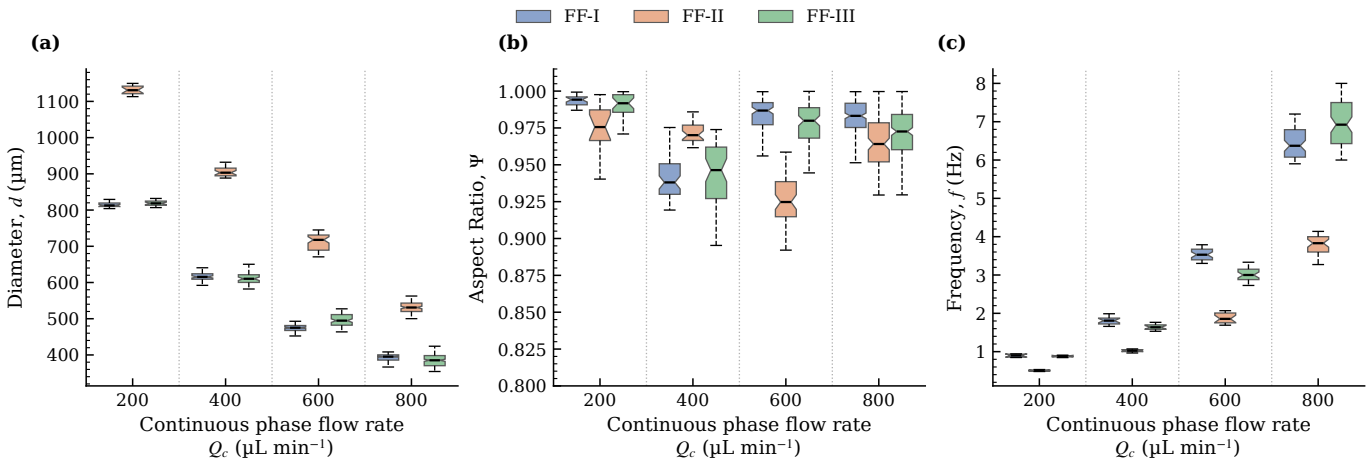

Fig. 5. (a) Droplet diameter, (b) aspect ratio, and (c) generation frequency distributions for the three flow-focusing geometries as a function of the continuous-phase flow rate Q_c ($Q_d = 20$ µL/min fixed). Boxes show the interquartile range with notches indicating the 95% confidence interval of the median; whiskers extend to the full data range.

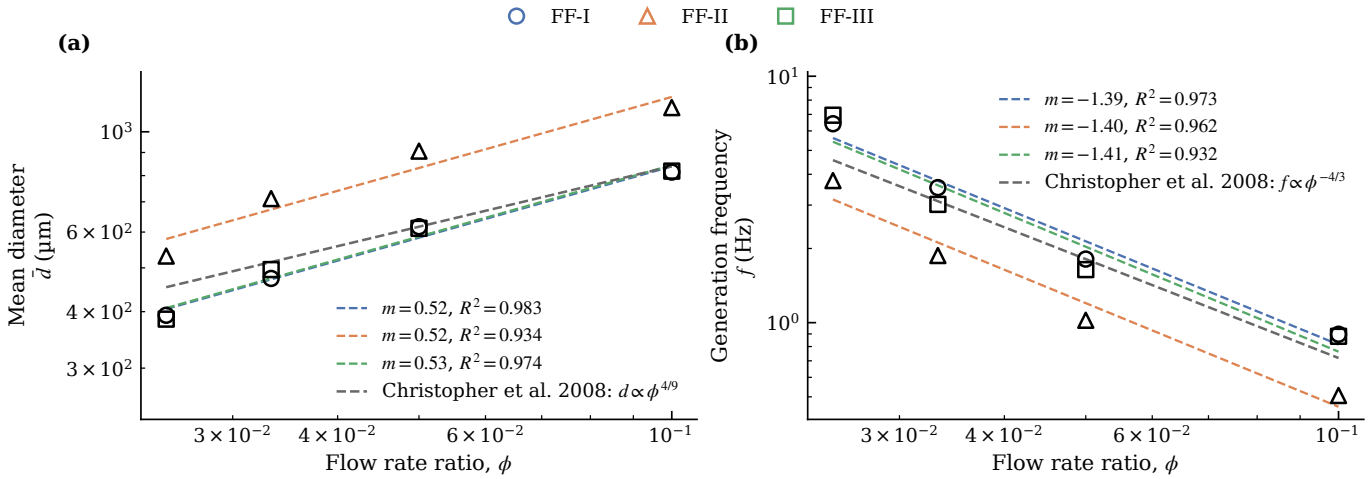

Fig. 6. (a) Mean droplet diameter and (b) generation frequency versus flow-rate ratio ϕ, on logarithmic axes, for the three geometries. Dashed colored lines show the fitted power law for each device; the grey dashed line shows the mass-conservation prediction from Christopher et al. [21].

The scaling of f with ϕ (Fig. 6(b)) follows a power law $f \propto \phi^m$ with $m = -1.39$ (FF-I, $R^2 = 0.973$), $m = -1.40$ (FF-II, $R^2 = 0.962$), and $m = -1.41$ (FF-III, $R^2 = 0.932$). These values are in close agreement with the theoretical prediction $f \propto \phi^{-4/3}$ ($m_{\text{theory}} \approx -1.333$) derived from the same mass-conservation argument combined with the Christopher et al. $V \propto Ca^{-1/3}$ scaling [21]. The frequency scaling was measured directly from droplet-crossing counts and does not depend on the spherical approximation required to relate diameter to volume; it therefore provided the more robust benchmark against the mass-conservation prediction, and its close agreement with the T-junction exponent indicates that the frequency response of all three FF geometries to the flow-rate ratio was governed by a mechanism near the T-junction limit.

VI. Conclusion

This work demonstrated that three distinct flow-focusing geometries (FF-I symmetric cross-junction, FF-II tapered-entry diverging nozzle, and FF-III straight-entry diverging nozzle) can be fabricated simultaneously in a single build via masked stereolithography (MSLA) 3D printing, with a total print time under 2 h 30 min. A two-cycle resin-glazing protocol restored optical transparency to the green-state parts, enabling reflected-light droplet imaging directly through the printed device body without recourse to PDMS soft lithography or clean-room infrastructure. The complete workflow, from geometry design to functional device, is achievable within a single working day, making rapid geometry iteration practical.

Across the systematic dataset ($Q_d = 20$ µL/min, $Q_c = 200$–800 µL/min), all three geometries produced monodisperse droplets ($\text{CV}_d < 4.1\%$) in the dripping regime, confirming that MSLA-printed devices can sustain stable, uniform

droplet generation. The mean droplet diameter and generation frequency each followed clear power laws in the flow-rate ratio ϕ, with near-identical exponents across the three designs ($m \approx 0.52$–0.53 for diameter and $m \approx -1.39$ to -1.41 for frequency). This indicated that the scaling mechanism relating droplet metrics to ϕ was conserved across junction geometries, even though the absolute droplet size is strongly geometry-dependent: FF-II produced droplets 1.3–$1.5\times$ larger than FF-I and FF-III at every condition, an effect attributed to the gradual convergence of its tapered entry walls, which sustains a longer dispersed-phase thread before pinch-off. The measured frequency exponents agree closely with the mass-conservation prediction derived from the T-junction scaling of Christopher et al. [21]; the diameter exponents lie slightly higher, within the uncertainty of a four-point fit and the spherical approximation used to relate diameter to volume.

Several limitations should be noted. The scaling relationships were obtained with a single fluid pair, a fixed surfactant concentration and a fixed Q_d, and for three junctions only; their extension to other viscosity ratios, surfactant loadings and broader classes of flow-focusing designs remains to be verified. The proposed pinch-off mechanisms are inferred from droplet metrics rather than observed directly, and the droplets were not tested in a biological assay. As next steps, the interfacial tension and viscosities of both phases will be measured directly (e.g. pendant-drop method), allowing Ca to be computed from first principles and the diameter-scaling offset to be re-examined. The three geometries will then be reproduced in CFD (volume-of-fluid) simulations complemented by direct flow visualization at the orifice, and the dataset will be extended to variable Q_d to verify the $V \propto Ca^{-1/3}$ and $f \propto Ca^{4/3}$ scalings independently. Finally, cytotoxicity assays of the chip material will be performed to confirm biocompatibility, followed by droplet generation with a cell-laden dispersed phase to produce cell spheroids and assess aggregate uniformity and viability.

Acknowledgment

The authors thank the Biophotonics and Biomedical Optics Laboratory and the Phototherapy and Microbiological Analysis Laboratory, both at the Federal University of ABC (UFABC), for providing laboratory space for the experiments reported in this work.

***Abstract*—** Ozonated water has emerged as a promising alternative for the disinfection of gutta-percha cones because of its broad-spectrum antimicrobial activity and the absence of toxic residues. However, information regarding its effects on the chemical structure of gutta-percha remains limited. Therefore, this study aimed to investigate the chemical effects of a hydrodynamic ozonated water system on gutta-percha using Fourier-transform infrared spectroscopy with attenuated total reflectance (FTIR/UATR), assessing whether ozone-induced chemical modifications remained detectable after superficial material removal. Three experimental conditions were evaluated: untreated gutta-percha, gutta-percha exposed to hydrodynamic ozonated water for 7 min, and ozonated gutta-percha after mechanical removal of a thin superficial layer. FTIR/UATR spectra were acquired in the range of 4000–550 cm^{-1} using 20 scans, and the spectra were qualitatively compared based on band position, shape, and relative intensity. The ozonated specimens exhibited broadening of the hydroxyl stretching region (3390–3445 cm^{-1}), changes in the spectral profile around 1667 cm^{-1}, and reduced intensity of the band near 795 cm^{-1}, consistent with ozone-induced chemical modifications of the polyisoprene matrix. After superficial abrasion, these spectral changes were no longer detectable, and the resulting spectral profile became comparable to that of untreated gutta-percha. These findings suggest that the chemical modifications induced by hydrodynamic ozonation were predominantly associated with the superficial region of the material under the conditions evaluated. However, the qualitative FTIR/UATR approach does not allow quantitative determination of the degree or depth of oxidation. Complementary surface-sensitive and depth-resolved analyses are therefore warranted to further characterize the extent of ozone-induced chemical modifications. The results support the potential application of hydrodynamic ozonated water as a gutta-percha disinfection strategy while highlighting the need for further investigation of the effects of superficial chemical modifications on sealer adhesion and long-term obturation performance.

***Keywords*—** Gutta-percha; Hydrodynamic ozonation; FTIR/UATR.

I. INTRODUCTION

Endodontic infections are predominantly microbial diseases that affect the root canal system and periapical tissues and are recognized as the primary cause of the development and persistence of apical periodontitis. These infections are characterized by the formation of organized biofilms and by the high adaptive capacity of microorganisms to the intraradicular environment, making their complete elimination during endodontic treatment challenging [1,2,3,4,5]. Therefore, the clinical success of endodontic therapy depends on a substantial reduction of the microbial load, adequate shaping and disinfection of the root canal system, and the achievement of an effective three-dimensional seal capable of preventing reinfection of the endodontic space [5,6,7,8].

Among the materials used for root canal obturation, gutta-percha (GP) remains the material of choice and is considered the gold standard in Endodontics because of its biocompatibility,

dimensional stability, radiopacity, low cytotoxicity, ease of handling, and compatibility with different obturation techniques[9,10,11]. Chemically, commercial GP is a composite material composed predominantly of trans-1,4-polyisoprene associated with zinc oxide, barium sulfate, waxes, resins, plasticizers, and pigments, whose proportions may vary according to the manufacturer [9,13,14,15]. This composition directly influences its physical, mechanical, and thermal properties, as well as its behavior during clinical procedures performed before obturation [13,14,15].

Although GP cones are commercially available as sterile products, several studies have demonstrated that they may become contaminated during storage, transportation, clinical handling, or exposure to the operative environment, making disinfection immediately before insertion into the root canal essential [9,10,11,12]. For this purpose, different chemical agents, such as sodium hypochlorite, chlorhexidine, alcohol, and peracetic acid, have been widely used because of their high antimicrobial activity. However, depending on the concentration employed and the exposure time, these agents may induce surface alterations, structural modifications, and changes in the physicochemical properties of GP, thereby compromising its adaptation to the root canal walls and, consequently, the quality of the obturation seal [12,13,14,15].

In this context, ozonated water has attracted increasing interest as an alternative for the disinfection of dental biomaterials due to its high oxidative potential, broad-spectrum antimicrobial activity, effectiveness against microorganisms organized in biofilms, and rapid decomposition into oxygen without leaving toxic residues at the end of the process. Furthermore, the use of hydrodynamic ozonation systems enhances ozone transfer into water, resulting in more stable dissolved ozone concentrations and improving its disinfecting efficacy. Recent studies have demonstrated that this system provides high disinfection efficiency against *Enterococcus faecalis* contaminated GP cones while preserving their mechanical and morphological properties following treatment with ozonated water [19].

Despite the promising findings regarding the antimicrobial activity of ozonated water, studies investigating its potential effects on the chemical composition and thermal stability of GP remain limited. Considering that structural modifications may compromise the clinical performance of the obturation material, it is essential to determine whether exposure to a hydrodynamic ozonated water system promotes changes in its polymeric matrix or inorganic constituents.

In this regard, Fourier-transform infrared spectroscopy (FTIR) is a widely employed technique for the characterization of biomaterials, allowing the identification of functional groups, chemical bonds, and possible structural changes resulting from different treatments [16,17].

Therefore, the present study aimed to evaluate the chemical effects of hydrodynamic ozonation on gutta-percha by means of Fourier-transform infrared spectroscopy with attenuated total reflectance (FTIR/UATR), comparing untreated, ozonated, and superficially abraded ozonated specimens to determine whether ozone-induced oxidation is limited to the material surface or affects deeper layers of the polymeric matrix.

II. Materials and Methods

A. Study design

This in vitro study aimed to investigate the chemical effects of a hydrodynamic ozonation system on gutta-percha cones using Fourier-transform infrared spectroscopy with attenuated total reflectance (FTIR/UATR). The experimental design comprised three conditions: untreated gutta-percha (control group), gutta-percha exposed to ozonated water for 7 min using the hydrodynamic ozonation system and ozonated gutta-percha after the mechanical removal of a thin superficial layer. FTIR/UATR analysis was performed to compare the chemical profiles of the three conditions and determine whether the oxidative changes induced by ozonation were restricted to the material surface or extended into its internal structure.

B. Gutta-percha samples

Standardized GP cones (DiaDent ML.029™, size 70; DiaDent Group International, South Korea) from the same manufacturing batch were used throughout the study to minimize compositional variability. The samples were randomly divided into two experimental groups: control group, *in natura* and cones exposed to the hydrodynamic ozonation system (Figure 1).

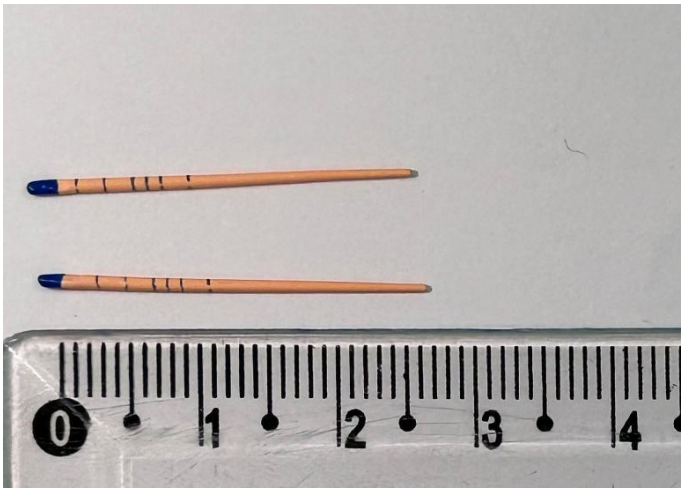

Fig 1. Gutta-percha cone used in the experimental procedures. In the scale bar shown below, the distance between adjacent tick marks corresponds to 1 mm. Author's own work.

C. Hydrodynamic ozonation system

The system consisted of a 500 mL water reservoir connected to a centrifugal pump. A Venturi injector was attached to the pump outlet, with a third inlet for ozone gas, enabling dynamic mixing with water. The fluid was directed to a tubular head via silicone tubing, where the gutta-percha samples were positioned for disinfection (Figure 2). The kinetic effect of ozonated water and ozone's oxidative action were expected to remove and oxidize organic material deposited on the sample surfaces. Experiments were conducted in a climate-controlled environment at 21 °C. An ozone generator (MS3G, MS Ltd.a, Brazil) was set to a concentration of 57.2 mg/L, with oxygen gas flow adjusted to 0.250 L/min. Initially, the system was activated without samples to allow complete ozonation of the water and internal

disinfection of the system, requiring 10 min to inactivate any residual microorganisms.

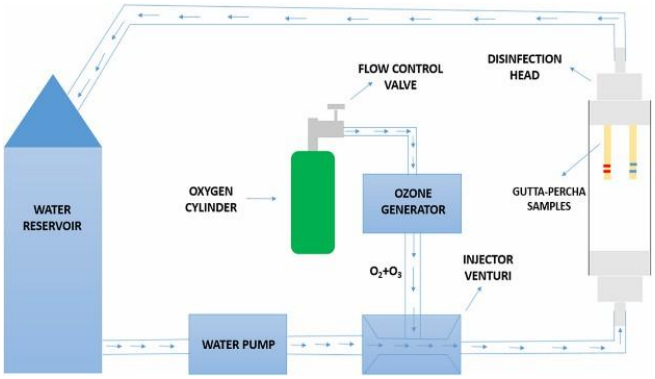

Fig. 2 Schematic representation of the system used for gutta-percha disinfection with ozonated water via a hydrodynamic setup. The samples, consisting of eight units, were internally fixed within the tubular head and exposed to the dynamic flow of ozonated fluid. **Source:** souza *et al.,* 2026

D. Fourier transform infrared spectroscopy (FTIR)

A chemical analysis was performed to investigate the effects of hydrodynamic ozonation on the surface of gutta-percha cones. Fourier-transform infrared (FTIR) spectra were acquired in triplicate under three experimental conditions: (1) untreated gutta-percha cones (*in natura*), (2) gutta-percha cones exposed to ozonated water for 7 min using a hydrodynamic ozonation system, and (3) ozonated gutta-percha cones after mechanical removal of a thin superficial layer using a sterile scalpel blade (scraping) to expose the underlying material.

FTIR analyses were carried out using a Spectrum Frontier spectrometer (PerkinElmer, Waltham, MA, USA) equipped with a universal attenuated total reflectance (UATR) accessory. Spectra were collected over the range of 4000–550 cm^{-1} using 20 accumulated scans and a gain setting of 1. All measurements were performed under controlled laboratory conditions at 21 °C and 48% relative humidity.

The spectra obtained from the three experimental groups were qualitatively compared to identify possible chemical modifications induced by ozone exposure and to determine whether these changes were confined to the surface or extended into the internal structure of the gutta-percha.

E. Data analysis

The FTIR spectra obtained from the three experimental groups were qualitatively analyzed by comparing the position, intensity, and shape of the characteristic absorption bands associated with the chemical constituents of gutta-percha. Special attention was given to spectral regions related to hydroxyl groups, carbon-carbon double bonds, and the trans-1,4-polyisoprene structure to identify possible chemical modifications induced by ozone exposure.

The spectra of untreated gutta-percha, ozonated gutta-percha, and ozonated gutta-percha after superficial layer removal were compared to determine whether the observed oxidative changes were restricted to the material surface or extended into the underlying layers.

III. Results

A. Structural Characterization of Dental Gutta-Percha by FTIR/UATR

The FTIR/UATR spectra of untreated gutta-percha (A), ozonated gutta-percha (B), and ozonated gutta-percha after superficial scraping (C) are presented in Figure 3. All experimental groups exhibited the characteristic absorption bands of gutta-percha, confirming the preservation of the material's chemical composition after treatment. The main bands were observed at approximately 3444 cm^{-1} (O–H stretching), 2962, 2913, and 2848 cm^{-1} (C–H stretching), 1667 cm^{-1} (C=C stretching of the polyisoprene backbone), 1481, 1418, and 1381 cm^{-1} (CH_2 and CH_3 bending vibrations), 1173, 1117, 1074, and 1016 cm^{-1} (C–C and C–O stretching), and 795 cm^{-1}, which is associated with the trans-1,4-polyisoprene structure.

Qualitative comparison of the spectra revealed chemical changes after exposure to the hydrodynamic ozonation system. The ozonated specimens showed a broader absorption band in the hydroxyl stretching region (approximately 3390–3445 cm^{-1}), suggesting the formation of oxygen-containing functional groups on the material surface. In addition, broadening of the band centered at approximately 1667 cm^{-1} was observed, indicating oxidation of the unsaturated polyisoprene chains and increased interaction with adsorbed water. A reduction in the intensity of the absorption band near 795 cm^{-1} was also detected, consistent with ozone-induced consumption of carbon–carbon double bonds in the trans-1,4-polyisoprene matrix.

After mechanical removal of a thin superficial layer, the FTIR spectrum became comparable to that of untreated gutta-percha. The broadening of the hydroxyl band, the changes observed around 1667 cm^{-1}, and the reduction in the 795 cm^{-1} band were no longer evident, indicating that the chemical modifications induced by hydrodynamic ozonation were predominantly restricted to the outer surface of the material, with no detectable alterations in the underlying polymeric structure.

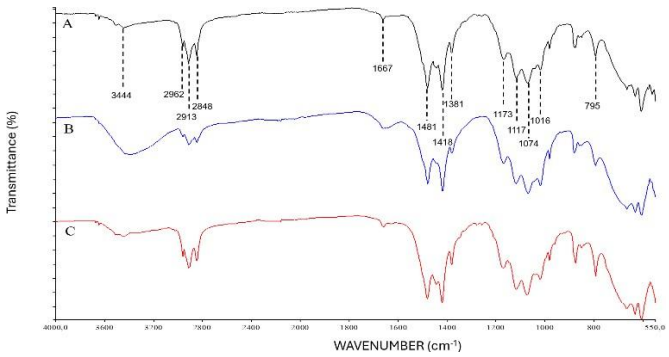

Fig 3 Representative FTIR/UATR spectra of untreated gutta-percha (A), ozonated gutta-percha (B), and ozonated gutta-percha after superficial scraping (C).

IV. Discussion

The FTIR/UATR analysis demonstrated that exposure of gutta-percha to hydrodynamic ozonated water induced localized chemical modifications in the superficial region of the material, as evidenced by the broadening of the hydroxyl stretching band (3390–3445 cm^{-1}), changes in the spectral profile around 1667 cm^{-1}, and a reduction in the intensity of the band near 795 cm^{-1}. These findings are consistent with the ozonolysis mechanism of unsaturated polymers, in which ozone preferentially reacts with carbon–carbon double bonds (C=C), initially forming unstable ozonides that subsequently decompose into oxygen-containing products, including hydroxyl, carbonyl, and hydroperoxide groups [20].

Although dental gutta-percha is composed predominantly of trans-1,4-polyisoprene, whereas natural rubber consists mainly of cis-1,4-polyisoprene, both materials contain unsaturated polymeric chains with carbon–carbon double bonds that are susceptible to oxidative attack by ozone. Therefore, the oxidation mechanism described for natural rubber can be considered an appropriate chemical model for interpreting the spectroscopic changes observed in gutta-percha. Kim et al. [20] demonstrated that ozone exposure of polyisoprene results in progressive changes in spectral bands associated with C=C bonds and the formation of oxygen-containing functional groups, supporting the interpretation of the present findings. Similarly, Rodrigues et al. [21] reported ozone-induced surface effects in natural rubber associated with the oxidation of unsaturated polymeric structures.

In the present study, the broadening of the band in the 3390–3445 cm^{-1} region suggests the formation or increased contribution of oxygen-containing groups following ozonation, whereas the changes around 1667 cm^{-1} are consistent with modifications involving unsaturated regions of the polyisoprene matrix. Likewise, the reduced intensity of the band near 795 cm^{-1} is compatible with changes involving the trans-1,4-polyisoprene structure and the consumption or modification of carbon–carbon double bonds during ozonolysis. However, these interpretations should be considered qualitative because the present FTIR/UATR analysis was based on comparison of band position, shape, and relative intensity rather than on quantitative determination of oxidation products or functional-group concentrations.

An important aspect of the present findings is the comparison between ozonated gutta-percha before and after mechanical removal of a superficial layer. Following superficial scraping, the spectral changes observed after ozonation were no longer detectable, and the resulting spectrum became comparable to that of untreated gutta-percha. This finding suggests that the chemical modifications detected by FTIR/UATR were predominantly associated with the superficial region of the material under the conditions evaluated. However, the present experimental design does not allow the exact depth of oxidation to be quantitatively determined. In particular, the thickness of the mechanically removed layer was not measured, and the FTIR/UATR analysis was not performed as a depth-resolved or spatially resolved technique. Therefore, the disappearance of the spectral changes after scraping should be interpreted as evidence consistent with a predominantly superficial modification rather than as definitive confirmation of a specific oxidation depth.

This limitation is relevant because FTIR/UATR provides information about the chemical composition within the region sampled by the attenuated total reflectance interaction, while the mechanical scraping procedure provides a qualitative comparison between the exposed surface and the underlying material. Complementary techniques could provide a more precise characterization of the oxidation process. For example, X-ray photoelectron spectroscopy (XPS) could be used to quantitatively evaluate changes in surface elemental composition and carbon–oxygen chemical states, whereas depth-resolved micro-FTIR or other spatially resolved spectroscopic approaches could provide additional information regarding the distribution of chemical modifications as a function of depth. Raman spectroscopy could also complement FTIR by providing additional information regarding changes in the polyisoprene structure. Therefore, future studies combining surface-sensitive and depth-resolved techniques would be important to quantify both the degree and spatial extent of ozone-induced oxidation.

From an endodontic perspective, the superficial nature of the detected modifications is relevant because gutta-percha is used in combination with an endodontic sealer to achieve an adequate root canal filling. Surface characteristics of gutta-percha, including chemical composition, surface energy, roughness, and wettability, may influence its interaction with endodontic sealers. Previous studies have demonstrated that chemical surface modification of gutta-percha can alter surface free energy and sealer wettability, with effects on bond strength depending on the treatment and the type of sealer evaluated [22,23]. In addition, different endodontic sealers may exhibit substantially different adhesion to gutta-percha [24]. Therefore, the superficial oxidation observed in the present study could potentially modify the interaction between ozonated gutta-percha and endodontic sealers. Nevertheless, the direction and clinical relevance of this effect cannot be established from the present data because adhesion, wettability, interfacial bonding, microleakage, and obturation performance were not directly evaluated.

The preservation of the underlying polymeric structure is also relevant to the potential application of hydrodynamic ozonation as a gutta-percha disinfection strategy. Previous work using the same hydrodynamic ozonation approach demonstrated effective disinfection of Enterococcus faecalis-contaminated gutta-percha while preserving mechanical and morphological characteristics after treatment [19]. The present findings add a chemical perspective to these observations by indicating that detectable FTIR/UATR modifications were associated predominantly with the superficial region rather than with the underlying polymeric structure. Nevertheless, chemical preservation of the bulk material should not be interpreted as evidence of complete preservation of long-term clinical performance, since aging, repeated exposure, interaction with endodontic sealers, and storage conditions may influence the behavior of the material over time.

Taken together, the main lesson learned from this study is that the evaluation of a disinfection method for gutta-percha should consider not only its antimicrobial effectiveness but also the extent and nature of the chemical modifications induced in the biomaterial. Under the conditions evaluated, hydrodynamic ozonation produced detectable spectral changes that were no longer observed after superficial material removal, suggesting that the chemical effects were predominantly associated with the surface region. At the same time, the qualitative nature of the FTIR/UATR analysis highlights the need for caution when interpreting the degree and depth of oxidation.

The findings also identify relevant research gaps. Future investigations should quantitatively determine the degree and depth of ozone-induced oxidation, evaluate changes in surface energy and wettability, and investigate the interaction of

ozonated gutta-percha with different classes of endodontic sealers. Bond-strength, interfacial adaptation, microleakage, and long-term aging studies would be particularly important to establish whether the superficial chemical modifications observed in the present study have beneficial, neutral, or detrimental effects on obturation performance. Such investigations would allow the chemical findings obtained here to be more directly correlated with the functional and clinical behavior of ozonated gutta-percha.

V. Conclusion

The present study demonstrated that hydrodynamic ozonated water induced detectable chemical modifications in the superficial region of gutta-percha under the conditions evaluated. FTIR/UATR analysis revealed spectral changes associated with ozone-induced modifications of the polyisoprene matrix, including changes in the hydroxyl stretching region, the band around 1667 cm^{-1}, and the band near 795 cm^{-1}. After mechanical removal of a superficial layer, these spectral changes were no longer detectable, suggesting that the chemical modifications were predominantly associated with the superficial region of the material.

However, the qualitative nature of the FTIR/UATR analysis and the absence of a quantitative depth-resolved assessment limit the determination of the exact degree and depth of ozone-induced oxidation. Therefore, complementary surface-sensitive and depth-resolved techniques are needed to further characterize these modifications. In addition, further studies should investigate whether the observed superficial chemical changes influence the interaction of gutta-percha with endodontic sealers, as well as long-term obturation performance.

Overall, the findings support the potential of hydrodynamic ozonated water as a gutta-percha disinfection strategy while indicating that its chemical effects should be further characterized to establish their functional and clinical relevance.

Conflict of Interest

***Abstract*— The purpose of this study was to investigate the potential of methylene blue with red laser light as a photo crosslinking method in type B gelatin films, compared with the effect of UVC radiation and EDC. Preliminary results with methylene blue showed higher crosslinking capacity compared to UVC.**

Keyword - methylene blue, crosslinking, ultraviolet radiation, photodynamic therapy.

I. INTRODUCTION

Collagen is the most abundant fibrous protein in animal tissues and the primary protein that makes up the extracellular matrix (ECM). In the extracellular matrix, collagen fibers contribute to its tensile strength and structural organization [1]. Derived from the hydrolysis and irreversible denaturation of collagen, gelatin is a linear polymer with a high degree of similarity to the amino acids that make up collagen; it can be sourced from the skin of mammals, primarily pigs and cattle. For extraction purposes, gelatin can be treated with acidic or alkaline agents and is classified accordingly as Type A or Type B [2].

In the field of tissue engineering, gelatin is considered a biocompatible and biodegradable material, and its versatility as a biomaterial for scaffold formation is one of advantages over collagen, as its lower cost and higher solubility in a variety of solvents [3]. However, gelatin has limitations in its mechanical properties, with a short degradation rate and low thermal stability [4]. To overcome this inherent characteristic, crosslinking methods aimed at promoting intra- and intermolecular bonds have been proposed to increase rigidity, enhance stability, increase molecular weight, and improve mechanical properties; this approach has been considered the most commonly explored strategy for addressing the limitations of this biomaterial [5].

Crosslinking processes are commonly carried out using chemical agents, which are designed to interact with functional groups in the collagen structure, promoting the formation of crosslinks. However, despite their crosslinking potential, chemical agents may exhibit high toxicity and low biocompatibility. Among traditional chemical agents, N-(3-dimethylaminopropyl)-N'-ethylcarbodiimide hydrochloride, known as EDC, is recognized for its ability to form isopeptide bonds between carboxyl and amine groups, exhibiting high aqueous solubility and lower toxicity compared to other aldehyde-based chemical agents, such as glutaraldehyde [6].

Physical crosslinking methods using ultraviolet (UV) radiation are known to promote crosslinking through the formation of chemical bonds via the aromatic groups of tyrosine and phenylalanine. Despite potential sterilizing benefits, the use of UV as a crosslinking agent depends on its dosimetry, such as fluency, exposition time and power. Currently, the use of UV as a crosslinker has been best evaluated in combination with photosensitive chemical agents [7].

Methylene Blue (MB) is a photosensitive dye belonging to the class of phenothiazine compounds, with a broad absorption band in the 550–700 nm range, Fig.1, whose monomers exhibits maximum absorption peaks at a wavelength of 664 nm and dimers exhibits maximum absorption peaks at 590 nm [8]. MB is a recognized photosensitizing agent in Photodynamic Therapy (PDT). Photodynamic Therapy is a non-invasive therapeutic technique defined by the combination of a light source, a photosensitizing agent, and the presence of molecular oxygen. The interaction of these components generates photophysical and photochemical processes that are responsible for the onset of biological effects at the site of application. The photosensitizing agent is activated by a light source with a wavelength that is absorbed by the photosensitizer; this specificity is intended to trigger its photosensitive reactions, which occur due to the presence of molecular oxygen and may result in the production of reactive oxygen species (ROS-Reactive Oxygen Species), capable of interacting locally [9].

Reactive oxygen species, such as singlet oxygen, are already known in the literature to react with the carbonyl groups of collagen and promote new bonds between its amino acids, increasing the formation of covalent crosslinks. This process is used, for example, for corneal crosslinking through exposure to ultraviolet radiation in combination with vitamin B2 [10]. UV light is also widely used in the photo-crosslinking of gelatin methacryloyl hydrogels (GelMA) with an aqueous photoinitiator [11]. However, due to light scattering in tissues and depending on its wavelength, ultraviolet radiation has a

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

limited depth of tissue penetration, ranging from 0.5 to 2.5 mm in healthy skin tissues [12].

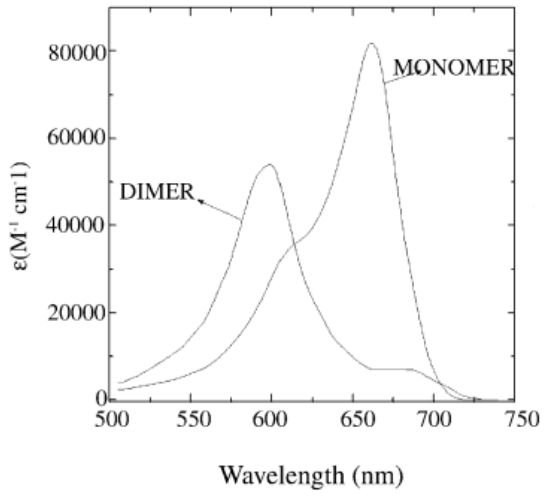

Fig.1. Absorbance spectra of dimer and monomer species of MB [8].

Considering that higher wavelengths are generally safer for *in vivo* applications compared to lower wavelengths, given the direct correlation between photon energy and the phototoxicity of the light source [13], and that red light has a penetration depth in soft tissues of 1 to 3 mm - greater than of UV light [14], the combination of red light with methylene blue - whose maximum absorption lies within the therapeutic window of the red laser [15] - may be an innovative approach for performing photo-crosslinking in deeper tissues.

Based on the premise that new crosslinking processes may contribute to the development of innovative collagen-based materials for biomedical applications [7], this study aims to understand the potential of photodynamic therapy with methylene blue and red laser as a new crosslinking process in type B gelatin films, in comparison with other traditional crosslinking methods.

II. Material and Methods

All reagents were purchased from Sigma-Aldrich (USA), including: N-(3-dimethylaminopropyl)-N-ethylcarbodiimide hydrochloride (EDC), methylene blue (MB), 2,2,2-trifluoroethanol (TFE), and type B bovine skin gelatin.

A. Preparation of gelatin films

A.1 Preparation of pure type-B gelatin films

Five grams of type B gelatin were mixed in 100 mL of 2,2,2-trifluoroethanol, subjected to continuous mechanical stirring at 500 rpm for 24 h. From the resulting solution, 20 mL of the monotonic solution were added and poured into 10 cm diameter Petri dishes. The plates were placed in an exhaust hood for 24 h and then the thickness of the films was checked with a micrometer and their masses on a Shimadzu -ATX 224 analytical balance.

A.2 Preparation of type-B gelatin film with MB

2 mL of 0.05% MB was added to the surfaces of the type B gelatin films, Fig.2, with a pasteur pipet and the solution was left to immersion for 5 or 7 minutes. After that, samples were removed and kept in dark until the red laser irradiations.

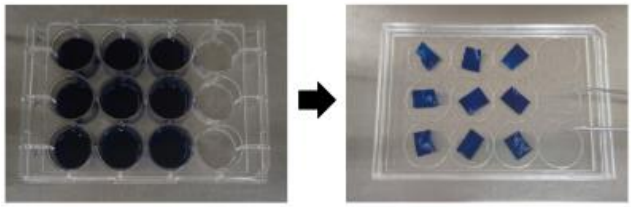

Fig.2. Immersion process of type B gelatin films in MB (0.05%).

B. Crosslinking of type-B gelatin film

B.1 Crosslinking of pure gelatin using EDC

EDC (148 g/mol) was used to prepare EDC-crosslinked type B gelatin films at a gel/EDC molar ratio of 1:1 by immersing the films in a solution of distilled water with EDC for 24 hours. Subsequently, the films were wrapped in greaseproof paper and left to dry in an exhaust hood for 24 hours.

B.2 Crosslinking of pure gelatin with UVC radiation

The crosslinking of twenty 4.7 x 1 cm gelatin samples was performed using a LucMat Lamp 20W/GL UVC (254 nm). For that, the samples were positioned in a support within a laminar hood flow, at 10 cm distance. The irradiation of the samples followed the time and dose parameters shown in Table 1.

TABLE I. Irradiation Parameters (UVC)

Sample	***UVC exposure***	***Dose (J/cm²)***
Type-B pure gelatin	10 min	0,0259
	30 min	0,0779

B.3 Crosslinking of MB-incorporated gelatin by red laser

The crosslinking of thirty 1,5 x 1,5 cm MB-incorporated gelatin films was performed using a red Laser (OrthoLase, DMC, Brazil, 660nm). For that, samples were placed in Petri dishes within a laminar hood flow, and the irradiations were performed according to the Table II.

TABLE II. Irradiation Parameters (Red Laser)

Sample	***Immersion time in the MB***	***Irradiation time with red laser***	***Dose (J/cm²)***
Type-B pure gelatin	5 min	10 min	0,7639
	7 min	15 min	1,1459
	7 min	20 min	1,5278

C. *Film Characterization*

C.1 Water Absorption Percentage

Three 1.5 × 1.5 cm samples from each group, were weighed to determine their initial mass (M0) and then immersed in distilled water for specific periods (0, 2, 4, 6, 8,

10, 15, 20, 25, 30, 40, 50, and 60 min). The samples were then dried, and their dry mass (Mt) was weighed again [16]. The water absorption rate was calculated using Equation 1.

$$Water\ Absorption\ Percentage = Mt - M0 / M0 \times 100\% \quad (1)$$

C.2 Mechanical Properties

Tensile testing was performed on a Tytron™ 250 Universal Testing Machine and TestWorks 4 software to obtain Young's Modulus, tensile strength, and elongation at break. An initial test length of 30 mm was used on a 250 N load cell at a speed of 5 mm.min-1.

III. Results and Discussion

The results of the water absorption indicated that the MB-incorporated gelatin films irradiated with red laser, Fig. 3, for an extended period exhibited greater resistance to water absorption. The 7-minute immersion period in the MB, followed by 20 minutes of red light, proved to be the most effective treatment for strengthening the gelatin film's bonds, as evidenced by the film's reduced water retention due to its stiffening. Gelatin exhibits low stiffness and unstable mechanical behavior in the presence of water [17]. The aqueous absorption test on gelatin films is recognized for contributing to the understanding of gelatin's polymeric behavior in an aqueous environment and the stability of biomaterials [18]. Pure gelatin contains hydrophilic amino acids with amino and hydroxyl groups in its structure, which in aqueous solutions tend to form hydrogen bonds with water molecules, promoting greater water incorporation into the polymer chains. The use of cross-linking agents in gelatin tends to reduce swelling by promoting covalent bonds that restrict polymer expansion [19]. These preliminary results obtained with MB and red light demonstrated the ability to alter the structural behavior of the gelatin film by reducing its swelling. Further chemical analyses should be conducted in this study to better understand the potential of MB's cross-linking mechanism on gelatin films.

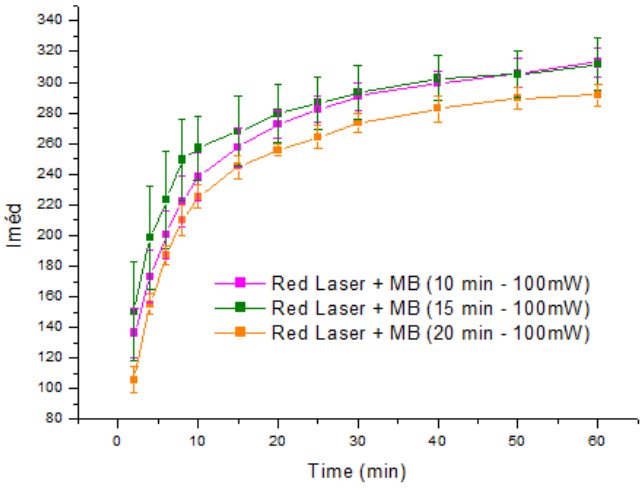

Fig.3. Percentage of water absorption for MB-incorporated gelatin after red laser irradiation. Bars indicate standard deviation.

However, to better understand these results regarding the percentage of water absorption, the degree of water absorption of type B gelatin films subjected to other traditional cross-linking methods was compared, Fig. 4. The results shown in Fig. 4 reveal that pure gelatin films exposed to UVC for 10 min and 30 min exhibited lower water repellency compared to MB incorporated gelatin films after red laser irradiation. While chemical crosslinking with EDC traditionally yields strong covalent bonds [7], PDT-treated films exhibited superior performance compared to UVC-crosslinked films.

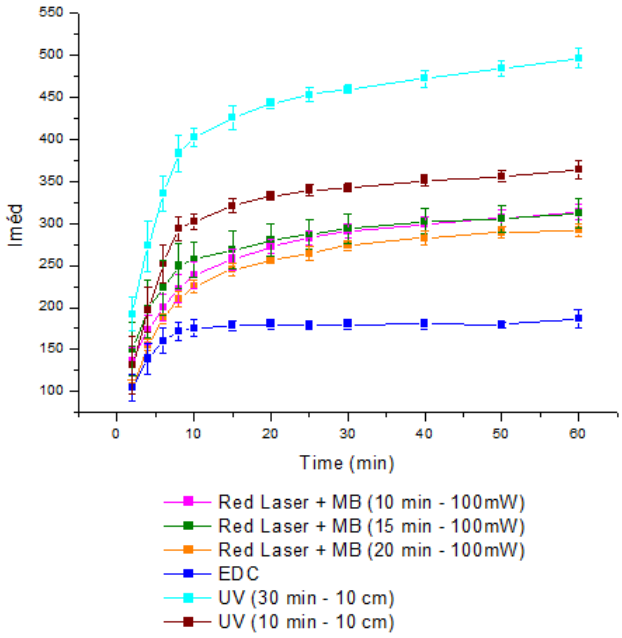

Fig. 4. Percentage of water absorption for all samples of this study. Bars indicate standard deviation.

Mechanical evaluation showed reduced stiffness in MB-incorporated samples following 20 minutes of irradiation, reflected by their elongation at break (Table III). Following this trend, the group crosslinked with EDC demonstrated the lowest stiffness. On the other hand, 30-minute UVC irradiation resulted in the highest elongation at break, showing a significant increase compared to neat gelatin samples.

Despite significant variations in stiffness, EDC-treated neat gelatin displayed significantly higher Young's modulus and tensile strength than any other experimental group. Mechanical analysis indicates that each crosslinking agent imparts distinct physical properties to gelatin, potentially enabling tailored clinical applications for the same biomaterial.

Literature demonstrates that the chemical and mechanical properties of gelatin hydrogels can be tailored for diverse applications. For instance, low-stiffness hydrogels-offering high flexibility- are ideal for injectable formulations, making them suitable for controlled drug delivery and soft tissue regeneration, such as skin and vascular tissues. Conversely, hydrogels with high mechanical strength are better suited for hard tissue engineering, including bone and dental applications.

Moreover, methylene blue-mediated photodynamic therapy using red laser light is well-established in clinical practice. These results highlight the potential for producing gelatin hydrogels with versatile applications by adjusting the light dose according to the intended clinical outcome.

TABLE III. MECHANICAL PROPERTIES OF ALL FILMS TESTED.

Groups	***Thickness (mm)***		***Young's modulus (MPa)***		***Tensile strength (MPa)***		***Elongation at break (%)***	
	Mean	SD	Mean	SD	Mean	SD	Mean	SD
Pure gelatin	0.12	0	1.04	0.73	0.16	0.10	48.46	37.57
Pure gelatin with EDC	0.16	0.03	7.17	4.09	2.25	1.60	30.93	17.79
Pure gelatin with 10 min UVC	0.13	0.01	1.11	0.14	0.31	0.14	36.26	11.24
Pure gelatin with 30 min UVC	0.14	0.01	0.97	0.08	0.65	0.36	84.20	48.61
Gelatin + MB and Red Laser (10 min)	0.13	0	0.49	0.09	0.19	0.07	44.93	23.25
Gelatin + MB and Red Laser (15 min)	0.13	0	0.58	0.02	0.22	0.21	40.53	34.86
Gelatin + MB and Red Laser (20 min)	0.13	0	0.78	0.41	0.10	0.04	19.50	3.41

The preliminary results presented in the characterization tests of type B gelatin films containing methylene blue and irradiated with a red laser suggest that photodynamic therapy using methylene blue and red laser has potential as a new cross-linking approach, that represents a highly adaptable methodology tailored to the researcher's requirements, with the added benefits of low cost, low toxicity and broad availability. However, tests to chemically understand and evaluate the structure of gelatin films must be conducted, in addition to cytotoxicity tests, to support further discussion. This study supports the view that methylene blue - an agent already widely used in antimicrobial photodynamic therapy and considered safe for in vivo applications [14] should also be further explored for the cross-linking of gelatin with a view toward tissue engineering in the biomedical field.

IV. CONCLUSION

This study revealed the promising potential of photo-crosslinking method for type B gelatin films. Further tests should be conducted to better understand the specifics of using methylene blue in the crosslinking process.

Abstract*—Vero cells, derived from African green monkey kidney epithelial cells and exhibiting a fibroblast-like morphology, these cells are widely used in biological research due to their stability and susceptibility to viral infection. These characteristics make them a valuable model for *in vitro* studies, including cytotoxicity and drug screening assays. Traditional two-dimensional (2D) cell culture systems, although well established, often fail to accurately reproduce the complexity of *in vivo* environments. In contrast, three-dimensional (3D) culture models, such as spheroids, better mimic cell–cell interactions, extracellular matrix deposition and physiological conditions. Among emerging 3D culture techniques, the hanging drop method, a microdroplet-based approach, enables the formation of scaffold-free cellular spheroids in a controlled microenvironment. This technique has gained attention for its simplicity, reproducibility, and ability to generate more physiologically relevant models for *in vitro* assays, including biomaterial testing. Furthermore, microdroplet-based systems show promising potential for integration with advanced platforms such as organ-on-a-chip technologies, which aim to replicate tissue-level functions *in vitro*. These combined approaches may, in the future, enhance the predictive accuracy of cytotoxicity and pharmacological studies. This study aims to obtain and characterize Vero cell spheroids using the hanging drop method. It enables the evaluation of their interaction with biological systems, including cytotoxicity and biological evaluation assays, expanding the potential application in biomaterial assessment, contributing to the advancement of 3D *in vitro* models in biomedical research. The results demonstrated the formation of compact and structurally stable Vero cell spheroids after 7 and 21 days of culture, with preserved morphology and nuclear integrity after post-processing.

Keywords— Vero cells, cell culture, In Vitro, Hanging Drop, Organ-on-a-chip.

I. INTRODUCTION

Vero cells are a continuous cell lineage derived from the kidney epithelial cells of the African green monkey (*Cercopithecus aethiops*) (ATCC CCL-81). Due to their robustness, ease of maintenance in culture, and high susceptibility to viral infection, these cells are widely used in biomedical research, particularly in virology, toxicology and vaccine development studies [1], [2]. Their permissiveness to viral replication and adaptability to different experimental conditions make them a reliable in vitro model for cellular and molecular investigations and an attractive candidate for the development of advanced three-dimensional culture systems.

Cell culture techniques play a fundamental role in experimental biology by enabling controlled investigation of cellular behavior under defined conditions [3]. Conventional two-dimensional (2D) monolayer cultures remain the most widely used model because of their simplicity, reproducibility, and low operational cost. However, their inability to reproduce the complex cell–cell and cell–extracellular matrix interactions found in native tissues limits their physiological relevance and predictive capacity [4], [5]. These limitations have driven the development of three-dimensional (3D) culture systems, which more closely mimic the architecture, organization, and biological responses observed in vivo [4]–[6].

Among the available 3D culture models, multicellular spheroids have attracted considerable attention because they reproduce key structural and functional characteristics of native tissues, including enhanced cell–cell interactions, extracellular matrix deposition, and physiological gradients [7], [8], [24]. Consequently, spheroids have emerged as physiologically relevant models for cytotoxicity assessment, tissue engineering, and biomaterial testing [6], [9]. Their application in biocompatibility assessment is particularly relevant, as the biological evaluation of biomaterials remains an essential step in the development of biomedical devices and regenerative medicine strategies [3], [21], [22], [25].

Among the different methods available for spheroid generation, the hanging-drop technique stands out as a simple, scaffold-free, and highly reproducible approach [11]–[13]. In this method, cells are suspended in microdroplets, promoting spontaneous aggregation through gravitational forces and enhanced cell-cell interactions. This strategy enables the formation of compact and structurally organized spheroids that more closely resemble physiological tissue microenvironments [11], [21], [22]. In addition, recent advances have demonstrated that hanging drop-based microdroplet systems can be integrated with microfluidic platforms, allowing controlled perfusion, nutrient exchange, and real-time monitoring of three-dimensional spheroids [13], [14].

Microfluidic and organ-on-a-chip technologies have emerged as promising tools for the development of

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

microphysiological systems capable of reproducing tissue architecture and biological responses under controlled conditions [15]–[19]. These platforms combine microfluidic, cell biology, and engineering to stimulate relevant microenvironments, including fluid flow, shear stress and cellular interactions [20]–[23]. Such characteristics have contributed to the increasing application of organ-on-a-chip devices for drug development and biomaterial testing, offering improved predictive capacity, reduced costs, and decreased reliance on animal models [15], [16], [18].

Despite the significant advances in three-dimensional culture systems and organ-on-a-chip technologies, studies describing the long-term generation and morphological characterization of Vero cell spheroids using the hanging-drop method remain scarce, particularly regarding their potential integration into microfluidic platforms [23].

Therefore, this study aimed to generate and characterize Vero cell spheroids using the hanging-drop method as a reproducible three-dimensional in vitro platform for biomaterial biocompatibility and cytotoxicity assessment, with potential future integration into microfluidic and organ-on-a-chip systems. By establishing a simple and reproducible protocol for long-term spheroid culture, this work provides a foundation for the development of advanced three-dimensional in vitro models and microphysiological systems.

II. Methodology

A. Vero Cells Cultivation

Vero cells (CCIAL 057) were cultivated in HAM F10 medium supplemented with 10% fetal bovine serum (FBS) and maintained at 37 °C in a humidified atmosphere containing 5% CO_2 [1]. The culture medium was replaced twice weekly, and cell passaging was performed when cultures reached a confluent monolayer. Cell growth and morphology were monitored by phase-contrast microscopy using an inverted microscope (Axio Vert A1, Zeiss). This cell line is widely used as a standard model for cytotoxicity assessment and cellular response studies [25], [26].

B. Hanging Drop Microdroplet Culture Method

Spheroids were generated using the hanging-drop microdroplet technique. A cell suspension obtained from 7 and 21-day Vero cell cultures was dispensed onto the lid of a Petri dish as individual droplets. The dish was then inverted, allowing gravitational forces to promote cell sedimentation and aggregation at the lowest point of each droplet [11]–[13].

C. Spheroid Characterization

After spheroid formation by the hanging-drop method, samples were initially examined by direct and phase-contrast microscopy. For additional microscopic evaluation, selected droplets containing spheroids were transferred onto glass coverslips, and 5 µL of glutaraldehyde 2,5% solution was added to each droplet for cell fixation. After a 10-minute fixation period, the samples were washed to remove residual fixative and prepared for subsequent microscopic analyses. Subsequently, spheroids were stained with 4′,6-diamidino-2 phenylindole (DAPI) and analyzed by fluorescence microscopy.

Spheroids were visualized using a light microscope (Axio Vert A1, Zeiss) and a fluorescence microscope (Axio Imager A2, Zeiss).

III. Results and Discussions

Vero cell spheroids were obtained using the hanging-drop method with cells at passage numbers below 160. Each droplet had a final volume of 25 µL and contained cells at a density of 8×10^5 cells/mL, corresponding to approximately 20,000 cells per droplet. The droplets were then seeded into two separate Petri dishes and cultured for 7 days (Fig. 1a) and 21 days (Fig. 1b), respectively.

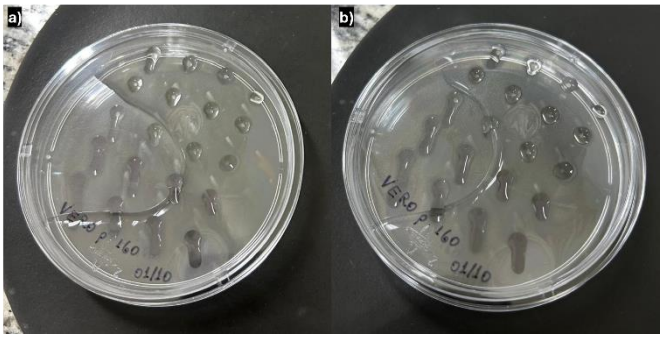

Fig. 1 Petri dishes with Vero cell hanging droplets spheroids cultures: a) 7 days; and b) 21 days.

Subsequently, the samples were analyzed using different imaging techniques: brightfield light microscopy (Fig. 2), phase-contrast microscopy (Fig. 3), and fluorescence microscopy stained with DAPI (Fig. 4).

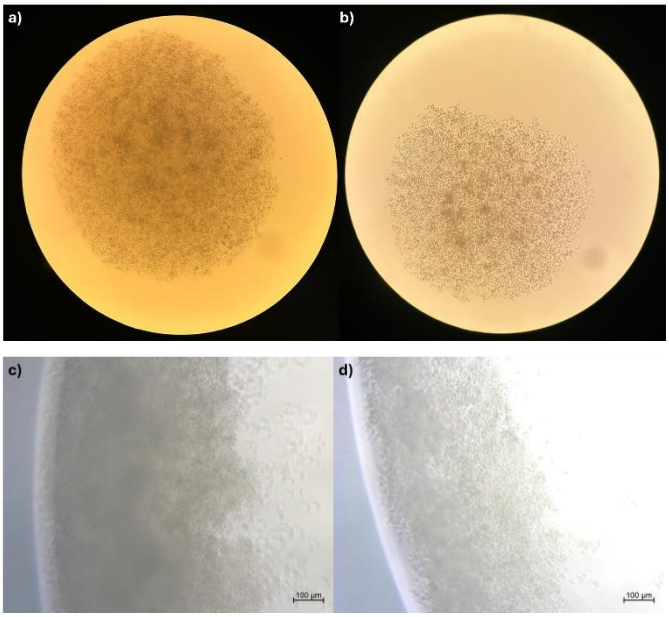

Fig. 2 a,b Direct light microscopy. Vero cells cultivated for a) 7 days; and b) 21 days. Magnification 100x; c,d Light microscopy, phase-contrast. Vero cell cultivated for c) 7 days; and d) 21 days. Magnification 400x.

Spheroid morphology was monitored using brightfield light microscopy (Figure 2a and 2b), allowing for the evaluation of spheroid formation compaction and cellular integrity throughout the 7-day (Fig. 2a) and 21-day (Fig. 2b) culture periods.

Figure 2c and 2d display Vero cell spheroids after 7 days of cultivation using phase-contrast microscopy. The images reveal the emergence of compact, spherical aggregates that conform to the geometry of the microdroplet. This morphology confirms successful spheroid condensation and consistent maintenance of the 3D structure over the cultivation period. The cells exhibit high affinity for one

another, forming stable structures that reflect the micro-confinement of the droplet environment.

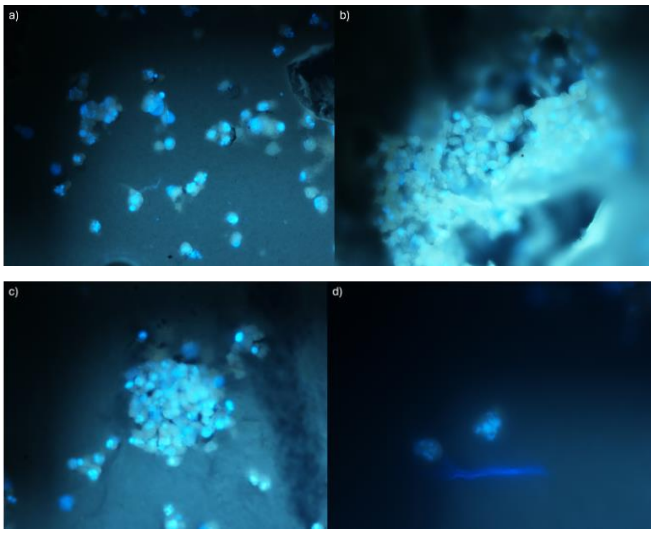

Fig. 4 Fluorescence microscopy with DAPI staining. Vero cell spheroid cultured for: a,b) 7 days; and c,d) 21 days. Magnification 400x.

Fluorescence microscopy with DAPI staining (Figure 4) was employed to evaluate cell nucleus. The images demonstrate well-defined nuclear DNA throughout the spheroid, with no evidence of fragmented DNA or extracellular debris.

Furthermore, the structural resilience of the spheroids was evaluated during post-processing. Upon inversion of the culture plate, the microdroplets spread due to gravitational forces and lost their initial spherical geometry. Nevertheless, the cellular aggregates remained intact, indicating that spheroid integrity was maintained independently of droplet confinement. This observation demonstrates that stable cell–cell interactions had already been established during culture, allowing the aggregates to preserve their three-dimensional architecture despite the loss of external physical support. Such behavior is consistent with the hanging-drop technique, in which gravity-driven cell sedimentation and the absence of substrate adhesion promote spontaneous cellular self-assembly into compact and reproducible spheroids while minimizing mechanical stress during formation [10], [11], [27]. The preservation of spheroid integrity after post-processing is particularly relevant because mechanically stable aggregates are less susceptible to disruption during routine procedures, including medium replacement, staining, imaging, and downstream biological assays [4], [12].

The progressive compaction observed after both 7 and 21 days, together with the preservation of nuclear integrity demonstrated by DAPI staining, further indicates successful spheroid maturation and sustained cellular viability. As spheroids mature, enhanced intercellular adhesion and cytoskeletal organization contribute to increased mechanical stability and structural cohesion, allowing the aggregates to better reproduce the cellular organization and microenvironment found in native tissues than conventional monolayer cultures [4], [6], [7]. The maintenance of spheroid morphology throughout the 21-day cultivation period further demonstrates the suitability of the proposed culture conditions for prolonged three-dimensional growth. Long-term structural stability is particularly advantageous for experimental models requiring extended observation periods, repeated analyses, and chronic biological assays [12]. Moreover, the compact organization observed in the present study agrees with previous reports showing that hanging-drop cultures produce homogeneous spheroids [10], [11], [27].

Vero cells are extensively used in virology owing to their robust proliferative capacity, broad susceptibility to viral infection, and adaptability to different culture conditions [1], [2]. The successful generation of compact and viable Vero spheroids observed in this study therefore reinforces the applicability of this well-established cell line to more physiologically relevant three-dimensional models. Previous studies have shown that Vero cell spheroids improve the evaluation of host–pathogen interactions and increase the sensitivity of biological assays when compared with conventional monolayer cultures [3], [23]. Collectively, these findings demonstrate that the hanging-drop protocol provides a simple strategy for producing structurally stable Vero cell spheroids suitable for future long-term culture, antiviral screening, virus production, and other advanced *in vitro* applications [10]–[12], [23].

The ability to maintain structurally preserved spheroids for up to 21 days demonstrates the efficacy of the proposed protocol and highlights its potential for long-term *in vitro* studies requiring repeated experimental manipulation. Although the present study successfully demonstrates the formation and morphological characterization of Vero cell spheroids, additional functional analyses, including metabolic activity, proliferation, cell viability, quantitative measurements of the spheroids, will be necessary to further validate this model for specific biomedical applications.

IV. Conclusion

This study successfully demonstrated the generation and characterization of 3D Vero cell spheroids using the hanging-drop method. The proposed scaffold-free protocol enabled the formation of compact, structurally stable cellular aggregates that maintained their morphology and nuclear integrity throughout the cultivation period, including after post-processing. These findings establish a simple, and low-cost strategy for generating long-term Vero cell spheroids, providing a reliable three-dimensional *in vitro* model for future biological investigations.

Future studies should focus on the functional characterization of these spheroids and their integration into microfluidic organ-on-a-chip platforms to develop more physiologically relevant models for biological research, cytotoxicity and biomaterial interactions. In addition, the proposed that the culture system may serve as a promising platform for biomaterial evaluation and, potentially, for applications in tissue engineering and regenerative medicine.

***Abstract*—Osteochondral injuries pose a significant clinical challenge due to the structural and functional complexity of the interface between articular cartilage and subchondral bone. In this context, various strategies based on 3D biomanufacturing and bioprinting have been explored with the aim of developing biomimetic constructs for Tissue Engineering. Among the main challenges associated with extrusion-based bioprinting is the development of bio-inks with appropriate rheological properties, structural stability, and cytocompatibility. The objective of this study was to develop and characterize gelatin/carrageenan-based bioinks incorporating hydroxyapatite, with a view toward future applications in biofabricated systems for osteochondral regeneration. The formulations were prepared with different concentrations of hydroxyapatite and evaluated for their rheological properties using viscosity and thixotropic recovery tests, investigating parameters related to printability and pseudoplastic behavior. Additionally, the formulations underwent preliminary evaluation of extrusion and structural fidelity. Furthermore, FTIR spectroscopy and X-ray diffraction (XRD) analyses were performed to investigate the interaction between the ceramic phase and the polymer matrix.Finally, the cytocompatibility of the bioinks will be investigated via cell viability assays over different culture periods. It is expected that the incorporation of hydroxyapatite will promote changes in the properties viscoelastic materials for the development of bioactive formulations with potential application as a mineralized phase in osteochondral biofabrication strategies.**

I. Introduction

Lesions of the osteochondral tissues represent one of the greatest therapeutic challenges in modern orthopedics, significantly affecting the quality of life of millions of people worldwide. Characterized by the simultaneous degeneration of articular cartilage and subchondral bone, these lesions have a low capacity for spontaneous regeneration, largely due to the avascular nature of cartilage and the complexity of the osteochondral interface. It is estimated that, globally, more than 250 million people suffer from degenerative joint diseases, such as osteoarthritis, which are often exacerbated by failures in osteochondral tissue regeneration[1]. In this context, various strategies based on tissue engineering and biomanufacturing have been extensively explored for the development of biomimetic structures capable of promoting tissue regeneration. To enable the fabrication of these customized and hierarchical architectures, biomaterials are selected based on the need to balance mechanical support and cellular bioactivity. Among the biomaterials most commonly used in the fabrication of scaffolds for bone applications, ceramics,such as hydroxyapatite (HAp), calcium phosphates, and bioglasses,stand out, as do natural polymers, including alginate, chitosan, and gelatin [2, 3].Among manufacturing approaches, extrusion bioprinting stands out for its ability to produce three-dimensional structures containing cells and biomaterials with controlled geometries. However, the success of this process depends directly on the physicochemical and

rheological properties of the bioinks, which must exhibit appropriate extrusion behavior, structural stability, and cytocompatibility. In the field of bioprinting, the development of polymeric bioinks plays a fundamental role in the construction of biomimetic cellular microenvironments, particularly hydrogels based on natural polymers. In this context, the combination of gelatin and i-carrageenan offers complementary properties that favor its application in tissue engineering. While i-carrageenan offers gelling capacity and structural similarity to glycosaminoglycans present in the extracellular matrix, gelatin provides bioactive RGD-type sequences that promote cell adhesion and interaction [4, 5].On the other hand, hydroxyapatite is the main inorganic component of human bones and, therefore, serves as an excellent additive for hydrogels in bone tissue engineering. Thus, on its own, HAp can promote adhesion, proliferation, and extracellular matrix deposition by osteoblasts[6, 7]. Thus, the combination of these two polymers generates a polysaccharide-protein hybrid network capable of forming gels under physiological conditions, balancing mechanical support, cellular bioactivity, and potential rheological adjustment for applications in 3D bioprinting. Thus, the objective of this study is to develop and characterize gelatin/carrageenan-based bioinks containing hydroxyapatite, investigating the influence of the ceramic phase on rheological properties and initial cell viability, with a view toward future applications in biofabricated systems for osteochondral regeneration.

II. METHODOLOGY

A. Gel inks preparation

Bioinks delopment were based on gelatin/carrageenan systems , with a focus on the study and influence of hydroxyapatite [8, 9]. To this end, gelatin- and carrageenan-based bioinks were prepared by dissolving the polymers in DMEM/PBS under magnetic stirring and temperature control. After complete solubilization, different concentrations of hydroxyapatite (HAp) were incorporated into the polymer matrix to obtain mineralized bioactive formulations. The formulations will be divided into:

- GC: gelatin/carrageenan (control)
- HAp 0.2%: gelatin/carrageenan + 0.2% HA
- HAp 2%: gelatin/carrageenan + 2% HA
- HAp 20%: gelatin/carrageenan + 20% HA

B. Rheological tests

the rheological characterizations of the bionks were conducted to understand the the viscoelastic properties relavant to controlled extrusion and deposition. the tests were conducted on an anton paar MCR102 rotational rheometer using a plate-plate geometry (PP25, 25 mm, 0.7 mm gap) at 25 °C. To prevent slippage along the walls and ensure reliable data acquisition at high shear rates (1000 s^{1}), the geometry surfaces were roughened using fine-grit sandpaper (P600), the surfaces of the geometry were modified using fine-grit sandpaper (P600). This technique increases surface roughness, preventing material displacement and ensuring effective stress transfer. Thus, viscosity curves (0.01–1000 s^{1}) and amplitude sweeps (0.1, 1.0, 10 rad s^{1}, LVE = 0.02) were used to determine structural integrity during printing. Frequency sweeps (0.1–300 rad s^{1}) investigated the response of the ink. Three-stage recovery tests simulated behavior during and after deposition: pre-shearing (1 s^{1}, 30 s), rest (1 s^{1}, 25 s), shearing (10 s^{1}, 50 s), and regeneration (1 s^{1}, 250 s)[10, 11]. All rheological measurements were performed in duplicate

C. Extrusion-Based 3D printing

Initially , the 3D extrusion-based from 593ICAN LTDA (Brazil) was tested using Hap 20% ink which served as the ink with the ideal viscosity. The printing speed was set to 10 mm s^{1} using conical nozzles with inner diameters of 20 gauge (580 µm) and 22 gauge for the higher-viscosity hydrogels and using repetier-Host V2 1.3 software, to compare the printed geometries. G-code files containing the printing paths were generated using BioScaffoldsPg software [11].

D. Structural/Physical-Chemical Characterization

The characterization of biomaterials was conducted using a set of physicochemical and structural techniques to evaluate the properties essential for bioprinting and the functional performance of the scaffolds. The structural stability of hydroxyapatite and the integrity of the crystalline phases in the bioprinted scaffolds were evaluated by X-ray diffraction (XRD) on an Aeris (Malvern Panalytical), with a 2 scan from 10° to 80° (continuous mode, 0.02°/s) and indexing via HighScore software. The focus will be on detecting possible crystallographic changes or interactions resulting from the association with the gelatin/-carrageenan hydrogel In addition, Fourier-Transform Infrared Spectroscopy (FTIR) was performed using a PerkinElmer Spectrum 100 instrument (diamond crystal), with 16 scans between 4000–550 cm^{1} and a resolution of 4 cm^{1}.

E. Cell Viabillty

To assess the potential cytotoxicity of the formulations, L929 mouse fibroblast-like cells (BCRJ Cell Bank, code 0188, NCTC clone 929) were cultured in the presence of each gel formulation. Cells at the 28th passage were seeded into 96-well plates at a density of 1 × 10 cells per well and cultured in DMEM under a humidified atmosphere containing 5% CO_2 at 37 °C for 24 h.

After this period, the culture medium was replaced with 100 µL of fresh medium, and 100 µL of gel was added to each well. Cells were incubated under the same conditions for an additional 24 h. Subsequently, the gels were removed, and the wells were washed twice with PBS to eliminate residual material.Next, 100 µL of MTT solution [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] (Thermo Fisher Scientific, USA) at a concentration of 0.5 mg mL^{1} was added to each well and incubated for 4.5 h. The MTT solution was then removed and replaced with 100 µL of dimethyl sulfoxide (DMSO) to dissolve the formed formazan crystals. Absorbance

was measured at 540 nm using a microplate reader (LMR-96, Loccus, Brazil).Cell viability was determined by comparing the absorbance values of the samples with those of the negative control, consisting of a alumina phosphate extract prepared according to ISO 10993-5 and known to be non-cytotoxic. DMSO (20%) and Triton X-100 (1%) diluted in DMEM were used as positive controls. Data are presented as the mean of eight replicates.

III. Results and Discussion

A. Rheological tests

In the development of a gelatin/ -carrageenan polymer blend as a matrix for a chondral bioink the influence of the gradual incoporation of the hydroxyapatite (HAp) was rheological behavior of the systematically evaluated. All formulations shown in Figure 1 exhibited shear-thinning behavior, characterized by a decrease in viscosity with increasing shear rate profile typical of polymeric systems intended for extrusion bioprinting. This behavior is consistent with the literature on polymeric hydrogels, in which the continuous matrix phase dominates the flow profile ,even after the incorporation of solid phases. [9, 12, 13]. Thus, moderate variations in HAp content resulted in slight changes in viscosity without compromising the shear-thinning behavior of the formations. Formulations containing 6% gelatin and 0,3% -carrageenan, combined with different concentrations of HAp (0; 0.2; 2, and 20% m/v), with the aim of identifying a range of ceramic content capable of providing structural reinforcement without compromising the system's extrudability or causing clogging of the print nozzle, a critical aspect for biomanufacturing applications([12, 14]. Formulations containing 20% HAp exhibiting the highest resistance to flow across the entire range of shear rates evaluated. In contrast , the formulations containing 0.2% and 2% exhibited rheological behavior similar to that of the control,suggesting that low concentrations of the ceramic phase were insufficient to promote a significant increase in resistance to flow, this indicate that,within this concentration range, the polymer matrix still dominates the flow, and the ceramic phase acts primally as a dispersed filler without significantly altering the shear-thinning behavior-a phenomenon also observed in the other polymer hydrogels with low HAp contents . finally, the increase in viscosity observed for the formulation containing 20% HAp suggets a structural reinforcement effect promoted by the ceramic phase, possibility associated with the restriction of polymer chain mobility and increased physical interactions among the matrix components. [14, 15].in addition interactions may occur between the sulfate groups of the carrageenan,and calcium ions present on the surface of hydroxyapatite , contributing to the formation of a more stabile structural network[16] In the time-recovery test (3ITT) , all formulations shown in figure 2 exhibited thixotropic behavior with rapid recovery , as evidenced by the abrupt decrease in viscosity during high-shear application, followed by partial recovery on the structure upon returning to low-shear conditions.In the first stage of the test , conducted at a low strain rate ,a progressive increase in viscosity was observed as

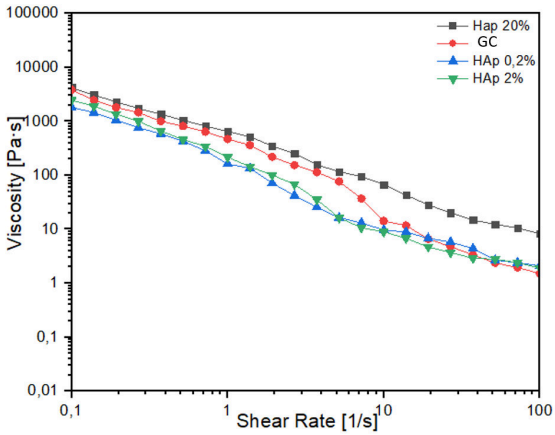

Fig. 1. – Shear-thinning behavior of control and HAp formulations at different concentrations.

the HAp content increased; formulation containing 20% HAp exhibited the highest initial viscosity initial viscosity values, indicating greater structural organization at rest. Subsequently, during the high-shear stage, all formulations underwent a sharp decrease in viscosity, a behavior associated with the reversible breakdown of the physical interactions responsible for the stability of the polymer network. [14, 17].The formulation containing 20% Hap exhibited the highest initial viscosity values, indicating greater structural organization at rest. However, during the high-shear stage, all formulations underwent a sharp decrease in viscosity, a behavior associated with the reversible breakdown of the physical interactions responsible for the stability of the polymer network. In this regard, the formulation containing 20% HAp maintained a higher residual viscosity than the other formulations even under high shear, suggesting greater structural resistance to flow-induced disorganization [18, 19]. In contrast, the formulations containing 0.2% and 2% HAp exhibited behavior more similar to that of the control, indicating that reduced concentrations of the ceramic phase had a limited influence on resistance to structural collapse. On the other hand, this range of formulations with low rheological perturbation relative to the pure matrix is useful for incorporating cells and biomolecules, whereas 20% maximizes structural support [14, 17, 20]. After the high shear was discontinued, a gradual recovery in viscosity was observed for all samples, demonstrating the hydrogel's three-dimensional network's ability to partially reconstruct itself. The initial increase in viscosity and greater recovery observed for the formulation containing 20% HAp in this study suggest the formation of a more interconnected particulate network, capable of sustaining the structure even after temporary disruption under flow. suggesting that high concentrations of HAp contributes to increased structural stability and post-shear recovery capacity of the formulations, while maintaining thixotropic behavior suitable for applications in extrusion bioprinting[14].

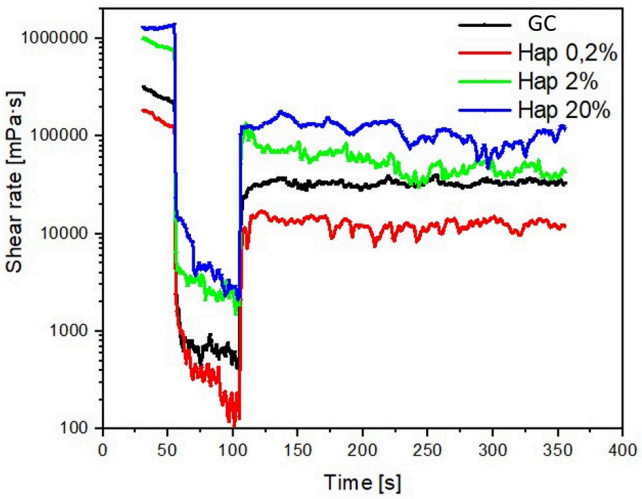

Fig. 2. Temporal recovery of viscosity (3ITT) for formulations with different hydroxyapatite concentrations.

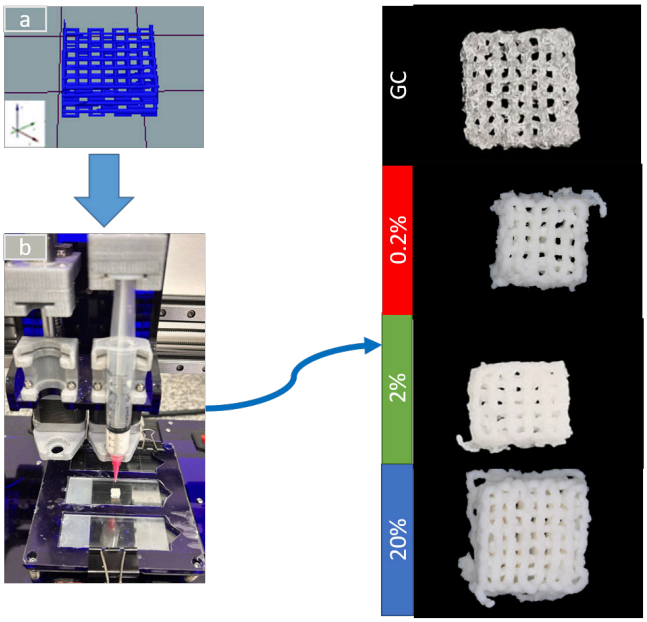

Fig. 3. CAD design, bioprinting process, and printed structures with varying hydroxyapatite concentrations.

B. Printed scaffolds and morphology

The scaffolds were fabricated by layer-by-layer deposition of hydrogels, based on the previously defined CAD model. Before fabricating the final samples, printing parameters—such as deposition speed, extrusion pressure, extrusion ratio, and porosity—were systematically optimized to obtain structures with high fidelity to the digital model and adequate structural integrity. The results of this optimization process are shown in Figure 3A–C.

C. Structural/Physical-Chemical Characterization

The FTIR spectra of the formulations containing gelatin/carrageenan and different concentrations of the ceramic phase are shown in Figure 3. Characteristic bands of both the polymer matrix and the organic material are observed, indicating the coexistence of the components and possible intermolecular interactions between them. Similar patterns of Amide I/II and sulfate bands have been described in gelatin/carrageenan gels, where subtle shifts are associated with the formation of polyelectrolyte complexes between the protein and the sulfated polysaccharide; Due to the conformational reorganization of gelatin in the control samples and those with lower ceramic content, broad bands are observed in the region between 3200–3400 cm¹, which are attributed to the stretching of hydroxyl O-H/N-H groups and are consistent with the FTIR spectra of gelatin[21, 22]. Which are characteristics of both gelatin and carrageenan, associated with the hydrogen bonds present in the hydrogel matrix. In the region between 1600–1500 cm¹, bands associated with the amide groups of gelatin—especially type I and type II—are observed; these are associated with the C=O and N-H groups in the protein structure of gelatin. Meanwhile, the region between 1220–1260 cm¹ may be associated with the sulfate groups (S=O) of carrageenan[21–24]. As the hydroxyapatite content increased, particularly in the formulation containing 20 wt%, a progressive increase in the intensity of the absorption bands between 900 and 1100 cm¹ was observed. This spectral region is mainly associated with the asymmetric stretching vibration of phosphate (PO^3) groups, characteristic of hydroxyapatite. The higher intensity of these bands reflects the increased contribution of the ceramic phase to the composite spectrum and confirms the successful incorporation of hydroxyapatite into the polymeric matrix. The absence of significant band shifts suggests that the primary chemical structures of the polymer components were preserved after ceramic incorporation, while the intensity changes are predominantly related to the higher concentration of phosphate groups in the formulations. [25, 26]. This behavior indicates a greater contribution of the inorganic phase to the spectrum and suggests good incorporation of the ceramic particles into the polymer matrix. The sample containing 20% exhibited significantly more intense and well-defined bands, especially near 1000 cm¹, indicating a predominance of vibrations from the mineral phase. The increase in the intensity of these bands may be associated with the greater number of available phosphate/ groups, as well as with increased interfacial interaction between the ceramic and the hydrogel polymers.In addition, Figure 4 shows the diffractograms of the starting materials, highlighting the striking differences in their structural organization. Gelatin exhibited a diffuse halo centered at approximately 20°, which is characteristic of predominantly amorphous materials and is consistent with the molecular disorganization expected following the partial denaturation of collagen. Unlike gelatin, carrageenan exhibits a semicrystalline pattern characterized by the coexistence

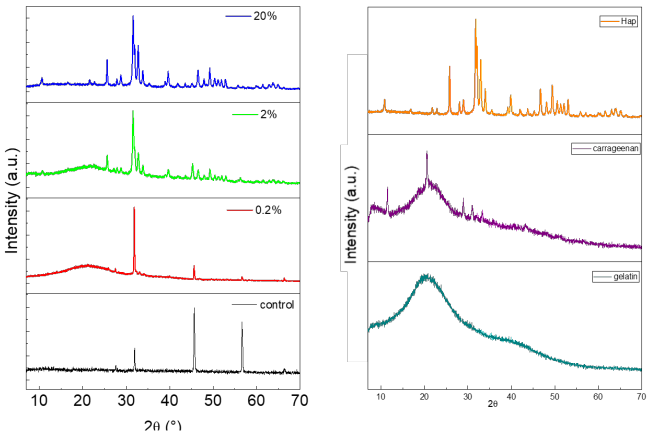

Fig. 4. XRD patterns of composite samples with varying hydroxyapatite contents (left) compared to reference crystalline phases (right).

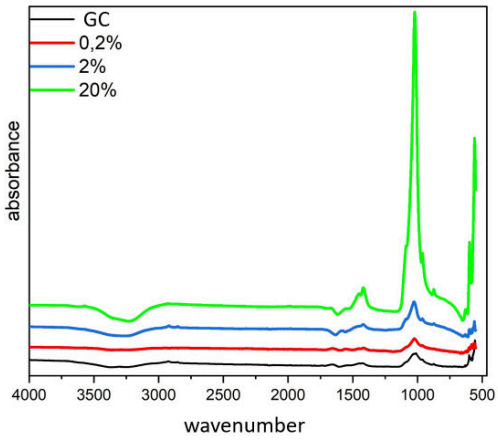

Fig. 5. FTIR spectra of control and hydroxyapatite-containing formulations at different concentrations.

of an amorphous halo with discrete reflections distributed throughout the diffractogram (15°, 24°, 33°, 34°)[27, 28]. This behavior stems from the partial organization of the galactan chains into helical structures capable of forming junction domains stabilized by intermolecular bonds and electrostatic interactions. In contrast, hydroxyapatite exhibited a highly crystalline diffraction pattern, with intense reflections at the peaks of 25.9°, 31.8°, 32.9°, 34.1°, 39.8°, and 46.7°, respectively, consistent with the hexagonal structure typical of stoichiometric hydroxyapatite[6, 16, 29]. In the case of hydrogels, it is possible to see how a gradual increase in the concentration of the mineral phase led to a significant increase in the intensity of the crystalline reflections associated with hydroxyapatite, while maintaining the characteristic amorphous halo of the polymer matrix. This behavior indicates that the incorporation of the ceramic phase increases the crystalline fraction of the system without substantially altering the predominantly amorphous nature of the gelatin/carrageenan blend[30].

These structural differences suggest that, when combined, the three constituents may perform complementary functions in the bio-ink formulation. While the predominantly amorphous nature of gelatin promotes chain mobility and the formation of a continuous polymer network, the semicrystalline organization of carrageenan contributes to the formation of junction zones responsible for increasing the hydrogel's structural stability. At the same time, the high crystallinity of hydroxyapatite provides a stable inorganic phase, which is potentially capable of acting as a mechanical reinforcing agent and providing sites for interactions with the polymer matrix, in addition to imparting bioactivity to the formulation. Together, these structural characteristics provide a favorable basis for the development of bioinks for bone tissue engineering, in which the balance between structural stability, rheological properties, and bioactivity is essential for performance during printing and tissue regeneration.

D. Cell Viabillty

MTT assays were performed to determine the percentage of viable cells adhering to the hydrogel samples (fig 6). the results showed that the number of viable cell onto the systems of gelatin/carragenaan. Preliminary cell viability results obtained by the MTT assay demonstrated that all gelatin/i-carrageenan hydrogels containing different concentrations of hydroxyapatite (Hap) exhibited high cytocompatibility toward L929 fibroblast-like cells, indicating that the incorporation of the ceramic phase did not induce detectable cytotoxic effects under the experimental conditions evaluated [31–33]. Among the investigated formulations, the hydrogel containing 2 wt% HAp exhibited the highest metabolic activity, consistent with previous studies reporting that low to moderate HAp contents may enhance cellular metabolic activity while maintaining high cell viability [8, 34, 35]. Although the formulation containing 20 wt% HAp showed a lower metabolic response than the 2 wt.% HAp group, cell viability remained within a range considered compatible with tissue engineering applications, suggesting that even highly mineralized formulations can be well tolerated when the ceramic phase is homogeneously incorporated into the polymeric matrix[36–38]. Collectively, these preliminary findings indicate that hydroxyapatite can be successfully incorporated into the gelatin/-carrageenan hydrogel without substantially compromising cytocompatibility, reinforcing the potential of this biomaterial platform for future applications in extrusion-based 3D bioprinting and osteochondral tissue engineering[39–41] .

IV. Conclusion

This study investigated gelatin/-carrageenan hydrogels containing increasing concentrations of hydroxyapatite to establish the relationship between ceramic content, physicochemical structure, rheological behavior, and biological response. ATR-FTIR analyses confirmed the successful incorporation of hydroxyapatite into the polymeric network while preserving the

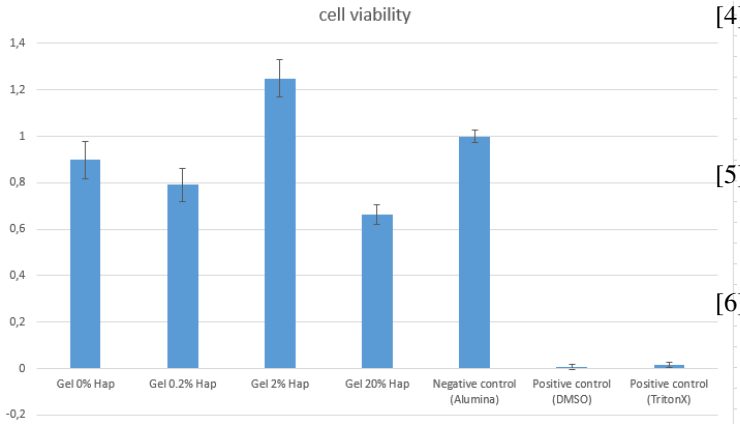

Fig. 6. MTT assay results showing cytotoxicity and cell viability of hydrogels containing varying hydroxyapatite contents compared to controls.

characteristic functional groups of both polymers. Structural characterization demonstrated that increasing hydroxyapatite content enhanced the contribution of the mineral phase without compromising the integrity of the hydrogel matrix. Rheological analyses revealed that the ceramic phase significantly influenced the viscoelastic behavior of the formulations, leading to improved mechanical stability and printability. Furthermore, the biological assays demonstrated that the developed composite hydrogels supported cellular viability, indicating good cytocompatibility. Overall, the formulation containing an optimized hydroxyapatite content exhibited a balanced combination of structural integrity, rheological performance, and biological properties, highlighting its potential as a bioink for bone tissue engineering applications.

Abstract*— This study evaluated the potential of a multi-component, thermoresponsive hydrogel framework, designated as SMARTGELP, to serve as a biomimetic matrix for neural tissue engineering applications within an in vitro oxidative stress model relevant to ischemic neural injury. Viscoelastic properties and the dynamic gelation temperature (T_{gel}) were characterized via dynamic oscillatory rheology, while human neuroblastoma cells (SH-SY5Y) were seeded onto the matrix to evaluate 3D cellular metabolic activity and morphological distribution via resazurin reduction assays and inverted phase-contrast microscopy, and were encapsulated within the matrix to evaluate the modulation of hydrogen peroxide-induced oxidative stress via flow cytometry using the CellROX® Orange fluorogenic probe. Rheological characterization indicated a dynamic sol-gel transition at 32 °C and a storage modulus (G') of approximately 740 Pa at 37 °C, yielding a value close to the range reported for brain tissue stiffness in the literature. Metabolic evaluation via resazurin reduction demonstrated that metabolic activity remained above 95% of the negative control at 24 and 48 hours, displaying stable, controlled 3D kinetics (97% to 103%) compared to the accelerated metabolic activity of standard 2D cultures. Morphological analyses revealed the initial establishment of dense 3D cellular clusters at 24 hours, which transited into a more diffuse state at 72 hours, tracking the progressive physical restructuring and controlled erosion of the hydrogel network over time. Furthermore, flow cytometry quantification demonstrated a symmetrical retraction of the population curves under acute injury conditions, with the SMARTGELP matrix maintaining lower baseline oxidative activation parameters (ROS(%) of 4,28% at 24 hours and 5,40% at 72 hours) compared to the positive controls. The convergence of these rheological, morphological, and biochemical indicators suggests that the design of the SMARTGELP architecture can address multiple parameters of structural support, mechanical compliance, and redox baseline maintenance, indicating its potential for further investigation as an in vitro oxidative stress model relevant to ischemic neural injury.

Keywords*— *neural tissue engineering, thermoresponsive hydrogel, SMARTGELP, SH-SY5Y cells, mechanical compliance, oxidative stress modulation.

I. INTRODUCTION

Neural tissue engineering constitutes a major area of regenerative medicine, focusing on the functional restoration of the central nervous system (CNS) following injuries such as ischemic stroke, traumatic brain injury, or neurodegenerative diseases [1]. Ischemic stroke, which accounts for more than 80% of all stroke cases worldwide, triggers a devastating pathological cascade in the ischemic penumbra [2]. This process is initiated by an abrupt reduction in blood flow and an immediate failure of anaerobic glycolysis, which disrupts transmembrane ion pumps and leads to severe bioenergetic collapse [2], [3]. Importantly, this homeostatic disorder forces a massive extracellular accumulation of glutamate, inducing catastrophic neuronal death through the overstimulation of ionotropic receptors and calcium overload [2]. Concomitantly, this cascade stimulates the excessive production of reactive oxygen species (ROS), which exaerbates oxidative damage, brain edema, and neuronal necrosis[2].

Thus, a fundamental barrier to neural repair is the rapid degradation of the brain's native extracellular matrix (ECM) within these ischemic and necrotic zones [2]. The destruction of this specialized structural support creates a hostile microenvironment that inhibits cell survival and impedes the cellular migration required for the functional recovery of the tissue [2]. To overcome this limitation, research has turned toward developing biomaterials that simulate the cerebral microenvironment and resolve the inherent chemical-mechanical mismatch between rigid interface materials and the delicate neural tissue [4]. In this context, injectable smart hydrogels have emerged as promising frameworks due to their ability to fill the injury cavity and offer a three-dimensional (3D) scaffold that mimetizes the native ECM [4].

The brain parenchyma is exceptionally soft, establishing an ideal stiffness range between 0.1 and 1.0 kPa, where cell survival and neurite outgrowth are optimized [5]. Stiffness values outside this range promote reactive gliosis - the primary inhibitory factor in regeneration -, redirecting the fate of neural stem cells toward the astroglial lineage [6]. Hence, the delivery strategy requires thermoresponsive systems that transition from an injectable liquid to a solid gel state in situ in response to body temperature (37 °C) [7]. However, the utility of the conventional thermoresponsive polymer Poloxamer 407 (F127) is limited by its restricted mechanical strength and accelerated degradation [8]. Similarly, the rapid structural loss of pure natural polymers, such as hyaluronic acid (HA), results in the premature collapse of the scaffold [9].

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

To overcome these structural and stability limitations, the rational combination of F127 with HA and gelatin (GL) represents a strategic design. HA, a key component of the cerebral ECM, increases stiffness and attenuates the inflammatory response [10], while GL confers biological properties that stimulate cell adhesion, proliferation, and neurite outgrowth [11]. Considering the demand for platforms that promote mechanical mimicry and bioactivity with enhanced stability, this work proposes the evaluation of an in vitro oxidative stress model relevant to ischemic neural injury, using an injectable and thermosensitive hydrogel, designated as SMARTGELP (F127-HA-GL), carefully optimized at a mass ratio of 70/20/10 to try achieve a neuromimetic elastic modulus within the 0.1 to 1.0 kPa range. Therefore, this study aims to validate the potential of SMARTGELP as a rationally designed platform, evaluating its capacity to modulate and attenuate the inflamation effects of ischemic injuries through biochemical assays involving hydrogen peroxide (H_2O_2).

II. Materials and Methods

A. Hydrogel Preparation

The thermoresponsive SMARTGELP hydrogel was prepared as a structured polymer blend to achieve a final composition of 70/20/10 %w/w of Poloxamer 407 (F127, Sigma-Aldrich, USA), medium molecular weight hyaluronic acid (HA; MW = 380 kDa, #9067-32-7, Engenharia das Essências, Brazil), and gelatin (GL, Sigma-Aldrich, USA), using sodium carboxymethylcellulose (CMC, Sigma-Aldrich, USA) as a compatibilizing agent.

Precursor solutions were prepared individually and sequentially to promote solubilization of each component prior to mixing, aiming to minimize aggregate formation and support the homogeneity of the final system. A 20% w/w F127 aqueous solution was obtained by adding the polymer powder to chilled deionized water under constant magnetic stirring in an ice bath for 1 hour, followed by storage under refrigeration for 12 hours to allow complete dissolution. Concurrently, a 1% w/w gelatin solution to deionized water was prepared with the addition of 0.01% w/w CMC, under magnetic stirring at 50 °C until homogenization. A 2% w/w HA solution to deionized water was prepared at room temperature under constant stirring until polymer dispersion was achieved.

The SMARTGELP formulation was prepared under cooling to preserve the sol state of the components and prevent premature gelation during processing. Calculated volumes of the previously stabilized HA and GL/CMC solutions were gradually added to the F127 solution, maintained in an ice bath under continuous magnetic stirring. After visual homogenization of the system, the precursor mixture was stored under refrigeration. The formulation pH (~7.4) was determined at room temperature using a calibrated pH meter (Hanna HI 221, Hanna Instruments, Woonsocket, RI, USA).

B. Rheological Characterization

The viscoelastic properties and the quantitative gelation temperature (T_{gel}) were determined by dynamic oscillatory rheology using a stress-controlled rheometer (Rheostress RS600, Thermo Fisher Scientific, Massachusetts, USA) equipped with a cone-and-plate geometry (diameter: 20 mm; angle: 2º). The evolution of the storage (G') and loss (G") moduli was monitored during a temperature ramp from 25 to 47 °C, under a constant heating rate of 1 °C·min^{-1}. To ensure that measurements remained within the linear viscoelastic region, where G' and G" are independent of strain amplitude, a frequency of 1 Hz and an oscillatory strain of 0.01 (1%) were fixed, mitigating the probability of structural disruption of the forming network during the sol-gel transition [12]. The rheological T_{gel} was defined by the crossover point where G' = G", corresponding to the transition from a predominantly viscous behavior (G" > G') to a predominantly elastic behavior (G' > G").

C. Cell Viability Analysis

The in vitro biological evaluation of SMARTGELP was performed using SH-SY5Y cells (ATCC - CRL-2266) to characterize metabolic activity and morphological evolution in 3D culture.

Prior to the viability assays, the SMARTGELP hydrogel was sterilized by filtration through a 0.22 µm membrane (Millipore, USA), a procedure adopted given that F127-based hydrogels may undergo structural changes when subjected to autoclaving or ultraviolet light, and was kept under refrigeration to preserve its flow state until use. Predefined hydrogel volume (50 µL) was deposited into 24-well culture plates (Kasvi, Brazil, #K12-024) and kept at 37 °C for 5 minutes to allow in situ gelation prior to cell seeding.

Following the sol-gel transition, SH-SY5Y cells were seeded onto the polymeric matrix at a density of $5x10^4$ cells per well, followed by the addition of 500 µL of culture medium consisting of Dulbecco's Modified Eagle Medium/Nutrient Mixture F-12 (DMEM/F12, Gibco, USA, #12400024), supplemented with 10% fetal bovine serum (FBS, Gibco, USA, #12657-029) and 1% penicillin-streptomycin (Gibco, USA, #15140-122).

Cellular metabolic activity was evaluated at 24 and 48 hours after seeding using the resazurin reduction assay, adopting the following control groups: negative control (cells incubated in culture medium) and positive control (cells incubated in culture medium containing dimethyl sulfoxide, DMSO, 1:1 v/v with culture medium, i.e., 50% DMSO; R&R, Brazil, CAS: 67-68-5). Data were expressed as a percentage of the negative control metabolic activity, as detailed in the Statistical Analysis section.

D. Oxidative Stress Assay

To evaluate the cytoprotective potential and the modulation of oxidative stress, SH-SY5Y cells seeded at a density of $5x10^4$ cells/well were differentiated with 10 µM retinoic acid (Sigma-Aldrich, USA, #R2625) and 0.5% FBS for 5 days.

Oxidative stress was induced by exposing the cultures to 200 µM H_2O_2 (#L0032-P1L, Molekular Química) in differentiation medium for 1 hour. Upon completion of the injury interval, the wells were washed with phosphate buffered saline for treatment application, which consisted of encapsulating $5x10^4$ cells in 50 µL of SMARTGEL per well.

Following the sol-gel transition process, 500 µL of differentiation medium was added per well, and the plate was incubated at 37 °C and 5% CO_2. The in vitro assays were monitored at 24 and 72-hour intervals using n = 4, as detailed in the Statistical Analysis section. The production of reactive oxygen species (ROS) was quantified using the CellROX® Orange reagent (Invitrogen, USA, #C10443) according to the protocol provided by the manufacturer, remaining in incubation for 30 minutes prior to verification via flow cytometry (BD Accuri C6 Plus, Becton Dickinson, USA). Morphological modifications were monitored using an

inverted microscope (Olympus IX51, Olympus Corporation, Japan) coupled to a DP30BW digital camera unit.

E. Statistical Analysis

All experiments were performed with n = 4, and results are expressed as mean ± standard deviation. Statistical analysis was performed using one-way ANOVA followed by Tukey's post hoc test for multiple comparisons, with statistical significance set at *p < 0.05, **p < 0.01, ***p < 0.001, and ****p < 0.0001.

III. RESULTS AND DISCUSSION

A. Sol-Gel Transition

The viscoelastic profile of the SMARTGELP matrix as a function of temperature suggested a three-phase behavior characteristic of F127-based systems (Fig. 1)[13]. At lower temperatures, the matrix remained in a sol state, exhibiting low viscoelastic moduli values and a predominantly viscous character (G" > G').

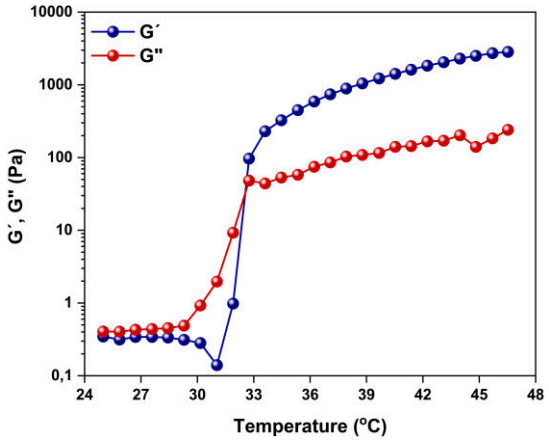

Fig. 1. Viscoelastic profile of the SMARTGELP matrix as a function of temperature. The dynamic oscillatory response illustrates the temperature-dependent storage modulus (blue) and loss modulus (red). The crossover point (G' = G") recorded at 32 °C identifies the rheological gelation threshold (T_{gel}), transitioning from a predominantly viscous behavior (G" > G') to a structured elastic network (G' > G').

Subsequent thermal enhancement induced an elevation in both moduli, a phenomenon associated with the progressive thermal aggregation and self-assembly of the F127 unimers into micellar networks [13].

The dynamic T_{gel} was recorded at 32 °C. This intersection marked the physical transition from a predominantly viscous behavior to a structured elastic arrangement (G' > G") [13].

At the physiological temperature of 37 °C, the SMARTGELP reached a storage modulus of approximately 740 Pa, approaching the lower range of stiffness values reported for brain tissue in the literature (0.1 to 1.0 kPa), although direct comparison is limited by differences in measurement technique and frequency between studies [5]. Literature indicators suggest that substrate compliance within this neuromimetic range can support neuronal phenotype differentiation while mitigating adverse astroglial responses or reactive gliosis associated with excessive rigidity [6], [14].

B. Cell Viability and Metabolic Activity

The biological performance of the SMARTGELP matrix was evaluated using the SH-SY5Y cell line seeded onto the three-dimensional matrix, Fig. 2. For the 50 µL hydrogel volume condition, the cellular metabolic activity, assessed via the resazurin reduction assay, remained above 95% at both 24 and 48 hours post-seeding, demonstrating no statistically significant reduction in comparison to the negative control group, suggesting the SMARTGELP architecture allowed a sufficient diffusive flux of oxygen, nutrients, and metabolites.

Comparatively, while the negative control exhibited an accelerated proliferation profile from 24 to 48 hours (~100% to ~135%) typical of standard two-dimensional monolayer cultures, the metabolic activity within the SMARTGELP remained stable and controlled, varying from ~97% to ~103%. This behavior suggests that the three-dimensional architecture of the hydrogel matrix modulates cell growth kinetics compared to the accelerated proliferation observed in the 2D negative control [15].

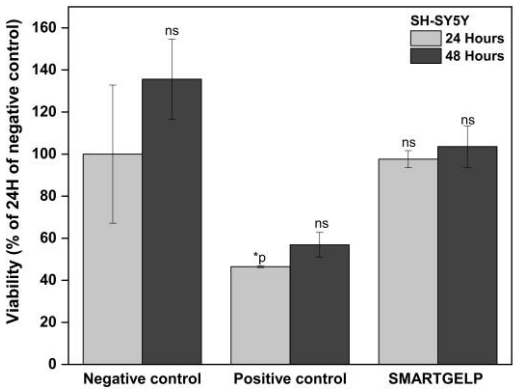

Fig. 2. Evaluation of SH-SY5Y cell metabolic activity and growth kinetics within the SMARTGELP matrix after 24 hours (light gray) and 48 hours (dark gray) of incubation. Metabolic activity was quantified via the resazurin reduction assay and expressed as a percentage relative to the 24-hour negative control group (%). As resazurin reduction reflects metabolic activity rather than a direct measure of cell viability or proliferation, these values should be interpreted accordingly. Experimental groups comprise the standard culture condition showing accelerated 2D monolayer proliferation (negative control), the cytotoxic setup (positive control), and the 3D engineered framework establishing homeostatic metabolic maintenance (SMARTGELP). Data are presented as mean ± standard deviation.

This stable metabolic outcome can be associated with the integration of GL and HA into the synthetic F127 base. While pure poloxamer matrices frequently exhibit non-adhesive characteristics, the inclusion of GL provides functional RGD sequences known to mediate cell anchoring via integrin receptors [16].

C. Cytocompatibility Analysis

The temporal evaluation of intracellular oxidative profiles quantified by flow cytometry (Fig. 3) shows a visible alignment with the cellular architecture monitored via inverted phase-contrast microscopy (Fig. 4), providing a physical context to the redox parameters.

At the 24-hour interval, the physiological baseline established by the negative control group revealed a standard two-dimensional monolayer distribution, where cells displayed typical flattened and spread morphologies adhering to the substrate, corresponding to a basal activation rate of 6,24% within the gated region. In contrast, the positive control group manifested a rightward shift along the biexponential fluorescence axis, registering an increased fraction of hyperproductive reactive oxygen species events at 20,48%. This shift matches the phase-contrast observations of sparse cell clusters and early indications of cell membrane alteration, which are consistent with the triggering of

deleterious pathways linked to mitochondrial membrane potential disruption or exacerbated cytoplasmic oxidase activity under acute stress [17].

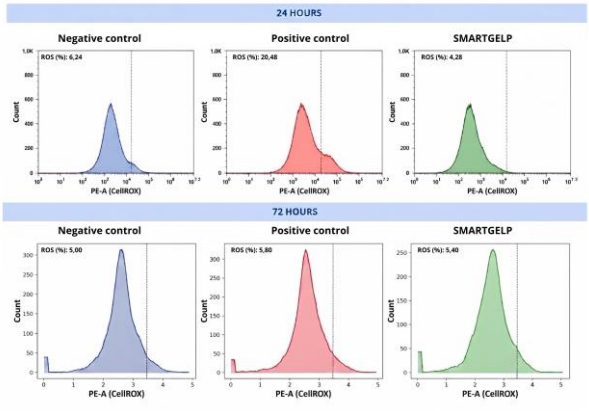

Fig. 3. Flow cytometry histograms of intracellular reactive oxygen species (CellROX® Orange fluorescence intensity) in SH-SY5Y cells across the negative control, positive control, and SMARTGELP groups, at 24 and 72 hours of exposure.

Among the evaluated conditions at 24 hours, the SMARTGELP matrix exhibited a substantial density of uniform, tightly packed 3D cellular clusters, which accompanied a symmetrical retraction of the population curve toward lower fluorescence channels, reaching the lowest activation level at 4,28%. This initial convergence suggests that the 3D spatial microenvironment, mechanical compliance, and biochemical anchoring sites within the hybrid framework support cell aggregation while maintaining lower intracellular oxidative stress levels, indicating potential radical scavenging activities or a mitigation of detachment-induced ROS production during the acute phase [18], [19].

By 72 hours, microenvironmental modifications resulting from progressive nutrient depletion and metabolic byproduct accumulation accompany a compression of the kinetic separation boundaries between the groups [19]. The long-term positive control group manifested a pronounced reduction in visible cell density and increased fragmentation, while the late negative control group maintained stretched, polarized morphologies with a lower overall cell density compared to its 24-hour baseline. These architectural variations correspond to the attenuated absolute differences measured in their late-stage ROS(%) rates, which reached 5,80% for the positive control and 5,00% for the negative control. This parallel may reflect the early acute oxidative imbalance being followed by metabolic clearance of the original stress or by an adaptive selection of surviving cells exhibiting compensatory scavenger regulation; however, given the pronounced reduction in cell density observed in the positive control at 72 hours (Fig. 4), part of this decrease in ROS(%) may also reflect a smaller surviving cell population being analyzed, rather than redox recovery alone [17].

Under this same long-term perspective, the large cellular clusters within the SMARTGELP framework transited into a more diffuse state within the volume of the hydrogel, aligning with the expected physical restructuring and controlled erosion of the matrix over time. This architectural transition proceeded under stable redox parameters, as the SMARTGELP group maintained a long-term ROS(%) of 5,40%, remaining closely aligned with baseline homeostatic levels. This behavior points to chronic cytocompatibility and suggests that incorporating the components into the SMARTGELP network assists in controlling cellular exposure rates, ensuring that matrix alteration proceeds without inducing delayed oxidative toxicity over time [20], [21].

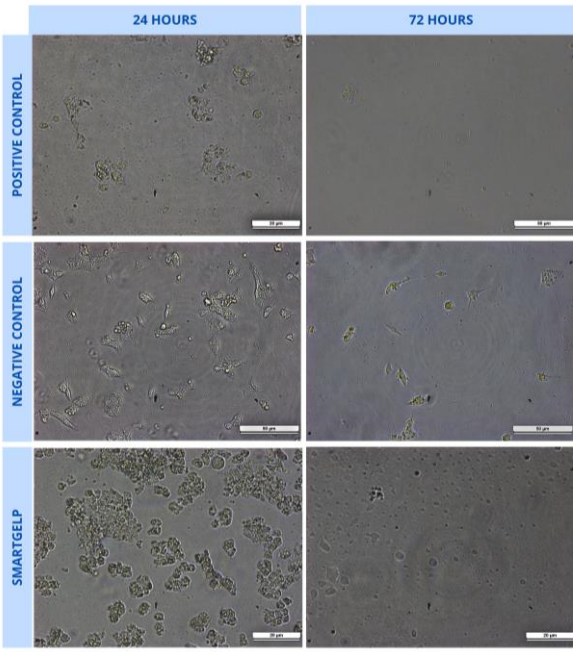

Fig. 4. Inverted phase-contrast light microscopy micrographs of SH-SY5Y cells after 24 hours and 72 hours of incubation across the experimental groups: positive control, negative control, and SMARTGELP matrix. At 24 hours, micrographs illustrate sparse cellular distribution in the positive control, standard flattened 2D monolayer adherence in the negative control, and dense 3D cellular clustering within the SMARTGELP network. At 72 hours, the images show a pronounced cell reduction and fragmentation in the Positive control, maintained stretched morphologies under lower density in the Negative control, and a structural transition to a diffuse cellular state accompanying matrix rearrangement in the SMARTGELP framework.

It should be noted that the morphological observations reported here, including cell clustering and its progressive diffusion over time, do not by themselves confirm a specific neural phenotype or a defined mechanism of action; cell aggregation can also arise from factors such as limited substrate adhesion, cellular stress, or matrix contraction, and quantitative neural marker analysis would be needed to support such an interpretation. Taken together, these parallel morphological and biochemical indicators suggest that the combination of structural shielding with localized metabolic stabilization in the SMARTGELP framework may contribute to a more favorable microenvironment, offering preliminary support for further investigation of tissue engineering interventions relevant to ischemic neural injury.

IV. Conclusion

In this work, the SMARTGELP matrix was developed as a multifunctional, thermoresponsive framework aimed at neural tissue engineering applications.

The structural and rheological characterization suggests that the hybrid polymeric network approaches stiffness values reported for brain tissue in the literature, although direct comparison is limited by differences in measurement technique and frequency between studies. By transitioning to a structured elastic gel below body temperature and positioning its compliance within the neuromimetic stiffness window, the matrix provides a soft support designed to interface with neural tissue model systems.

Biologically, the platform indicated a capacity to accompany changes in cell distribution alongside

microenvironmental conditions. The initial observation of three-dimensional cellular aggregates followed by a transition into a more diffuse state suggests that the progressive physical remodeling of the matrix can proceed under monitored redox parameters. By maintaining stable intracellular reactive oxygen species profiles over the evaluated culture periods, the hybrid framework suggested compatibility with the cellular environment.

This study has some limitations worth noting. The current in vitro configuration represents an oxidative stress model relevant to ischemic neural injury rather than a complete model of ischemic stroke, and the SH-SY5Y monoculture does not reproduce the cellular and structural complexity of the injured cerebral tissue. Establishing a direct cytoprotective effect would require a factorial design comparing cells with and without hydrogel exposure, in the presence and absence of H_2O_2, within the same experiment. Additionally, the resazurin reduction assay reflects metabolic activity rather than a direct measure of cell viability or proliferation, and a hydrogel-only control (without cells) could help clarify the influence of the matrix on reagent diffusion and signal. Future work incorporating these additional experimental groups, together with quantitative neural marker analysis, could further support the interpretation of the platform's protective potential.

Consequently, the convergence of these rheological, morphological, and biochemical indicators suggests that the design of the SMARTGELP architecture may address parameters of structural support, mechanical compliance, and redox baseline maintenance, indicating its potential for further investigation as an in vitro oxidative stress model relevant to ischemic neural injury.

ACKNOWLEDGMENT

***Abstract*—This paper presents the development of a low-cost food 3D printer for educational purposes, achieved by adapting an Ender 3 V3 SE 3D printer. The original fused filament fabrication extrusion system was replaced with a redesigned extrusion head configured to operate with a 20 ml Luer Lock syringe, utilizing a trapezoidal lead screw driven by a stepper motor. Three linear guide axes handle axis movement. An ESP32 running a dedicated, specific program was used for bed leveling. The printer uses a 1-millimeter nozzle for food extrusion and was initially tested with pastes and doughs, such as mashed potatoes, cookie dough, and peanut butter. The project plans future upgrades for temperature control, enabling the printing of products such as chocolate. The total cost of the adaptation was approximately R$ 4,000.00. This work was developed at the Instituto Nacional de Telecomunicações (INATEL) as part of an undergraduate research project (Iniciação Científica) and will be presented at the Inatel Technological Fair (FETIN).**

***Index Terms*—Food 3D printing; additive manufacturing; syringe extrusion; educational prototype; rapid prototyping.**

I. Introduction

Food 3D printing, a branch of additive manufacturing, has emerged as a promising technology with the potential to expand the possibilities for production, customization, and the development of nutritional matrices. This technology enables the creation of complex and customized food structures, offering new opportunities for food design and, crucially, for clinical nutrition. The ability to precisely control the composition, macrostructure, and geometry of the ingredients enables the development of personalized diets for hospital patients, easy-to-swallow formulations aimed at treating dysphagia, and systems for the controlled release of nutrients and bioactive compounds [1], [2].

Additive manufacturing has consolidated itself over the last few decades in fields such as engineering, medicine, and industrial design, being widely used for rapid prototyping and the fabrication of components with complex geometries. Its application in the health and nutrition sector represents a natural evolution of this technology, driven by the growing demand for customized, on-demand products. Among the different methods used for food 3D printing, syringe extrusion stands out as one of the most versatile techniques for semi-solid food materials, such as hospital purees, enriched gels, and doughs [3]. In this process, the material is deposited layer by layer through an extrusion nozzle, allowing precise control over the shape and dimensions of the final product.

Despite the progress observed in recent years, the adoption of this technology is still limited by the high cost of commercial equipment and the complexity of its implementation. Most food 3D printers available on the market are intended for industrial applications or specialized research, making them inaccessible to educational institutions, small laboratories, and researchers with limited financial resources [4]. Furthermore, obtaining adequate printing parameters and controlling the rheological properties of food materials remain significant challenges to ensuring extrusion quality and process repeatability.

Given this scenario, this paper presents the development of a low-cost food 3D printer achieved by adapting a commercial Creality Ender-3 V3 SE filament printer (FDM technology). The main contribution of this project lies in the development of a new print head, completely redesigned to operate with a 20 mL Luer Lock syringe, while preserving the printer's original electronic structure and firmware. The developed mechanical assembly includes specific brackets for the syringe, a drive motor, positioning sensors, and an extrusion system based on a trapezoidal lead screw and linear guides. Since replacing the original print head made it impossible to use the equipment's native calibration sensors, an auxiliary system based on an

ESP32 microcontroller was developed. This system is responsible for automatic bed leveling without requiring complex modifications to the manufacturer's original firmware. Additionally, adaptations were made to the PrusaSlicer software parameters, enabling its use for slicing and parameterizing the food printing process.

A. Motivation and Objectives

Food 3D printing is a technology with strong potential for applications in clinical research, nutritional product development, and educational activities. However, the high cost of commercial platforms remains one of the primary limiting factors for its widespread adoption in educational institutions and research centers, especially in undergraduate laboratories, where resources allocated for equipment acquisition are often restricted.

In this context, adapting a commercial FDM 3D printer emerges as an economically viable alternative to enable experimental activities using components widely available on the market. In addition to reducing the initial investment, this approach facilitates maintenance, component replacement, and future platform modifications—features that are particularly relevant in academic environments.

To demonstrate the economic viability of the proposed solution, Table I presents a comparison between the approximate costs of commercial food 3D printing platforms and the prototype developed in this work. It is observable that utilizing an architecture based on the adaptation of a commercial FDM printer allows for a significant reduction in acquisition costs, expanding access to this technology for teaching and research applications.

Table I
COST COMPARISON BETWEEN COMMERCIAL PLATFORMS AND THE DEVELOPED PROTOTYPE.

Platform / Equipment	**Approximate Cost**
Foodini (Natural Machines) [5]	R$ 30,000.00 to R$ 33,000.00
byFlow Focus [6]	R$ 25,000.00 to R$ 40,000.00
Cocoa Press [7]	R$ 8,000.00 to R$ 20,000.00
Developed prototype	**R$ 4,000.00**

Source: Adapted by the authors (2026).

It can be observed that the developed prototype features a cost 50% lower than the lowest-priced commercial platform considered, and is up to approximately 85% more affordable when compared to top-of-the-line industrial systems. This significant reduction was achieved by repurposing the mechanical and electronic structure of the commercial FDM printer, concentrating the investment strictly on the components necessary for the controlled extrusion of semi-solid materials.

In addition to the comparison with commercial equipment, the cost obtained also proved to be competitive against open-source platforms described in the literature. The Printer.HM system has an approximate cost of £900 for its basic configuration, while the adapter developed by Rogers [8] requires approximately US$600 in components, excluding the base printer.

The central objective of this study is to develop and validate a low-cost food 3D printing platform aimed at educational and research applications in additive food manufacturing, helping to lower the financial barriers to accessing this technology. To achieve this, we propose adapting a commercial FDM printer through the development of a syringe extrusion system, implementing an auxiliary automatic bed leveling system using an ESP32, establishing printing parameters for semi-solid food materials, and conducting experimental validation of the developed platform.

II. METHODOLOGY

A. Base Printer

The development of the food 3D printer was carried out by adapting a commercial *Creality Ender-3 V3 SE* 3D printer. This model was chosen due to its low cost, wide availability of components, and robust mechanical structure—features that facilitate modifications and future expansions of the project. The printer features a Cartesian architecture and a motion system suitable for applications requiring precise axis positioning.

To enable food printing, the original fused deposition modeling (FDM) extrusion assembly was removed, while preserving the printer's mechanical structure and its original electronic board. Consequently, all modifications were concentrated on developing a new extrusion system, allowing the equipment's original firmware to be maintained.

B. Mechanical Design

The entire mechanical design was developed using *Autodesk Fusion 360* software, in which all the parts required for the printer's adaptation were modeled.

Key components developed include the syringe mounting bracket, the drive motor bracket, the attachment elements for the X-axis carriage, the positioning sensor mounts, and the components responsible for the syringe plunger movement system. The design was conceived modularly, allowing for easy disassembly, maintenance, and future modifications.

Following the modeling stage, all parts were fabricated using 3D printing and assembled onto the original structure of the Ender-3 V3 SE.

Figure 1 shows the syringe bracket modeled and printed.

Fig. 1. Developed syringe bracket for printer adaptation. Source: The authors (2026).

C. Extrusion System

The extrusion system was developed to use disposable *20 mL Luer Lock syringes*, which serve as the reservoir for the food material.

The plunger is driven by a *NEMA 17* stepper motor (the standard motor used in additive manufacturing applications) coupled to a *trapezoidal lead screw*, which converts the rotational motion of the motor into linear displacement. This mechanism allows precise control over the amount of material extruded during printing.

To ensure the alignment of the moving assembly and prevent lateral forces on the syringe, *three linear guides* were used to maintain uniform displacement throughout the entire plunger stroke.

An interchangeable extrusion nozzle was installed at the tip of the syringe, allowing the use of different diameters depending on the food material being used.

D. Leveling System

During the development of the new print head, it was found that the original position of the *BLTouch* sensor became incompatible with the syringe extrusion system. If it remained fixed during printing, the sensor could collide with the deposited material or with components of the new print head.

To solve this problem, an auxiliary system was developed based on an **ESP32** microcontroller, used *exclusively during the automatic bed leveling procedure*.

Before printing begins, the ESP32 mechanically positions the BLTouch sensor (Figure 2) into the appropriate position to perform the mesh bed leveling. Once this procedure is complete, the sensor is retracted to a safe position, remaining away from the printing area throughout the entire printing process. This preserves the functionality of the printer's original leveling system without interfering with the geometry of the new extrusion head.

This solution made it possible to keep the original firmware of the Ender-3 V3 SE, requiring only a complementary mechanical and electronic adaptation for the temporary actuation of the sensor.

Fig. 2. BLTouch sensor positioning system using an ESP32. Source: The authors (2026).

E. PrusaSlicer Configuration

Since no modifications were made to the printer's firmware, the necessary adaptations for food printing were focused on configuring the *PrusaSlicer* software. Only the print parameters related to the extrusion process were modified, including the initialization G-code (*Start G-code*) and termination G-code (*End G-code*), alongside specific parameters for the syringe extrusion system, such as plunger feed rate, flow factor, and layer height. These modifications enabled the generation of toolpaths compatible with the new print head while preserving the printer's original electronics and firmware, in line with similar adaptations reported in the literature [9]–[11].

F. Mathematical Modeling of Extrusion Flow

To properly configure the extrusion flow in PrusaSlicer, it was necessary to establish the relationship between the plunger feed rate of the syringe and the material deposition speed onto the platform. The volumetric flow modeling was based on the principle of mass conservation for incompressible fluids, which is widely used in the calibration of syringe extrusion systems [12], [13].

Let us consider a syringe with an internal diameter $D_{Syringe}$ (mm) whose plunger moves at a linear speed $v_{Syringe}$ (mm/s). The cross-sectional area of the syringe is given by:

$$A_{Syringe} = \frac{\pi \cdot D_{Syringe}^2}{4} \tag{1}$$

The volumetric flow rate Q (mm³/s) generated by the displacement of the plunger is, therefore, the product of the area and the displacement per unit of time [12], [14]:

$$Q = A_{Syringe} \cdot v_{Syringe} = \frac{\pi \cdot D_{Syringe}^2}{4} \cdot v_{Syringe} \tag{2}$$

On the other hand, during deposition, the extruded material forms a continuous bead on the platform, whose volume per unit of time can be described by the geometry of the printed line. Given that w is the extruded line width (mm), h is the layer height (mm), and v_{print} is the travel speed of the print head (mm/s), the volume deposited per second is expressed as [11], [12]:

$$Q = w \cdot h \cdot v_{print} \tag{3}$$

By the principle of mass conservation for incompressible fluids, the flow rate exiting the syringe (2) must equal the flow rate deposited on the platform (3) [10], [13]. Equating both expressions:

$$\frac{\pi \cdot D_{Syringe}^2}{4} \cdot v_{Syringe} = w \cdot h \cdot v_{print} \tag{4}$$

Isolating the plunger velocity $v_{Syringe}$ yields the fundamental parameter for calibrating the slicer:

$$v_{Syringe} = \frac{4 \cdot w \cdot h \cdot v_{print}}{\pi \cdot D_{Syringe}^2} \tag{5}$$

Equation (5) establishes that, for a fixed diameter syringe, the plunger speed must be adjusted proportionally to the print speed, line width, and layer height. This result is consistent with the work of Pusch et al. [12], who demonstrated the need to calibrate the volumetric flow in desktop syringe systems, and with the adaptations implemented by Contreras et al. [11], who applied similar relationships when converting an Ender 3 for bioprinting.

By applying this mathematical relationship, it was possible to calibrate PrusaSlicer's extrusion multiplier for different deposition geometries. This ensured that the amount of extruded material corresponded exactly to the volume expected by the slicer, without requiring changes to the original firmware's *E-steps*. This approach bypasses electronic modifications on the printer since the motor motion logic remains unaltered, with the adaptation performed entirely within the slicing software [9], [15].

It is worth noting that (5) is valid for incompressible fluids and disregards rheological effects such as shear-rate-dependent viscosity, which are common in bioinks and food materials. For applications involving non-Newtonian materials, it is recommended to include an empirical correction factor obtained through extrusion test runs, as discussed by Ozbolat [13] and Piedade et al. [14]. In the present work, since the material used exhibits pseudoplastic behavior, additional manual adjustments were performed experimentally to compensate for viscosity variations during the printing process.

G. Materials Used

The initial tests were conducted using semi-solid food materials that do not require active temperature control, including mashed potatoes, cookie dough, and peanut butter.

The methodology used for mechanical validation is consistent with recent studies on the adaptation of FDM printers to syringe extrusion, in which food materials or rheological substitutes are initially used to verify the continuity of extrusion and deposition stability before conducting more comprehensive quantitative trials [8], [15].

As a future development of the project, we intend to incorporate a thermal control system into the print head, expanding the range of materials processable by the platform. The inclusion of this module will enable the printing of temperature-sensitive materials, such as chocolate and other food formulations that require controlled heating or cooling during extrusion. Similar solutions have been employed in platforms dedicated to chocolate 3D printing, where temperature control is crucial to maintaining the material's proper viscosity, ensuring extrusion continuity, and preserving the geometric fidelity of the produced structures [8]. Additionally, the developed modular architecture allows for the future integration of complementary modules, such as UV lighting systems, which are used in soft material extrusion platforms to promote *in situ* curing of photosensitive materials [15]. Although this functionality is not intended for conventional food printing, its implementation demonstrates the platform's potential for expansion into experimental applications and for processing special food formulations and other extrudable materials.

III. Results and Discussion

The development resulted in a functional food 3D printing platform based on the adaptation of the *Creality Ender-3 V3 SE* printer. Figure 3 presents an overview of the printer after the installation of the developed syringe-based extrusion system.

Fig. 3. Overview of the developed food 3D printer. Source: The authors (2026).

The main modifications made to the original printer are summarized in Table II. The adaptation consisted of the complete removal of the original fused deposition modeling (FDM) extrusion system and the installation of a print head designed specifically for the extrusion of semi-solid materials. The assembly was designed to use 20 mL Luer Lock syringes, allowing for rapid replacement of the material reservoir and facilitating cleaning and sanitization procedures.

The entire mechanical assembly was developed in a CAD environment using *Autodesk Fusion 360* software and subsequently fabricated via 3D printing. The developed components include the syringe bracket, the drive motor mount, the plunger displacement system, sensor brackets, the ESP32 enclosure, and other necessary fasteners to integrate the new print head into the printer's original frame. The three-dimensional models developed in this project are available for consultation and reproduction at the following addresses: print head [*https://a360.co/44JrYqv*], ESP32 enclosure [*https://a360.co/4eYl2ue*], and X-axis limit switch bracket [*https://a360.co/4eWFHiu*]. The approximate cost of the components used in the adaptation was R$ 4,000.00 , including mechanical, electronic, and drive components, considering the cost of the base printer.

The developed extrusion mechanism utilizes a *NEMA 17* stepper motor coupled to a trapezoidal lead screw to drive the

Table II
MAIN MODIFICATIONS MADE TO THE PRINTER.

Item	Description
Base printer	Creality Ender-3 V3 SE
Print head	Mechanical design developed to use a 20 mL Luer Lock syringe.
Extrusion system	NEMA 17 motor driving a trapezoidal lead screw.
Linear guides	Three 6 mm linear guides for plunger alignment.
Leveling	Retractable BLTouch sensor actuated by an ESP32.
Firmware	Original printer firmware preserved.
CAD Software	Autodesk Fusion 360.
Slicing	PrusaSlicer with parameters adapted for food extrusion.
Tested materials	Mashed potatoes, cookie dough, and peanut butter.

syringe plunger, while three linear guides ensure alignment throughout the entire displacement. The platform was experimentally validated through mechanical and motion system verification. The X, Y, and Z axes of the Ender-3 V3 SE base printer were operated across their full range of motion, confirming that the new print head assembly does not interfere with the original movement system. The automatic bed leveling system was also validated during printer assembly. The mechanism developed using an *ESP32* microcontroller temporarily positions the *BLTouch* sensor only during the bed leveling procedure. Upon completion of this stage, the sensor automatically returns to a retracted position, avoiding interference with the new print head or deposited material during part fabrication and preserving the original printer firmware without requiring changes.

Preliminary extrusion tests were conducted using semi-solid materials to verify the functional operation of the developed syringe-based extrusion system. Peanut butter was loaded into the 20 mL syringe and extruded through the developed mechanism. The material was successfully ejected from the syringe with a continuous and visually stable flow, demonstrating that the combination of the NEMA 17 stepper motor, trapezoidal lead screw, and plunger-guiding system is capable of generating the displacement required for semi-solid material extrusion. No apparent interruptions or mechanical instabilities were observed during the test.

A second experimental assessment was performed using a bridge configuration with Nivea cream as the extruded material. The test was used to qualitatively evaluate the behavior of the deposited filament under unsupported conditions, with particular attention to filament continuity and its tendency to collapse as the unsupported span increases. The bridge configuration provides a practical assessment of the interaction between extrusion consistency and the ability of the deposited material to maintain its geometry after deposition. Figure 4 presents the bridge-collapse test arrangement.

The observed behavior of the extruded filament in the bridge test demonstrates that the deposited material can form a continuous unsupported span before progressive collapse occurs, providing a qualitative indication of the platform's ability to maintain filament geometry after deposition, a prerequisite for dimensional accuracy in layered fabrication. Together, the peanut butter extrusion and bridge-collapse tests provide complementary evidence of the platform's functionality: the first evaluates the ability of the mechanism to continuously eject a semi-solid material from the syringe, whereas the second evaluates the behavior of the deposited filament after extrusion. These preliminary results support the mechanical feasibility of the proposed syringe-based architecture for food extrusion applications.

Regarding the quantitative performance metrics requested for a comprehensive characterization, the following considerations can be drawn from the present study. The dimensional accuracy of extrusion-based food printing is influenced by multiple factors, including printing parameters, rheological properties, extrusion rate, layer height, and post-processing conditions [19], [20]. The successful bridge test, although qualitative, demonstrates that the extrusion system is capable of producing continuous filaments under unsupported conditions, which is a necessary condition for achieving dimensional accuracy in layered structures. Moreover, the Creality Ender-3 V3 SE base platform features a positioning accuracy of ±0.1 mm in the X and Y axes according to the manufacturer [20], which establishes a baseline for the achievable dimensional accuracy of the mechanical system. While quantitative measurements of dimensional accuracy (e.g., printed geometry dimensions) were not performed in this preliminary study, the combination of the base platform's positioning accuracy and the observed filament stability suggests that the system has the potential to produce dimensionally consistent structures.

The mechanical architecture was designed to promote repeatable plunger displacement. The three linear guides constrain the syringe plunger during actuation, while the trape-

zoidal lead screw provides controlled linear displacement driven by the NEMA 17 stepper motor. The use of three linear guides for plunger alignment is expected to contribute to extrusion repeatability by reducing lateral forces during plunger displacement. This mechanical design choice follows the principles adopted in open-source soft-material extrusion platforms, where guided plunger motion has been associated with improved deposition consistency [15]. The preliminary extrusion tests demonstrated stable operation, suggesting that the system is capable of repeatable deposition. Statistical repeatability, however, was not quantitatively determined through repeated depositions or mass measurements in the present study.

Extrusion consistency was assessed through the visual observation of the extruded flow during the peanut butter test, which remained continuous and stable throughout the procedure. Although quantitative measurements of extrusion consistency (e.g., coefficient of variation of deposited mass or filament diameter) were not performed, the visual uniformity of the extruded flow is consistent with observations reported for syringe-based extrusion of semi-solid materials, where coefficients of variation below 10% are typically achieved for adequately formulated pastes and food inks [19]. This suggests that the developed mechanism provides a suitable basis for consistent material deposition, provided that the material rheology remains within the operational range of the system. Future work will include quantitative measurements of extrusion consistency to establish the statistical performance of the system.

Regarding printing time, the developed platform retains the motion system of the Ender-3 V3 SE, whose maximum motion speed is specified by the manufacturer at up to 250 mm/s for conventional FDM operation [20]. For syringe-based food extrusion, however, the practical printing speed is expected to be lower because the achievable deposition rate depends on material rheology, syringe geometry, and plunger displacement. The mathematical formulation in (5) provides a basis for relating plunger velocity and printing speed to the required volumetric flow rate, enabling the estimation of printing time for a given geometry once the material-specific parameters are determined. A systematic experimental evaluation of printing speed and printing time for different materials was not performed in the present study.

To position the developed platform within the current landscape of low-cost food and soft-material extrusion systems, Table III presents a technical comparison between the proposed system and two representative platforms reported in the literature: the syringe-pump system by Heriyanto et al. [9], and the *Printer.HM* platform [15].

The comparative analysis highlights three distinctive features of the proposed platform. First, unlike adaptations that require modifications to firmware [10], [11], the proposed approach preserves the original electronics and firmware. Second, the use of a dedicated ESP32 microcontroller for automatic bed leveling enables the use of the BLTouch sensor without permanent modifications to the print head, avoiding collisions during printing. Third, the inclusion of three linear guides for plunger alignment, combined with a trapezoidal lead screw, provides mechanical stability during deposition. Rogers [8] successfully demonstrated chocolate printing with temperature control, whereas the proposed platform currently focuses on semi-solid materials and provides a modular architecture that allows future thermal integration. Heriyanto et al. [9] developed a syringe-pump mechanism compatible with multiple syringe sizes, while the proposed system emphasizes integration with a commercially available FDM platform while preserving its original firmware. Compared with the *Printer.HM* platform [15], the proposed system provides a lower estimated acquisition cost while incorporating an automated leveling mechanism based on an independent ESP32 controller.

Leveling	ESP32 + BLTouch	Manual	Manual
Tested materials	Semi-solid materials	Dough	Food pastes
Estimated cost (USD)	US$ 700	US$ 450	US$ 1,100

Source: Compiled by the authors based on [9], [15].

The preliminary experimental results demonstrate the functional operation of the developed food extrusion platform and provide qualitative evidence of continuous material ejection and filament stability after deposition. Nevertheless, a comprehensive quantitative characterization remains necessary to determine extrusion repeatability, dimensional accuracy, deposited mass variation, and printing time under controlled conditions. These measurements constitute an important next stage for establishing the statistical performance of the platform. Among the proposed future developments, the implementation of temperature control in the print head stands out, enabling the processing of materials such as chocolate and other formulations requiring controlled heating [8]. Additionally, the future incorporation of UV lighting modules could expand the platform's use to photosensitive materials [15]. The modular architecture adopted during development allows these modifications to be incorporated without significant changes to the original printer structure.

IV. CONCLUSION

This work presented the development of a low-cost food 3D printing platform obtained by adapting a commercial FDM printer for syringe-based extrusion of semi-solid materials. The proposed system integrates a 20 mL Luer Lock syringe, a NEMA 17 stepper motor, a trapezoidal lead screw, and three linear guides for controlled plunger displacement, while preserving the original electronics and firmware of the *Creality Ender-3 V3 SE*.

The experimental results demonstrated the functional operation of the developed extrusion mechanism. Peanut butter was successfully ejected from the syringe with a continuous and

visually stable flow, confirming the ability of the mechanism to generate the required plunger displacement for semi-solid material extrusion. A complementary bridge-collapse assessment using Nivea cream provided a qualitative evaluation of filament stability under unsupported conditions, demonstrating the applicability of the platform to the study of post-deposition material behavior.

The developed architecture also incorporates an ESP32-controlled retractable BLTouch system for automatic bed leveling, allowing the sensor to be deployed during the leveling procedure and retracted during printing. This approach preserves the original printer firmware and reduces the need for permanent modifications to the base machine. The estimated total cost of approximately US$700 further supports the suitability of the platform for educational and research applications.

The comparison with related low-cost extrusion platforms indicates that the proposed system combines syringe-based extrusion, automated leveling, mechanical plunger guidance, and preservation of the original printer control architecture within a comparatively low-cost platform. These characteristics provide a modular basis for further development of food and soft-material additive manufacturing systems.

Although the present study provides functional and qualitative experimental validation, quantitative characterization of extrusion repeatability, dimensional accuracy, deposited mass variation, and printing time remains necessary to fully establish the performance limits of the platform. Future work will therefore focus on controlled quantitative testing, as well as the implementation of temperature control for thermally sensitive materials such as chocolate and additional modules for expanding the range of printable materials.

Overall, the developed platform demonstrates the feasibility of converting a commercially available low-cost FDM printer into a modular syringe-based food extrusion system while retaining its original electronics and firmware. The resulting architecture provides a practical foundation for further research, experimentation, and educational applications in food additive manufacturing.

ACKNOWLEDGMENT

The authors would like to thank the National Institute of Telecommunications (INATEL) for the institutional support and the infrastructure made available for the development of this work.

Special thanks to Prof. Dr. Maysa Costa Alves for her guidance, valuable technical contributions, and supervision throughout the development of this undergraduate research project (Iniciação Científica).

The authors also thank Prof. Dr. Fabiano Valias de Carvalho, coordinator of the Biomedical Engineering course, for encouraging research and scientific development.

***Abstract* — This study investigated the mechanical behavior of cryogenically treated Biosilicate scaffolds by combining micro-computed tomography, finite element analysis, and experimental compression testing. Three-dimensional reconstructions were used to generate computational models representative of the fabricated scaffolds. The experimental results showed a compressive strength of approximately 50 MPa and an effective elastic modulus of 1.0 GPa. Finite element simulations based on the μ-CT-reconstructed geometry showed good agreement with the experimental stress–strain response, while simulations performed on an idealized CAD model of the scaffold architecture identified critical stress concentration regions at filament intersections, with a maximum principal stress of approximately 30–47 MPa. These findings demonstrate the potential of integrating micro-computed tomography and finite element analysis to evaluate and optimize porous scaffolds for bone tissue engineering applications.**

Keywords— Biosilicate, scaffold, finite element analysis, micro-computed tomography.

I. INTRODUCTION

Bioceramics have been extensively investigated for bone regeneration applications due to their excellent biocompatibility and chemical similarity to the mineral phase of bone tissue [1]. Among these materials, bioactive glasses and glass-ceramics have attracted attention due to their high bioactivity and ability to form a hydroxyapatite layer upon contact with biological fluids, supporting cell adhesion, osseointegration, and new bone formation [2, 3].

Biosilicate® (BioS), a bioactive glass-ceramic, has gained considerable interest due to its well-established bioactivity, osteoconductive properties, and potential for bone tissue engineering applications [4]. When processed into three-dimensional scaffolds, BioS can provide a suitable environment for cell adhesion, proliferation, and differentiation, supporting bone regeneration [5, 6].

For successful bone tissue engineering applications, scaffolds must achieve an appropriate balance between porosity and mechanical performance compatible with the host tissue [7, 8, 9] . An interconnected porous network is essential for cell migration, vascularization, and nutrient transport, while sufficient structural integrity is required to withstand physiological loads during the regeneration process. However, increasing porosity generally compromises the mechanical strength of the scaffold, representing a major challenge in the design of porous biomaterials [8].

In addition to chemical composition, the mechanical performance of scaffolds is strongly influenced by their three-dimensional architecture, including porosity, pore interconnectivity, filament diameter, and pore distribution. Although additive manufacturing enables precise control of scaffold geometry, subsequent processing steps, such as cryogenic treatment (CT) and sintering [10, 11], may induce dimensional and microstructural changes that alter the fabricated architecture. Consequently, its mechanical response. Accurate characterization of the resulting scaffold geometry is therefore essential for understanding its mechanical behavior [9] .

Although several studies have investigated the bioactivity and mechanical properties of BioS scaffolds, few have addressed the influence of their actual three-dimensional geometry on mechanical behavior by combining micro-computed tomography (μ-CT), finite element analysis (FEA), and experimental mechanical testing [12, 13]. Moreover, the combined use of μ-CT-based and idealized CAD-based finite element models remains limited. While μ-CT-based models represent fabricated architecture, idealized CAD models can be used to identify stress concentration regions associated with the scaffold design and support structural optimization.

Therefore, this study investigates the mechanical behavior of cryogenically treated BioS scaffolds by correlating μ-CT-based finite element simulations with experimental uniaxial compression tests. In addition, finite element simulations based on an idealized CAD model were performed to identify critical

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

stress concentration regions associated with potential failure sites and to provide insights for future scaffold design optimization.

II. MATERIALS AND METHODS

A. Materials

The printing paste was formulated using hydrogel polyethylene glycol 400 (PEG-400, Synth, 380–420 g/mol), Laponite XLG (Colormix, BYK Additives & Instruments), and Biosilicate (BioS) powder, supplied by the Laboratory of Vitreous Materials (LaMaV), Federal University of São Carlos (UFSCar).

B. Scaffold Fabrication

The BioS scaffolds were fabricated by direct ink writing (DIW) following the methodology previously described by Daguano et al. (2022) [14]. Scaffolds with nominal dimensions of 10 × 10 × 5 mm, comprising 15 layers, were printed using a 580 µm conical nozzle (20 G) and BioScaffolds V2.0 software. An air gap of 1.55 mm was used, resulting in a theoretical porosity of 70%.

After printing, the samples were subjected to cryogenic treatment (CT), which consisted of successive cycles of freezing at -86 °C for 2 h in an ultralow-temperature freezer (New Brunswick Scientific), followed by thawing at room temperature (25 °C) for 2 h. These cycles were repeated over a total treatment period of 72 h. Subsequently, the scaffolds were sintered at 900 °C for 2 h using a heating rate of 1 °C/min. Non-sintered scaffolds were used for the control group.

C. Shape Fidelity and Dimensional Shrinkage Relative to the Designed Geometry

The shape fidelity of the scaffolds was evaluated by comparing the designed pore geometry with the pore geometries obtained after printing, cryogenic treatment (CT), and sintering. Optical images were analyzed using ImageJ software to determine the Printability parameter (Pr) [15], according to equation (1):

$$\mathrm{Pr} = \frac{\mathrm{L}^2}{16\mathrm{A}} \qquad (1)$$

Where A is the pore area and L is its perimeter. Pr = 1 indicates correspondence with the designed geometry, while Pr ≠ 1 indicates distortion.

The scaffold dimensions in the X, Y, and Z directions were measured using a digital caliper (DIGIMES, Brazil). The corresponding linear shrinkage was then calculated according to equation (2):

$$Shrinkage(\%) = \frac{L_i - l_f}{L_i} \times 100 \qquad (2)$$

Where L_i and L_f are the initial and final dimensions, respectively (i= X, Y and Z).

D. Morphological and Mechanical Characterization

The scaffolds' surface morphology was examined by field-emission scanning electron microscopy (FEG-SEM, Tescan). Prior to imaging, the samples were sputter-coated with a 20 nm thick gold layer.

The mechanical behavior of the scaffolds was evaluated by uniaxial compression testing using a universal testing machine (EMIC DL 2000, Instron) equipped with a 5 kN load cell. The tests were performed at a crosshead speed of 1 mm/min, with the load applied perpendicular to the printing plane. The compressive strength was determined from the maximum stress recorded during the test. The results are presented as the mean and standard deviation (n = 5). Statistical significance between the compressive strength of the control and sintered groups was evaluated using GraphPad Prism (version *v*8.0, 2022), One-way ANOVA, with a significance level set at $p < 0.0001$.

E. Micro-Computed Tomography and Computational Modeling

The three-dimensional architecture of the scaffolds was characterized by micro-computed tomography (µ-CT) using a SkyScan 1272 CMOS Edition microtomograph (Bruker, Kontich) with a spatial resolution of 12 µm and 1200 ms exposure time. The acquired images were reconstructed using NRecon software (Bruker) and subsequently processed in CTAn software by automatic segmentation based on the Otsu 3D algorithm.

The three-dimensional reconstructions obtained from µ-CT were used to generate computational models employed for FEA. First, the reconstructed geometries were processed using routines developed in MATLAB and subsequently imported into HyperMesh software (Altair Engineering, Troy, MI, USA), where the geometries were discretized and the finite element meshes were generated. The numerical simulations were performed using Abaqus software (Dassault Systèmes, Providence, RI). The simulations were carried out under boundary conditions equivalent to those adopted in the experimental uniaxial compression tests, including geometrically nonlinear analysis with large deformations and frictional contact interactions between the scaffold and the loading surface.

The numerical models were calibrated against the experimental force-displacement data to estimate the effective solid-phase elastic modulus. The quality of this numerical-experimental fit was quantitatively assessed using the coefficient of determination (R^2) and the Root Mean Square Error (RMSE).

In parallel, an idealized CAD model of the scaffold architecture, based on the nominal design parameters (10 × 10 × 5 mm, 15 layers, 580 µm nozzle diameter), was developed and discretized into a finite element mesh using HyperMesh software (Altair Engineering, Troy, MI, USA). Linear static analysis was performed in OptiStruct (Altair Engineering) under a 5 kN compressive load applied through a sliding, frictionless contact interface between the scaffold and rigid loading platens. The same elastic modulus (E = 1.0 GPa), obtained from the

calibration against the experimental stress–strain curve, was assigned to this model. The maximum principal stress criterion was applied to identify regions of tensile stress concentration and potential failure sites, given its suitability for representing the fracture behavior of brittle porous ceramics, in which crack initiation is typically governed by local tensile stresses [12].

III. RESULTS AND DISCUSSION

A. Shape Fidelity Characterization

The shape fidelity characteristics of the scaffolds before and after sintering are summarized in Table 1.

Table 1 - Geometric parameters, printability, and linear shrinkage of BioS scaffolds before and after sintering.

Parameter	BioS Scaffold Control (non-sintered)	BioS Scaffold (Sintered)
Air gap (mm)	1.00 ± 0.10	0.89 ± 0.09
Pr	0.96 ± 0.04	0.91 ± 0.03
Linear Shrinkage (X, Y, and Z) (%)	---	5.4 ± 0.5 5.9 ± 0.8 11.0 ± 0.7

The measured air gap decreased from 1.00 ± 0.10 mm in the non-sintered scaffolds to 0.89 ± 0.09 mm after sintering. The printability parameter (Pr) remained close to 1 in both conditions, with values of 0.96 ± 0.04 and 0.91 ± 0.03 for the non-sintered and sintered scaffolds, respectively, indicating good preservation of the designed pore geometry. Following sintering, linear shrinkage values of 5.4 ± 0.5%, 5.9 ± 0.8%, and 11.0 ± 0.7% were observed in the X, Y, and Z directions, respectively. This behavior is expected and is associated with the removal of polymeric components and densification of the ceramic structure during thermal processing [14, 16, 17].

These results confirm that, despite the dimensional changes induced by sintering, the designed architecture was satisfactorily preserved. The effects of the processing steps on the microstructural features and mechanical behavior of the scaffolds are further presented in Fig. 1.

Fig. 1(a) shows the BioS scaffolds after 3D-printing and CT, exhibiting a well-defined three-dimensional architecture with highly interconnected pores. Although a reduction in the air gap was observed after sintering, Fig. 1(b), as previously described, this dimensional change did not compromise the overall macroporous architecture. The interconnected pore structure is relevant for bone tissue engineering applications, as it provides pathways for cell infiltration and nutrient transport [9].

The SEM micrographs presented in Fig. 1(c–d) correspond to the scaffolds before and after sintering at 900 °C, respectively. Prior to heat treatment, the scaffold exhibited a microstructure composed of discrete ceramic particles with a high volume of interparticle voids. Following sintering, a more consolidated and homogeneous microstructure was observed, accompanied by a marked reduction in interparticle porosity. These microstructural changes indicate effective densification promoted by the sintering process while preserving the overall integrity of the printed architecture [14, 16].

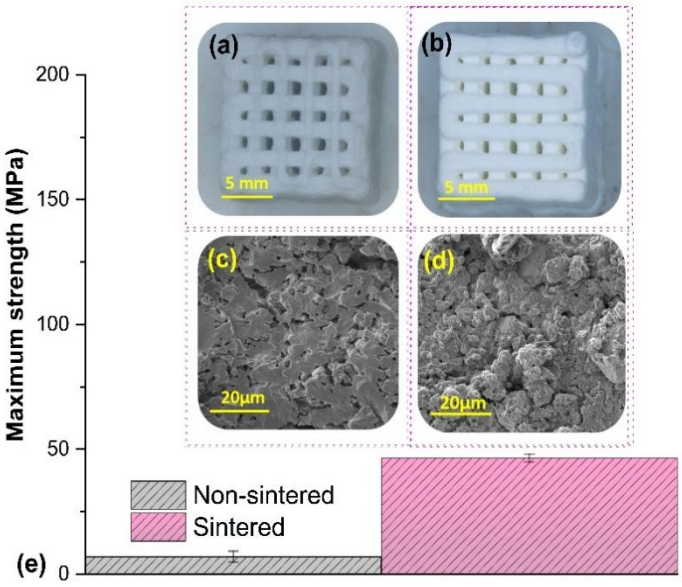

Fig.1 - Structural and mechanical characterization of BioS scaffolds: macroscopic view (a,b) and SEM micrographs (c,d) of non-sintered and sintered scaffolds, respectively. Maximum strength obtained from uniaxial compression tests of the scaffolds before and after sintering (d).

The compressive mechanical behavior of the scaffolds is presented in Fig.1(e). The non-sintered scaffolds exhibited a compressive strength of 5.9 ± 1.2 MPa, whereas the sintered scaffolds demonstrated a statistically significant increase ($p < 0.0001$), reaching values of 46.5 ± 1.6 MPa. This substantial improvement can be attributed to the consolidation of the ceramic network during sintering, which enhances particle bonding and load transfer throughout the structure, resulting in a significant increase in mechanical strength [17, 18].

B. Morphological, Mechanical Analyses, and Computational Modeling

Although the morphological and mechanical analyses provide valuable information regarding scaffold characteristics, they offer only limited insight into the three-dimensional architecture. Therefore, µ-CT was employed to reconstruct the actual scaffold geometry and generate representative computational models for subsequent finite element simulations, as shown in Fig. 2.

Fig. 2(a–d) presents three-dimensional µ-CT reconstructions of the sintered BioS scaffolds, confirming that the designed architecture was preserved after thermal processing. This is evidenced by the regular filament arrangement and the fully interconnected porous network maintained throughout the structure, providing a high-fidelity representation of the as-fabricated scaffolds.

A quantitative morphometric comparison between the idealized CAD geometry and the µ-CT reconstruction further confirmed the structural fidelity of the processing route. While the idealized CAD model possessed a theoretical porosity of 70% and a nominal filament diameter of 580 µm, µ-CT analysis of the sintered scaffolds revealed a reduced filament diameter of 450 ± 30 µm (0.45 ± 0.03 mm) and an open porosity of approximately 20%. Furthermore, the total porosity decreased by 30.14% from the non-sintered control group to the sintered scaffolds. These microstructural changes are highly consistent

with the observed post-sintering volumetric shrinkage and successfully validate the structural representations employed in the numerical models.

Furthermore, Fig. 2(e–f) compares the raw µ-CT data with the computationally processed model used for finite element (FE) mesh generation. The excellent geometric agreement between them demonstrates that the segmentation and processing procedures successfully retained the scaffold's key structural features, yielding a reliable model for numerical simulations.

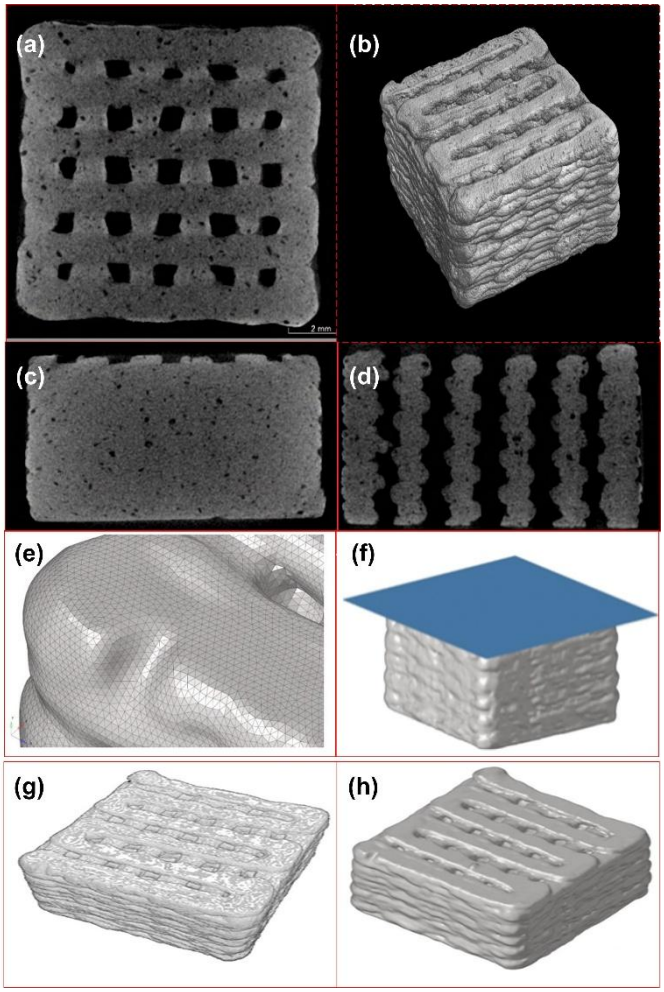

Fig. 2 - Three-dimensional µ-CT reconstructions of sintered BioS scaffolds: (a) front, (b) side, and (c) top views; (d) detailed side view highlighting the filament stacking architecture. A qualitative comparison is shown between (e) the raw µ-CT reconstruction and (f) the computationally processed model. The finite element analysis (FEA) setup illustrates (g) the applied boundary conditions and (h) the generated mesh.

The processed geometries were imported into HyperMesh to generate the finite element mesh, as illustrated in Fig. 2 (g–h). Comprising 3,232,395 linear tetrahedral (C3D4) elements and 600,299 nodes, this discretization accurately captured the geometric complexity of the scaffolds and was subsequently exported to Abaqus for numerical simulation.

Fig. 3 illustrates the mechanical response of the BioS scaffolds under compression, plotting Force (N) against Displacement (mm). The data is separated into experimental results and two computational models.

Experimental curve exhibits an initial non-linear region (0 to 0.2 mm) followed by a pronounced linear elastic regime. The curve reaches a peak force of approximately 5500 N at a displacement of 0.65 mm, indicating structural failure. This is followed by a sharp drop and a long, fluctuating plateau extending up to 2.0 mm, typical of cellular solid crushing behavior. The compression tests performed on the scaffolds demonstrated the typical mechanical behavior of brittle ceramic materials. The elastic limit nearly coincided with the maximum compressive stress, indicating the limited plastic deformation capacity of the scaffolds. Once the maximum stress was reached, structural failure was initiated through the nucleation and propagation of cracks within the ceramic structure [19, 20].

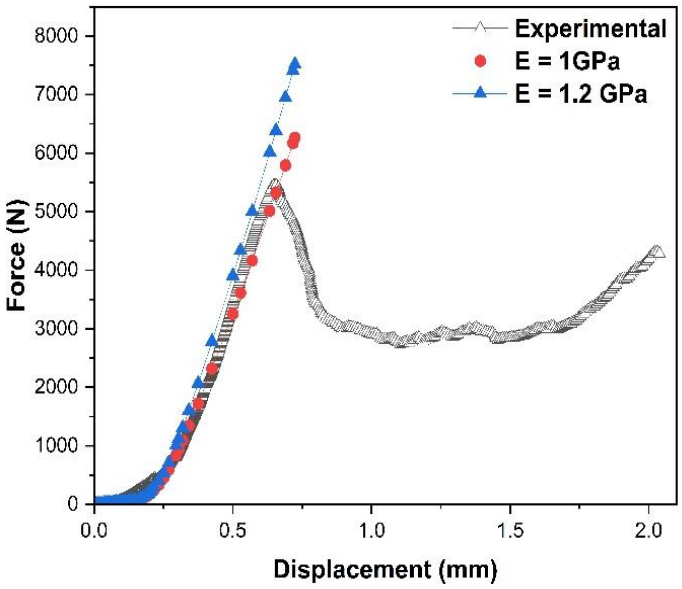

Fig. 3 - Experimental and computational force-displacement curves for BioS scaffolds under uniaxial compression. The experimental data (grey open triangles) is compared against finite element simulations adopting a solid phase Young's modulus of E = 1 GPa (red circles) and E = 1.2 GPa (blue triangles).

The Poisson's ratio was adopted from values reported in the literature, whereas the elastic modulus was estimated by fitting the numerical response to the experimental stress–strain curve. Although no formal optimization procedure was employed to refine the fitting process, the adopted approach provided representative and physically consistent mechanical properties for the analyzed scaffolds.

The numerical simulations were performed in Abaqus using an implicit dynamic analysis under a quasi-static assumption. This approach is highly suitable for nonlinear problems where inertial effects are negligible, effectively treating the compressive loading as a slowly applied static load to ensure robust convergence despite geometric nonlinearities and contact interactions.

The parameter identification process revealed that a solid-phase elastic modulus of 1.0 GPa yielded the most accurate representation of the experimental macroscopic stiffness. The calibrated numerical model demonstrated high accuracy throughout the linear elastic regime, confirmed by an error metric of $R^2 = 0.98$ and an RMSE of 202.32 N (3.72%). While this procedure calibrates effective modulus rather than serving as an independent validation, the obtained value is physically consistent for highly porous ceramic scaffolds.

The experimental curve shows that the transition between the elastic limit and the peak compressive force is virtually absent, which is characteristic of brittle ceramics. Following this

maximum load, the scaffold undergoes abrupt structural failure due to crack initiation and propagation.

To determine the appropriate solid phase elastic modulus, values of 1.0 GPa and 1.2 GPa were evaluated. The 1.0 GPa model yielded the best fit with the experimental force–displacement curve. Although considerably lower than the modulus typically reported for dense ceramic materials (~70 GPa), this difference is directly attributed to the intrinsic porosity of the processed scaffolds [14, 21] .

The high porosity of the microstructure substantially reduces the effective stiffness of the material, as the elastic modulus decreases markedly with increasing porosity. Therefore, the results suggest that the observed mechanical response is directly governed by the porous microstructure developed during scaffold processing [22, 23].

Overall, the numerical models accurately captured the mechanical behavior of the BioS scaffolds sintered at 900 °C. Reaching a compressive strength of approximately 50 MPa, these scaffolds demonstrate the efficiency of higher sintering temperatures in promoting ceramic network densification and reducing porosity. These results emphasize that the mechanical performance of the fabricated scaffolds is fundamentally governed by the interplay between their porous architecture and degree of structural consolidation.

The finite element simulations also revealed the internal stress distribution of the scaffold under compressive loading. As illustrated in Fig. 4, the numerical setup applied to the idealized CAD model includes a 5 kN compressive load. This detailed view highlights the orthogonal stacking architecture of the filaments and reveals the fine finite element mesh (discretization) generated over the cylindrical surfaces for the numerical simulation. In this manner, the detailed inset confirms that the adopted mesh discretization accurately captures the geometric complexity of the scaffold architecture, particularly at the critical filament intersections and stacking regions.

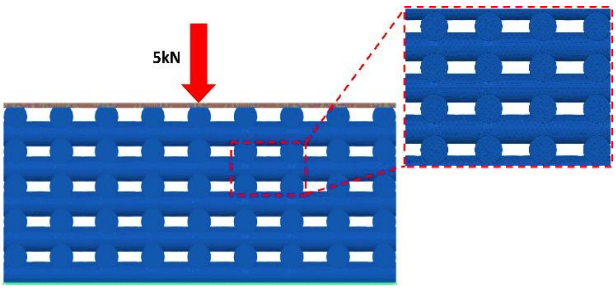

Fig. 4 - Computational setup for the finite element analysis of the BioS scaffold under uniaxial compression. A 5 kN compressive load is applied to the upper surface of the model, while the magnified inset highlights the filament stacking architecture and the generated mesh discretization.

The finite element analysis (FEA) of the idealized CAD model provided critical insights into the internal mechanics of the scaffolds under compression (Fig. 5). The displacement field (Fig. 5a) revealed that deformation was predominantly localized in the central region of the structure, demonstrating that the macroscopic mechanical response is highly dependent on the internal filament arrangement and pore distribution.

Furthermore, the maximum principal stress distribution (Fig. 5b) highlighted localized tensile stress concentrations, primarily at the intersections between adjacent filaments. Excluding localized mesh singularities at the load application node and artificial stress concentrations from the rigid contact interface, tensile stresses reached approximately 30–47 MPa at these critical junctions. In contrast, the bulk of the scaffold body exhibited moderate stresses in the range of 5–15 MPa. Because small microstructural heterogeneities and localized stress concentrations act as preferential sites for crack initiation, these intersections represent the primary failure origins, which is highly consistent with the brittle fracture mechanisms typically observed in porous ceramics [24].

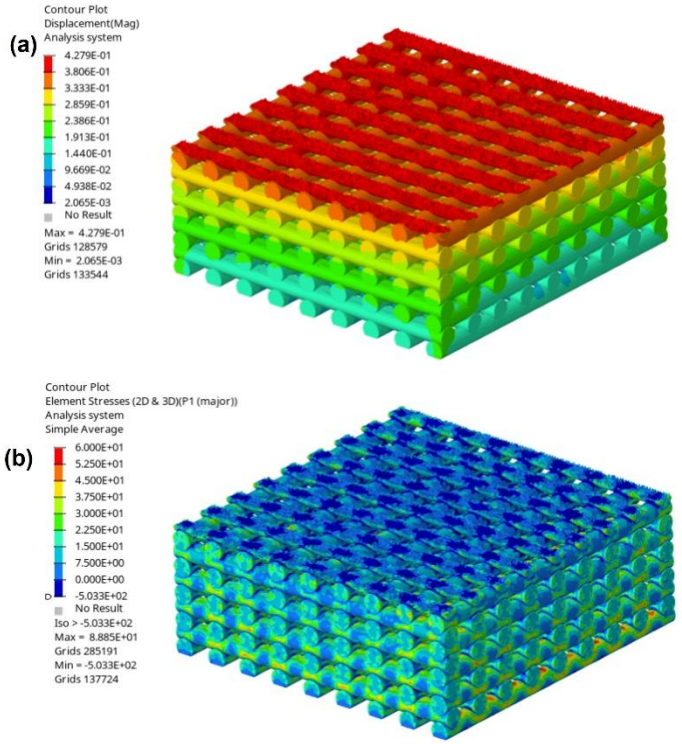

Fig. 5 - Finite element analysis results obtained from the idealized CAD model under simulated compressive loading. (a) Displacement distribution (mm): the hatched outline denotes the initial undeformed configuration, while the colored scaffold represents the deformed state. (b) Maximum stress distribution (MPa): localized tensile stress concentrations are identified predominantly at the filament intersection regions.

IV. CONCLUSIONS

The integration of µ-CT reconstructions and finite element analyses elucidated the critical relationship between the scaffold's microarchitecture and its macroscopic mechanical response. Structurally, the 3D reconstructions confirmed that the scaffolds sintered at 900 °C successfully preserved their designed architecture. This structural fidelity, combined with the enhanced densification achieved during sintering, yielded an experimental compressive strength of approximately 50 MPa.

Computationally, the numerical models demonstrated excellent agreement with the experimental force–displacement data, identifying an effective solid-phase elastic modulus of 1.0 GPa. Furthermore, simulations of the idealized CAD model revealed that internal stress distributions are fundamentally governed by the filament arrangement. Tensile stress concentrations reaching 30–47 MPa were localized specifically at the filament intersections, pinpointing these junctions as primary failure initiation sites. Ultimately, this combined experimental and numerical approach provides a robust

framework for the future design and topological optimization of BioS scaffolds in bone tissue engineering applications.

Abstract— **Polycaprolactone (PCL) is widely used to fabricate scaffolds for tissue engineering, but sterilization may alter its thermal and mechanical properties or produce cytotoxic residues. This study evaluated the effects of hydrogen peroxide plasma sterilization on 3D-printed PCL and PCL/Bioglass composite specimens containing 20 wt% Bioglass (PCL/BG). Filaments were produced by extrusion and used to manufacture specimens by fused deposition modeling. The specimens were sterilized using a 55-min hydrogen peroxide plasma cycle and characterized by thermogravimetric analysis, tensile testing, and an indirect cytotoxicity assay using L929 fibroblasts. Sterilization caused no macroscopic changes or statistically significant alterations in the elastic modulus, yield stress, or yield strain of either material. The thermal degradation onset temperatures remained practically unchanged, with values of 378 and 380 °C for nonsterile and sterilized PCL specimens, respectively, and 275 °C for both nonsterile and sterilized PCL/BG specimens. Cell viability remained close to or above 90% in all groups, with no statistically significant differences among treatments ($p > 0.05$). The PCL/BG specimens exhibited lower thermal stability and yield stress than neat PCL, which may be associated with polymer degradation during composite-filament processing rather than with sterilization. These findings support its use as a low-temperature sterilization method for PCL-based materials intended for biomedical and tissue-engineering applications.**

Keywords **- PCL; Bioglass, Plasma Sterilization; 3D Printing.**

I. Introduction

Polycaprolactone (PCL) is a semicrystalline aliphatic polyester widely used in the development of biomaterials, scaffolds, and medical devices due to its biocompatibility, biodegradability, processability, and structural stability in long-term applications [1]. In tissue engineering, PCL has been extensively investigated for the fabrication of three-dimensional structures using techniques such as 3D printing, electrospinning, and porous molding-based methods. These techniques enable the production of scaffolds with controlled architecture, interconnected porosity, and mechanical properties tailored to the intended application. However, despite its advantages, the functional performance of PCL depends directly on its physical properties, including surface morphology, crystallinity, thermal stability, molar mass, dimensional integrity, and mechanical strength [2, 3, 4, 5].

For PCL-based biomaterials to be used in biological assays or clinical applications, the sterilization step is indispensable. The presence of microbial contaminants can compromise material safety, interfere with cellular responses, and render its biomedical application unfeasible [6]. However, the choice of sterilization method represents a challenge, since physical, chemical, or radiative processes may alter the properties of the polymer. Methods such as ethylene oxide (EtO) (ISO 11135), gamma radiation (ISO 11137), hydrogen peroxide plasma (HPP) (ISO 14937), ultraviolet radiation (ISO 14937), alcohol (ISO 14937), peracetic acid (ISO 14937), ozone (ISO 14937), dry heat (ISO 20857), and autoclaving (ISO 17665) have been used to sterilize or disinfect polymeric materials, but their effects vary according to the composition, geometry, porosity, and manufacturing method of the material [7, 8].

Among the available sterilization methods, EtO and gamma radiation are the most widely used for PCL-based materials in the biomedical field. Ethylene oxide operates at low temperatures and low relative humidity, which minimizes thermomechanical stress on the polymer matrix . Studies have shown that EtO sterilization preserves the structural integrity, surface texture, crystallinity, and shape memory behavior of PCL-based scaffolds, making it a suitable option when dimensional fidelity and morphological preservation are critical requirements [9]. However, residual EtO absorbed by the material may require extended aeration periods before biological use, and concerns regarding cytotoxic residues and environmental hazards have been

raised [10]. Gamma radiation, in turn, is a penetrating and highly effective sterilization method, but its interaction with PCL chains can induce simultaneous chain scission and cross-linking events [11]. Additionally, gamma irradiation has been reported to lead to a significant decrease in molecular weight accompanied by an increase in crystallinity of PCL fiber mats, though mechanical properties did not always change significantly [12, 13]. These structural modifications may influence the kinetics of degradation, cell–scaffold interactions, and long-term mechanical performance of the device.

HPP sterilization has emerged as a promising low-temperature alternative, particularly suited for heat-sensitive polymeric biomaterials. The method is based on the generation of a plasma state in which hydrogen peroxide is ionized, producing reactive free radicals that non-specifically interact with molecules essential to microbial metabolism and reproduction, resulting in rapid and effective microbicidal action at temperatures generally below 50 °C [14]. At the end of the sterilization cycle, the process is designed to promote the decomposition of hydrogen peroxide into water vapor and oxygen [15]. However, potential retention of process-related species and material compatibility should be evaluated for each material and device geometry, particularly for porous or complex structures. Therefore, characterization of the effects of HPP sterilization on both material properties and biological response remains important for PCL-based biomedical devices.

Accordingly, the present study aimed to investigate the effect of H_2O_2 plasma sterilization method on the physical properties of 3D printed specimens of PCL and PCL/Bioglass (80/20 w/w) composite, hereafter referred to as PCL/BG , contributing to the definition of safer and more suitable sterilization protocols for biomedical and tissue engineering applications.

II. Materials and methods

A. Materials

Polycaprolactone (PCL; average Mn 80,000; product no. 440744) was purchased from Sigma-Aldrich/Merck). Bioglass (bioactive glass ceramic 45S5) was supplied by Vetra Biomaterials, Brazil)

B. Preparation of PCL and PCL/BG (80/20 w/w) filament

PCL and PCL/BG filaments with a diameter of 1.75 mm were produced using a twin-conical-screw microextruder (MC 40, Xplore) at a temperature of 150 °C and screw rotation speeds ranging from 100 to 250 rpm.

For the PCL/BG (80/20) composite, PCL and BG particles with a diameter of 5 µm were initially mixed and homogenized using a LAB 16 single-screw mini-extruder (AX Plásticos). The extruder was operated at a screw speed of 40 rpm and a maximum torque of 28 N·m, using a temperature profile of 140, 130, and 115 °C. The resulting composite extrudate was subsequently pelletized and used as feedstock in the MC 40 microextruder to produce filaments with a controlled diameter.

C. 3D printing of PCL and PCL/BG

The test specimens were manufactured by fused deposition modeling (FDM) using a Creality Ender-3 S1 3D printer. Pure PCL specimens were printed at a nozzle temperature of 190 °C, whereas the PCL/bioglass composite specimens were printed at 180 °C. For both compositions, the build plate temperature was maintained at 38 °C. The three-dimensional models were prepared for printing using PrusaSlicer, with a rectilinear infill pattern and 100% infill density. Except for the nozzle temperature, all printing parameters were kept constant to minimize variability between samples.

D. Sterilization by hydrogen peroxide plasma

The 3D printed PCL and PCL/BG specimens were placed in Tyvek packaging (DuPont, Michigan, USA) and sterilized using the 55-min "rapid cycle" of a STERRAD 100S system (Advanced Sterilization Products/Johnson & Johnson, New Jersey, USA). This sterilization protocol was validated in previous work using the direct inoculation method introducing microorganisms into a culture medium which confirmed the absence of microbial growth in the sterilized samples [16].

E. Thermal analysis

Thermogravimetric analysis was performed on the raw material, filament and 3D printed PCL and PCL/BG specimens before and after sterilization by using a Shimadzu DTG-60H equipment. Samples were heated from room temperature to 500ºC at a heating rate of 10ºC/min under a nitrogen atmosphere at a flow rate of 50mL/min to obtain an inert atmosphere.

F. Tensile stress x strain test

Tensile tests were performed on 3D printed PCL and PCL/BG specimens before and after sterilization using an INSTRON 3369 universal testing machine. A crosshead speed of 5mm/min was used. The values of elastic modulus, yield stress and yield strain were determined and reported as the mean values obtained from three specimens (n=3).

G. *In Vitro cytotoxicity assay*

Indirect cytotoxicity was evaluated according to ISO 10993-5 using L929 fibroblasts. The assay aimed to determine whether hydrogen peroxide plasma sterilization induced the release of cytotoxic compounds from the 3D-printed PCL and PCL/bioglass specimens. Samples sterilized by UV irradiation were used as a comparison group. Material extracts were prepared by incubating the specimens in complete culture medium at an extraction ratio of 0.1 g/mL for (24 ± 2) h at (37 ± 1) °C. L929 fibroblasts were seeded at a density of 1×10^4 cells per well and allowed to adhere for 24 h. The culture medium was then replaced with the respective material extracts, and the cells were exposed for an additional 24 h. Cells maintained in complete culture medium were used as the viable control, whereas cells exposed to culture medium containing 50% DMSO were used as the positive cytotoxicity control. Cell metabolic activity was assessed using 0.01% resazurin, and cell viability was calculated

relative to the viable control. Statistical analysis was performed using an ordinary one-way ANOVA followed by Dunnett's multiple comparisons test, with each material group compared with the viable control. Homogeneity of variances was assessed using the Brown–Forsythe test, and statistical significance was set at $p < 0.05$. The positive cytotoxicity control was used to confirm assay responsiveness and was excluded from the inferential statistical analysis.

III. Results and Discussion

A. PCL and PCL/Bioglass filament

After the processing difficulties associated with PCL and the PCL/BG composite had been overcome, filaments with a diameter of 1.75 mm were successfully obtained (Fig. 1a). The processing difficulties encountered with pure PCL were probably related to chain entanglement and intermolecular interactions resulting from the high molar mass of the PCL used.

The addition of Bioglass altered the melt characteristics and caused darkening of the PCL/BG filament. Moisture adsorbed onto Bioglass as well as the presence of ions present in the biomaterial are critical factors in composite production since during thermal processing, water and ions may catalyze the hydrolysis of PCL ester bonds, reducing the molar mass of the polymer and causing filament darkening [17,18].

B. 3D printing of PCL and PCL/BG

The specimens were successfully fabricated by FDM using the optimized printing parameters, as shown in Table I. The printed samples presented a well-defined geometry and preserved the overall shape of the digital model. Continuous filament deposition was observed throughout the printing process, resulting in specimens with regular layer stacking and no evident macroscopic defects, such as warping, delamination, or incomplete filling. The use of 100% rectilinear infill produced fully filled specimens suitable for subsequent characterization and testing. Representative images of the printed specimens are shown in Figure 1b and 1c.

TABLE I. Printing parameters for PCL and PCL/BG

Parameters	*PCL*	*PCL/BG*
Nozzle temperature (ºC)	190	180
Bed temperature (ºC)	38	38
Extrusion multiplier	1	1
Fill (%)	100	100
Speed (mm/s)	20	20

No macroscopic differences were observed in either the PCL or PCL/BG specimens before and after sterilization (Fig. 1b and 1c).

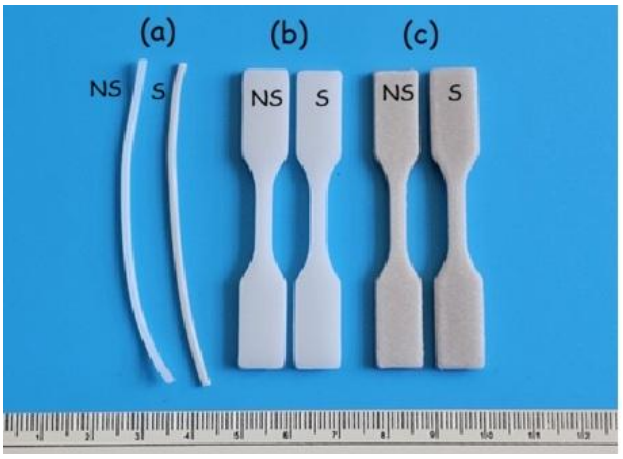

Fig. 1. Photographs of (a) PCL and PCL/BG filament, (b) PCL specimens produced by 3D printing before and after H_2O_2 plasma sterilization, and (c) PCL/BG specimens produced by 3D printing before (NS) and after (S) H_2O_2 plasma sterilization.

C. Thermogravimetric Analysis

TGA analysis is an important method for evaluating the thermal stability of polymeric materials and it can also provide an indirect assessment of polymer degradation because the thermal stability depends partly on the average molar mass of the polymer. Fig. 2 shows the TGA curves of PCL raw material, PCL and PCL/BG filaments and 3D printed specimens before and after hydrogen peroxide plasma sterilization. In this study, thermal stability was evaluated using the onset temperature of thermal degradation (T*onset*), in accordance with ISO 11358-1 standard. Two distinct sets of curves were observed: one for neat PCL and another for the PCL/BG composite. The thermal stability of the composite was significantly lower than that of neat PCL. This difference was probably caused by degradation during the processing and fabrication of the PCL/BG filament, as discussed in Section III-A. However, the T*onset* values of the 3D-printed specimens remained practically unchanged after sterilization, as shown in Table II. This finding indicates that the sterilization process did not cause detectable thermal degradation of the 3D-printed PCL or PCL/BG specimens. .

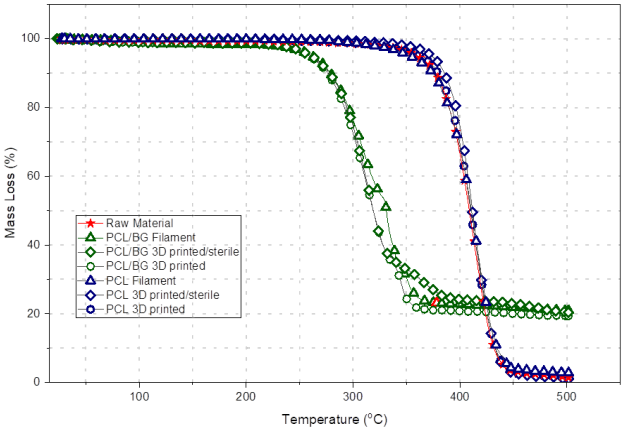

Fig. 2. TGA curves of PCL raw material, PCL and PCL/BG filaments; and PCL and PCL/BG 3D printed specimens before and after hydrogen peroxide plasma sterilization.

TABLE II. VALUES OF ONSET TEMPERATURE (TONSET) AND RESIDUAL MASS DETERMINED FROM THE TGA CURVES..

sample	T*onset* (ºC)	Residual mass (%)
RM	378	zero
PCL filament	372	zero
PCL 3d printed	378	zero
PCL 3d printed sterile	380	zero
PCL/BG filament	278	20 %
PCL/BG 3d printed	275	20 %
PCL/BG 3d printed sterile	275	20 %

The residual mass of 20% observed for the composite samples corresponds to the bioactive-glass content of the composite. Bioactive glass does not undergo thermal degradation below 500 °C under an inert atmosphere.

The TGA results also indicated that 3D printing did not cause detectable degradation of PCL or PCL/BG, even though the printing temperatures were considerably higher than the melting temperature of PCL. This conclusion is supported by the similar T*onset* values obtained for the materials before and after 3D printing.

D. Tensile stress x strain Behaviour

The mechanical properties of a polymeric material can provide an indirect indication of degradation caused by polymer-chain scission because these properties depend partly on the average molar mass of the polymer. In this study, the mechanical properties of the 3D-printed specimens were determined from tensile stress-strain curves. Figure 3 presents the tensile behavior of the specimens, and Table III summarizes their mechanical properties.

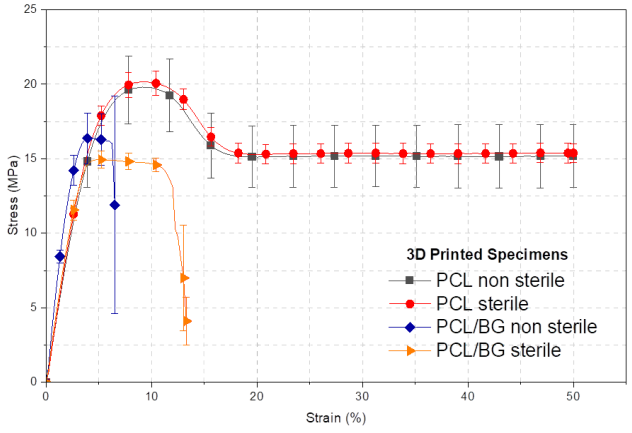

Fig. 3. Tensile stress x strain average curves (n=3) of PCL and PCL/BG 3D printed specimens before and after hydrogen peroxide plasma sterilization.

All specimens exhibited typical ductile behavior. This behavior was particularly evident for neat PCL, which did not rupture even at strains exceeding 50%. The elastic modulus, yield stress, and yield strain of the 3D-printed PCL specimens did not differ significantly before and after sterilization, as shown in Table III.

Although the PCL/BG composite specimens also exhibited ductile behavior, they had a higher elastic modulus and lower yield stress and yield strain than pure PCL. An increase in elastic modulus is expected when a rigid filler is incorporated into a polymer matrix. The lower yield-stress values of the PCL/BG composite relative to pure PCL may provide further evidence of PCL degradation during composite-filament production.

TABLE III. MECHANICAL PROPERTIES OF 3D PRINTED PCL AND PCL/BG SPECIMENS.

Properties	***PCL***		***PCL/BG***	
	Non sterile	Sterile	Non sterile	Sterile
Elastic Modulus (MPa)	4.2 ± 0.5	4.5 ± 0.2	5.3 ± 0.5	4.4 ± 0.2
Yield Stress (MPa)	14.6 ± 0.5	14.2 ± 0.5	12.3 ± 0.7	12.4 ± 0.6
Yield Strain (%)	3.9 ± 0.3	3.6 ± 0.3	2.1 ± 0.2	2.8 ± 0.2

The results indicate that hydrogen peroxide plasma sterilization did not cause detectable degradation of the materials investigated. No statistically significant differences were observed between the mechanical properties of the 3D-printed PCL or PCL/BG specimens before and after sterilization.

E. *In Vitro cytotoxicity assay*

The indirect cytotoxicity assay demonstrated that extracts obtained from all 3D-printed specimens maintained high L929 cell viability after 24 h of exposure (Figure 4). Mean cell viability was 97.79% for PCL/BG-HPP, 90.89% for PCL/BG-UV, 99.82% for PCL-HPP, and 101.7% for PCL-UV, relative to the viable control. No overall differences were detected among the evaluated groups (one-way ANOVA, $F(4,55) = 0.5216$, $p = 0.7202$). Moreover, Dunnett's multiple comparisons test showed that none of the material groups differed significantly from the viable control ($p > 0.05$).

These findings indicate that neither the PCL nor the PCL/bioglass specimens released compounds capable of producing a detectable cytotoxic response under the evaluated extraction and exposure conditions. Importantly, the high viability observed for the HPP-sterilized groups indicates that no detectable extract-mediated cytotoxic effect was associated with the sterilization process under the conditions evaluated. Although hydrogen peroxide sterilization cycles are designed to promote peroxide decomposition, this assay does not directly quantify residual hydrogen peroxide or other process-related species. This observation is particularly relevant because sterilization procedures may potentially alter polymeric materials or leave process-related residues that could affect cellular responses. Nevertheless, the viability of cells exposed to extracts from HPP-sterilized PCL and PCL/BG specimens remained close to that of the viable control.

The presence of bioglass also did not result in a detectable cytotoxic effect. Although the PCL/BG-UV group showed the lowest mean viability (90.89%), this reduction was not statistically significant compared with the viable control ($p = 0.6411$), and viability remained high. Furthermore, the comparable cellular responses observed for PCL and PCL/BG specimens suggest that the incorporation of bioglass, under the conditions investigated, did not

introduce soluble components at concentrations sufficient to impair L929 metabolic activity.

Taken together, these results support the cytocompatibility of both 3D-printed PCL and PCL/BG specimens and indicate that hydrogen peroxide plasma sterilization can be applied without compromising their biological response in the indirect cytotoxicity assay. However, as this assay evaluates the effects of soluble compounds released from the materials over a 24 h exposure period, these findings specifically demonstrate the absence of detectable extract-mediated cytotoxicity and should not be interpreted as a comprehensive assessment of long-term cellular interactions with the materials.

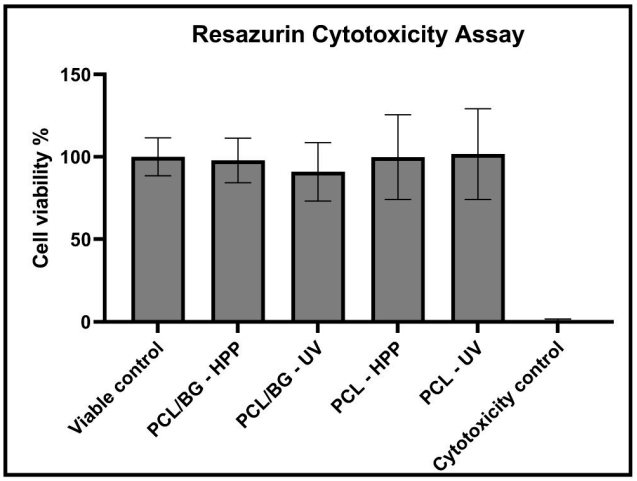

Fig. 4. L929 cell viability after 24 h of exposure to extracts obtained from 3D-printed PCL and PCL/BG specimens subjected to hydrogen peroxide plasma sterilization or treatment with UV irradiation. Data are presented as mean ± standard deviation. No statistically significant differences were observed among the experimental groups ($p > 0.05$).

IV. Conclusion

The results of this study demonstrate that hydrogen peroxide plasma sterilization is a suitable low-temperature method for 3D-printed PCL and PCL/BG biomedical devices. No macroscopic changes were observed after sterilization, and the thermal degradation onset temperatures remained practically unchanged for both materials. The tensile tests also showed no differences in the elastic modulus, yield stress, or yield strain between nonsterile and sterilized specimens. Furthermore, the indirect cytotoxicity assay showed high L929 cell viability in all groups, indicating that the indirect cytotoxicity assay showed no detectable extract-mediated cytotoxicity associated with the sterilized specimens under the evaluated conditions.

The lower thermal stability and yield stress of PCL/BG compared with neat PCL were most likely associated with degradation during composite-filament processing rather than with hydrogen peroxide plasma exposure. Overall, hydrogen peroxide plasma sterilization preserved the evaluated thermal, and mechanical properties of the 3D-printed materials while maintaining their in vitro cytocompatibility. These findings support the use of this sterilization method for PCL-based scaffolds intended for biomedical and tissue-engineering applications. Further studies should evaluate its effects on surface properties, long-term degradation, and biological performance under application-specific conditions.

***Abstract*—Tissue engineering is a way to help organs and living tissues grow back after they are damaged by disease and cannot repair themselves easily. One important step in this field is to take cells from the patient's own body. These cells are removed from the original tissue and grown on special surfaces like dense films or three-dimensional scaffolds. The films or scaffolds can be made from natural or synthetic materials. After the cells grow, the whole structure is put back into the patient's body. In this context, this study evaluated the hydrolytic degradation behavior and cell interaction aspects of dense poly(lactic acid) (PLA) films, a material widely investigated as a substrate for tissue engineering. PLA films were obtained by solvent evaporation and subjected to *in vitro* degradation protocols, 70 °C (accelerated degradation) for up to 7 days, with monitoring of mass loss and macro- and microstructural morphology. In parallel, the adhesion and growth of Vero cells on the films were evaluated for up to 7 days of culture. The results indicated progressive mass loss and opacification of the films throughout degradation, in the accelerated assay, and show that Vero cells were able to adhere, spread, and possibly proliferate on the substrate, maintaining morphology typical of the cell line and without apparent signs of cytotoxicity. It is concluded that PLA constitutes a biodegradable and biocompatible substrate with potential application for tissue regeneration, like bone, cartilage or skin.**

***Index Terms*—Poly(lactic acid); Biodegradation; Tissue engineering; Cell culture; Biocompatibility.**

I. Introduction

The difficulty of certain injured organs and tissues to repair themselves spontaneously has, in recent decades, driven the development of tissue engineering as an approach that combines cells, biomaterials, and signaling molecules to induce tissue regeneration [1], [2]. Biomaterials, presented as three-dimensional scaffolds, or dense films, provide temporary structural support for cell adhesion, migration, and proliferation and should later be resorbed as a new extracellular matrix deposited by the cells themselves [1], [3].

Among the polymeric biomaterials used for this purpose, the poly(α-hydroxy acids) stand out — a class of synthetic aliphatic polyesters that includes poly(lactic acid) (PLA), poly(caprolactone) (PCL), poly(glycolic acid) (PGA), and poly(p-dioxanone) (PDO) [4]. PLA is a promising alternative due to its biocompatibility and biodegradability. Furthermore, its degradation products are eliminated through the body's own metabolic pathways, which reduces postoperative risks and costs [1], [4].

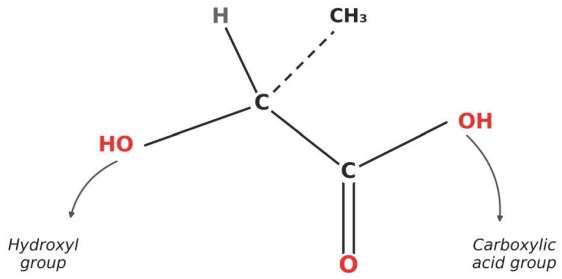

Fig. 1. Biofunctionality of lactic acid: hydroxyl and carboxylic acid groups of the monomeric unit [4], [5].

PLA degradation occurs predominantly through simple hydrolysis of the ester bonds in the main chain, forming hydroxyl and carboxyl end groups (Fig. 2).

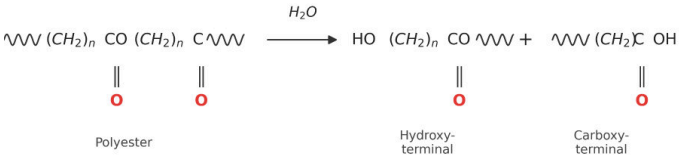

Fig. 2. Hydrolysis of the polyester ester bonds, forming hydroxyl and carboxyl terminal groups [1], [5].

The resulting oligomers are converted into lactate and pyruvate and, in the presence of acetyl-CoA, are incorporated

into the Krebs cycle, ultimately being eliminated as CO_2 and H_2O through respiration and urine (Fig. 3) [1], [6].

The kinetics of this degradation depend on factors such as molar mass, crystallinity, shape, thickness, pH, and medium temperature [4], [7]. The literature reports resorption times for PLA ranging from a few weeks to several years, depending on the stereoisomer and the morphology of the device [8].

Bioresorbable PLA devices have already been used *in vitro* as a scaffold for different cell types, including bone, chondral, and epidermal cells, with no evidence of toxicity, with cells adhering, proliferating, and producing extracellular matrix components [9]. Recent studies support this potential in bone, cartilage, and meniscus tissue engineering, while also pointing to limitations of pure PLA, such as low initial cell adhesion and local acidification during degradation, which have driven the development of blends and composites [10], [11], [12]. These limitations are starting points for improvement rather than reasons to discard the material: PLA's hydrophobicity and low surface energy can be reduced through plasma treatments, adhesion-protein coatings, or bioactive fillers, while its mechanical fragility and degradation kinetics can be adjusted through copolymerization (as in PLGA) or blending with natural polymers [10], [12]. Understanding how these limitations appear under simple *in vitro* conditions, like those used in this study, is a necessary step before moving to material modification strategies or more complex *in vivo* assays.

Thus, this study aimed to characterize the hydrolytic degradation behavior of PLA films under 70 °C and to evaluate the adhesion, spreading, and morphological maintenance of Vero cells cultured on this substrate, contributing to the discussion of its potential as a substrate for tissue regeneration.

II. Materials and Methods

A. Preparation of PLA films

Dense films were obtained by dissolving PLA (PLA2002D, NatureWorks®/Cargill) in chloroform at 10% (w/v), at room temperature. The solution was poured onto glass plates and kept in a fume hood for approximately one week, until complete evaporation of the solvent.

B. Hydrolytic degradation assay

In vitro degradation protocol was carried out, adapted from Barbanti et al. [4]. Three rectangular samples (2.5 × 1.0 cm) were sterilized in 70% alcohol, immersed in buffer solution (pH 7.2) and kept in an oven at 70 °C for 1 and 7 days, characterizing an accelerated degradation assay, following ISO 13781 [13]. The results were presented as mean ± standard deviation.

C. Cell culture on PLA

Fibroblast-like Vero cells (african green monkey kidney, reference CCL-81, ATCC) were cultured in medium 199 supplemented with 10% fetal bovine serum and antibiotic, at 37 °C. High-density inocula (1×10^3 cells/mL) were seeded onto PLA samples previously sterilized with ethylene oxide, with medium changes every 3 days. The positive control consisted of cells cultured directly on the plate. Adhesion was evaluated by phase-contrast microscopy after 30 min and 2 h of incubation, and cell morphology after 2, 5, and 7 days, by staining with toluidine blue and methylene blue under inverted and upright light microscopes (Axiovert A1, Zeiss).

III. Results

A. Hydrolytic degradation

In the accelerated degradation assay at 70 °C (Fig. 3), mass loss was much more pronounced, reaching about 25% within just 7 days, highlighting the strong dependence of degradation kinetics on medium temperature.

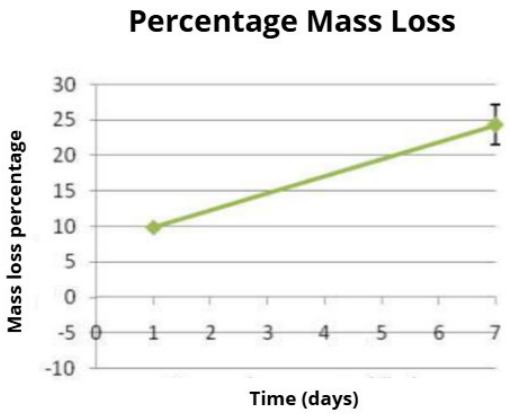

Fig. 3. Percentage mass loss of PLA during accelerated degradation at 70 °C. The results were made in triplicate and are presented as mean ± standard deviation.

Macroscopically (Fig. 4), the initially transparent films became opaque as degradation progressed, an effect that was much more pronounced and rapid at 70 °C, where deformation was already observed after 1 day and complete fragmentation after 7 days.

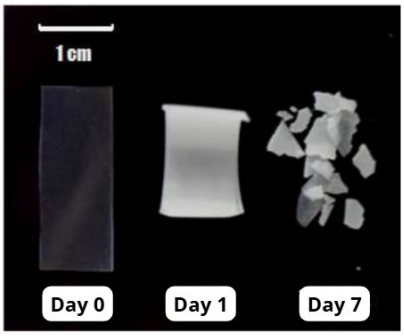

Fig. 4. Macroscopic appearance of the PLA films during accelerated degradation at 70 °C (0, 1, and 7 days).

Stereomicroscopic analysis (Fig. 5) confirms this pattern: at 70 °C, surface cracks are already observed on the first day, progressing to intense brittleness and surface irregularity after 7 days.

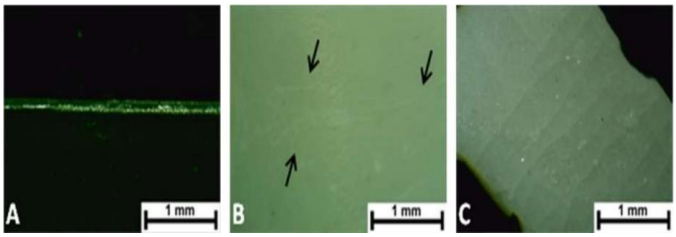

Fig. 5. Stereomicroscopy of the PLA films during accelerated degradation at 70 °C: (A) before degradation; (B) 1 day; (C) 7 days. Magnification: 30×.

B. Cell interaction with PLA

The adhesion process of Vero cells to the substrate is illustrated in Fig. 6. Up to 30 min of incubation, the cells appeared rounded and in suspension. After 2 h, the onset of cell spreading on the film could already be observed.

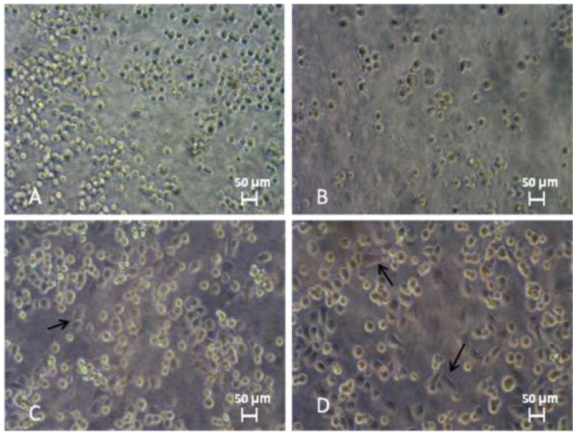

Fig. 6. Adhesion of Vero cells on PLA by phase-contrast microscopy: (A, B) 30 min; (C, D) 2 h of incubation.

Within 2 days of culture (Fig. 7), the cells already formed a monolayer at the edge of the material, similar to the positive control, and on the film itself they appeared slightly less spread, with an estimated confluence of 60–70%.

At 5 days (Fig. 8), the typical fibroblast morphology was maintained, with increased confluence (∼80–90%) both in the control and on the biomaterial, with no signs of cell degeneration.

After 7 days (Fig. 9), a further increase in cell density on the PLA was observed, with the formation of a confluent monolayer of fibroblastic morphology, both at the edge and on the surface of the film, indicating maintained viability throughout the entire evaluation period.

IV. Discussion

In vitro degradation assays represent a low-cost simulation of PLA behavior after implantation, although they do not fully reproduce factors present *in vivo*, such as inflammatory response and local vascularization [14]. The temperature increase in the accelerated assay (70 °C) markedly intensified degradation kinetics as expected from the literature on this material [15], [16], [17].

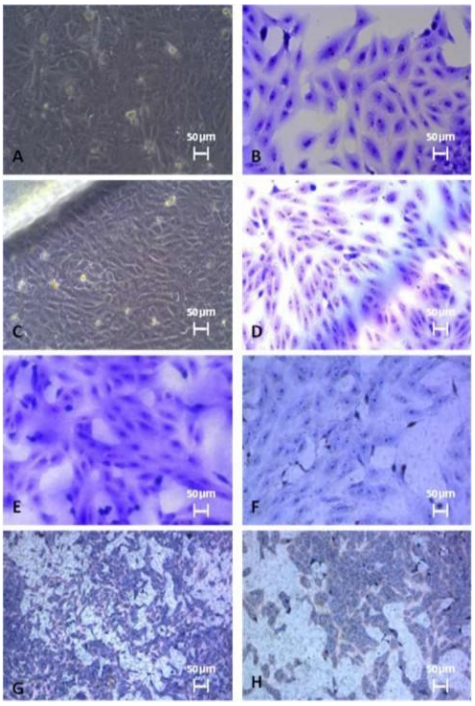

Fig. 7. Vero cells after 2 days of culture: (A, B) positive control; (C–H) cells at the edge and on the PLA film.

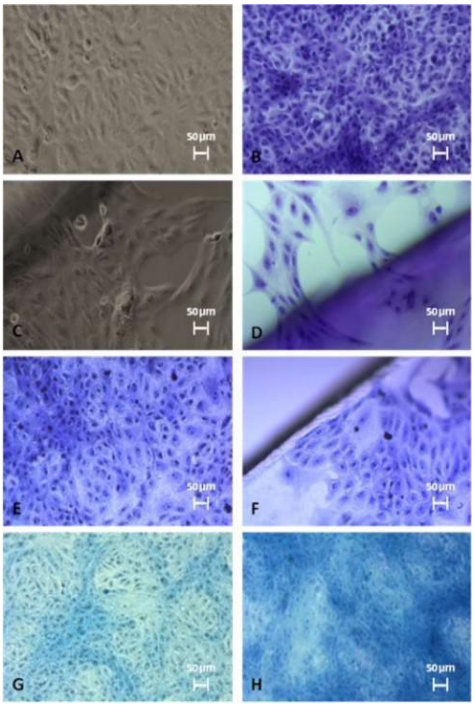

Fig. 8. (A-H) Vero cells after 5 days of culture, stained with toluidine blue and methylene blue.

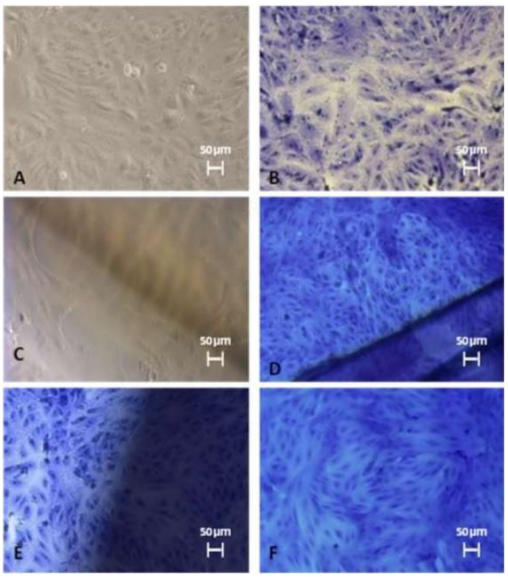

Fig. 9. Vero cells after 7 days of culture at the edge and on the PLA film, stained with toluidine blue.

The increasing opacity of the films throughout degradation is associated with pore formation and the rearrangement of crystalline regions of the polymer, since hydrolysis occurs preferentially in the amorphous phase, and the relative crystalline fraction tends to increase over the course of the process, altering the optical and mechanical properties of the material [4].

Regarding cell interaction, the observed pattern of initial adhesion with rounded cells, followed by progressive spreading and the formation of confluent monolayers, is consistent with the classic sequence described for fibroblasts on synthetic substrates [18]. The maintenance of the typical Vero cell line morphology, both on PLA and in the positive control, throughout the 7 days of culture suggests the absence of relevant cytotoxic effects of the substrate, in agreement with previous results obtained with PLA films applied [9].

These results reinforce the potential of PLA as a biodegradable substrate for tissue regeneration, applicable to contexts such as bone, cartilage, and skin repair, in agreement with the literature [11], [12].

It is also important to weigh these findings against the intrinsic limitations of PLA as a biomaterial. Its hydrophobic nature and the low density of anchoring sites for adhesion proteins may explain the slightly lower cell spreading observed on the film compared to the positive control in the first days of culture. Likewise, the accumulation of acidic hydrolysis byproducts within the material, evident in the pronounced brittleness observed in the 70 °C assay, is a phenomenon widely described as a potential trigger of inflammatory response in *in vivo* applications, although this was not directly assessed in the present in vitro study [10], [11]. These limitations open avenues for future work related to the incorporation of bioactive fillers or surface treatments (plasma, grafting of adhesion molecules) to improve the initial cell response [16], [19], as well as the development of blends or copolymers (such as PLA/PLGA or PLA combined with natural polymers) to modulate degradation kinetics and mitigate local acidification, and the fabrication of three-dimensional, porous scaffolds instead of dense films, so as to favor nutrient diffusion and cell infiltration in contexts closer to clinical application [20], [21]. Other biological and physico-chemical characterizations, such as quantitative cytotoxicity, film's thickness, wettability, roughness, residual solvent and scanning electron microscopy surface analyses will be considered in future studies.

V. Conclusion

The hydrolytic degradation of PLA films was pronounced under accelerated conditions (70 °C), accompanied by its opacification and evident structural weakening, reinforcing the fact that PLA does not constitute a permanent material. The cell interaction assays showed that Vero cells were able to adhere, spread, and proliferate onto the PLA films, in a monolayer, maintaining the morphology characteristic of the Vero cell line and with no evidence of cytotoxicity. Together, these results support PLA as a biodegradable and biocompatible material, with potential application as a substrate for cell growth in tissue regeneration strategies, as for bone, cartilage and skin regeneration.

Abstract*—Hydrogel-based systems have emerged as promising non-viral platforms for localized gene delivery due to their tunable physicochemical properties and biocompatibility. This study investigated poly(vinyl alcohol) (PVA)-based hydrogels incorporating DNA and modified with chitosan (CHI), poly(ethylene glycol) (PEG), or poly(lactic acid) (PLA) to evaluate their potential for sustained gene delivery. Hydrogels were produced using a freeze-thaw method and characterized by Fourier transform infrared spectroscopy, fluorescence analysis, swelling behavior, DNA release kinetics, thermogravimetric analysis, mechanical and rheological analyses, and scanning electron microscopy. Short-term cytocompatibility was assessed in astrocyte and glioblastoma cell lines, while GFP-associated fluorescence was qualitatively evaluated in SUM-159PT breast cancer cells exposed to plasmid-loaded hydrogels. The results confirmed DNA incorporation and demonstrated that polymer composition influenced swelling behavior, DNA release kinetics, mechanical properties, and the temporal pattern of GFP-associated fluorescence. CHI- and PLA-containing formulations showed persistent GFP-associated fluorescence at later experimental time points, consistent with their sustained DNA-release behavior. All formulations showed favorable short-term cytocompatibility under the conditions evaluated. Overall, polymer-modified PVA hydrogels represent tunable matrices with potential for localized and sustained non-viral DNA delivery.

Keywords— gene delivery, hydrogels, poly(vinyl alcohol), non-viral vectors, tissue engineering, biomaterials.

I. Introduction

Gene therapy has emerged as a promising strategy for the treatment of genetic disorders, cancer, and tissue damage through the delivery of nucleic acids capable of modulating cellular function. However, the clinical translation of gene therapy remains limited by the instability of genetic material, low cellular uptake, and rapid clearance following administration [1].

Hydrogels have attracted considerable attention as non-viral gene delivery systems because of their high water content, biocompatibility, tunable mechanical properties, and ability to provide localized and sustained release [2]. Among hydrogel-forming polymers, poly(vinyl alcohol) (PVA) stands out due to its low toxicity, ease of processing, and capacity to form physically crosslinked networks through freeze-thaw cycles [3].

Strategies involving the incorporation of secondary polymers can further optimize hydrogel performance. Chitosan (CHI) can enhance DNA interactions through electrostatic attraction, poly(ethylene glycol) (PEG) can improve porosity and biocompatibility, and poly(lactic acid) (PLA) can increase structural stability and prolong release profiles [4].

This study aimed to develop and characterize PVA-based hydrogels modified with CHI, PEG, and PLA for sustained non-viral gene delivery. The influence of polymer composition on physicochemical properties, DNA release behavior, short-term cytocompatibility, and GFP-associated fluorescence in plasmid-exposed cells was investigated to assess the potential of these formulations as tunable matrices for sustained DNA delivery.

II. Materials and Methods

A. Hydrogel Preparation

Poly(vinyl alcohol) (PVA)-based hydrogels were prepared by physical crosslinking using a freeze-thaw method. A 20% (w/v) PVA aqueous solution was prepared at 90 °C under constant stirring. Salmon sperm DNA or GFP-encoding plasmid DNA was incorporated into the polymeric matrix to obtain DNA-loaded formulations.

To modulate hydrogel properties, chitosan (CHI), poly(ethylene glycol) (PEG), and poly(lactic acid) (PLA) were individually incorporated into the PVA-based formulations. CHI was dissolved in acetic acid, PEG in ultrapure water, and PLA was initially dissolved in chloroform before incorporation into the PVA-based system. After mixing, the PVA-PLA formulation was maintained at room temperature, allowing chloroform evaporation, and subsequently subjected to the same freeze-thaw protocol used for the other formulations. No additional drying or processing step was specifically applied to the PVA-PLA hydrogel. Residual chloroform was not quantitatively determined. No macroscopic phase separation was visually observed after

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

incorporation of the PLA solution into the PVA-based formulation.

The resulting formulations were designated as PVA-DNA, PVA-CHI-DNA, PVA-PEG-DNA, and PVA-PLA-DNA. Hydrogels were subjected to three freeze-thaw cycles consisting of freezing at −20 °C for 12 h and thawing at 25 °C for 12 h. After gelation, samples were washed with ultrapure water to remove residual reagents.

B. Physicochemical Characterization

The chemical composition of the hydrogels was investigated by attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) in the range of 4000–500 cm^{-1}. DNA incorporation was evaluated using GelStar™ nucleic acid staining, UV-visible absorption spectroscopy, fluorescence spectroscopy, and agarose gel electrophoresis. A calibration curve was established using the PVA-based system as the reference matrix because PVA represented the major polymeric fraction of all hydrogel formulations. Formulation-specific blanks were used to account for background contributions from the respective hydrogel matrices. Hydrogel sample masses were standardized among formulations; however, a complete DNA mass balance including released and residual DNA was not independently determined. Identical amounts of GelStar™ were used for fluorescence-based measurements to ensure comparability among samples.

Hydrogel morphology was examined by scanning electron microscopy (SEM) after freeze-drying and gold sputter coating. Because lyophilization may modify the native hydrated network through ice-crystal formation and sublimation, SEM micrographs were used for qualitative morphological comparison rather than quantitative determination of porosity or pore size.

Swelling behavior was evaluated by immersing dried hydrogels in ultrapure water and sodium bromide (NaBr) solutions at 10 and 100 mM. NaBr was selected based on its suitability for DNA-containing systems and its ability to provide controlled ionic conditions while preserving double-stranded DNA stability [5]. The NaBr experiments were designed to investigate the influence of the ionic environment on hydrogel swelling rather than to reproduce physiological conditions. The swelling ratio was calculated from the difference between swollen and dry weights.

Thermogravimetric analysis (TGA) was performed under a nitrogen atmosphere from 25 °C to 500 °C at a heating rate of 10 °C min^{-1}.

C. Mechanical and Rheological Characterization

Mechanical characterization was performed using a TA.XT Plus Texture Analyzer (Stable Micro Systems Ltd., UK). Texture profile analysis was conducted using a P/10 cylindrical Delrin probe (10 mm diameter). The probe compressed the hydrogel samples at 11 mm s^{-1} to a depth of 3 mm, with a 5-s interval between two consecutive compression cycles. Measurements were performed at 25 °C using eight replicates per formulation. Data were analyzed using Texture Exponent software (version 6.1.16.0). The following mechanical parameters were determined: compressibility, calculated from the area under the first force-time curve (AUC1); hardness, defined as the maximum force during the first compression; cohesiveness, calculated as the AUC2/AUC1 ratio; elasticity, determined from the time ratio between compression cycles; and resilience, calculated from the energy ratio during the first compression.

Tensile strength (TS) and elongation at break (EB%) were additionally determined using the TA.XT Plus Texture Analyzer. Samples were cut into 50 × 10 mm strips and tested using a P/1S probe with double-sided adhesive tape to secure the specimens. Tensile strength was calculated as the maximum force at rupture divided by the cross-sectional area of the specimen, whereas elongation at break was expressed as the percentage increase in specimen length at fracture relative to its initial length.

Rheological measurements were performed using a HAAKE MARS III rheometer (Thermo Fisher Scientific, Germany) equipped with a parallel-plate geometry (35 mm diameter) and a 1 mm gap. Temperature was maintained at 25.0 ± 0.1 °C using a Peltier temperature-control system. Dynamic oscillatory frequency-sweep measurements were performed from 100 to 0.01 Hz at a constant applied stress of 50 Pa. The storage modulus (G′) and loss modulus (G″) were recorded as functions of frequency to characterize the viscoelastic behavior of the hydrogel formulations.

D. DNA Release Studies

DNA release kinetics were evaluated by immersing the hydrogels in phosphate-buffered saline (PBS, pH 7.4) under continuous agitation at 25 °C. The release experiments were performed at 25 °C under standardized physicochemical conditions established for comparison among formulations. Aliquots were collected at predetermined intervals and analyzed by UV-visible spectroscopy at 260 nm. DNA concentrations were determined from a calibration curve established using the PVA-based system as the reference matrix, since PVA represented the major polymeric fraction of all formulations. Formulation-specific hydrogel blanks were used for background correction to minimize contributions from the respective polymeric matrices. Release profiles were fitted using pseudo-first-order and pseudo-second-order kinetic models to describe DNA release behavior and polymer-DNA interactions. Model performance was compared using the coefficient of determination (R^2) and the Akaike Information Criterion (AIC).

E. In vitro Biological Assays

The cytocompatibility of the hydrogels was assessed using immortalized human astrocytes (IM-HA) and glioblastoma cells (U87). Cells were cultured under standard conditions and exposed to the hydrogel formulations for 72 h. Cell metabolic activity was determined using the resazurin reduction assay.

Transfection experiments were conducted using SUM-159PT triple-negative breast cancer cells. Cells were seeded directly onto hydrogels containing GFP-LC3 plasmid DNA and cultured at 37 °C under 5% CO_2. Fluorescence microscopy was performed at different time points to qualitatively assess GFP-associated fluorescence in cells exposed to the DNA-loaded hydrogels. DNA-free and plasmid-free hydrogel controls were included to assess background fluorescence associated with the experimental system. All compared fluorescence images were acquired using identical microscopy and exposure settings.

F. Statistical Analysis

Data are presented as mean ± standard deviation from at least three independent experiments. Statistical analyses included the Shapiro-Wilk test for normality, Levene's test for

homogeneity of variances, one-way analysis of variance (ANOVA) followed by Tukey's post hoc test, and Kruskal-Wallis tests when parametric assumptions were not satisfied. Differences were considered statistically significant when $p < 0.05$.

III. Results and Discussion

A. DNA Incorporation and Chemical Characterization

The successful incorporation of DNA into the PVA-based hydrogels was confirmed through complementary spectroscopic, colorimetric, and electrophoretic analyses (Figure 1).

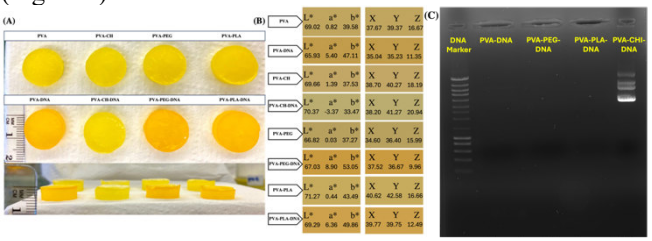

Fig. 1. (A) Visual assessment of PVA-based hydrogels with and without DNA following nucleic acid dye staining. (B) Colorimetric characterization of hydrogels showing L*, a*, b* and XYZ coordinates measured with a Jobin-Yvon Spex Fluorolog 3–22 spectrofluorometer. (C) Agarose gel electrophoresis (8 % gel) confirming DNA presence and quantification in PVA-CHI-DNA hydrogel. DNA bands were visualized using the CaPture Chemiluminescence System.

ATR-FTIR spectra revealed characteristic absorption bands associated with PVA, CHI, PEG, PLA, and DNA, confirming the presence of all components within the hydrogel network (Figure 2).

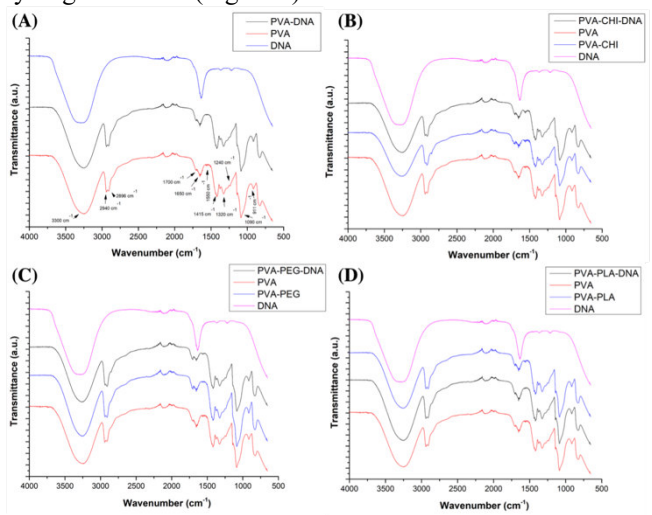

Fig. 2. FTIR-ATR spectra of (A) PVA; (B) CHI; (C) PEG; and (D) PLA with and without DNA.

The broad absorption band observed between 3300 and 2940 cm^{-1}, corresponding to O–H and N–H stretching vibrations, shifted after DNA incorporation, indicating changes in hydrogen-bond interactions within the polymeric matrix [6]. DNA-containing formulations also exhibited increased intensity in the carbonyl stretching region (1700–1650 cm^{-1}), suggesting enhanced molecular interactions between DNA phosphate groups and the hydrogel components [7].

Additional evidence of DNA incorporation was obtained through GelStar™ nucleic acid staining and fluorescence spectroscopy. PVA-DNA, PVA-PEG-DNA, and PVA-PLA-DNA hydrogels displayed strong fluorescence signals, indicating efficient DNA entrapment within the polymer network (Figure 1). In contrast, PVA-CHI-DNA hydrogels showed lower fluorescence intensity but generated distinct DNA bands during agarose gel electrophoresis, suggesting a more reversible interaction between chitosan and DNA.

The absorbance and emission spectra demonstrated that hydrogel composition significantly influenced the local environment surrounding the encapsulated DNA [8] (Figure 3).

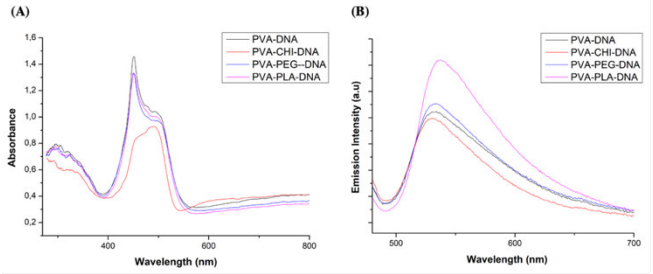

Fig. 3. Absorption (A) and Emission spectra (B) from the GelStar™ Nucleic Acid Gel Stain in the hydrogels with DNA. Excitation at 452 nm.

PVA-PLA-DNA exhibited the highest fluorescence emission intensity, while PVA-CHI-DNA showed fluorescence quenching effects, likely associated with electrostatic interactions between positively charged chitosan and negatively charged DNA phosphate groups [9].

Overall, these findings demonstrate that the polymer composition modulates DNA retention and molecular interactions within the hydrogel matrix, directly influencing the potential performance of these materials as non-viral gene delivery systems.

B. Swelling Behavior and DNA Release Kinetics

The swelling behavior of DNA-loaded hydrogels was evaluated in water and sodium bromide solutions to investigate the influence of ionic strength on hydrogel performance (Figure 4). All formulations exhibited rapid water uptake followed by equilibrium swelling, with distinct profiles depending on polymer composition.

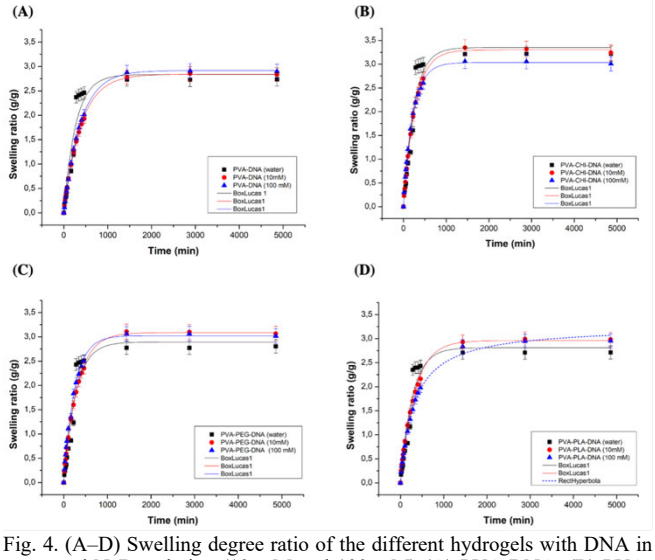

Fig. 4. (A–D) Swelling degree ratio of the different hydrogels with DNA in water and NaBr solution (10 mM and 100 mM) (A) PVA-DNA; (B) PVA-CHI-DNA; (C) PVAPEG-DNA; and (D) PVA-PLA-DNA.

Among the tested formulations, PVA-CHI-DNA showed the highest swelling ratio in all media, reaching values above 3.0 g/g. This behavior can be attributed to the hydrophilic nature of chitosan and its ionizable amino groups, which promote water absorption and network expansion.

NaBr was employed as a controlled ionic medium to investigate the influence of ionic conditions on hydrogel swelling while maintaining conditions compatible with double-stranded DNA stability [5]. Therefore, the NaBr experiments should be interpreted primarily as physicochemical characterization of the polymer networks rather than as a simulation of the physiological environment. Although the present experiments allowed direct comparison among hydrogel formulations under standardized conditions, evaluation in PBS or cell culture medium at 37 °C would provide a closer representation of physiological conditions and should be considered in future studies.

Increasing ionic strength affected the swelling behavior differently depending on the polymer incorporated into the hydrogel matrix. While higher salt concentrations reduced the swelling of PVA-CHI-DNA due to electrostatic shielding effects [10], PVA-PEG-DNA and PVA-PLA-DNA maintained relatively stable swelling profiles, suggesting weaker ionic interactions with DNA.

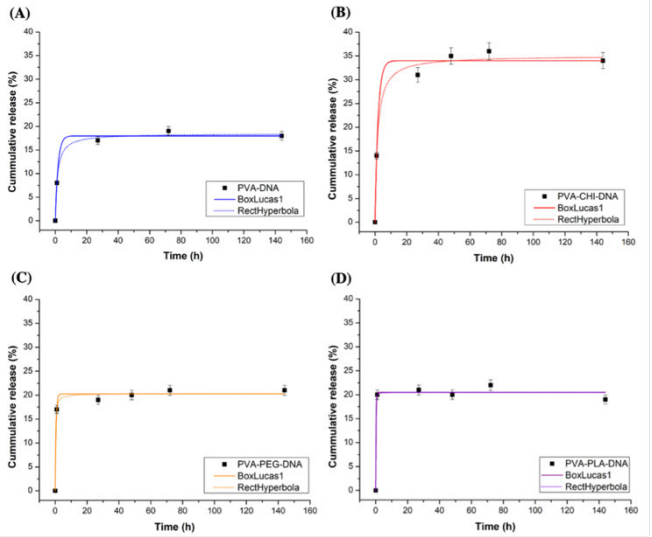

Fig. 5. (A–D) Cumulative DNA release over time for the hydrogels (A) PVA-DNA; (B) PVA-CHI-DNA; (C) PVA-PEG-DNA; and (D) PVA-PLA-DNA.

DNA release studies demonstrated formulation-dependent release profiles (Figure 5). PEG- and PLA-containing hydrogels exhibited comparatively controlled release profiles, whereas the higher swelling capacity of PVA-CHI-DNA may have facilitated DNA diffusion through the polymeric network.

Kinetic modeling indicated that the pseudo-first-order model provided the best empirical fit for most formulations, demonstrating formulation-dependent release kinetics. These findings highlight the importance of polymer selection for tailoring hydrogel performance according to specific therapeutic requirements.

C. Morphological and Mechanical Properties

Scanning electron microscopy of the freeze-dried hydrogels revealed distinct morphological features depending on polymer composition (Figure 6). PVA-DNA exhibited a comparatively homogeneous morphology, whereas incorporation of CHI, PEG, and PLA resulted in visible changes in the apparent surface and internal organization of the dried matrices. PVA-CHI-DNA showed more pronounced void-like structures and surface heterogeneity, whereas PEG- and PLA-containing formulations exhibited comparatively more compact morphologies.

These observations should, however, be interpreted qualitatively. Because SEM analysis was performed after freeze-drying, ice-crystal formation during freezing and subsequent sublimation may modify the native hydrated network and generate or enlarge apparent voids. Therefore, the SEM micrographs do not provide a quantitative measurement of hydrogel porosity or pore size in the hydrated state [11].

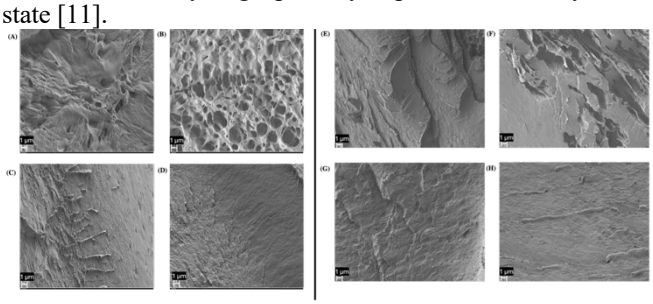

Fig. 6. SEM micrographs of hydrogels with or without DNA: (A) PVA; (B) PVA-CHI; (C) PVA-PEG; (D) PVA-PLA; (E) PVA-DNA; (F) PVA-CHI-DNA; (G) PVA-PEG-DNA; and (H) PVA-PLA-DNA. Magnification: 3000×.

Thermogravimetric analysis demonstrated that polymer incorporation modified the thermal stability of the hydrogels, reflecting differences in intermolecular interactions among the hydrogel components (Figure 7). The observed variations indicate that DNA and polymer additives can either strengthen or weaken the hydrogel network depending on their chemical compatibility [12].

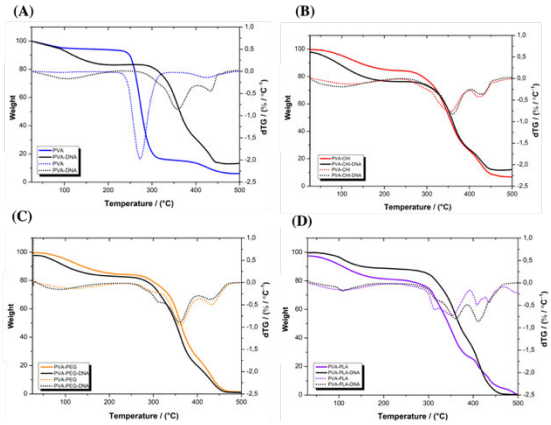

Fig. 7. TG curves (solid line) and respective DTGs (dotted line) for hydrogels without or with DNA: (A) PVA and PVA-DNA; (B) PVA-CHI and PVA-CHI-DNA; (C) PVA-PEG and PVA-PEG-DNA; and (D) PVA-PLA and PVA-PLA-DNA.

Mechanical characterization demonstrated that polymer composition and DNA incorporation influenced the mechanical behavior of the PVA-based hydrogels. Tensile testing revealed formulation-dependent differences in tensile strength and elongation at break (Figure 8), indicating that incorporation of the secondary polymers altered both resistance to deformation and extensibility of the hydrogel matrices.

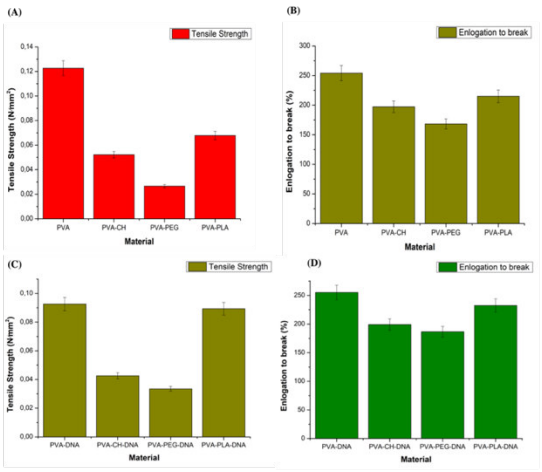

Fig. 8. Tensile strength and Elongation at break for the different hydrogels: (A) and (B) without DNA; and (C) and (D) with DNA.

Oscillatory rheological analysis further demonstrated composition-dependent viscoelastic behavior (Figure 9). The storage modulus (G′) and loss modulus (G″) varied among the formulations over the investigated frequency range, indicating that incorporation of CHI, PEG, PLA, and DNA affected the balance between elastic and viscous responses of the polymer networks. Together, the tensile and rheological results demonstrate that the mechanical properties of the PVA-based hydrogels can be modulated through polymer composition and DNA incorporation.

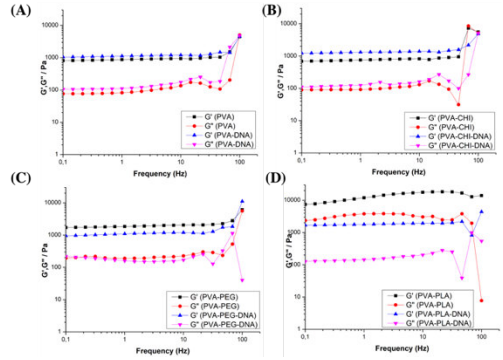

Fig. 9. Mechanical spectra of hydrogels: (A) PVA and PVA-DNA; (B) PVA-CHI and PVA-CHI-DNA; (C) PVA-PEG and PVA-PEG-DNA; and (D) PVA-PLA and PVA-PLA-DNA. Storage modulus (G′) and loss modulus (G″) were recorded at 25 °C over a frequency range of 100–0.01 Hz under a constant applied stress of 50 Pa.

The combination of distinct morphological features, tunable mechanical properties, and composition-dependent thermal behavior further demonstrates the influence of polymer modification on the physicochemical properties of the PVA-based hydrogel matrices.

D. Biocompatibility and Transfection Performance

The cytocompatibility of the developed hydrogels was evaluated using immortalized human astrocytes and glioblastoma cells. Metabolic activity assays demonstrated that all formulations maintained high metabolic activity after 72 h of exposure, indicating favorable short-term cytocompatibility under the experimental conditions evaluated (Figure 10).

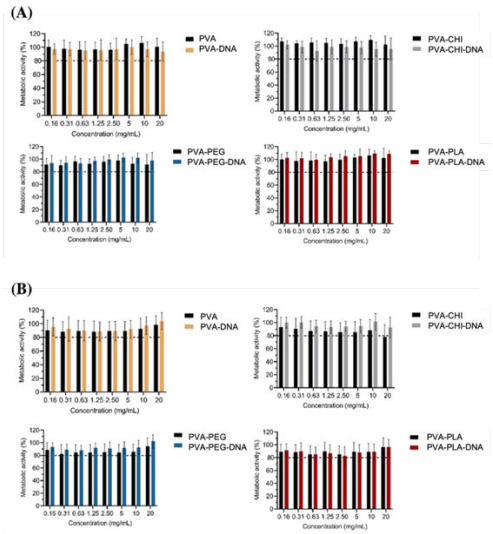

Fig. 10. (A) Metabolic activity of astrocyte cells and (B) U87 cells exposed to different PVA hydrogels after 72 h. Statistical values were calculated using one-way ANOVA. Data are presented as the means ± SD. (n = 9).

The ability of the hydrogels to provide plasmid DNA to SUM-159PT cells was qualitatively investigated using GFP-LC3-containing formulations (Figure 11). DNA-free and plasmid-free hydrogel controls were included to assess background fluorescence associated with the experimental system. The control conditions exhibited background fluorescence, whereas cultures exposed to DNA-loaded hydrogels showed more evident GFP-associated signals.

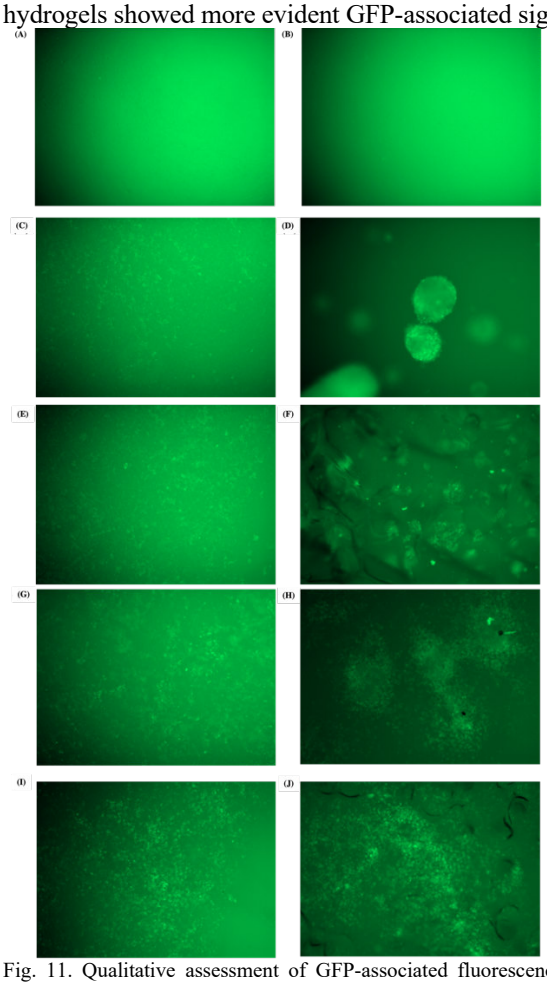

Fig. 11. Qualitative assessment of GFP-associated fluorescence in SUM-159PT breast cancer cells. (A) DNA-free control; (B) plasmid-free hydrogel control; (C–F) cells exposed to PVA-DNA, PVA-CHI-DNA, PVA-PEG-DNA, and PVA-PLA-DNA hydrogels, respectively, after 6 days of incubation; and (G–J) cells exposed to PVA-DNA, PVA-CHI-DNA, PVA-

PEG-DNA, and PVA-PLA-DNA hydrogels, respectively, after 16 days of incubation.

Distinct GFP-associated fluorescence patterns were observed depending on hydrogel composition and incubation time. At the 6-day time point, PVA-DNA and PVA-PEG-DNA formulations showed comparatively more evident fluorescence signals, suggesting greater initial DNA availability to the cells. In contrast, GFP-associated fluorescence remained detectable at later time points in cultures exposed to PVA-CHI-DNA and PVA-PLA-DNA hydrogels, consistent with the sustained DNA-release behavior observed for these formulations [14].

The persistence of GFP-associated fluorescence in the CHI- and PLA-containing formulations suggests that hydrogel composition influences the temporal profile of plasmid availability and the resulting GFP-associated fluorescence signal. However, because transfection was evaluated qualitatively by fluorescence microscopy and long-term metabolic activity was not independently assessed in SUM-159PT cells at the corresponding time points, these observations should not be interpreted as quantitative evidence of transfection efficiency or long-term cytocompatibility.

Overall, these results indicate that polymer modification of PVA hydrogels can modulate DNA-release behavior and the temporal pattern of GFP-associated fluorescence. Further studies incorporating quantitative transfection analysis and matched long-term cytocompatibility measurements are required to establish the efficiency and safety of these formulations for sustained gene-delivery applications.

IV. Conclusion

Polymer-modified PVA hydrogels showed potential as platforms for sustained non-viral DNA delivery. Incorporation of CHI, PEG, and PLA modulated the physicochemical properties of the PVA matrix, including swelling behavior, DNA retention and release profiles. The formulations showed favorable short-term cytocompatibility in IM-HA and U87 cells, while GFP-associated fluorescence was observed in SUM-159PT cultures exposed to plasmid-loaded hydrogels at different experimental time points. In particular, the persistence of fluorescence associated with CHI- and PLA-containing formulations was consistent with their sustained DNA-release behavior. However, quantitative transfection efficiency and long-term cytocompatibility in SUM-159PT cells were not evaluated and should be addressed in future studies. Overall, these findings support further investigation of polymer-modified PVA hydrogels as tunable matrices for localized and sustained DNA delivery under physiologically relevant conditions.

Abstract*—Hyaluronic acid (HA) fillers are the gold standard for facial volumization, with hyaluronidase as the only reversal agent. In Brazil, the commercially available hyaluronidase (Biometil) is measured in Reduced Turbidimetric Units (UTR), a system with no validated equivalence to international standards (IU/USP), which prevents the direct transposition of published dosing protocols. This study characterized, by dynamic oscillatory rheometry (20 °C, 10 Hz, 1 % strain), the enzymatic degradation of Rennova Ultra Volume Lido (23 mg/mL, Hi™ technology) exposed to four concentrations of Biometil hyaluronidase (25, 50, 100 and 150 UTR) and to a control group (0 UTR), with n = 1 sample per condition. The G′ and G″ time series were fitted to an extended exponential model that incorporates the interval between mixing and the first reading, and all estimates reported derive from this model. The time to the in vitro rheological dissolution threshold (G′ = 30 Pa), counted from enzyme–substrate contact, was 136.9 min [95 % CI 136.2–137.6], 28.9 min [28.4–29.3], 14.7 min [14.4–14.9] and 6.0 min [5.5–6.4] for 25, 50, 100 and 150 UTR, the 25 UTR value being obtained by extrapolation beyond the observed window. The G′ = G″ crossover, which marks the effective loss of elastic predominance, occurred at 26.7 min [25.3–29.0] in the 150 UTR group, with G′ = G″ = 4.24 Pa [3.80–4.57], and only by extrapolation in the remaining groups. The model further estimates that 9.7 % [9.4–10.2], 23.2 % [22.3–24.2], 45.3 % [44.9–45.8] and 52.8 % [51.8–54.3] of the elastic modulus had already been lost before the first reading, a proportion that increases with dose. Under the controlled conditions tested, the results indicate dose-dependent rheological susceptibility and provide a preliminary experimental reference, specific to the Rennova Ultra Volume Lido–Biometil pair, within the UTR system. Validation at 37 °C, independent experimental replication and models incorporating tissue diffusion are required before any extrapolation to clinical protocols.

Keywords—hyaluronic acid; hyaluronidase; rheology; dermal filler; elastic modulus; UTR; enzymatic degradation.

I. Introduction

Cross-linked hyaluronic acid (HA) dermal fillers are biomaterials widely used in minimally invasive aesthetic procedures worldwide [1], [2]. Their mechanical properties arise from the three-dimensional polymer network formed by entangled and chemically cross-linked HA chains. The predominance of HA in the aesthetic field is attributed to its biocompatibility, clinical versatility and, above all, to the reversibility conferred by hyaluronidase, which provides a safety margin unique among injectable materials used in clinical practice [2], [4].

Hyaluronidase (EC 3.2.1.35) is an endoglycosidase that depolymerizes HA through hydrolytic cleavage of β-1,4 glycosidic bonds and represents the first-line treatment for filler-related complications, from aesthetic irregularities to vascular occlusions [1], [3], [5]. Despite its clinical importance, its use in this context is considered off-label by both the FDA and ANVISA [2], [3].

Enzymatic cleavage progressively disrupts the HA network, reducing polymer-chain connectivity and consequently altering the balance between elastic and viscous responses of the hydrogel. dose range, , an approximately The efficacy of enzymatic reversal is modulated by the rheological properties of the filler, particularly the elastic modulus G′ and the degree of cross-linking, which may determine resistance to enzymatic penetration through steric hindrance [4], [6].

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) – Finance Code 001.

Fillers with high G′ tend to require substantially higher doses of hyaluronidase for complete dissolution [5], [6]. In vitro studies that follow this degradation rheologically commonly stop the assay when G′ reaches 30 Pa, a value defined by Faivre et al. as the lowest elastic modulus that can be reliably measured with this type of geometry [6]; it is therefore an operational endpoint of the measurement rather than a physical marker of complete dissolution.

In the Brazilian context there is an additional methodological gap: whereas international studies use hyaluronidase measured in International Units (IU) or USP Units, products available in Brazil — such as Biometil — are measured in Reduced Turbidimetric Units (UTR) [7], a system with no direct equivalence to international standards [2], [7]. This discrepancy prevents the direct transposition of published dosing protocols to national practice.

Rennova Ultra Volume Lido (manufactured by Humedix Co., Ltd., South Korea; distributed in Brazil by Innovapharma) is one of the most widely used fillers in the Brazilian facial harmonization market, formulated with 23 mg/mL of cross-linked HA and 0.3 % lidocaine [9]. Despite its widespread use, there are no independent rheological data or specific enzymatic degradation studies for this product in the literature.

This study aims to characterize, by dynamic oscillatory rheometry with continuous monitoring of G′ and G″, the rheological susceptibility of Rennova Ultra Volume Lido to Biometil hyaluronidase at four concentrations expressed in UTR, generating a preliminary experimental reference specific to this product–enzyme pair in the unit used in Brazil.

II. Materials and Methods

A. Materials

The following materials were used: Rennova Ultra Volume Lido filler (23 mg/mL cross-linked HA + 0.3 % lidocaine; Innovapharma, Brazil); Biometil hyaluronidase (3,000 UTR, Cristália, Brazil); and a manufacturer-supplied diluent (0.45 % sodium chloride and 0.7 % mannitol).

B. Enzymatic Stock Preparation

The Biometil vial (3,000 UTR) was reconstituted with 3.0 mL of the manufacturer's diluent, yielding a working stock of 1,000 UTR/mL (1 UTR/µL). This concentration allows the pipetted enzyme volume to be numerically equal to the target dose in UTR, minimizing pipetting errors.

C. Experimental Groups and Volumes

Each sample was prepared at a total volume of 500 µL in a 1:1 ratio (HA:EDV): 250 µL of filler and 250 µL of enzyme dilution vehicle (EDV, enzyme + diluent), as detailed in Table I. The 1:1 ratio was adopted as an adaptation of the 3:1 ratio described by Safran et al. (2025) [10], validated for peripheral diffusion models; the present protocol employs direct homogenization, which dispenses with the additional volume intended for diffusion. The implications of this choice are discussed in Section IV-E.

TABLE I. Experimental groups and preparation volumes

Group	Dose	HA (µL)	Enzyme (µL)	Diluent (µL)	EDV (µL)	Total (µL)
C	0 UTR	250	0	250	250	500
1	25 UTR	250	25	225	250	500
2	50 UTR	250	50	200	250	500
3	100 UTR	250	100	150	250	500
4	150 UTR	250	150	100	250	500

D. Mixing and Transfer Procedure

Sample preparation was standardized to minimize the interval between homogenization and the start of measurement, since hyaluronidase acts immediately upon contact with HA [5]. The sequence was: (1) aspirate 250 µL of HA into the syringe; (2) add the diluent with a calibrated pipette; (3) add the enzymatic solution with a calibrated pipette; (4) immediately transfer to the rheometer plate; (5) lower the upper geometry; (6) remove excess sample; (7) place the solvent trap; (8) start the measurement. Despite this standardization, a non-zero interval remains between mixing and acquisition of the first data point. This interval was not timed during the assays; it is estimated by the parameter τ of the kinetic model described in Section II-F and interpreted in Section IV-B.

E. Rheological Parameters and Data Acquisition

All measurements were performed on an ARES-G2 rheometer (TA Instruments) with 40 mm parallel-plate geometry, 0.2 mm gap, 20 °C, 1 % strain amplitude and an angular frequency of 62.83 rad/s (10 Hz), recording G′ and G″ over time with one point every 60 s. Acquisition proceeded for 43 to 110 min depending on the group; these windows delimit the estimates flagged as extrapolated in Tables II and III. Each experimental condition corresponds to a single independently prepared sample (n = 1); no independent experimental replicates were performed, owing to limited material. The statistical analysis derives entirely from the confidence intervals estimated for the parameters of the kinetic model (Section II-F). The control group maintained G′ stable throughout the assay, with a coefficient of variation of 0.47 %, confirming that the diluent vehicle has no relevant effect on gel viscoelasticity.

The temperature of 20 °C was adopted in place of the physiological 37 °C after significant solvent evaporation was identified at body temperature in pilot assays, even with the solvent trap — a known limitation of open parallel-plate geometry in low-viscosity systems. This choice reduces the absolute rate of the enzymatic reaction and limits the direct transposition of the times reported here to physiological conditions, as discussed in Section IV-E.

The frequency of 10 Hz was selected on two grounds: maintaining the torque signal above the minimum threshold of the instrument for reliable reading in partially degraded gels, in which lower frequencies yield insufficient torque; and higher temporal resolution of the kinetics, particularly relevant in the high-dose groups [11], [12].

The 1 % strain amplitude was validated by a prior amplitude sweep on the control formulation (0.01 % to 995 % strain, 51 points). The G′ plateau in the low-strain region

was 95.3 Pa, and the limit of the linear viscoelastic region (LVR), taken as the strain at which G′ falls 10 % below the plateau [17], was 15.8 %. At 1 % strain, G′ corresponded to 98.2 % of the plateau value.

F. Data Analysis

The raw G′(t) and G″(t) time series of each treated group were fitted to an extended exponential (Weibull) model, of the same functional form for both moduli:

$$G'(T) = Y_0' \cdot \exp[-(k' \cdot T)^{\beta'}]$$

$$G''(T) = Y_0'' \cdot \exp[-(k'' \cdot T)^{\beta''}], \quad T = t + \tau$$

where T is the time counted from enzyme–substrate contact, t is the time recorded by the rheometer, τ is the interval between contact and the first reading, k is the degradation constant and β is a shape parameter capturing departures from simple first-order kinetics. Y0′ and Y0″ were fixed at the moduli of the control group at the first reading (121.49 Pa and 27.66 Pa), which represent the intact state of the hydrogel before enzymatic action. The parameter τ is a property of the sample, not of the observed modulus; it was therefore estimated in the G′ fit and held fixed in the G″ fit of the same group, so that both models share a single time axis.

The time to the rheological dissolution threshold, T30, defined as the instant at which G′ reaches 30 Pa, follows analytically from the model parameters:

$$T_{30} = [-\ln(30 / Y_0')]^{1/\beta'} / k'$$

The crossover instant, Tcross, at which G′ = G″, is obtained from the positive root of

$$(k' \cdot T)^{\beta'} - (k'' \cdot T)^{\beta''} = \ln(Y_0' / Y_0'')$$

solved numerically, and the corresponding modulus, Gcross, is obtained by substituting Tcross into either equation.

Fitting was performed by nonlinear least-squares regression (SciPy, Python 3), with multiple starting values to reduce the risk of local minima. Confidence intervals of 95 % for the parameters of both models (k′, τ, β′, k″ and β″) and for the quantities derived from them (T30, Tcross and Gcross) were obtained by moving-block bootstrap of the residuals, refitting the model at each iteration; for quantities depending on both moduli, the two series were resampled and refitted jointly.

III. Results

The model described the observed kinetics with R^2 between 0.998 and 0.9997 for G′ (Fig. 1) and between 0.940 and 0.993 for G″ (Fig. 2) in all treated groups. The parameters fitted for G′ and the estimated time to the dissolution threshold are listed in Table II; the same model was fitted to the loss modulus, and the corresponding parameters and the crossover time are given in Table III, laid out with the same columns as Table II to allow direct comparison between the two moduli.

TABLE II. Extended Exponential Model Parameters for the Storage Modulus G′ and the Characteristic Time Derived From It, With 95 % Confidence Intervals

Group	k′ (min⁻¹) [95 % CI]	τ (min) [95 % CI]	β′ [95 % CI]	R^2	T30 (min) [95 % CI]

150 UTR	0.29817 [0.27140–0.33099]	2.06 [1.74–2.42]	0.583 [0.552–0.611]	0.9980	6.0 [5.5–6.4]

Y0′ fixed at 121.49 Pa, storage modulus of the control group at the first reading. T30: time to G′ = 30 Pa, counted from enzyme–substrate contact (T = t + τ). 95 % CI by moving-block bootstrap of the residuals. n = 1 experimental sample per group. [a] Value extrapolated beyond the observed experimental window.

TABLE III. Extended Exponential Model Parameters for the Loss Modulus G″ and the Characteristic Time Derived From It, With 95 % Confidence Intervals

Group	k″ (min⁻¹) [95 % CI]	τ (min)[a]	β″ [95 % CI]	R^2	Tcross (min) [95 % CI]
25 UTR	0.01203 [0.01178–0.01225]	1.10	0.414 [0.405–0.424]	0.9889	1150 [b] [1060–1246]
50 UTR	0.03331 [0.03270–0.03396]	1.62	0.480 [0.468–0.492]	0.9932	152.1 [b] [141.7–163.2]
100 UTR	0.08931 [0.08385–0.09519]	2.73	0.398 [0.379–0.419]	0.9396	126.6 [b] [115.6–139.7]
150 UTR	0.12330 [0.11925–0.12833]	2.06	0.528 [0.508–0.546]	0.9898	26.7 [25.3–29.0]

Y0″ fixed at 27.66 Pa, loss modulus of the control group at the first reading. Tcross: time to the G′ = G″ crossover, counted from enzyme–substrate contact. Columns and conventions identical to those of Table II. [a] τ is not re-estimated in the G″ fit: being a property of the sample rather than of the observed modulus, it was fixed at the value obtained in the G′ fit of the same group (Table II), so that both models share a single time axis. [b] Value extrapolated beyond the observed experimental window.

T30 decreases monotonically with enzyme concentration, from 136.9 min at 25 UTR to 6.0 min at 150 UTR, with confidence intervals that do not overlap between consecutive doses; equivalently, the degradation constant k′ rises from 0.0135 to 0.2982 min^{-1} over the same dose range, an approximately 22-fold increase. A log–log regression between dose and T30 yields an exponent of −1.66 (R^2 = 0.975; 95 % CI: −2.47 to −0.84), compatible both with simple inverse proportionality between dissolution time and enzyme concentration and with a supralinear gain.

The shape parameter β′ remained between 0.50 and 0.58 in all groups, consistently below 1, and the same behavior was observed for β″ (0.40 to 0.53). The estimated values of τ were 1.10, 1.62, 2.73 and 2.06 min for 25, 50, 100 and 150 UTR, compatible in order of magnitude with the manual mixing and transfer procedure described in Section II-D. From these values, the model estimates that 9.7 % [95 % CI 9.4–10.2], 23.2 % [22.3–24.2], 45.3 % [44.9–45.8] and 52.8 % [51.8–54.3] of the elastic modulus had already been lost at the instant of the first reading.

The comparison between Tables II and III shows that, in all groups, k″ is lower than k′ and β″ is lower than β′: the loss modulus decays more slowly than the storage modulus, and

the confidence intervals of k′ and k″ do not overlap at any concentration. As a consequence, the two moduli converge. The crossover times estimated for each dose are compared with the corresponding T30 values in Fig. 3a. The modulus at the crossover instant, Gcross, was 1.42 Pa [95 % CI 1.16–1.70], 3.13 Pa [2.83–3.43], 2.00 Pa [1.64–2.38] and 4.24 Pa [3.80–4.57] for 25, 50, 100 and 150 UTR, respectively (Fig. 3b). Only the 150 UTR group reached the crossover within the experimental window, at 26.7 min [25.3–29.0]; in the remaining groups the crossover is an extrapolation, and in the 25 UTR group it projects beyond 19 h, so that it should be read as not attained within any practically relevant window rather than as a usable time estimate.

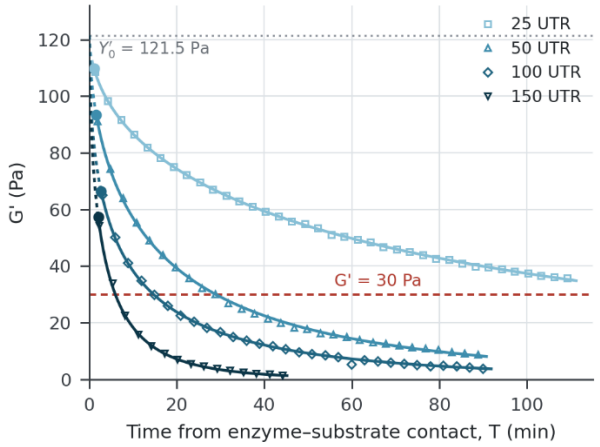

Fig. 1. Storage modulus G′ as a function of the time counted from enzyme–substrate contact (T = t + τ). Markers: measured data. Solid lines: fitted model. Dotted segments: region preceding the first reading, reconstructed by the model. Filled circle: first reading of each group. The dashed line indicates the 30 Pa threshold.

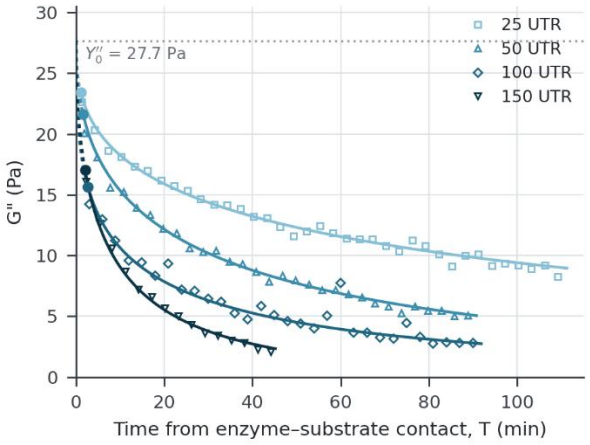

Fig. 2. Loss modulus G″ as a function of the time counted from enzyme–substrate contact, with the same extended exponential model and the same τ as the G′ fit. Graphical conventions identical to those of Fig. 1.

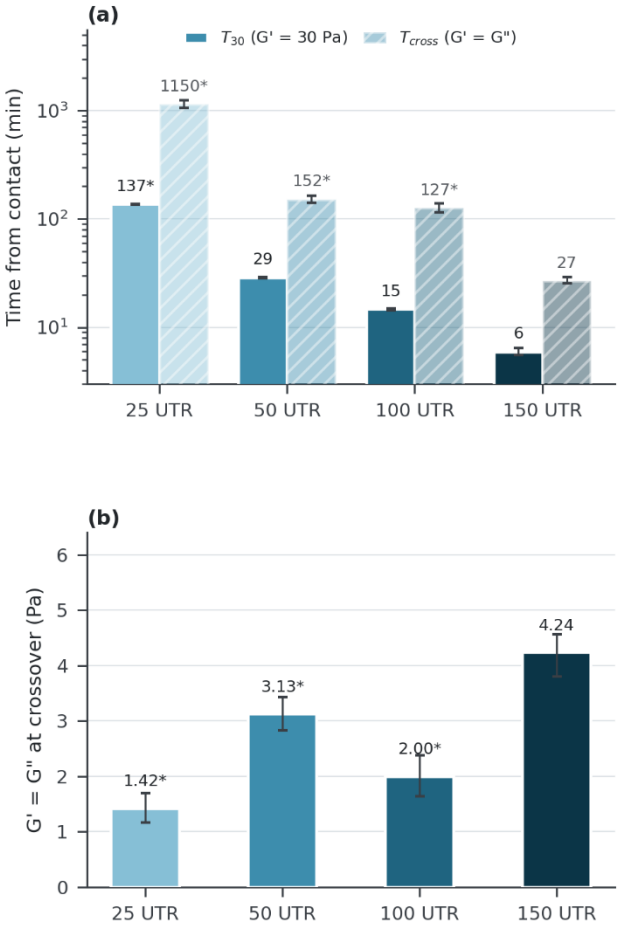

Fig. 3. (a) Time to the dissolution threshold (T30) and modulus crossover time (Tcross), both counted from enzyme–substrate contact, on a logarithmic scale. (b) Modulus at the crossover (G′ = G″). Error bars: 95 % CI by bootstrap. The asterisk (*) marks values extrapolated beyond the observed experimental window.

IV. Discussion

The rheological profiles show that the enzymatic degradation of Rennova Ultra Volume Lido is strongly dependent on enzyme concentration and directly associated with the progressive disruption of the hydrogel network. Fitting the same kinetic model to G′ and G″ on a common time axis allows the description not only of the degradation rate but also of the change in the viscoelastic regime of the material.

A. Meaning of the Shape Parameter

The value of β consistently below 1, for both moduli and at all concentrations, indicates progressive damping of the apparent degradation rate. This behavior is expected when the enzyme acts on a substrate whose structure changes continuously during the reaction itself. Hyaluronidase cleaves the HA chains and, in doing so, progressively alters the molar mass, the network architecture and the degree of entanglement of the system. In the early stages the substrate consists of long, strongly entangled chains whose cleavage removes elastically active junctions and produces marked drops in G′ per cleavage event. As the reaction advances, the remaining fragments are smaller and less entangled, and each new cleavage produces a proportionally smaller impact on the modulus. Added to this is the intrinsic heterogeneity of

enzymatic action, which acts preferentially on the most accessible regions of the network and leaves the most densely cross-linked domains for last. The combined result is kinetics that are not simple first-order but damped, which the parameter β describes compactly.

The consistency of β across the four concentrations indicates that this damping is a characteristic of the Rennova Ultra Volume Lido–Biometil system rather than an artifact of an isolated dose: enzyme concentration changes the rate of degradation, expressed in k, but not the shape of the curve.

B. Dead Time and Degradation Prior to the First Reading

The main limitation of the experimental design — the impossibility of measuring the moduli at the instant of enzyme–substrate contact — was addressed by modeling. The parameter τ provides a quantitative estimate of that interval, and its magnitude (1.1 to 2.7 min) is compatible with the manual procedure described.

The most relevant consequence is that the fraction of degradation occurring before the first record increases with dose, from 9.7 % at 25 UTR to 52.8 % at 150 UTR. In the latter condition, the estimated time for loss of half the initial modulus (1.79 min) is shorter than τ itself (2.06 min), that is, more than half of the degradation had already occurred before the first reading. This explains the variability of the initial moduli recorded across groups, which does not arise from material heterogeneity but from the progress of the reaction before recording began, and justifies referring all estimates presented here to enzyme–substrate contact rather than to the first reading of the instrument.

One limitation of the model deserves note. If τ represented only handling time, it would be expected to be approximately constant across groups, which is not observed. An alternative fit with τ shared across all groups yields τ = 1.68 min and describes the data almost as well as the model with free τ. This indicates that τ absorbs, besides the actual handling time, part of the incomplete specification of the model — notably the assumption that degradation follows the same functional form from time zero, including the mixing period, during which enzyme–substrate contact is not yet homogeneous. The values of τ should therefore be interpreted as order-of-magnitude estimates of the dead time rather than as its direct measurement.

C. Dissolution Threshold and Crossover of the Moduli

The threshold of G′ = 30 Pa was adopted from recent in vitro degradation studies [6], where it is defined as the lowest elastic modulus that can be reliably measured with this type of geometry, and therefore as the point at which the assay is stopped rather than as a structural transition of the gel. In the present system it corresponds to approximately 25 % of the modulus of the intact hydrogel, and to roughly one order of magnitude below the G′ reported for the volumizing fillers discussed in Section IV-D [14]. It is important to note, however, that reaching this threshold is not equivalent to the loss of elastic predominance: in all groups G′ remains higher than G″ at the instant T30, and the material continues to behave predominantly as a viscoelastic solid, albeit a much weakened one.

The effective loss of elastic predominance occurs only at the G′ = G″ crossover — the point at which tan δ = 1 —,and the contrast between the two landmarks is substantial. In the 150 UTR group the 30 Pa threshold is reached at 6.0 min, whereas the crossover occurs at 26.7 min — more than four times later. In the 50 and 100 UTR groups the crossover projects to 152 and 127 min, well beyond the observed window, and at 25 UTR it is not attained within any practically relevant horizon. These two landmarks therefore describe distinct structural events: the first corresponds to weakening of the network to the point of losing mechanical support capacity; the second, to the fall of connectivity below the percolation threshold, beyond which viscous dissipation dominates the behavior of the material [4], [14], [15].

The fact that k″ < k′ and β″ < β′ in all groups supports this reading. Enzymatic cleavage preferentially reaches the elastically active bonds that hold the network together [4], [5], [13], so that G′ decays faster than G″; the resulting fragments, although smaller and less entangled, retain the capacity to dissipate energy through viscous flow, which sustains G″ for longer. The convergence of the two moduli is the quantitative expression of this asymmetry.

It should be noted that the moduli at the crossover lie between 1.4 and 4.2 Pa, a range in which the torque approaches the minimum threshold of the instrument for reliable reading. The values of Gcross should therefore be interpreted as an indication of the order of magnitude of the final state of the material, and not as measurements of precision comparable to those obtained at higher moduli.

D. Comparison With the Literature

The results reinforce that a high G′, in isolation, does not determine enzymatic resistance. Fillers with the same volumizing indication and comparable modulus ranges may behave differently towards hyaluronidase [13], [16], depending on the manufacturing technology that governs the architecture of the polymer network [6]. Restylane Lyft (NASHA™ technology; 25 mg/mL), a biphasic particulate gel with high G′ (977 Pa at 5 Hz) [14], dissolves with 2.5 USP units of recombinant hyaluronidase in a single-dose in vitro protocol [16], an exceptionally low dose explained by its particulate morphology, which facilitates enzyme diffusion and maximizes the contact area [4]. At the opposite end, Juvéderm Volux (25 mg/mL; 665 Pa at 5 Hz) and Voluma (15 mg/mL; 271 Pa at 5 Hz) [14], monophasic gels of Vycross™ technology, are reported as the most resistant commercially available, requiring up to 300 USP for the dissolution of 0.2 mL [6], [16].

Germani et al. (2025) [15] evaluated Rennova UltraDeep (Hybrid MoBi™) with 100 UTR of Biometil hyaluronidase, attributing to it a moderate-to-slow degradation profile; that analysis was conducted by digital photography rather than rheometry, which precludes direct comparison with the thresholds adopted here. Comparison with the other studies [2], [6], [8], [16] remains limited by the absence of a validated conversion factor between UTR and IU/USP and by the heterogeneity of volumes, geometries and endpoint criteria. The values reported here apply to 0.25 mL of product under direct homogenization at 20 °C and should not be converted to other conditions without experimental verification.

It should be emphasized that the data do not establish any dose as a minimum requirement for dissolution and do not support recommendations of clinical conduct. Under the conditions tested, lower doses reach comparable levels of degradation provided sufficient reaction time; the translation

of this observation to any clinical scenario would depend on multiple factors, such as physiological temperature, diffusion in tissue, enzymatic clearance, applied volume and filler technology.

E. Limitations

First, the study lacks experimental replication: each condition corresponds to a single sample, and the confidence intervals presented reflect only the uncertainty of the fit over one time series, not the variability between independent preparations.

Second, conducting the measurements at 20 °C — an approach adopted to avoid the evaporation artifacts observed at 37 °C in pilot assays — reduces the absolute reaction rate; the times reported here should be interpreted as relative kinetic references, ordered by dose, rather than as predictors of the in vivo reversion rate.

Third, the protocol employs direct homogenization, eliminating the diffusional barrier that in vivo is often the rate-limiting step, so that the assay measures the intrinsic susceptibility of the network rather than the kinetics of reversal in tissue.

Fourth, the estimates of Tcross for 25, 50 and 100 UTR and of T30 for 25 UTR lie beyond the observed window and depend on the validity of the model outside the fitted interval.

Finally, the results describe a single filler and a single enzyme formulation, there is no validated conversion between UTR and IU/USP, and the rheological changes are interpreted as disruption of the polymer network without independent structural confirmation.

F. Perspectives

The resulting experimental agenda includes, in order of priority, independent replication of the conditions with a sample size allowing inference between groups; repetition of the protocol at 37 °C with evaporation mitigation by humidity chamber or sealed geometry; explicit standardization of time zero, by timing the preparation or by in situ mixing, which would turn τ into a measured quantity; complementary physicochemical characterization of the degraded material, by infrared spectroscopy, size-exclusion chromatography or microscopy, correlating the rheological changes with the molar mass distribution of the fragments; extension of the design to other fillers and other hyaluronidases, including recombinant ones; and, finally, models that reintroduce the diffusional barrier, followed by ex vivo, animal and clinical studies.

V. Conclusion

This study indicates that Rennova Ultra Volume Lido exhibits dose-dependent rheological susceptibility to Biometil hyaluronidase in the range of 25 to 150 UTR, under controlled in vitro conditions at 20 °C. Fitting the same exponential model to G' and G'' —on a common time axis anchored at the enzyme-substrate contact point— allowed for the estimation of the time to reach 30 Pa (T30) as 136.9, 28.9, 14.7, and 6.0 min for 25, 50, 100, and 150 UTR (with non-overlapping confidence intervals between consecutive doses) and demonstrated that the reduction in T30 stems directly from the increase in the degradation constant k' with enzyme concentration.

The joint modeling of the two moduli further separated two landmarks that the analysis of G' alone confounds: the operational endpoint of the assay, at $G' = 30$ Pa, and the loss of elastic predominance, at the $G' = G''$ crossover — the latter a genuine change in the viscoelastic regime of the material, which occurs substantially later and was observed within the experimental window only in the 150 UTR condition, at 26.7 min. The model also quantified the degradation occurring before the first reading, between 9.7 % and 52.8 % depending on dose, establishing that any comparison between concentrations in this type of assay must be referred to enzyme–substrate contact.

The range of 50 to 100 UTR identified as capable of driving 0.25 mL of the product to the rheological threshold in less than 30 min constitutes the first product-specific experimental rheological reference for the Rennova Ultra Volume Lido–Biometil pair within the Brazilian UTR system. It is, however, a preliminary reference, derived from a single sample per condition, obtained at 20 °C and without a diffusional barrier, and not a clinical dose recommendation.

Two methodological lessons emerge from this study. The first is that the interval between mixing and the first reading is not an operational detail: at the highest dose it contains more than half of the degradation, so a protocol that does not control it measures only the late phase of the reaction. The second is that following G' alone conflates the point at which the assay ceases to be measurable with the point at which the material changes viscoelastic regime; modelling both moduli on a common time axis separates the two. Three questions remain open and bound the scope of the reference proposed here: how the UTR system relates quantitatively to IU/USP, how the degradation kinetics scale with physiological temperature, and how much of the susceptibility measured here survives the diffusional barrier that direct homogenization removes.

Abstract — Biomaterial-guided bone regeneration has driven the development of biocompatible inks for 3D printing that mimic the mineral composition of native bone tissue, becoming an interesting solution for personalized medical devices for bone regeneration. In this work, chitosan hydrogels were prepared and reinforced with whitlockite (WK)doped with zinc at concentrations of 0.5% and 1% (mol %). The formation of the Zn-doped WK phase was confirmed by X-ray diffraction (XRD). Four formulations were evaluated: Chi (chitosan, control), Chi-WK (chitosan + WK), Chi—WK—0.5Zn (chitosan + WK doped with 0.5 % Zn), and Chi-WK-1Zn (chitosan + WK doped with 1% Zn). The rheological behavior was characterized by a shear rate sweep, an amplitude sweep to determine the linear viscoelastic region (LVR), a frequency sweep, and a recovery test, all performed with a 0.1 mm gap. All formulations exhibited shear-thinning and viscoelastic (G' > G") behaviors, with Chi-WK showing the highest storage modulus in the LVR (~1,775 Pa) and the highest flow index in the Shear Rate Sweep test (n = 0.382), while Chi-0,5Zn and Chi-1Zn showed the lowest flow indices (n = 0.118 and n = 0.113, respectively), evidencing more pronounced shear-thinning behavior. The recovery test demonstrated structural recovery capacity in all formulations, supporting their potential suitability for extrusion-based 3D printing, to be confirmed by direct printing trials. Zinc doping modulated the viscoelastic properties of the hydrogels, making them more suitable for 3D printing and contributing to the development of bioactive inks for bone scaffolds.

Keywords — Chitosan; Whitlockite; Zinc doping; Hydrogels; 3D printing; Rheology; Bone scaffolds.

I. INTRODUCTION

Bone tissue engineering has sought biocompatible and printable inks capable of mimicking both the organic and mineral phases of native bone. Extrusion-based 3D printing has emerged as a promising technology for fabricating scaffolds with complex geometries and controlled distribution of cells and bioactive agents, enabling the construction of customized three-dimensional constructs for regenerative medicine applications [1-2]. The success of these platforms depends directly on the rheological properties of the ink, which must exhibit shear-thinning behavior during extrusion, a dominant elastic character for structural support after deposition, and rapid recovery capacity of the gel network [2].

Among the biopolymers used as a base for 3D printing inks, chitosan stands out for its biocompatibility, biodegradability, antimicrobial activity, and ability to form hydrogels with tunable rheological properties for extrusion-based 3D printing [1-2]. Chitosan has reactive amino ($-NH_2$) and hydroxyl (-OH) groups, capable of interacting with inorganic particles and metal ions through coordination, thereby modulating the viscoelastic properties of the hydrogel and favoring the formation of three-dimensional networks with thixotropic behavior [1].

To confer bioactivity and stimulate bone regeneration, polymeric hydrogels have been reinforced with calcium phosphate-based bioceramics [3]. Among these ceramics, whitlockite (WK, $Ca_{18}Mg_2(HPO_4)_2(PO_4)_{12}$) - which is the second most abundant inorganic phase in human bone tissue (up to 20% by mass), being particularly relevant in young bone and in remodeling processes – has recently arisen interest in the field of biomaterials. Unlike hydroxyapatite or β-tricalcium phosphate, WK exhibits an intermediate solubility between them and, besides releasing PO_4^{3-} Ca2+ ions, also leaches Mg^{2+} ions under physiological dissolution, which actively participate in osteogenic signaling pathways. WK nanoparticles have been shown to stimulate osteogenic differentiation of stem cells, inhibit osteoclastic activity, and promote in vivo transformation into hydroxyapatite, resulting in faster bone regeneration with greater structural density [4], [5].

The incorporation of zinc into calcium phosphates is a strategy widely investigated to enhance bone repair. Zinc is an essential trace element for bone metabolism that stimulates osteoblast proliferation and differentiation, inhibits osteoclastic resorption, and exerts local antimicrobial action [6]. In bioceramics, the atomic substitution of Ca^{2+} by Zn^{2+} in the crystal lattice modulates the ionic release profile without compromising the structure of the mineral phase. Additionally, piezoelectric Zn-doped WK has been linked to the modulation of cellular processes through mechano-electrical stimulation, and, in addition to increasing mechano-electrical conversion, it has attracted interest in doped inorganic phases for multifunctional biomaterials [7].

Rheological characterization is a central tool for assessing the suitability of hydrogel as an ink for 3D printing. The determining parameters include: apparent viscosity and the shear-thinning index, the viscoelastic moduli G' and G", the linear viscoelastic region (LVR) that defines the stiffness and elastic behavior of the gel at rest, and structural recovery capacity that determines the shape fidelity of the printed filament. The balance between fluidity during extrusion and

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

firmness after deposition represents the main challenge in developing hydrogel inks [1-2].

Given this context, the present work proposes the development and rheological characterization of chitosan hydrogel inks reinforced with zinc-doped WK (0.5% and 1%), synthesized by the chemical precipitation method with hydrothermal aging. The formation of the WK phase was confirmed by XRD prior to incorporation into the hydrogel, and the rheological behavior of the four formulations was systematically evaluated as a basis for the future application of these compositions as bioactive inks for 3D printing of bone scaffolds.

II. MATERIALS AND METHODS

A. Synthesis of the chitosan hydrogel

To prepare 15 mL of hydrogel, an acid solution was obtained by mixing 7.5 mL of distilled water, 6 mL of acetic acid (Sigma Aldrich), 1.5 mL of lactic acid (Sigma Aldrich), and 0.45 g of citric acid (Casa Americana, Brasil), homogenized under magnetic stirring for 20 min. **For the WK-reinforced formulations (Chi-WK, Chi-WK-0.5Zn, and Chi-WK-1Zn), WK powder (pure or zinc-doped) was then added to the acid solution at 10% (w/w) relative to the chitosan mass to be subsequently incorporated, corresponding to 0.09 g of WK per 0.9 g of chitosan (final WK concentration of 0.6% w/v in the 15 mL hydrogel batch).** Next, 0.9 g of low-molecular-weight chitosan (final concentration of 6% w/w) was added to the solution, ensuring complete submersion of the polymer. The mixture was left to rest for at least 12 h and subsequently homogenized by ultrasound for 2 h (with water exchange every 1 h). To remove bubbles, the gel was transferred to syringes with sealed tips and centrifuged at 3600 rpm for 30 min.

B. Synthesis of zinc-doped whitlockite

The synthesis of undoped whitlockite was carried out by chemical precipitation, followed by hydrothermal aging, according to the protocol. Undoped whitlockite was used as a control parameter in our studies. The process was divided into two days. On the first day, two separate solutions were prepared. The alkaline solution was obtained by dissolving 14.2660 g of $Ca(OH)_2$ (99,5 %, Sigma Aldrich) and 3.3640 g $Mg(OH)_2$ (99,5 %, Sigma Aldrich) in 250 mL of distilled water, under magnetic stirring at 70 °C for 1 h. The acidic solution was prepared by adding 16.275 mL of H_3PO_4 (Sigma-Aldrich) to 250 mL of distilled water in a volumetric flask. The acidic solution was dripped onto the alkaline solution at a rate of 2.5 mL/min using a peristaltic pump, maintaining the temperature at 70 °C. The resulting suspension was transferred to a reactor (autoclave) and subjected to hydrothermal aging at 70 °C for 48 h, with an expected yield of ~90%. The general reaction equation is in Eq. 1:

$$9Ca(OH)_2 + Mg(OH)_2 + 7H_3PO_4 \rightarrow Ca_9Mg(HPO_4)(PO_4)_6 + 18OH^- + 2H_2O \quad \text{(Eq. 1)}$$

On the second day, the solution was removed from the reactor and cooled for 1 h (with the aid of cold running water, if necessary). The precipitate was transferred to 50 mL Falcon tubes and centrifuged at 3,600 rpm for 5 min. The washing cycle was repeated 5 times: (1) removal of the supernatant; (2) filling the tube with distilled water up to 50 mL; (3) mechanical agitation for resuspension; and (4) centrifugation at 3,600 rpm for 5 min. After the last wash, the supernatant was discarded, and the tubes were labeled and stored in a freezer. The samples were subsequently freeze-dried.

Zinc-doped whitlockite: For the synthesis of the doped samples, a molar fraction of $Ca(OH)_2$ was replaced by $Zn(NO_3)_2$ (99,5 %, Sigma-Aldrich), keeping the total stoichiometry unchanged. For 0.5 mol% Zn: $Ca(OH)_2$ = 0.66731 g, $Zn(NO_3)_2$ = 0.01785 g. For 1 mol% Zn: $Ca(OH)_2$ = 0.66396 g and $Zn(NO_3)_2$ = 0.03570 g. The precipitation, hydrothermal aging, and washing protocols were identical to those used for undoped WK. The formation of the WK phase in all samples was confirmed by XRD after freeze-drying.

C. Structural confirmation by X-ray diffraction (XRD)

The formation of the whitlockite phase, both pure and zinc-doped, was confirmed by X-ray diffraction (XRD), validating the synthesis route employed prior to incorporation into the chitosan hydrogel. The diffractograms were compared with the reference standard for whitlockite (ICDD 00-011-0570), and the absence of significant secondary phases attested to the purity of the obtained phase. The observed peaks are consistent with the crystal structure of magnesium whitlockite previously characterized by X-ray diffraction and *ab initio* methods [5].

D. Experimental groups

For comparative evaluation, four hydrogel formulations were prepared, as described in Table I.

Group	Composition
Chi	Chitosan (control)
Chi-WK	Chitosan + pure WK
Chi-WK-0,5Zn	Chitosan + WK doped with 0.5 mol.% Zn
Chi-Wk-1Zn	Chitosan + WK doped with 1 mol.% Zn

TABLE I. Evaluated formulations.

E. Rheological characterization

The rheological behavior of the four formulations was evaluated through four tests, all performed with a 0.1 mm gap. A shear rate sweep test was performed to evaluate the apparent viscosity of the samples under conditions close to body/printing temperatures and to assess their shear-thinning behavior, which is relevant to material extrusion. The linear viscoelastic region (LVR) was determined to identify the strain range over which the viscoelastic response of the samples remains linear, a condition necessary for the correct interpretation of subsequent oscillatory tests. Then, we performed the frequency sweep test within the determined LVR to characterize the evolution of the storage (G') and loss (G") moduli as a function of frequency, thereby indicating whether each formulation is predominantly elastic or viscous. Finally, we carried out a recovery test (structural recovery) to evaluate the gel network's recovery capacity after a high-shear step, a property associated with shape fidelity during and after 3D printing.

The shear stress (τ) and apparent viscosity (η) data as a function of shear rate ($\dot{\gamma}$), obtained from the shear rate sweep

test at 37 °C, were fitted to the power-law model of *Ostwald–de Waele* [8] (Eq.2):

$$\mathbf{T = K \cdot \dot{\gamma}^{n}} \qquad \text{(Eq. 2)}$$

where K is the consistency index (Pa·s^n) and n is the flow index, which expresses the degree of shear-thinning (*shear-thinning* behavior) of the material (n < 1). The fitting was performed using log-log linear regression (log τ = log K + n·log $\dot{\gamma}$) on the raw data for each formulation. For Chi and Chi-WK groups, the fitting was performed over the entire available $\dot{\gamma}$ range after excluding the initial points corresponding to the rheometer's stabilization period. For Chi-WK-0.5Zn and Chi-WK-1Zn, stabilization and a slight reduction in τ were observed at high shear rates ($\dot{\gamma}$ > 25 s^{-1}), behavior consistent with slippage at the sample-geometry interface (*wall slip*), a phenomenon widely described for materials with a high fraction of dispersed particles [8]. In these cases, the fitting was restricted to the $\dot{\gamma}$ window where τ increased monotonically with shear rate (4–24 s^{-1}), thereby avoiding the inclusion of data affected by this experimental artifact.

III. RESULTS AND DISCUSSION

A. Confirmation of the WK phase by XRD

Initial characterization of the ceramic powders was necessary to ensure that WK was produced during synthesis. The undoped WK was already characterized, as published in [5]. The Zn-doped WK was characterized before and after calcination to evaluate whether the WK phase was formed prior to or after thermal treatment. For Zn-doped WK, formation of the whitlockite phase was confirmed by XRD for both doping concentrations, 0.5 and 1 mol% (Fig. 1).

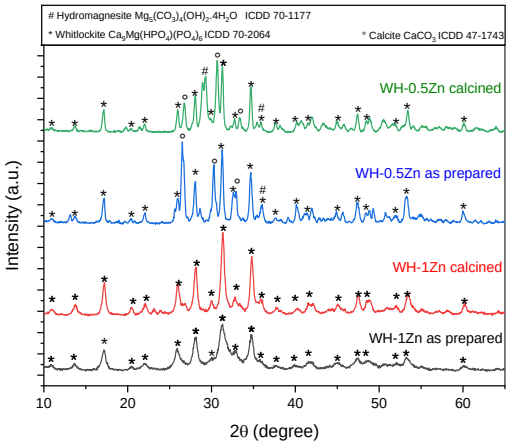

Fig. 1. X-ray diffractograms of pure and zinc-doped WK (0.5% and 1%). Peaks indexed according to ICDD 00-011-0570.

The diffractograms showed characteristic WK peaks, indexed to ICDD card 00-070-2064, thereby validating the synthesis route employed. No significant secondary phases were observed for the WK doped with 1 mol% of Zn, indicating satisfactory purity of the obtained phase. In these compositions, zinc doping did not alter the crystal structure of WK, confirming that Zn^{2+} was incorporated into the crystal lattice, partially replacing Ca^{2+}, as described in the literature for zinc-doped calcium phosphates [6]. However, for the 0,5 mol% Zn doping, additional formation of hydromagnesite and calcite was observed. Usually, carbonate phases form on the surfaces of calcium phosphate phases due to interactions between Ca^{2+} at the surfaces and atmospheric CO_2 under humid conditions, as described by Cerruti et al. [9]. Despite the undesired phases observed, we did not exclude the Chi-WK-0.5Zn formulation from the rheological characterization, as we aim to investigate its impact on rheological behavior. Notwithstanding, calcite is also a bioactive biomaterial, and both *in vitro* and *in vivo* studies have shown promising biological applications in bone regeneration [10].

B. Shear Rate Sweep

All formulations exhibited shear-thinning behavior (Fig. 2), confirmed by the flow indices n < 1 obtained from the power-law model fitting (Table II). The group Chi presented n = 0.167, indicating pronounced shear-thinning, whereas group Chi-WK exhibited the highest flow index (n = 0.382), suggesting lower shear sensitivity than the other formulations. The zinc-doped formulations, Chi-0.5WK (n = 0.118) and Chi-1WK (n = 0.113), showed the lowest flow indices among all samples, evidencing more pronounced shear-thinning behavior. These values fall within the range reported in the literature for hydrogels intended for direct ink writing (DIW) extrusion (n ≈ 0.3–0.6) [8], with G3 and G4 falling below this range, indicating greater ease of extrusion at lower applied pressures.

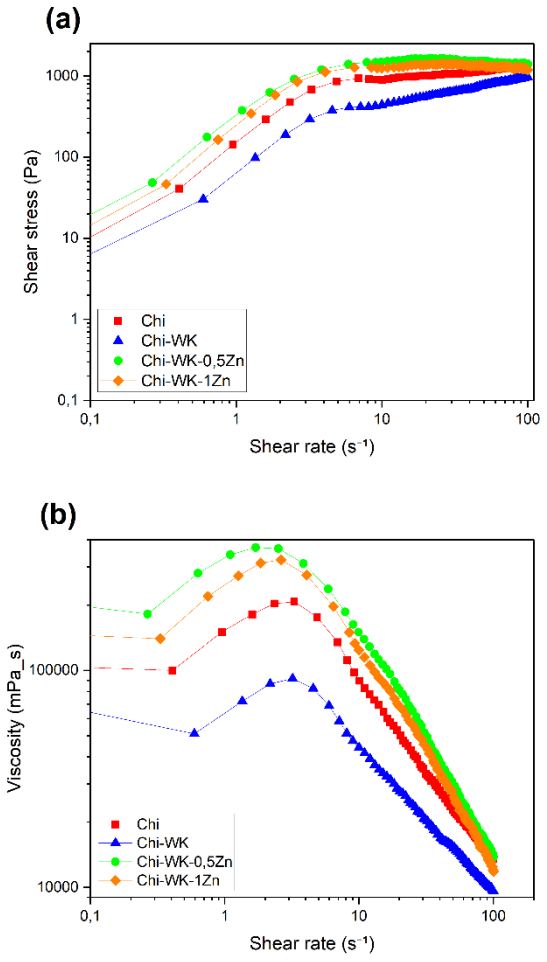

Fig. 2. Flow behavior at 37 °C for the four formulations: (a) shear stress and (b) apparent viscosity as a function of shear rate.

The consistency index (K) allows comparisons of resistance to flow of different ink formulations and is strongly

influenced by intermolecular interactions among the ink components. Adding undoped WK to chitosan decreased the consistency index (609.6 for Chi and 171.0 for Chi-WK). However, when Zn-doped WK is added, the consistency index increases from 1146,3 for Chi-WK-0.5Zn to 976.1 for Chi-WK-1Zn. It should be noted that the Chi-WK-0.5Zn sample also contained minor calcite and hydromagnesite phases, as identified by XRD (Section III.A); these secondary phases may additionally contribute to the observed rheological response, making it difficult to attribute the results in this specific formulation solely to Zn^{2+}–chitosan interactions. Bearing this limitation in mind, these data suggest that zinc ions leached from the doped ceramics may affect the intermolecular interactions of chitosan. It is known that some divalent ions, such as Zn^{2+}, Mn^{2+}, and Mg^{2+}, interact with electron pairs from NH_2 -COOH groups of chitosan, forming complexes involving intra- or intermolecular interaction among chitosan chains [11]. However, Ca^{2+} ions do not interact with amino and carboxyl groups as effectively as the other divalent ions [12-13]. Thereby, it is reasonable to assume that it may be the main cause of the found results. It should be noted that Zn^{2+} ion release and Zn–chitosan complex formation were not directly measured in this study (e.g., via ICP-OES for ion release or FTIR for coordination bonding); the proposed mechanism is therefore a hypothesis consistent with the observed rheological trends and previous literature [11]–[13], rather than a directly confirmed interaction.

We have to assume two different effects: 1) the first is the effect of the leached ions from the ceramics in the chitosan structure, where Zn-doped WK leaches Zn^{2+} ions that yields to more formation of chitosan complexes than undoped WK; 2) the second effect is the physical effect of the ceramics particles in the polymer, where these particles limit the polymer-polymer interactions, and thereby decrease the viscosity of the polymer. These effects compete with one another: one increases intermolecular interactions, while the other decreases them. While in compositions containing Zn-doped WK, the effect of Zn2+ ions was dominant, in compositions containing undoped WK, the physical effect of the particles became predominant.

These results are also evidenced by the viscosity measurement (Fig. 2). The viscosity follows the same trend as the consistency index. Considering that viscosity is also linked to intermolecular interactions among the ink formulation components, it is reasonable that both viscosity and K follow the same trend.

TABLE II. Power-law model parameters ($\tau = K \cdot \dot{\gamma}^n$) and viscosity at 10 s^{-1}

Group	n	K (Pa·s^n)	R^2	η at 10s^{-1}
Chi	0.167	609.6	0.978	90.1
Chi-WK	0.382	171.0	0.983	44.2
Chi-WK-0,5Zn	0.118	1146.3	0.929	149.4
Chi-Wk-1Zn	0.113	976.1	0.885	123.7

C. Linear Viscoelastic Region — LVR

The strain sweep test allowed identification of the LVR of each formulation and confirmed the predominantly elastic character of the hydrogels (G' > G") at small strain amplitudes. Within the LVR, the storage module remained constant, while above the linear viscoelastic limit, there was a progressive decrease in G', indicating structural collapse of the gel network.

Chi group presented G' in the LVR on the order of ~700 Pa, a value characteristic of moderate-concentration chitosan hydrogels [14]. Chi-WK group stood out with G' ~1,775 Pa within the linear region, the highest among the formulations. This result indicates that incorporating undoped WK promoted mechanical reinforcement of the hydrogel network, likely through physical interactions (hydrogen bonds, electrostatic interactions) between WK particles and chitosan chains. In a previous work from our research group in which bioactive glass particles (SiO_2-CaO-P_2O_5) were incorporated in chitosan hydrogels, we found that an increase in G' was modulated by the nergatively charged surface of the glass particles, which resulted in a possible hydrogen bond between silanol groups from the glass and amine or carboxylic acids from the chitosan [15]. In this work, we believe that hydrogen bonds between the phosphate groups of WK may cause a similar effect.

Interestingly, the Chi-WK-0.5Zn and the Chi-WK-1Zn groups showed G' ~1,307 and 1,109 Pa. These values are higher than those observed in the Chi group but lower than those in the Chi-WK group. Considering that the storage modulus reflects the ability of the hydrogel to store elastic deformation energy that, in turn, is stored in the deformation of chemical bonds, intermolecular interactions, and reversible structural deformation, we believe that the physical particle effect of the ceramic particles increases the storage modulus, while the formation of complexes with Zn^{2+} ions makes the chitosan structure more rigid, decreasing the amount of energy that can be stored in the hydrogel deformation. As noted above, the presence of secondary calcite and hydromagnesite phases in the Chi-WK-0.5Zn sample may also contribute to this intermediate behavior, and should be considered alongside the proposed Zn^{2+}-complexation mechanism.

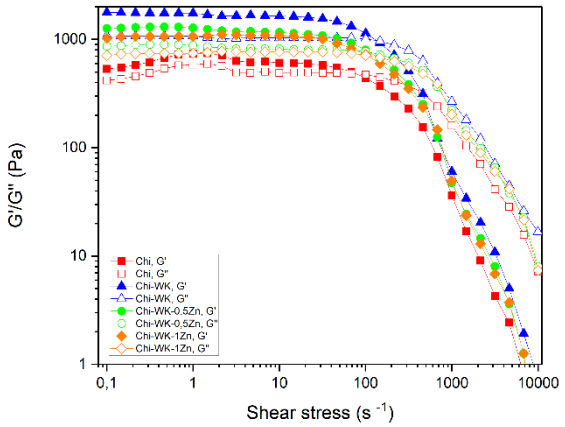

Fig. 3. G' and G" moduli as a function of strain amplitude at 5 °C (LVR).

D. Frequency Sweep (5 °C)

The frequency sweep, performed within the LVR of each formulation, confirmed the predominantly elastic character (G' > G") across the entire evaluated frequency range,

indicating that the formulations exhibit a coherent gel structure. Maintaining G' > G" throughout the sweep is an essential requirement for 3D printing inks, as it indicates that the material sustains its shape after deposition [1], [2].

Chi group presented G' on the order of ~50 Pa at 0.01 Hz, increasing to ~1,100 Pa at high frequencies, confirming frequency-dependent gel behavior. The Chi-WK group exhibited the highest moduli across the entire evaluated range, with G' reaching ~2,500 Pa, thereby reinforcing the role of undoped WK particles in strengthening the polymer network. Chi-WK-0.5Zn and Chi-WK-1Zn groups presented similar behavior to each other, with intermediate values between Chi and Chi-WK, confirming the same mechanism mentioned in the LVR discussion. No formulation exhibited crossover (G' = G") within the evaluated range, reinforcing the solid-gel behavior in all compositions.

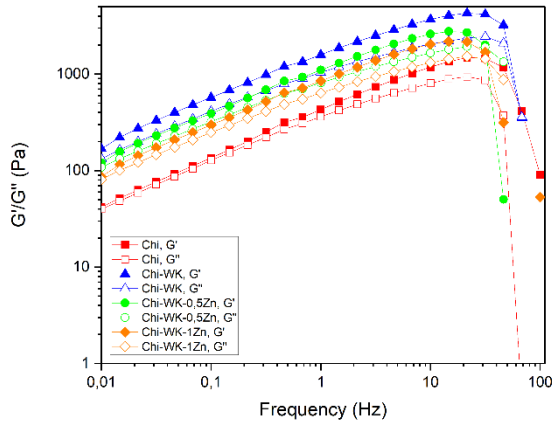

Fig. 4. G' and G" moduli as a function of angular frequency at 5 °C.

E. Structural Recovery

The recovery test assessed the ability of each formulation to reconstitute its gel network after a high-amplitude shear step. This thixotropic behavior is directly related to shape fidelity (*shape fidelity*) during and after 3D printing, as it determines the ability of the extruded filament to maintain its geometry [16].

All formulations demonstrated structural recovery above 96%. Chi group recovered 96.1%, while Chi-WK presented the highest absolute recovery, reaching 100.3% ($\eta_{initial}$ = 4,173.0 Pa·s), indicating complete network reconstitution after shearing. The Chi-WK-0.5Zn and Chi-WK-1Zn groups recovered 96.9% and 99.0%, respectively, both higher than the Chi group (our control), which recovered 96.0%. This behavior is consistent with the literature, which describes zinc doping as promoting reversible coordination interactions between Zn^{2+} ions and chitosan's functional groups, which dissociate under mechanical stress and reorganize once shearing ceases [6]. However, our results, along with the LVR and frequency sweep tests, provide evidence that the formation of zinc complexes makes the chitosan structure stiffer, and might be the cause of a lower recovery compared to the Chi-WK group. Nonetheless, all formulations show high recovery percentages, confirming thixotropic behavior and supporting their potential suitability for extrusion-based 3D printing, to be confirmed by direct printing trials.

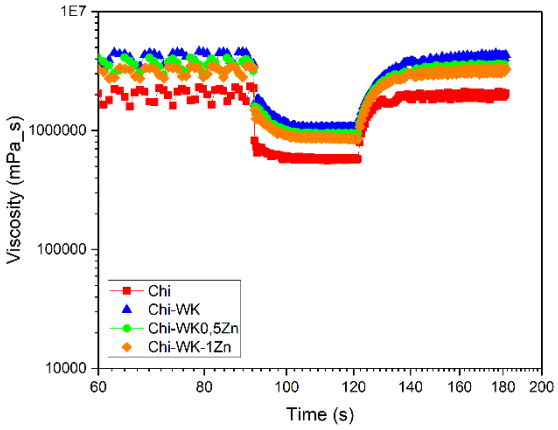

Fig. 5. G' recovery after high-amplitude shearing at 5 °C.

IV. CONCLUSION

This work demonstrated that chitosan hydrogels reinforced with undoped and zinc-doped whitlockite present promising rheological properties for application as 3D printing inks. The WK phase was confirmed by XRD in all synthesized samples, although the WK-0.5Zn composition also showed the formation of other minor phases, such as calcite and hydromagnesite. All formulations exhibited *shear-thinning* behavior, dominant elastic character (G' > G"), and structural recovery capacity after shearing. The incorporation of undoped WK promoted mechanical reinforcement of the hydrogel network via hydrogen bonding, thereby contributing to high recovery. Zinc doping modulated the viscoelastic properties, making the chitosan network stiffer and slightly decreasing the structure's strain. Overall, the results indicate that formulation Chi-WK presented the greatest mechanical reinforcement and structural recovery capacity, while the Chi-WK-0.5Zn and Chi-WK-1Zn formulations showed more pronounced shear-thinning behavior, favoring extrusion under lower pressures. Future studies should include 3D printing trials, cytotoxicity assessment, and in vitro bioactivity tests to confirm the clinical potential of the developed formulations.

ACKNOWLEDGMENTS

The authors thank the Faculdade Israelita de Ciências da Saúde Albert Einstein and the Federal University of ABC (UFABC) for the infrastructure provided for the development of this work. We also acknowledge the National Council of Science and Technology Development (CNPq, grant numbers 44319/2023-9 and 380534/2024-0) for the financial support.

***Abstract*— Breast cancer remains a leading cause of mortality worldwide, prompting significant research into nanoparticle-based drug delivery systems to improve therapeutic efficacy and reduce toxicity. This study aims to perform a bibliometric analysis of the global scientific production on this topic between 2018 and 2024, identifying key trends, influential networks, and research gaps. A search was conducted on the Scopus database in October 2025 using descriptors related to nanoparticles, breast cancer, and drug delivery. A total of 1,280 eligible original articles were analyzed. VOSviewer software was used to map co-authorship, keyword co-occurrence, and citation networks to visualize the field's intellectual structure. The analysis revealed China as the primary research hub, followed by the USA, Iran, and India. Research themes formed three main clusters: physicochemical development of nanosystems, in vitro biological evaluations, and in vivo animal studies. While the field is expanding, collaboration networks remain geographically fragmented, with limited international integration between major institutional centers. Research on nanoparticle-based delivery for breast cancer is growing but characterized by regional clusters. Future progress depends on strengthening global collaborative networks and fostering translational studies to bridge the gap between laboratory findings and clinical application.**

***Index Terms*—Breast cancer; Nanoparticles; Drug delivery systems; Scientometrics analysis; VOSviewer.**

I. Introduction

Breast cancer is a leading cause of morbidity and mortality among women worldwide, showing a continuous increase in incidence over the last decades and representing a substantial portion of the global cancer burden. Recent estimates from Globocan (2022) indicate that breast cancer remains among the types with the highest number of new cases, accounting for approximately 2.3 million diagnoses (11.6% of all cancer cases), and contributes significantly to mortality rates, being responsible for about 670,000 annual deaths across different regions of the world [1].

The reality in developing countries mirrors this global landscape. In Brazil, for instance, this neoplasm consolidates itself as a major public health challenge. According to recent national projections for the 2023–2025 period, thousands of new annual diagnoses are expected, positioning the disease among the most recurrent in the female population, with incidence and mortality rates showing significant regional variations [4].

To overcome the barriers of low specificity and high toxicity common to classical oncological treatments, the application of nanotherapies has expanded considerably. This strategy aims to improve drug biodistribution and reduce adverse effects, becoming a field of intense scientific investigation [5]. Despite the growing volume of publications on new nanosystems, there is a lack of studies that systematize this scientific production to identify global collaboration patterns and emerging technological trends.

Given this scenario, this study aims to perform a bibliometric analysis of the global scientific production on nanoparticle-based drug delivery systems for breast cancer, mapping the evolution of the field between 2018 and 2024. Our main conclusions indicate that, although scientific production has grown exponentially, largely led by China and focused on preclinical studies, international collaboration networks remain fragmented. This suggests that the advancement towards clinical application will crucially depend on strengthening global partnerships and greater investment in translational research.

II. Materials and Methods

This study is a scientometric review designed to analyze current global scientific output regarding nanoparticle-based drug delivery systems applied to breast cancer treatment.

Data collection was conducted on the Scopus database on October 17, 2025, selected for its comprehensive indexing of high-impact journals across health sciences, pharmacology, and materials science [3]. The 2018–2024 timeframe was adopted to focus the analysis on contemporary scientific production and identify emerging trends in the development and application of nanoparticle-based drug delivery systems for breast cancer therapy.

The search strategy was executed using Scopus title, abstract, and keyword fields (TITLE-ABS-KEY) with the following search string: TITLE-ABS-KEY (Nanoparticles) AND TITLE-ABS-KEY (breast cancer) AND TITLE-ABS-KEY (Drug delivery systems) AND TITLE-ABS-KEY (Cancer treatment) AND PUBYEAR > 2017 AND PUBYEAR < 2025

The search was conducted on October 17, 2025, capturing publications from 2018 to 2024. Search terms were selected to establish a comprehensive retrieval strategy covering nanoparticles, breast cancer, drug delivery systems, and cancer therapy. Broad descriptors directly tied to core research concepts were prioritized, as preliminary testing showed that narrower term combinations yielded significantly lower record recovery.

Inclusion criteria comprised original research articles published between 2018 and 2024, written in English, that explicitly addressed nanoparticle-based drug delivery systems targeted for breast cancer treatment. Exclusion criteria eliminated studies evaluating nanoparticles for unrelated therapeutic or technological applications, as well as works that did not incorporate nanoparticle systems.

The initial database search yielded 2,902 publications. Applying Scopus automated filters for document type (original articles) and language (English) reduced the dataset to 1,901 records. The retrieved records were exported to a spreadsheet for screening. Following duplicate removal, a single reviewer manually screened titles and abstracts against the predefined eligibility criteria. Studies unrelated to nanoparticle drug delivery for breast cancer—including those focused on alternative medical applications or lacking nanoparticle integration—were excluded. Ultimately, 1,280 articles met all inclusion criteria and were selected for scientometric analysis.

VOSviewer software was utilized to generate network maps and analyze co-authorship networks (by country, author, and organization), keyword co-occurrence, citation networks (sources and documents), organization co-citation, and bibliographic coupling among documents. In the visual networks, nodes represent entities such as countries, institutions, or authors, where node size reflects occurrence frequency. Node and connection colors distinguish discrete clusters, while line thickness indicates link strength between elements.

III. RESULTS

The scientometric analysis of the 1,280 selected articles allowed for a clear overview of the evolution of research on nanoparticle-based drug delivery systems applied to breast cancer treatment. As observed in Fig. 1, the growth of scientific production between 2018 and 2024 exhibits a predominantly upward trend, reflecting the consolidation of this theme as one of the most promising frontiers in cancer nanomedicine.

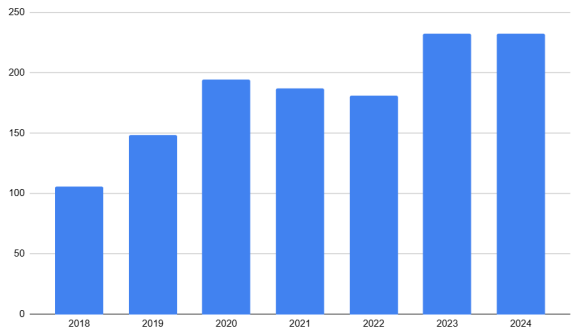

Fig. 1. Temporal distribution of publications on nanoparticle-based drug delivery systems applied to breast cancer treatment (2018–2024).

The year 2018 marks the beginning of the time series with 106 publications, followed by an increase to 148 articles in 2019. In 2020, further growth was observed, reaching 194 publications. In 2021 and 2022, there was a moderate decline, with 187 and 181 articles, respectively, while nevertheless maintaining a significant volume of scientific output. The upward trend resumed in 2023, with 232 identified articles—a figure that remained steady in 2024, also with 232 publications.

This temporal trend highlights sustained scientific interest in applying nanoparticles to drug delivery systems for breast cancer. Although publication growth was not strictly linear across all years, the most recent period concentrated the largest share of the dataset, with 464 articles published in 2023 and 2024, representing approximately 36.3% of the total analyzed corpus. This finding indicates the consolidation of the field in recent years and serves as a baseline to explore, in subsequent sections, the specific therapeutic approaches, materials, and nanostructured strategies that accompanied this temporal evolution.

A. Co-Authorship Analysis by Country

The analysis of co-authorship between countries demonstrates the geographical distribution of scientific production and international collaborations related to nanoparticle-based drug delivery systems for breast cancer treatment. The map generated by VOSviewer reveals an interconnected global network composed of multiple clusters representing the main research hubs and their respective collaborations, as shown in Figure 2.

The size of the nodes indicates the volume of publications from each country, while the thickness of the lines represents the intensity of cooperation. It is observed that China stands out as the primary center of scientific production in the area, presenting the largest node in the network and numerous connections with Asian, American, and European countries. This prominent position reflects the exponential growth of Chinese research in nanotechnology and oncology.

Secondarily, countries such as the United States, Iran, and India also appear as central actors in the international collaboration network, establishing consistent partnerships both among themselves and with other emerging nations. Iran, in particular, shows a high density of connections, indicating active cooperation with countries such as Turkey, China, Germany, and Italy, consolidating itself as an important regional hub in the application of nanoparticles in

anticancer therapies.

Brazil, although having lower centrality compared to Asian and North American countries, integrates a cluster involving European and Latin American nations (such as Portugal and Spain), demonstrating progressive insertion into international collaborations focused on translational research and the development of drug delivery systems.

Thus, the co-authorship map by country evidences that research on therapeutic nanosystems applied to breast cancer presents a global and interdisciplinary character, with strong Asian leadership—especially from China and Iran—and gradual growth in Latin American participation.

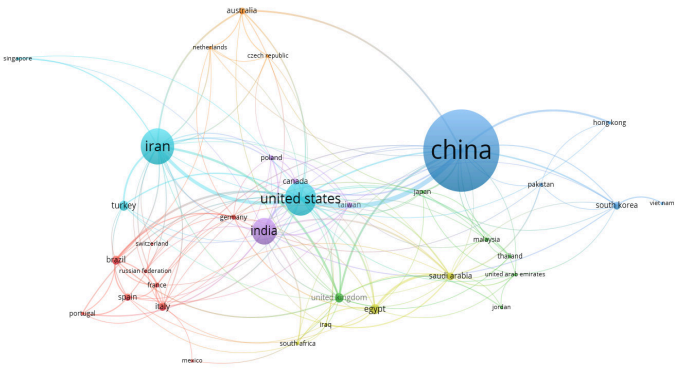

Fig. 2. Co-authorship map by country generated in VOSviewer, showing the geographical distribution and international connections of research on nanoparticle-based drug delivery systems applied to breast cancer. The size of the nodes represents the volume of publications, and the colors indicate collaboration clusters.

B. *Co-Authorship Analysis by Authors*

The author analysis highlights the collaborative structure among the main researchers working on nanoparticle-based drug delivery systems for breast cancer treatment. The map generated by VOSviewer shows the formation of different clusters (author groups) representing consolidated or emerging scientific cooperation networks, as illustrated in Fig. 3.

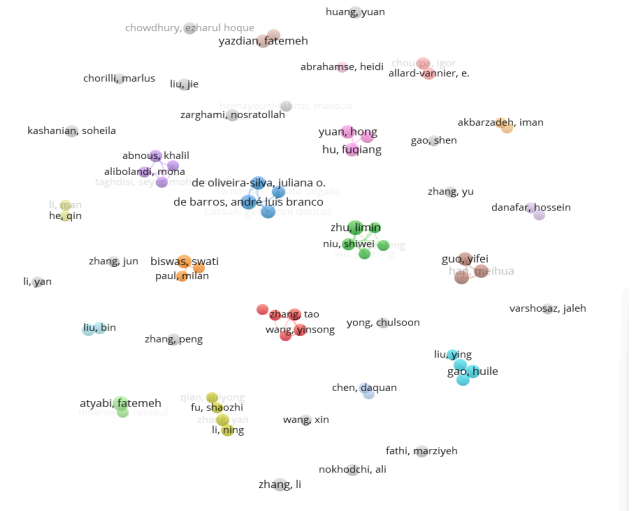

Fig. 3. Detailed view of specific author clusters, highlighting the distinct collaborative groups led by Asian and Latin American researchers.

The presence of multiple colored clusters is observed, indicating relatively independent collaboration nuclei with limited interconnectivity between them. Among the most prominent authors with high centrality in the network are Zhu, Limin; Niu, Shiwei; Guo, Yifei; Hu, Fuqiang; Yuan, Hong; De Oliveira-Silva, Juliana O.; and De Barros, André Luís Branco. These authors stand out due to the density of connections and node sizes, suggesting a higher number of co-authored publications and influence within the field.

The blue cluster, centered on De Oliveira-Silva and De Barros, represents an active network associated with Latin American research. The green cluster, led by Zhu, Limin, and Niu, Shiwei, evidences robust Asian collaboration. The red cluster, with Zhang, Tao, and Wang, Yinsong, and the pink cluster, with Hu, Fuqiang, and Yuan, Hong, also reflect collaborations concentrated in Asia, showing the significant contribution of this continent to the advancement of the area.

From this perspective, the co-authorship map demonstrates that scientific production on the topic is somewhat collaborative but still geographically fragmented, with strong production hubs and occasional intercontinental cooperation. This configuration reflects the recent and multidisciplinary growth of the area, driven by partnerships between research groups in nanotechnology, biomedical engineering, and pharmacology.

C. *Co-Authorship Analysis Among Organizations*

The co-authorship network among organizations highlights institutional articulation in the development of research on the subject. The map generated by VOSviewer shows a concentrated collaborative structure composed of a few strongly connected nodes, suggesting stable institutional relationships that are, however, still restricted to certain research nuclei, as shown in Figure 4.

Fig. 4. Collaboration map among organizations identified by VOSviewer. Nodes represent institutions and research groups, and the absence of robust connections indicates limited cooperation among the involved centers.

The formation of small, interconnected clusters is observed, where institutions such as the Drug Applied Research Center, the Department of Pharmaceutics, and the Department of Pharmaceutical Nanotechnology stand out. These centers appear as central nodes of the network, acting as axes of cooperation between different departments and universities.

The strong connection between these institutions indicates interdepartmental collaborations focused on the development of nanostructured systems applied to oncology, reinforcing the multidisciplinary nature of the area. On the other hand, institutions such as the Department of Biology, Islamic Azad University, and the Department of Life Science Engineering appear more peripherally, evidencing punctual or emerging collaborative participation within the global network.

The spacing between clusters demonstrates that, although

established partnerships exist, the institutional network still lacks broader international integration, with regional collaborations predominating. This pattern reinforces the scenario identified in the co-authorship analysis by authors, where there are strong local scientific production hubs located mainly in Asia and the Middle East, with lower involvement of European and Latin American institutions.

Overall, the results indicate that research on nanoparticle-based drug delivery presents consolidated institutional nuclei but remains geographically fragmented, suggesting opportunities for expanding global cooperation and scientific exchange between different regions.

D. Keyword Analysis

The keyword co-occurrence analysis allows for the identification of the main themes and research fronts structuring the field of nanoparticle-based drug delivery systems applied to breast cancer treatment. The map generated by VOSviewer (limited to the top 50 most frequent keywords) evidences a dense and interconnected network organized into three large thematic clusters representing the different conceptual and experimental approaches in the area, as illustrated in Figure 5.

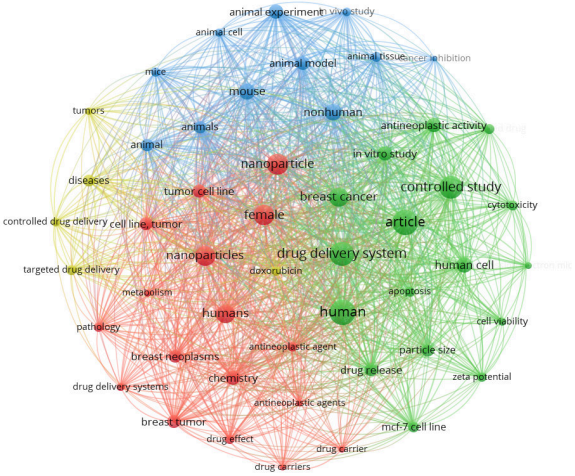

Fig. 5. Network visualization map of keyword co-occurrence generated by VOSviewer. Nodes represent index and author keywords, node size indicates occurrence frequency, and colors distinguish main thematic clusters.

The red cluster, centered on terms such as “nanoparticles”, “drug delivery systems”, “breast neoplasms”, “drug effect”, and “chemistry”, is associated with research on the development and physicochemical characterization of nanosystems. This group addresses topics related to formulation, stability, surface properties, as well as the evaluation of encapsulation efficiency and controlled drug release, such as doxorubicin. It represents a nucleus focused on materials engineering and pharmaceutical nanotechnology, aiming at optimizing the structural properties of nanoparticles for therapeutic application.

The green cluster aggregates terms such as “drug delivery system”, “controlled study”, “human cell”, “apoptosis”, “cytotoxicity”, and “in vitro study”, representing the biological and experimental branch of the area. This represents studies concentrating on preclinical tests seeking to evaluate the efficacy, selectivity, and safety of nanocarriers. This grouping highlights the interface between pharmacology, biotechnology, and cell biology, evidencing the application of nanoparticles as targeted therapeutic platforms.

The blue cluster is associated with terms such as “mouse”, “animal experiment”, “tumor model”, and “in vivo study”, indicating the set of preclinical research conducted in animal models. These studies are essential for translating in vitro results to in vivo contexts, allowing for the investigation of biodistribution, metabolism, and antitumor efficacy of nanostructured systems.

This co-occurrence network reveals a strong interrelationship between the physicochemical, biological, and applied aspects of the research. Furthermore, the high frequency of terms such as “breast cancer”, “drug release”, and “human” indicates that the area is in a consolidation phase, with increasing focus on biological assays and advanced therapeutic applications.

E. Source Citation Analysis

The source citation analysis highlights the main scientific journals that influence knowledge dissemination. As depicted in Figure 6, journals such as the International Journal of Nanomedicine, Pharmaceutics, and the International Journal of Pharmaceutics present the largest nodes, indicating a high frequency of citations and centrality in the network. These journals stand out for publishing studies with multidisciplinary approaches integrating nanotechnology, pharmacology, and bioengineering, reflecting their relevance in consolidating this research area. Additionally, titles such as the Journal of Drug Delivery Science and Technology and Biomaterials Science appear as important complementary sources, contributing to the diffusion of advances in biocompatible materials and controlled release strategies. The dispersion of other nodes demonstrates the diversity of journals that, although having lower citation impact, comprise the expanding scientific body on the subject.

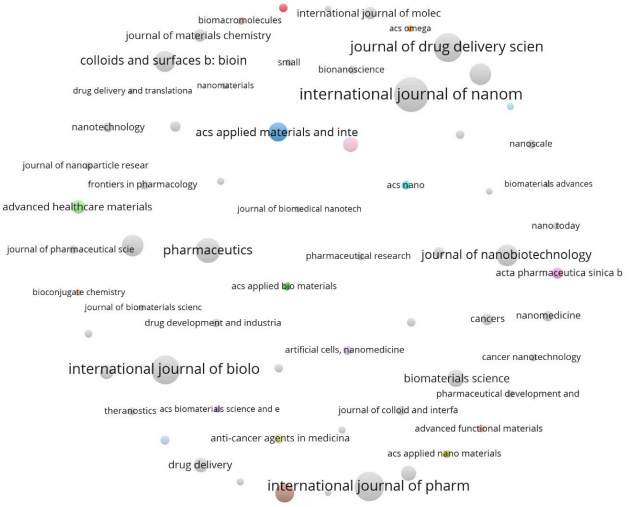

Fig. 6. Source citation map indicating the most influential journals in the analyzed research. The size of the nodes reflects citation frequency, highlighting journals such as International Journal of Nanomedicine, Pharmaceutics, and International Journal of Pharmaceutics.

F. Document Co-Citation Analysis

The document co-citation analysis highlights the main authors and works structuring the field of study on nanoparticle-based drug delivery systems applied to breast cancer treatment. As shown in Figure 7, the nodes are arranged in isolation, indicating the absence of consolidated collaborative networks.

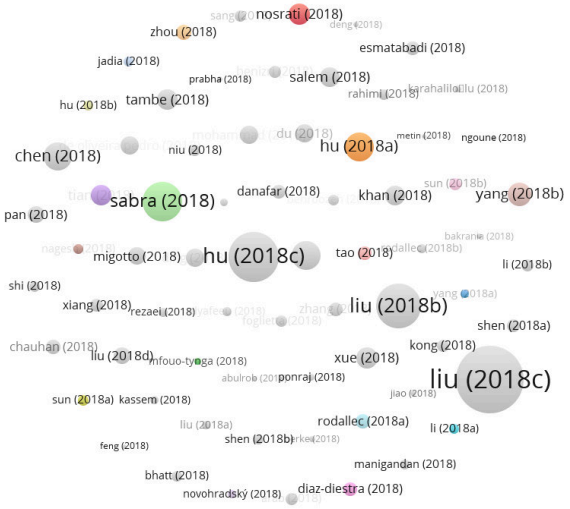

Fig. 7. Document co-citation map revealing the dispersed nature of recent studies. The isolation of nodes indicates weak connections between different research groups in the field.

This dispersion suggests that more recent studies are being conducted independently, possibly reflecting localized and individual efforts by research groups. Such a scenario points to a fragmentation of scientific production, which may limit the integrated advancement of knowledge in the area.

The formation of high citation density nuclei is observed around key works, particularly those by Hu (2018), Liu (2018), and Sabra (2018). These studies appear as central references, indicating they have exerted strong influence on the recent theoretical and methodological consolidation in the area.

G. Analysis of High-Impact Studies

The analysis of accumulated citation counts allows for the identification of the most influential and scientifically consolidated studies in the field of nano-oncology applied to breast cancer. Within the sample of 1,280 articles analyzed between 2018 and 2024, the highest-impact works are concentrated around three main technological axes: biomimetic systems for immune evasion, nanovaccines for antitumor immunotherapy, and multifunctional platforms for combination therapy. Table I summarizes the ten most cited works in the sample, highlighting the publishing journal and the total citations recorded in the Scopus database.

Table 1: most cited articles in the selected sample (2018–2024)

Authors	*Article Title*	*Journal*	Citations
J. Xu *et al.* (2020) [16]	"A general strategy towards personalized nanovaccines based on fluoropolymers for post-surgical cancer immunotherapy"	*Nature Nanotechnology*	468
S. Z. F. Phua *et al.* (2019) [17]	"Catalase-Integrated Hyaluronic Acid as Nanocarriers for Enhanced Photodynamic Therapy in Solid Tumor"	*ACS Nano*	341
L. Liu *et al.* (2018) [11]	"Combination Immunotherapy of MUC1 mRNA Nano-vaccine and CTLA-4 Blockade Effectively Inhibits Growth of Triple Negative Breast Cancer"	*Molecular Therapy*	313
L. Bayón-Cordero *et al.* (2019) [18]	"Application of solid lipid nanoparticles to improve the efficiency of anticancer drugs"	*Nanomaterials*	292
B. Bahmani *et al.* (2021) [19]	"Intratumoral immunotherapy using platelet-cloaked nanoparticles enhances antitumor immunity in solid tumors"	*Nature Communications*	251

S. Shen *et al.* (2021) [22]	"A nanotherapeutic strategy to overcome chemotherapeutic resistance of cancer stem-like cells"	*Nature Nanotechnology*	223
S. Li *et al.* (2020) [23]	"Engineering macrophage-derived exosomes for targeted chemotherapy of triple-negative breast cancer"	*Nanoscale*	220
D. R. Hu *et al.* (2018) [10]	"Oxygen-generating hybrid polymeric nanoparticles with encapsulated doxorubicin and chlorin e6 for trimodal imaging-guided combined chemo-photodynamic therapy"	*Theranostics*	215

Fonte: Data extracted from the Scopus database through scientometric analysis. Prepared by the authors (2025).

As demonstrated in Table I, the study led by Xu et al. (2020), published in Nature Nanotechnology, stands out as the highest-impact paper in the sample (468 citations), proposing a personalized fluoropolymer-based nanovaccine strategy for post-surgical immunotherapy. Subsequently, the works by Phua et al. (2019) and Liu et al. (2018) reinforce the trend toward utilizing hyaluronic acid-based carriers and mRNA nanovaccines combined with immune checkpoint blockade for the treatment of triple-negative breast cancer.

IV. Discussion

The results of this scientometric analysis encompassing 1,280 articles from the Scopus database reveal a profound conceptual and technological evolution in the development of nanoparticle-based drug delivery systems for breast cancer treatment.

A.Geopolitical Reconfiguration and Fragmentation of Institutional Networks

The findings demonstrate robust growth in scientific production regarding nanocarriers for breast cancer, corroborating global trends that position nanomedicine as a central pillar in overcoming the limitations of conventional chemotherapy [1]. Beyond a numerical increase, however, a geopolitical reconfiguration of knowledge is observed.

China's prominence as the leader in publication volume corroborates recent global trends described by Yang et al. [6]. According to the authors, this Chinese hegemony in the development of nanosystems for breast cancer is a reflection of strategic state policies. This quantitative leadership suggests the consolidation of a research ecosystem in China that prioritizes high publication volume, driven by robust governmental funding and strategic institutional direction toward mastering this technology. While the Western landscape tends to focus on translational complexity, the Chinese model has demonstrated an accelerated capacity to generate new pharmaceutical materials and vectors at scale [6].

Institutional collaboration analysis reveals that few centers act as reference hubs, while most institutions remain isolated or form restricted clusters. This fragmentation corroborates the regionalization pattern described by Yang et al. [6], where scientific production remains concentrated in local initiatives driven by national funding with limited international integration, explaining the peripheral position of Latin American countries observed in co-authorship maps. This pattern is also reflected in the co-citation analysis, which showed small, loosely connected clusters, suggesting that despite high publication volume, effective knowledge exchange between major Asian and Western hubs remains limited [6].

B.Specific Contributions to Biomaterials and Biomedical Engineering

Beyond updating bibliometric maps, the data obtained in this investigation reveal a technological transition in

biomaterials engineering applied to breast oncology. The thematic clustering of keywords (Fig. 5) exposes a paradigm shift in the physicochemical architecture of nanocarriers, corroborating and expanding recent bibliometric analyses on polymers and lipid vectors in biomedical engineering:

- Matrix Transition and Advanced Biopolymers: Unlike the early stages of oncological nanomedicine, which were predominantly marked by rigid first-generation liposomes and metallic or inorganic nanostructures, recent literature in Scopus demonstrates the consolidation of nanostructured lipid carriers (NLCs), solid lipid nanoparticles (SLNs), and biodegradable polymeric matrices—such as PLGA, chitosan, and hyaluronic acid. This transition is driven by the need to overcome biocompatibility and drug loading capacity bottlenecks, as highlighted by reviews in materials science [8].

- Overcoming the EPR Effect and Surface Engineering (Targeted Delivery): Co-occurrence maps show that the focus of biomaterials engineering has shifted from passive accumulation based on enhanced permeability and retention (EPR effect)—now recognized for its limitations in clinical settings [9]—to active targeting. Notably, functionalizing nanoparticles with specific ligands, such as monoclonal antibodies (anti-HER2/trastuzumab), aptamers, and peptides (RGD), promotes selective recognition and receptor-mediated endocytosis in breast tumor cells.

- Smart Stimuli-Responsive Nanosystems: Keyword analysis indicates substantial progress in designing biomaterials responsive to the tumor microenvironment (TME). The mapped literature highlights matrices capable of on-demand drug release in response to endogenous variations (intratumoral acidic pH, redox/glutathione GSH gradients, and matrix metalloproteinase overexpression) or exogenous stimuli, such as magnetic hyperthermia, photothermy, and ultrasound [7].

C. Main Seminal References and Emerging Trends in 2024

Document co-citation analysis (Fig. 7) identified the theoretical pillars underpinning research during this period. Seminal works from 2018 stand out as central references by introducing advanced strategies for treating aggressive tumors and Triple-Negative Breast Cancer (TNBC). Key approaches include nano-immunotherapy and mRNA vaccines combined with checkpoint blockade [11], oxygen-generating, stimuli-responsive polymeric systems designed to maximize penetration and chemotherapeutic efficiency [10], and targeted protein micelles for drug co-delivery and efflux pump inhibition [12].

In 2024, when academic output consolidated at the highest point of the time series (232 articles), scientometric analysis revealed the emergence of three primary technological axes:

- Immunonanomedicine and Nano-immunotherapy: A transition from using nanocarriers merely as drug delivery vehicles to active agents that reconfigure the tumor immune microenvironment. Strategies prioritize targeted delivery of immunomodulators, STING pathway agonists, and mRNA vaccines to enhance immune checkpoint blockade (e.g., anti-PD-1 and anti-PD-L1) and induce immunogenic cell death [13], [14].
- Integrated Oncological Theranostics: Co-incorporation of diagnostic or imaging agents (such as quantum dots and iron oxide nanoparticles) with therapeutic drugs into a single multifunctional nanoplatform, enabling real-time monitoring of drug release profiles and tumor regression.
- Biomimetic Platforms and Hybrid Vectors: Adoption of nanoparticles cloaked in mammalian cell membranes (such as platelets, erythrocytes, exosomes, or tumor cell membranes), conferring reticuloendothelial system evasion (stealth behavior) and enhanced homotypic targeting toward the tumor microenvironment [15].

V. Conclusions

From this perspective, it becomes evident that strengthening institutional partnerships, expanding international cooperation, and investing in translational studies are key elements to accelerate the scientific maturation of the field. In this scenario, future progress in breast cancer treatment tends to depend not only on increasingly sophisticated nanosystems but also on the capacity to build truly global scientific collaboration networks capable of integrating knowledge, leveraging technologies, and promoting innovations with real impact on clinical practice. Thus, it is expected that this analysis contributes to the understanding of the field's recent dynamics and serves as a basis to guide future research, stimulating initiatives that broaden integration between groups, strengthen evidence production, and favor the development of promising technologies for the care of breast cancer patients.

***Abstract*—Injectable hydrogels show potential for biomedical applications due to their biocompatibility and ability to facilitate controlled drug release. This study developed and characterized a hydrogel based on porcine gelatin, hyaluronic acid, propolis, and genipin, evaluating its gelation, degradation, and swelling properties. The material exhibited gelation under conditions close to physiological ones, structural stability, and low swelling capacity. The results indicate potential for applications in controlled substance release and tissue engineering.**

***Index Terms*—Injectable hydrogel, Natural biomaterials, Controlled release, Gelation, Physiological pH.**

I. Introduction

Traditional drug delivery systems, such as tablets or conventional pharmacological injections, often promote rapid drug release after administration, resulting in a high initial concentration of the drug in the body, a phenomenon known as burst release. This effect may lead to adverse reactions or reduced therapeutic efficacy over time due to the rapid elimination of the drug. This immediate release profile makes it difficult to maintain stable therapeutic levels within the body, potentially causing initial overdose episodes and requiring repeated administrations to sustain the desired pharmacological effect [1] [2].

Another relevant factor is that many systems used in biomaterials or drug delivery vehicles are based on synthetic polymers, which may present limitations related to biocompatibility, toxicity of degradation by-products, or poor interaction with biological tissues. These factors can trigger inflammatory responses or hinder their proper absorption by the body. Therefore, these limitations highlight the need for the development of new biomaterials capable of promoting controlled drug release, known as drug delivery systems [2] [3].

Among the most widely used matrices in drug delivery systems are hydrogels, which are polymeric materials characterized by a three-dimensional network architecture formed by hydrophilic polymers capable of absorbing and retaining large amounts of water while maintaining their structure due to the presence of physical or chemical crosslinks between polymer chains [4]. Among the different categories of hydrogels, injectable hydrogels represent a distinct subclass capable of overcoming biological barriers through subcutaneous injection. This type of administration enables the dispersion of the material within the skin or other tissues, allowing it to reach the desired site through different delivery pathways [5].

Natural biopolymers, such as gelatin, chitosan, and chitin, combined with bioactive compounds such as Allium sativum, Aloe vera, and propolis, exhibit therapeutic properties that support the development of injectable hydrogels for biomedical applications [6] [7]. Propolis stands out due to its antimicrobial, anti-inflammatory, antioxidant, and regenerative activities, contributing to wound healing and tissue repair processes [8].

Injectable hydrogels can be applied in several areas of medicine, such as cardiac regeneration after myocardial infarction, where they act as extracellular matrix-like scaffolds, promoting cell adhesion and proliferation, as well as the controlled release of bioactive molecules [9]. Another promising application is in the treatment of osteoarthritis and cartilage regeneration, as these materials can modulate the inflammatory environment, reduce oxidative stress, and stimulate tissue repair. Therefore, injectable hydrogels represent a versatile and promising therapeutic strategy for regenerative medicine [10].

Within this context, pH-responsive systems present important advantages, such as controlled substance release, enhanced targeting to the site of action, and improved interaction with the body [7]. Changes in the environmental pH can lead to the protonation or deprotonation of functional groups present in polymer chains, modifying the electrostatic interactions between them and directly influencing the organization and density of the hydrogel network. As a result, it is possible to regulate properties such as the swelling degree (the ability of the hydrogel to absorb and retain water within its structure, leading to the expansion of the polymeric network), the degradation rate (the process of polymer chain breakdown and consequent material disintegration over time within the body), and the drug release profile, promoting greater material

retention at the application site and enabling a more controlled therapeutic release [11].

Within this perspective, injectable hydrogels present the challenge of remaining in a liquid state during administration and forming a stable gel network after application, promoting tissue adhesion and retention of the therapeutic substance [7]. However, this transition must occur in a manner compatible with physiological conditions, such as temperature and pH, which influence the organization and stability of the polymeric network [11]. Changes in pH promote the protonation or deprotonation of functional groups, enabling the control of properties such as swelling (water absorption and retention by the matrix), degradation (breakdown of polymer chains over time), and substance release, thereby supporting more controlled therapeutic applications [11].

Given the above, the objective of this research is to develop an injectable hydrogel using natural materials with bactericidal and regenerative properties, as well as to investigate the parameters involved in the gelation rate of this hydrogel.

II. Materials and methods

Initially, a study was conducted on injectable hydrogels composed of natural polymers capable of undergoing gelation at body temperature, approximately 36.5°C, exhibiting high water solubility and responsiveness to the physiological pH of 7.4.

A. Materials

For the development of the hydrogel and the execution of the experimental assays, the following materials were used: porcine gelatin (300 Bloom), genipin, propolis, hyaluronic acid (HA), fluorescein, acetic acid, and phosphate-buffered saline solution (PBS, pH 7.4).

B. Hydrogel production and gelation

Initially, two experimental groups were established to evaluate hydrogel formation, designated as Group A and Group B. Each group had 5 batches of hydrogel (n = 5) to ensure the reproducibility of the results. The formulations were developed based on the methodology described in [12], with adaptations according to the objectives of this study. Group A consisted of 500 mg of porcine gelatin (99% purity, Sigma Aldrich), 100 mg of hyaluronic acid (HA; quality leve 100, 500 kDA, Sigma Aldrich), 100 mg of propolis (Apis Flora, 500 mg/g), and 50 mg of genipin (¿ 98%, Sigma Aldrich) as a crosslinking agent. Group B consisted of 750 mg of the same porcine gelatin, 100 mg of the same HA, 100 mg of the same propolis, and 75 mg of the same genipin.

For the preparation of the formulations, powdered porcine skin gelatin was dissolved in 9 ml of distilled water and 1 ml of acetic acid (99%, glacial) under vigorous stirring using a magnetic stirrer at approximately 60 °C for 15 minutes until complete solubilization. Powdered HA was dissolved in 10 ml of distilled water and maintained under vigorous stirring for 15 minutes at approximately 25 °C. Powdered propolis was dissolved in 10 ml of distilled water under vigorous stirring and mild heating (approximately 40 °C) to assist solubilization. Finally, genipin was added as a crosslinking agent at the concentrations corresponding to each experimental group.

Subsequently, for hydrogel formation from the Group B formulation, the gelatin solution was mixed with the HA solution at approximately 40 °C under vigorous stirring for 15 minutes until a visually homogeneous mixture was obtained. Afterwards, acetic acid was added to the solution. Subsequently, the propolis solution was incorporated, maintaining stirring for an additional 15 minutes. Fluorescein was previously prepared at a concentration of 0.35 mg/ml by dissolving it in distilled water. Then, 0.2 ml of this solution was added to the sample, which remained under stirring for an additional 15 minutes to ensure homogenization. After this step, genipin was incorporated, and the mixture was maintained under vigorous stirring for 30 minutes until the onset of crosslinking of the polymeric system.

Subsequently, the final hydrogel solution was weighed using an analytical balance (SHIMADZU, model ATY224R), and the hydrogel was divided into four beakers (B1, B2, B3, and B4) containing equivalent amounts, corresponding to 25% (5.09 mg) of the total prepared hydrogel (20.36 mg). Beaker B1 was designated as the control group and was used as a reference for comparison with the other groups. All assays were performed in triplicate to ensure the reproducibility of the results.

To perform the assays under conditions close to physiological conditions, a PBS solution was prepared using a concentration of 40 g of NaOH per mol. The solution was added dropwise until reaching an approximate pH of 7.

Each formulation was placed in a water bath at an approximate temperature of 36.5 °C, monitored using a mercury thermometer, and 2 ml of PBS solution was simultaneously added to each group. The mixtures remained in the water bath for 15 minutes to simulate physiological temperature and pH conditions, enabling the evaluation of gelation and hydrogel formation.

Thus, the samples were injected through a 25 G needle with a length of 25 mm using manual pressure to evaluate potential needle occlusion. Subsequently, gel formation and structural integrity, continuity of the polymeric matrix, and visual homogeneity of the system were evaluated. Photographic records of the obtained samples were performed for documentation of the results.

C. Characterization

1) Degradation: The sample was maintained at rest under dry conditions for 20 minutes. After this period, 3 ml of PBS solution at approximately 36.5 °C was added to the hydrogel, and the degradation process was monitored through photographic records at intervals of 5, 15, 30, 60, and 90 minutes, allowing the visual analysis of the degradation process over time.

2) Swelling: For swelling evaluation, 14.49 ml of PBS solution at approximately 36.5 °C was added to the system.

The evaluations were performed at 5, 15, 30, 60, and 90 minutes. At each time interval, the supernatant liquid was removed to allow the hydrogel mass to be measured using an analytical balance, enabling the quantitative monitoring of the swelling degree. Additionally, the removed liquid volume was measured using a graduated cylinder and subsequently returned to the system together with the hydrogel. When necessary, the volume was replenished with PBS solution, maintaining the initial volume constant throughout the entire assay. As control, the initial dry mass and volume were measured.

3) Fluorescein release rate: To evaluate the fluorescein release rate, 6 ml of PBS solution at approximately 36.5 °C was added to the system. The evaluations were performed at 5, 15, 30, 60, and 90 minutes. At each time interval, 2 ml of the supernatant solution was collected and stored in properly identified Eppendorf tubes. After collection, the removed volume was immediately replaced by adding 2 ml of PBS solution to the system, maintaining the initial volume constant and ensuring standardized experimental conditions throughout the entire assay.

The CELM spectrophotometer, model E-225 D, was calibrated using standard solutions prepared from an initial fluorescein concentration of 0.35 mg/ml diluted in distilled water. From this solution, five distinct concentrations were obtained through dilutions with factors of 7.5×, 8×, 12×, 16×, and 32×, corresponding to a progressive reduction of the initial concentration. The final concentrations obtained were 0.0467 mg/ml, 0.0438 mg/ml, 0.0292 mg/ml, 0.0219 mg/ml, and 0.0109 mg/ml. For each dilution, four absorbance measurements were performed to verify the linearity of the equipment response and estimate potential measurement errors.

Subsequently, the 2 ml samples reserved in the Eppendorf tubes were analyzed using the spectrophotometer to determine the fluorescein release rate over time by measuring absorbance at 490 nm.

The absorbance values of the experimental groups (B2, B3, and B4) were corrected by subtracting the mean absorbance of the control group (B1) at the time points of 5, 15, 30, 60, and 90 minutes. These data enabled the subsequent correlation with the released fluorescein concentration through the linear equation obtained from the calibration curve of the spectrophotometer, adjusted by linear regression using Microsoft Excel.

III. Results

The results obtained from the experimental assays were organized according to the methodological steps previously described, including hydrogel production, swelling and degradation assays, and the evaluation of the fluorescein release rate.

A. Hydrogel production and gelation

The formation of the hydrogels and the gelation process were evaluated after the crosslinking step, considering the two previously developed formulations (Figure 1). To promote the crosslinking reaction, genipin was maintained under stirring for 30 minutes, favoring the formation of the hydrogel polymeric network. After 15 minutes in a water bath at approximately 36.5 °C, both formulations exhibited gel formation.

In Group A, the formation of a hydrogel with a heterogeneous structure, lower structural integrity, and a bluish coloration due to the genipin reaction was observed. In contrast, Group B exhibited a more homogeneous and continuous structure, with greater uniformity of the polymeric matrix and absence of the characteristic blue coloration.

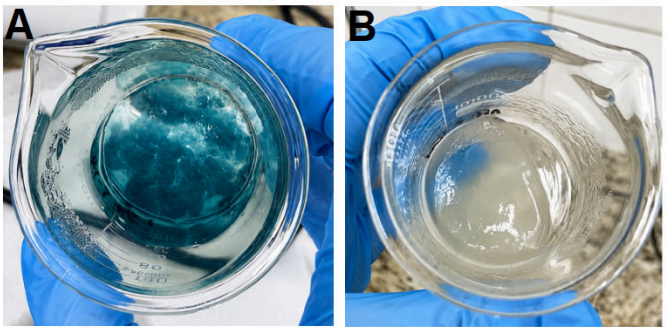

Fig. 1. Macroscopic appearance of the developed hydrogels: (a) Group A hydrogel and (b) Group B hydrogel. Authors, 2026.

Based on the structural characteristics observed during the macroscopic evaluation of the obtained hydrogels, Group B was selected for further investigation. Therefore, the subsequent assays and results presented in this study were conducted using the formulation that exhibited greater visual uniformity and improved structural integrity after the gelation process.

B. Degradation

After the addition of the PBS solution to the hydrogel, the sample was visually monitored at intervals of 5, 15, 30, 60, and 90 minutes through photographic records. Throughout the experimental period, the hydrogel maintained its structure, with no visible disintegration of the material or significant loss of its initial conformation, as presented in Figure 2.

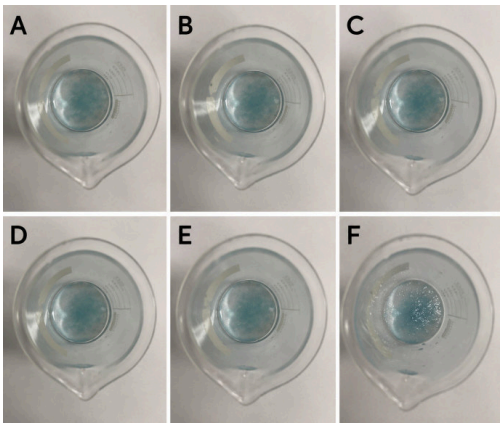

Fig. 2. Visual evaluation of hydrogel degradation over time. The images represent the samples after (A) 5 min, (B) 15 min, (C) 30 min, (D) 60 min, and (E) 90 min of the assay. In (F), the hydrogel is observed after 90 min without supernatant liquid. Authors, 2026.

During the initial time intervals, the hydrogel maintained its structural integrity. With increasing exposure time to the PBS solution, gradual structural changes and progressive darkening of the polymeric matrix were observed, indicating the progression of the degradation process.

C. Swelling

After the addition of the PBS solution to the hydrogel, the swelling process was monitored at intervals of 5, 15, 30, 60, and 90 minutes through the evaluation of the sample volume and mass. Throughout the entire experimental period, the hydrogel maintained its structural integrity, with no visible disintegration of the polymeric matrix.

The volume values of the PBS remaining external to the hydrogel remained relatively stable throughout the assay, presenting 14 ml at the 5, 15, and 90-minute intervals, with an increase to 14.3 ml at 30 minutes and a maximum value of 14.5 ml at 60 minutes. Regarding mass, values of 34.08 g at 5 minutes, 34.05 g at 15 minutes, 34.06 g at 30 minutes, 33.91 g at 60 minutes, and 33.95 g at 90 minutes were recorded. The initial values of weight and volume were 33.8 g and 13.2 ml, respectively.

In addition to the quantitative variations observed, gradual macroscopic changes in the hydrogel were identified throughout the analyzed intervals, including subtle modifications in the material's uniformity and coloration. The results obtained from the swelling assay are presented in Figure 3.

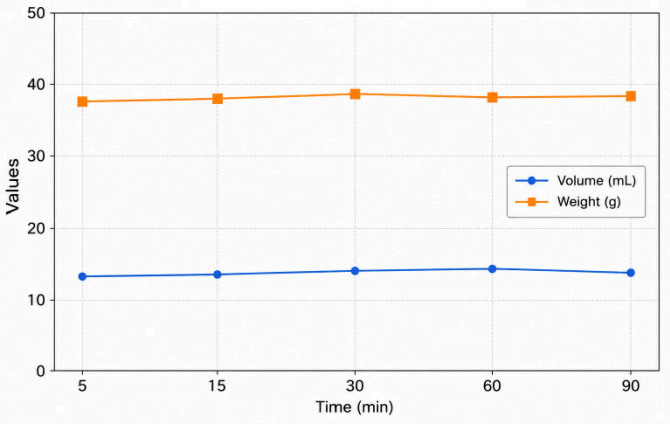

Fig. 3. Swelling and supernatant liquid volume over time. Authors, 2026.

D. Fluorescein release rate

Based on the mean absorbance values obtained for each dilution, the spectrophotometer calibration curve was constructed. The calibration results showed good agreement among replicates, considering that the calibration curve presented a coefficient of determination (R^2) of 0.9547.

The correlation between absorbance and the released fluorescein concentration was performed using the trendline equation $y = 21.46x - 0.0146$ (where y represents absorbance and x represents concentration), enabling the evaluation of the release profile of the system.

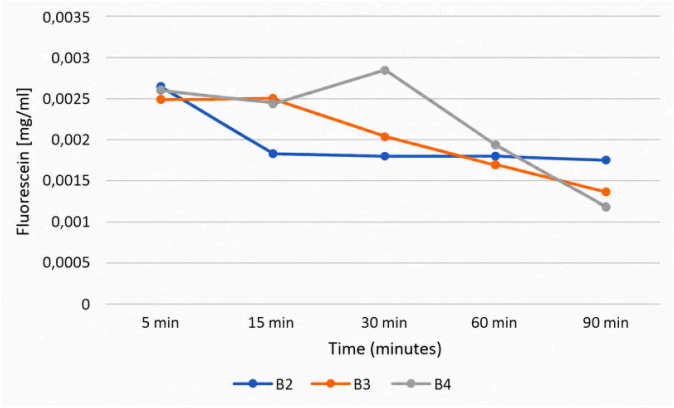

Fig. 4. Estimated fluorescein concentration released from the hydrogel over time. Authors, 2026.

The fluorescein release from the hydrogel was evaluated by spectrophotometry at different time intervals (5, 15, 30, 60, and 90 minutes). As presented in Figure 4, Group B2 exhibited a more pronounced initial reduction between 5 and 15 minutes, decreasing from approximately 0.00264 mg/ml to 0.00185 mg/ml. After this interval, the values remained practically constant until 90 minutes, ranging between 0.00175 and 0.00180 mg/ml, indicating stabilization of the concentration after the initial decrease. Group B3, in turn, showed a gradual and continuous reduction throughout the entire assay, with an initial concentration of approximately 0.00250 mg/ml and a final value of 0.00138 mg/ml at 90 minutes, representing the greatest overall reduction observed among the groups. In contrast, Group B4 showed an initial maintenance of concentration between 5 and 15 minutes, followed by an increase until 30 minutes, reaching a maximum value of approximately 0.00287 mg/ml. After this peak, a progressive reduction in concentration was observed, reaching 0.00119 mg/ml at 90 minutes, resulting in the lowest final concentration among the evaluated groups.

IV. Discussion

The 15-minute incubation period in a water bath at approximately 36.5 °C and pH 7.4, simulating physiological conditions, proved to be adequate for the gelation of the evaluated formulations. This interval was sufficient to promote the sol–gel transition under conditions similar to those encountered in the human body, enabling the formation of the polymeric network. Furthermore, the establishment of this gelation time is particularly relevant for in situ applications, as excessively slow gelation may lead to material dispersion at the administration site before hydrogel formation, thereby compromising its retention and therapeutic performance [13].

The results demonstrated that the formulation composition directly influenced the formation and structural stability of the hydrogels. In Group A, the lower concentrations of gelatin and genipin resulted in a less cohesive matrix with reduced structural integrity, indicating insufficient formation of the hydrogel's three-dimensional network [14].

In contrast, Group B exhibited a more continuous, homogeneous, and visually uniform structure, suggesting greater efficiency in the crosslinking process. The increased concentrations of gelatin and genipin may have favored the formation of a more organized and stable polymeric network, thereby contributing to improved hydrogel structural integrity. Genipin acts as a crosslinking agent by reacting with primary amine groups present in the gelatin polymer chains. This process occurs progressively, promoting the formation of intermolecular covalent bonds and the development of a more stable three-dimensional network. These findings indicate that the ratio between the formulation components exerts a significant influence on the physical and structural properties of the material [14].

The successful formation of the hydrogel under near-physiological conditions, such as a temperature of approximately 36.5 °C and pH 7.4, represents an important characteristic for biomedical applications, particularly in injectable controlled-release systems. Under these conditions, the material can remain in a liquid state during syringe administration, facilitating a minimally invasive delivery, and subsequently undergo in situ gelation at the application site [15].

From a physicochemical perspective, this behavior demonstrates the occurrence of sufficient interactions among the polymer chains to promote the formation of a stable three-dimensional structure under physiological conditions. Many polymeric systems face challenges related to the establishment of a three-dimensional network following administration due to limitations in gelation kinetics [15]. Therefore, the gelation capacity observed in the selected formulation indicates efficient organization of the polymeric matrix, favoring the entrapment of the incorporated compound within its structure. This characteristic directly contributes to a slower and more sustained drug release profile, increasing its residence time in the body and supporting its potential for controlled therapeutic delivery applications [16].

In the degradation assay, the hydrogel maintained its structural integrity throughout the 90-minute evaluation period, with no visible disintegration of the material. However, gradual changes in the system's uniformity, consistency, and coloration were observed during exposure to the PBS solution.

The occurrence of these reactions is directly dependent on the equilibrium between the protonated (-NH_3+) and deprotonated (-NH_2) forms of amine groups. Under more acidic conditions, the protonated form predominates. However, at pH values close to neutrality, such as those found in the physiological environment (pH 7.4), a greater proportion of amine groups is available in the deprotonated form (-NH_2), which favors the formation of crosslinks as well as the development of the characteristic blue coloration of the hydrogel [14] [17].

From a therapeutic application perspective, the degradation rate of the hydrogel is directly related to its potential use. Formulations exhibiting faster degradation are generally more suitable for short-term applications, such as the local delivery of anti-inflammatory drugs, anesthetics, or antimicrobial agents during acute conditions and the immediate postoperative period [13]. Conversely, materials with slower degradation profiles may be employed in treatments that require prolonged system activity, allowing for the sustained retention of the incorporated compound. Such systems are particularly advantageous for applications including ocular therapies, chemotherapy, and tissue engineering, where extended therapeutic action is desirable [9] [18] [19] [20].

In this context, the gradual degradation profile observed suggests the potential applicability of the hydrogel in longer-term therapeutic strategies, in which the material may function as a temporary scaffold for the sustained release of bioactive substances. Furthermore, the prolonged structural persistence of the hydrogel may contribute to a reduced frequency of administration, thereby enhancing therapeutic stability and improving patient comfort. Therefore, long-term studies and in vivo evaluations should be conducted to validate these findings and provide more robust conclusions regarding the hydrogel's stability, biodegradation behavior, and therapeutic potential for clinical applications.

In the swelling assay, the hydrogel exhibited limited absorption of the PBS solution, a phenomenon associated with water uptake into the polymeric matrix and the consequent partial separation of the polymer chains within the material's three-dimensional structure. This behavior is influenced by the presence of hydrophilic groups in gelatin and hyaluronic acid, which are capable of interacting with water molecules through hydrogen bonding. However, the crosslinking promoted by genipin favors the formation of a denser and more organized polymeric network, restricting chain mobility and reducing the available space for water incorporation. As a result, a lower degree of swelling is observed, even in the presence of water-affinitive groups, allowing only limited internal structural rearrangement without compromising the hydrogel's structural integrity [21] [22] [23].

Water uptake into the polymeric matrix also facilitates the diffusion and gradual release of the drug incorporated within the hydrogel. Consequently, the system functions as a reservoir capable of providing controlled release of the active substance over time. This mechanism contributes to minimizing the phenomenon known as burst release, which is characterized by the rapid and excessive initial release of the encapsulated drug [24].

To evaluate this release behavior, the results obtained from the spectrophotometer calibration showed good agreement among replicates, with low variability between measurements performed at the same concentration. This finding demonstrates the stability of the spectrophotometric readings and the suitability of the experimental procedure employed. Furthermore, the calibration curve exhibited a coefficient of determination (R^2) of 0.9547, indicating a strong linear correlation between concentration and absorbance within a range considered acceptable for experimental assays of this nature.

A greater release was observed during the initial time points, followed by a reduction throughout the course of the assay. This behavior is associated with the low swelling capacity of the hydrogel, which limits the diffusion of fluorescein through

the polymeric matrix. Consequently, the restricted water uptake and reduced expansion of the network structure decrease molecular mobility within the system, thereby slowing the release process over time.

The results suggest that the hydrogel exhibited limited fluorescein release throughout the assay, as a more pronounced release profile would be expected to result in an increase in the concentration of the surrounding medium, even after the dilution steps. These findings indicate that the polymeric matrix was able to effectively retain the incorporated compound, restricting its diffusion into the external environment and promoting a more controlled release behavior under the experimental conditions evaluated.

Therefore, therapeutic applications requiring prolonged and controlled drug administration may particularly benefit from this type of system. These include treatments for chronic wound healing, tissue regeneration, ocular therapies, growth factor delivery, and tissue engineering applications. Among the most relevant clinical applications are cardiac regeneration following acute myocardial infarction, as well as the treatment of osteoarthritis and articular cartilage regeneration. In these contexts, the injectable nature of hydrogels plays a crucial role, as the material can be administered initially in a liquid or low-viscosity state, facilitating its minimally invasive delivery directly to the target tissue. This initial fluidity enables administration through less invasive procedures, allowing better adaptation to the application site and reducing tissue damage when compared with solid implants or surgical approaches [9] [10].

Following injection, the system undergoes a sol–gel transition, resulting in the formation of a three-dimensional network that conforms to the tissue microenvironment and remains retained at the application site. In post-infarction cardiac regeneration, this retention is particularly important, as the hydrogel can be administered directly into the injured myocardium, reducing its rapid dispersion through the bloodstream and enabling the sustained delivery of cells or bioactive molecules to a tissue with limited regenerative capacity. Similarly, in osteoarthritis, gel formation within the joint space allows the material to remain in an environment characterized by high mobility and continuous synovial fluid turnover, conditions that would normally promote the rapid clearance of drugs administered in liquid formulations [9] [10].

Compared with conventional approaches based on simple liquid injections, in which the drug tends to diffuse rapidly or be cleared by systemic circulation, limited local retention and the need for repeated administrations to maintain therapeutic efficacy are commonly observed. In this context, hydrogels function as controlled-release matrices, allowing enhanced retention at the target site and sustained release over time. These properties contribute to improved therapeutic efficacy, reduced frequency of interventions, and better spatial and temporal control of therapy [18] [19] [20].

V. Conclusion

The present study successfully achieved its proposed objectives by developing and characterizing an injectable hydrogel based on porcine gelatin, hyaluronic acid, propolis, and genipin. The material exhibited gelation under near-physiological conditions, structural stability throughout the experimental assays, low swelling capacity, and a controlled fluorescein release profile, demonstrating characteristics that are compatible with biomedical applications.

The results reinforce the potential of the developed hydrogel for applications in controlled-release systems and tissue engineering. As future perspectives, additional physicochemical characterization, as well as in vitro and in vivo studies, are recommended to further investigate the material's performance and biocompatibility. Moreover, evaluating the antimicrobial activity of propolis is essential to broaden the understanding of the hydrogel's therapeutic potential and clinical applicability.

***Abstract*—Methacrylated hyaluronic acid (HAMA) is a photocrosslinkable hydrogel precursor with potential for 3D biofabrication. This study synthesized highly methacrylated HAMA and evaluated its suitability for masked stereolithography (MSLA) and extrusion-based 3D printing. HAMA was chemically validated by proton nuclear magnetic resonance spectroscopy and formulated at one, two, and three percent weight per volume with LAP as photoinitiator. The formulations were characterized by viscosity measurements and wet mass variation after different UV exposure times. HAMA showed a high degree of methacrylation of 80.7 percent. All formulations exhibited shear-thinning behavior, with viscosity increasing with polymer concentration. The 1% HAMA formulation was processed by MSLA, whereas 2 and 3% HAMA formulations were printed by extrusion. Wet mass variation depended on both polymer concentration and UV exposure time, with 30 s producing the most stable hydrogels and 15 s selected as an intermediate photocrosslinking condition for printed constructs. These results define a concentration-dependent processing window for highly methacrylated HAMA hydrogels and support their use as tunable photocrosslinkable precursors for 3D biofabrication.**

***Index Terms*—HAMA, hyaluronic acid, hydrogel, photocrosslinking, biofabrication**

I. Introduction

Hyaluronic acid (HA) is a natural glycosaminoglycan widely used in tissue engineering due to its biocompatibility, hydrophilicity, and role in extracellular matrix organization [1], [2]. However, native HA has limited structural stability and rapid degradation in aqueous environments, which restricts its use as printable hydrogel. Chemical modification is therefore required to improve its stability and enable controlled network formation. Methacrylation introduces photocrosslinkable methacrylate groups into the HA backbone, producing methacrylated hyaluronic acid (HAMA), a hydrogel precursor that can be stabilized by UV crosslinking [3].

This modification preserves its biological properties while enable the formation of hydrogels with tunable physicochemical properties. For three-dimensional printing, these properties must be adjusted according to the fabrication strategy. Light-based vat photopolymerization methods require photocrosslinkable precursors with enough flowability for liquid replenishment and uniform layer formation, whereas extrusion-based printing requires formulations that flow through the nozzle under shear and retain shape after deposition [4]–[7]. Therefore, polymer concentration, rheological behavior, and UV exposure time are fundamental parameters for defining the processing window of HAMA hydrogels. In this study, highly methacrylated HAMA was synthesized and chemically validated by ^{1}H NMR. The HAMA formulations at 1, 2 and 3% w/v were then evaluated in viscosity, UV-dependent wet mass variation and printability using light- and extrusion-based three-dimensional printing.

II. Materials and Methods

A. Synthesis of Methacrylated Hyaluronic Acid

Methacrylated hyaluronic acid (HAMA) was synthesized by reacting hyaluronic acid (HA) with methacrylic anhydride (MA). Briefly, HA was dissolved in phosphate-buffered saline (PBS) at 2% w/v under magnetic stirring overnight. After dissolution, MA was added to the HA solution using a peristaltic pump at a flow rate of 0.5 mL/h, under continuous stirring. The reaction was maintained for 3 h at room temperature, with pH kept around 7.5 using NaOH. The product was purified by dialysis against deionized water using a 12-14 kDa membrane for 7 days, lyophilized, and stored at 4 °C until use.

B. Chemical Characterization of HAMA

HA and HAMA were analyzed by proton nuclear magnetic resonance spectroscopy (^{1}H NMR). Samples were dissolved in D_2O containing TMSP/TSP as the chemical shift reference. After solubilization, 600 μL of each solution was transferred to NMR tubes. Spectra were acquired in a 600 MHz NMR spectrometer at 25 °C, with 128 scans and a relaxation delay of 3 s. The degree of methacrylation (DM) was calculated from the ratio between the methacrylate vinyl proton signals at 6.04–6.33 and 5.60–5.91 ppm and the N-acetyl methyl protons of HA at approximately 2.03 ppm, correcting for the number of protons contributing to each signal.

C. Preparation of HAMA Hydrogel Formulations

HAMA precursor solutions were prepared at 1, 2, and 3% w/v by dissolving lyophilized HAMA in PBS under magnetic stirring at room temperature. Lithium phenyl-2,4,6-trimethylbenzoylphosphinate (LAP) was added at 0.1% w/v as photoinitiator. All formulations were protected from light until use.

D. Rheological Characterization

The rheological behavior of HAMA formulations was evaluated using a rotational rheometer equipped with a 50 mm parallel-plate geometry and a 0.5 mm gap. Measurements were performed at 25 °C in triplicate. Apparent viscosity was measured as a function of shear rate, from 0.01 to 1000 s^{-1}.

E. Crosslinking Screening and Swelling Assay

To screen photocrosslinking conditions, 1, 2, and 3% HAMA formulations containing 0.1% w/v LAP were cast in PDMS molds and exposed to 405 nm light for 10, 15, and 30 s.

After photocrosslinking, the initial mass of each hydrogel was recorded, and the samples were immersed in PBS at 37 °C. At each time point, hydrogels were removed from PBS, gently blotted to remove excess of liquid, and weighed again. The wet mass variation was calculated as:

$$\text{Wet mass variation } (\%) = \frac{W_t - W_0}{W_0} \times 100$$

where W_0 is the initial hydrogel mass after photocrosslinking and W_t is the hydrogel mass at each time point.

F. MSLA 3D Printing

MSLA printing was performed using a Creality Halot R6 printer based on MSLA/LCD technology, equipped with a 405 nm UV light source and nominal intensity around 5000 $\mu\mathrm{W}/\mathrm{cm}^2$. The printing setup was adapted to reduce precursor volume. The 1% HAMA formulation was printed using geometries designed in CAD and sliced in CHITUBOX. After preliminary tests, printing was performed with 0.04 mm layer height, 10 bottom layers exposed for 60 s, and 10 s exposure for the subsequent layers.

G. Extrusion-Based 3D Printing

Extrusion-based printing was performed using 2 and 3% HAMA formulations at a 593iCan Printer. The formulations were loaded into 10 mL syringes and extruded through a 20G conical nozzle. Cylindrical constructs with a 10 mm diameter were printed with 5 layers and 0.4 mm layer height. After printing, the constructs were photocrosslinked under 405 nm light for 15 s and immersed in PBS until further analysis.

III. RESULTS AND DISCUSSION

A. Chemical Validation and Methacrylation Degree of HAMA

The successful methacrylation of HA was confirmed by ^{1}H NMR (Fig. 1). HAMA exhibited characteristic methacrylate vinyl proton peaks at 6.04–6.33 and 5.60–5.91 ppm. The N-acetyl methyl signal of HA at approximately 2.03 ppm was used as a reference for calculating the degree of methacrylation (DM). The resulting HAMA exhibited a DM of 80.7%, indicating a high level of functionalization and confirming its suitability as a hydrogel precursor for photocrosslinking.

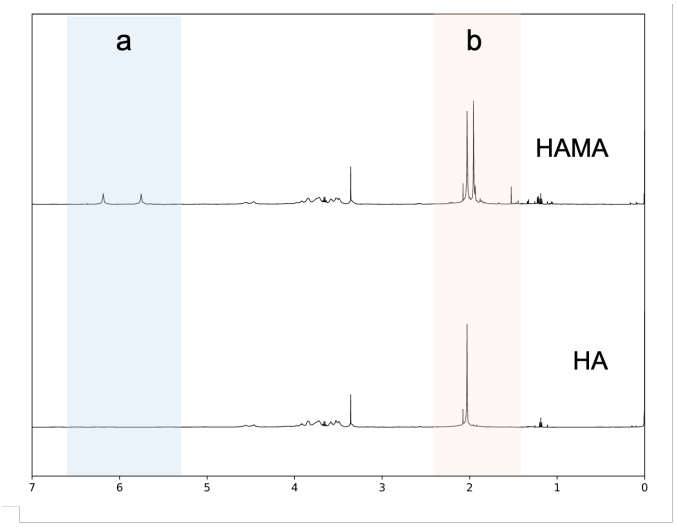

Fig. 1. ^{1}HNMR spectra of HA and HAMA. (a) HAMA peaks at approximately 6.04–6.33 and 5.60–5.91 ppm, absent in native HA. The methyl region (b), including the N-acetyl methyl protons of HA around 2.03 ppm

B. Rheological and Swelling Behavior of HAMA Formulations

The rheological behavior of HAMA formulations was concentration-dependent (Fig. 2). All formulations exhibited shear-thinning behavior, with viscosity decreasing as shear rate increased. This behavior is favorable for 3D printing because different fabrication strategies impose distinct flow requirements. In vat photopolymerization methods such as MSLA, low-viscosity photocrosslinkable precursors favor liquid replenishment and uniform recoating between layers, which are required for consistent layer formation [4], [5]. In extrusion-based printing, shear-thinning behavior facilitates flow through the nozzle under high shear, whereas higher viscosity at low shear contributes to filament stability and shape retention after deposition [6]–[8].

Among the tested formulations, 1% HAMA showed the lowest viscosity, indicating a formulation more compatible with light-based processing. The 2% HAMA formulation showed an intermediate behavior, suggesting a balance between flowability and post-deposition stability. In contrast, 3% HAMA showed the highest viscosity across the entire shear-rate range, indicating greater resistance to flow and improved potential for shape retention. Thus, the rheological profile provided the basis for defining the subsequent printing strategy, with 1% HAMA evaluated by MSLA and 2–3% HAMA evaluated by extrusion-based 3D printing.

The wet mass variation of HAMA hydrogels depended on both polymer concentration and UV exposure time (Fig. 3). For 1% HAMA, 10 s of UV exposure was insufficient to maintain hydrogel integrity after immersion in PBS, and samples started to lose structural integrity after approximately 30 min

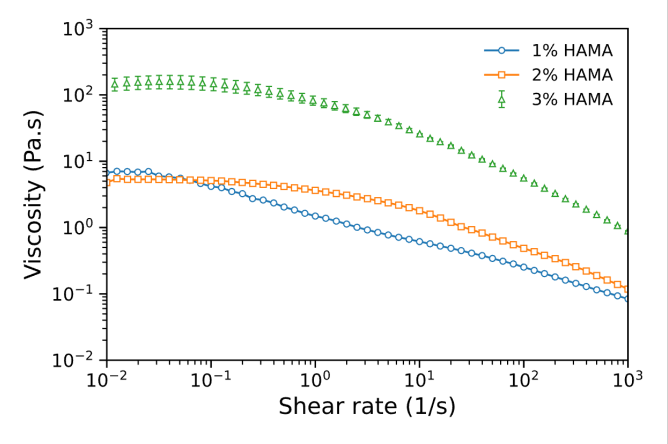

Fig. 2. Viscosity of 1, 2, and 3% HAMA formulations as a function of shear rate.

(Fig. 3A). In contrast, 15 and 30 s allowed the hydrogels to remain intact during the 120 min assay, although wet mass changes were still observed.

For 2% HAMA, hydrogels crosslinked for 10 s showed the highest wet mass increase, indicating insufficient network stabilization (Fig. 3B). Increasing UV exposure reduced wet mass variation, with 30 s producing a more stable profile. A similar trend was observed for 3% HAMA, but with lower overall wet mass variation (Fig. 3C). Notably, 3% HAMA crosslinked for 30 s remained nearly stable during the assay.

The long-term endpoint also confirmed the stabilizing effect of longer UV exposure (Fig. 3D). After 4 days, hydrogels crosslinked for 30 s showed the lowest wet mass variation across concentrations, with 3% HAMA remaining close to its initial mass. In contrast, 10 and 15 s exposures resulted in higher mass uptake for 2% and 3% HAMA, while 1% HAMA crosslinked for 15 s showed mass loss after prolonged incubation.

Overall, these results indicate that longer UV exposure increased hydrogel network stabilization, while higher HAMA concentration further improved wet mass stability. Although 30 s produced the lowest wet mass variation, 15 s was used as an intermediate photocrosslinking condition for the extrusion-printing experiments.

C. MSLA and Extrusion-Based 3D Printing of HAMA

Based on its lower viscosity and suitability for light-based processing, the 1% HAMA formulation was selected for mSLA printing using the adapted low-volume setup (Fig. 4a–c). Square and heart-shaped constructs were printed with 0.04 mm layer height, 60 s exposure for the bottom layers, and 10 s exposure for the subsequent layers. These geometries were used to evaluate shape formation and dimensional stability after incubation in PBS. Immediately after printing, the constructs preserved their overall geometry, with width and length values close to the nominal CAD dimensions (Fig. 4d,e). In contrast, height fidelity was already reduced immediately after printing, indicating lower dimensional accuracy in the vertical direction. After 7 d in PBS, this reduction became more pronounced, while width and length remained relatively stable (Fig. 4d,f). The lower height fidelity immediately after printing indicates a limitation in vertical dimensional accuracy under the selected printing conditions, while the additional reduction during incubation indicates limited vertical stability under hydrated conditions. The low polymer concentration may also contribute to this behavior by forming a polymer network with lower resistance to deformation under hydrated conditions. Thus, 1% HAMA can be processed by mSLA, although its vertical dimensional stability remains limited. Optimization of exposure time and layer height may improve vertical printing accuracy, while post-printing photocrosslinking may enhance dimensional stability under hydrated conditions.

Based on the rheological profile and crosslinking screening, 2% and 3% HAMA formulations were selected for extrusion-based printing. Both formulations were extruded through a 20G conical nozzle and photocrosslinked for 15 s after printing (Fig. 4g,h). The printed constructs maintained their circular geometry, indicating that the formulations retained their shape after deposition (Fig. 4i,j). However, filament fusion and collapse were observed, indicating limited printing fidelity and suggesting that post-printing photocrosslinking alone was not sufficient to fully preserve the designed pore architecture. Although the higher HAMA concentrations increased viscosity and allowed the printed constructs to maintain their overall circular geometry, the deposited filaments remained susceptible to spreading before complete network stabilization. Thus, under the tested conditions, these formulations may be more suitable for deposition strategies in which maintaining the overall shape is more important than internal architecture. Therefore, extrusion fidelity may be further improved by optimizing printing parameters, such as flow rate, printing speed, and photocrosslinking strategy. Layer-by-layer or in situ photocrosslinking during extrusion could improve filament stabilization by reducing spreading and improving pore definition.

Together, these results show that HAMA processability is strongly dependent on polymer concentration and photocrosslinking conditions. The low-viscosity 1% formulation was suitable for mSLA processing, enabling the fabrication of constructs with good shape fidelity. In contrast, the higher-viscosity 2% and 3% formulations could be processed by extrusion and maintained the overall construct geometry, although with limited filament and pore fidelity. Therefore, HAMA formulations can be tuned to match different three-dimensional printing strategies by adjusting polymer concentration, UV exposure time, and printing parameters. This formulation flexibility supports the use of highly methacrylated HAMA as a photocrosslinkable hydrogel precursor for future biofabrication applications.

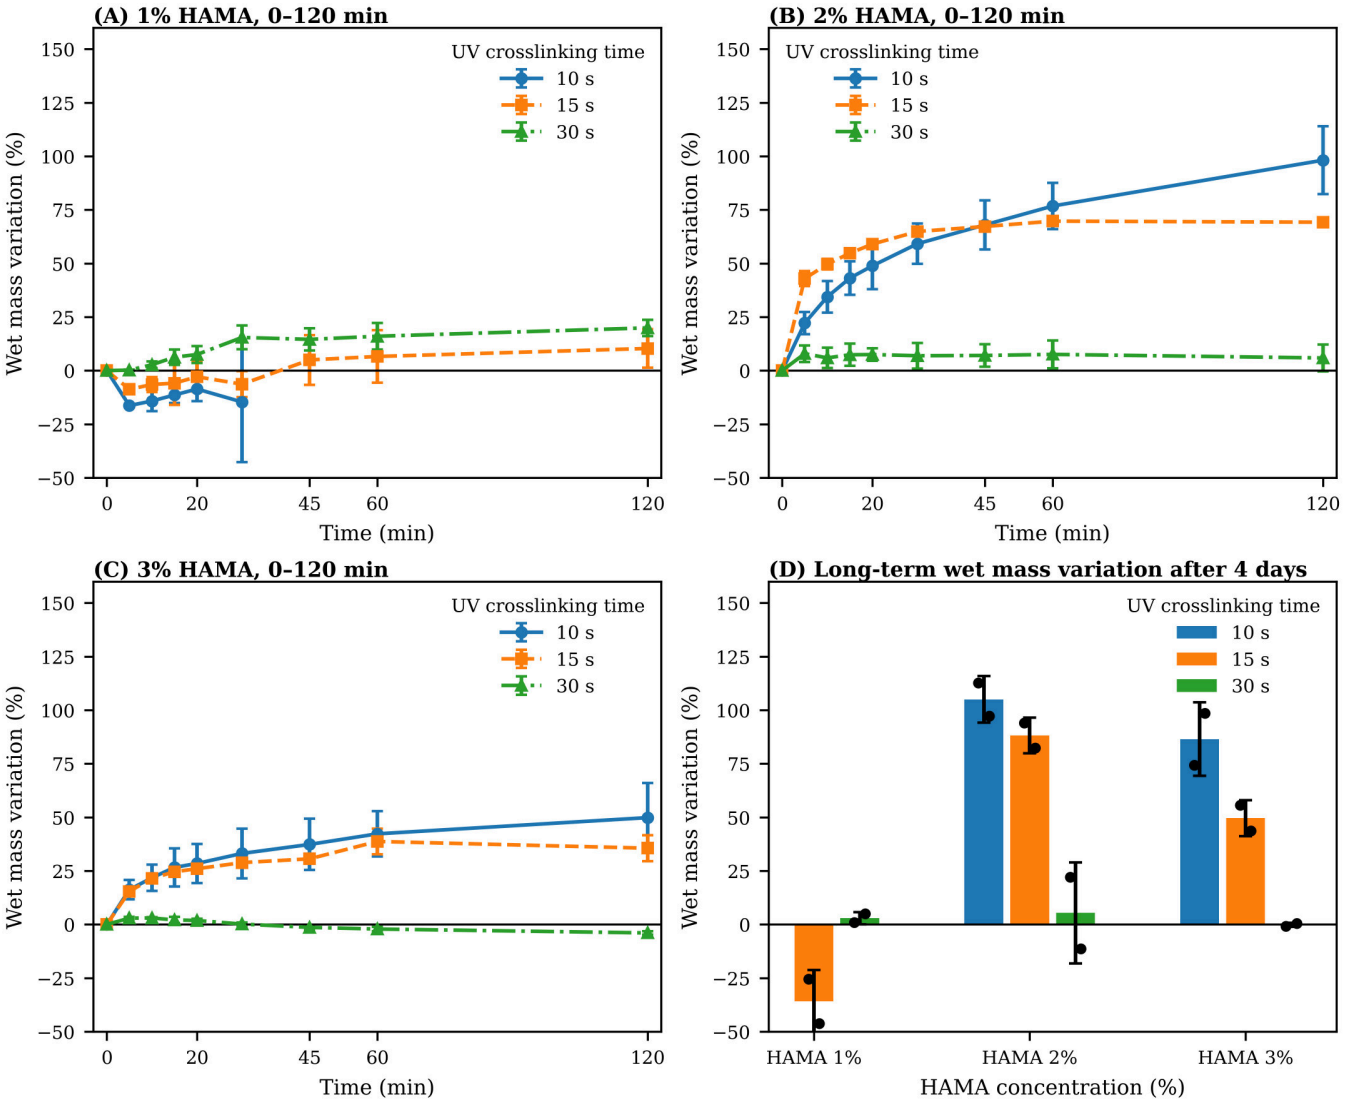

Fig. 3. Wet mass variation of HAMA hydrogels photocrosslinked for 10, 15, or 30 s and incubated in PBS at 37 °C. Time-course profiles are shown for (A) 1% HAMA, (B) 2% HAMA, and (C) 3% HAMA during the first 120 min. Panel (D) shows long-term wet mass variation after 4 d.

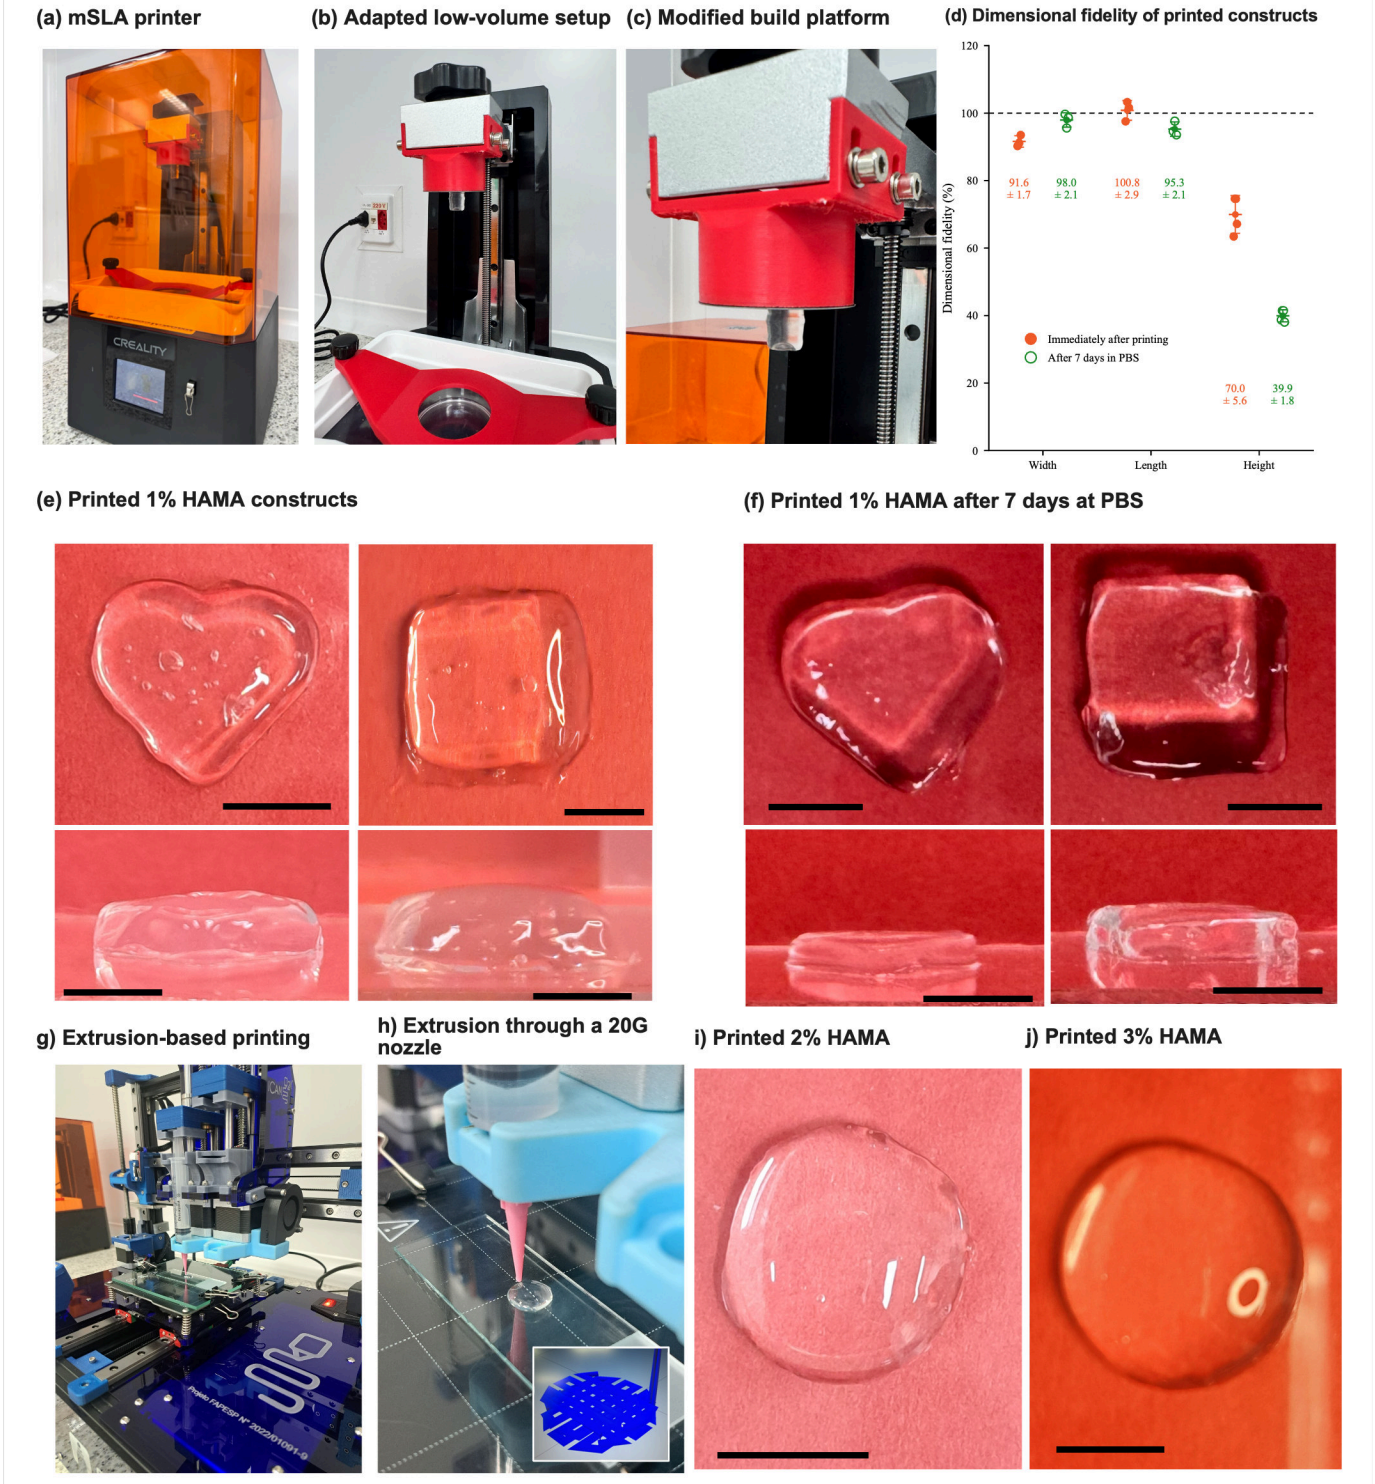

Fig. 4. Printing results of HAMA using light-based and extrusion-based approaches. (a) Creality Halot R6 MSLA printer. (b) Adapted low-volume setup used to reduce precursor volume during printing. (c) Modified build platform. (d) Dimensional fidelity of MSLA-printed 1% HAMA constructs immediately after printing and after 7 d in PBS. (e) MSLA-printed 1% HAMA constructs immediately after printing. (f) 1% HAMA constructs after 7 d in PBS. (g) Extrusion-based printing setup. (h) Deposition of HAMA through a 20G conical nozzle. (i,j) Representative extrusion-printed HAMA constructs obtained with 2% and 3% HAMA formulations after 15 s photocrosslinking. Scale bars: 5 mm.

Conclusion

Highly methacrylated HAMA was successfully synthesized and chemically validated by ^{1}H NMR, showing a DM of 80.7%. The hydrogel formulations exhibited concentration-dependent rheological behavior, with shear-thinning profiles and increased viscosity at higher polymer concentrations. UV exposure time also modulated wet mass stability, indicating that photocrosslinking conditions are key parameters for hydrogel network stabilization.

The 1% HAMA formulation was suitable for MSLA printing and enabled the fabrication of planar constructs, although height fidelity decreased after incubation in PBS. In contrast, 2% and 3% HAMA formulations were processed by extrusion-based printing and maintained the overall circular construct geometry, although filament spreading and loss of pore definition were observed. Overall, these findings demonstrate that highly methacrylated HAMA can be tuned by polymer concentration, UV exposure time, and printing strategy, supporting its use as a photocrosslinkable hydrogel precursor for future three-dimensional biofabrication applications.

***Abstract*—Multifunctional theranostic bioceramics have emerged as promising platforms for integrating diagnosis, therapy, tissue regeneration, and biomedical sensing within a single material system. Recent advances in rational ion co-doping have significantly expanded the functional capabilities of calcium phosphate bioceramics by incorporating magnetic, optical, angiogenic, antibacterial, and osteogenic properties. However, despite substantial progress in material design, current research remains fragmented across materials science, biology, photonics, and biomedical engineering, limiting the clinical translation of these technologies. This paper presents a comprehensive overview of recent developments in multifunctional ion-engineered bioceramics and identifies the major scientific and technological challenges hindering their translational advancement. Based on these research gaps, we propose the Translational Engineering of Bioceramics (TEB) Framework, a literature-informed conceptual methodology that systematically integrates clinical need identification, rational ion co-doping design, material engineering, multimodal characterization, computational and AI-assisted candidate prioritization, biological validation, prototype development, and translational planning. Rather than providing only a conventional literature review, this work introduces a systems-oriented engineering perspective aimed at structuring the prospective development and evaluation of next-generation theranostic biomaterials. The proposed framework provides a conceptual roadmap for investigating the coordinated development of multifunctional bioceramics toward biomedical device applications, while requiring prospective experimental validation to establish its practical utility.**

***Index Terms*—Theranostic, calcium phosphate, hydroxyapatite, ion co-doping, translational engineering, biomedical devices, biomaterials.**

I. Introduction

Biomedical Engineering is undergoing a profound transformation driven by the convergence of advanced biomaterials, nanotechnology, artificial intelligence, biophotonics, molecular imaging, and precision medicine. Rather than developing isolated therapeutic materials, current research increasingly seeks multifunctional biomedical platforms capable of simultaneously diagnosing, monitoring, and treating diseases while promoting tissue regeneration. This paradigm has accelerated the development of theranostic systems, which integrate diagnostic and therapeutic functions into a single biomaterial platform, enabling more personalized, minimally invasive, and clinically effective interventions [1]–[4].

Among the various classes of biomaterials investigated for theranostic applications, calcium phosphate bioceramics, particularly hydroxyapatite, have attracted considerable attention because of their excellent biocompatibility, bioactivity, osteoconductivity, biodegradability, and chemical similarity to natural bone. Beyond their traditional use as bone substitutes, recent advances in ionic substitution and co-doping strategies have expanded their functionality, allowing the incorporation of magnetic, optical, catalytic, antimicrobial, angiogenic, and osteogenic properties into a single material platform. These multifunctional characteristics position ion-engineered bioceramics as promising candidates for next-generation biomedical devices [5]–[9].

In parallel, photonic and magnetic therapeutic approaches, including Magnetic Fluid Hyperthermia (MFH), Photothermal Therapy (PTT), and Photodynamic Therapy (PDT), have

evolved from experimental concepts into clinically relevant strategies for cancer treatment and image-guided interventions. The combination of these modalities with multifunctional nanomaterials has demonstrated remarkable potential, particularly through synergistic PDT/PTT nanoplatforms and imaging-guided phototherapies, to improve therapeutic selectivity, reduce systemic toxicity, and enable real-time monitoring of treatment response. More recently, synergistic combinations of PDT and PTT have emerged as particularly promising due to their complementary mechanisms of action and compatibility with multimodal nanoplatforms [2], [3], [10]–[12].

Despite these remarkable advances, current research remains highly fragmented. Most studies focus on isolated aspects of material development, such as individual ionic substitutions, specific synthesis methods, single therapeutic modalities, or individual biological evaluations. Consequently, the field still lacks an integrated engineering strategy capable of systematically connecting rational material design, multifunctionality, advanced characterization, biological validation, artificial intelligence, prototype development, and clinical translation. This fragmentation may contribute to the limited progression of multifunctional theranostic bioceramics toward higher technological readiness levels and broader clinical evaluation.

In this context, this paper proposes a Translational Engineering Framework for next-generation multifunctional theranostic bioceramics. Rather than providing only a conventional literature review, the proposed framework conceptually organizes rational ion co-doping strategies, advanced synthesis routes, multimodal characterization, computational and AI-assisted candidate prioritization, biological validation, prototype development, and translational planning.

By organizing current knowledge into a unified engineering perspective, this work aims to provide researchers with a conceptual roadmap whose practical utility can be prospectively evaluated across the development of multifunctional biomaterials for regenerative medicine, biosensing, antimicrobial therapies, and precision medicine.

II. Literature Selection and Conceptual Framework Development

A structured narrative review was conducted to support the identification of scientific and translational gaps and the conceptual development of the Translational Engineering of Bioceramics (TEB) Framework. The review was designed as a framework-oriented synthesis rather than a systematic review or meta-analysis. Its purpose was to integrate evidence across materials science, biomedical engineering, theranostics, and computational materials design and to identify recurring challenges throughout the development pathway of multifunctional calcium phosphate bioceramics.

The literature search focused primarily on studies published between 2019 and 2026. Search terms were organized into three complementary thematic domains: ion-engineered calcium phosphate bioceramics, multifunctional/theranostic bioceramics, and computational or translational approaches to biomaterials development. An exploratory search using ("hydroxyapatite" OR "calcium phosphate") AND ("ion doping" OR "ionic substitution" OR "co-doping") retrieved 338 records. Restriction to records indexed with doping-related keywords reduced this set to 161, of which 128 were classified within Materials Science and 15 within Medicine. When "theranostic*" was added to this search, only two records were retrieved, both published in 2024.

A broader search combining ("hydroxyapatite" OR "bioceramic") with ("theranostic" OR "multifunctional" OR "magnetic" OR "photothermal" OR "photodynamic" OR "biosensing") retrieved 3,083 records; restricting this search using the same doping-related keywords reduced the set to 60 records. A third search combining ("biomaterials" OR "bioceramics") with ("artificial intelligence" OR "machine learning" OR "computational materials design" OR "translational engineering") retrieved 1,636 records, whereas application of the doping-related keyword restriction resulted in only one record, classified within Materials Science.

These exploratory counts indicate that, although substantial bodies of literature exist independently on ion-engineered bioceramics, multifunctionality, and computational biomaterials research, their intersection remains comparatively underrepresented. The predominance of Materials Science classifications in the ion-doping search further suggests a disciplinary concentration that supports examining these technologies through a broader biomedical translational perspective.

Studies were considered for the narrative synthesis when they contributed evidence concerning ion–structure–property relationships, multifunctional or theranostic performance, biological responses, multimodal characterization, computational or AI-assisted materials design, biomedical device integration, or translational barriers. Review articles were used to contextualize consolidated developments and identify complementary primary studies. The selected literature was synthesized thematically rather than quantitatively.

Recurring scientific, engineering, and translational challenges were mapped across the biomaterial development pathway and organized into eight interconnected domains: clinical need identification, rational ion co-doping design, material engineering, multimodal characterization, computational and AI-assisted optimization, biological validation, prototype development, and translational planning.

These domains informed the proposed stages and evaluation targets of the TEB Framework. Accordingly, the TEB Framework should be interpreted as a literature-informed, hypothesis-generating conceptual model rather than an experimentally validated translational pathway; its practical utility and performance require prospective experimental and real-world evaluation.

III. Current Landscape and Research Gaps

Calcium phosphate bioceramics have long been recognized as one of the most successful classes of biomaterials for

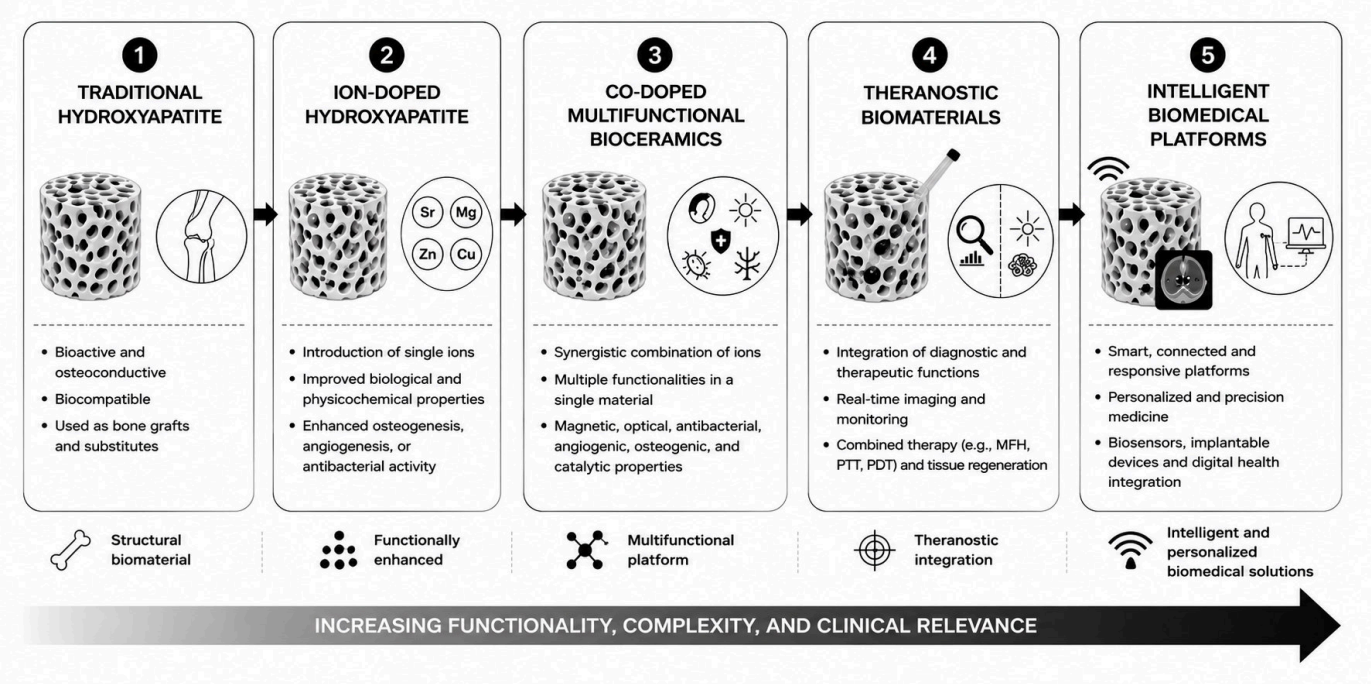

Fig. 1. Evolution of multifunctional bioceramics from traditional hydroxyapatite to intelligent biomedical platforms. *Conceptual illustration generated using generative AI and edited by the authors.*

orthopedic and dental applications due to their excellent biocompatibility, osteoconductivity, biodegradability, and chemical similarity to the mineral phase of human bone. Among them, hydroxyapatite (HAp) has become the most extensively investigated material because of its ability to support bone regeneration [13]–[17].

During the last two decades, however, the role of hydroxyapatite has expanded substantially. Rather than acting exclusively as passive scaffolds for tissue repair, calcium phosphate bioceramics have progressively evolved into multifunctional platforms capable of simultaneously interacting with biological tissues, responding to external stimuli, carrying therapeutic agents, and generating diagnostic signals. This transformation reflects the convergence of materials science, nanotechnology, photonics, and biomedical engineering toward the development of theranostic biomaterials, see figure 1.

One of the major driving forces behind this evolution has been the development of rational ionic substitution strategies, which enables simultaneous tuning of structural, mechanical, dielectric, surface, magnetic, and biological properties. The apatite crystal lattice presents remarkable structural flexibility, allowing calcium ions to be partially replaced by biologically active metallic ions without compromising the fundamental crystal structure [1], [17], [18]. This unique characteristic enables precise modulation of physicochemical, magnetic, optical, biological, and mechanical properties according to specific biomedical requirements, see table I.

Initially, ionic substitution focused primarily on improving osteoconductivity and mechanical performance. More recently, co-doping approaches have emerged as a powerful strategy for simultaneously introducing multiple biological and physical functionalities into a single biomaterial. Unlike single-ion substitution, co-doping enables synergistic interactions among different ions, allowing the simultaneous regulation of osteogenesis, angiogenesis, antibacterial activity, magnetic responsiveness, fluorescence, reactive oxygen species (ROS) generation, and imaging capabilities [19]–[26].

The selection of dopant ions is no longer exclusively based on chemical compatibility but increasingly follows a function-oriented engineering approach. Each ionic species contributes distinct biological or physical properties that can be strategically combined according to the intended clinical application [7], [9], [27]–[33].

Strontium and magnesium are widely recognized for stimulating osteoblast proliferation, bone mineralization, and inhibition of osteoclast activity, making them attractive for regenerative applications [34]–[36]. Cobalt and manganese have additionally demonstrated important roles in regulating angiogenesis, osteogenesis, and vascular remodeling. Cobalt promotes angiogenesis through hypoxia-mimicking mechanisms while simultaneously introducing magnetic properties useful for hyperthermia [37]–[40]. Iron provides superparamagnetic behavior suitable for magnetic fluid hyperthermia and magnetic resonance imaging [41]–[44]. Manganese contributes both to magnetic imaging and reactive oxygen species generation, whereas chromium may enhance luminescence and photonic responses. Other ions, including zinc, copper, silver, gadolinium, and erbium, further expand the multifunctionality of calcium phosphates by incorporating antimicrobial, imaging, sensing, and optical capabilities [45]–[49].

TABLE I
:REPRESENTATIVE IONIC DOPANTS AND THEIR MULTIFUNCTIONAL ENGINEERING ROLES IN NEXT-GENERATION THERANOSTIC BIOCERAMICS.

Functional Objective	**Representative Ions**	**Primary Mechanism**	**Engineering Functionality**	**Biomedical Applications**
Osteogenesis	Sr, Mg, Zn	Stimulation of osteoblast differentiation, mineralization, and inhibition of osteoclast activity	Bioactive scaffolds with enhanced bone regeneration	Bone regeneration, orthopedic implants, dental implants, tissue engineering
Angiogenesis	Co, Sr	Hypoxia-mimicking pathways (HIF-1α/VEGF) and vascular stimulation	Vascularized biomaterials and regenerative scaffolds	Bone repair, critical-size defects, regenerative medicine
Magnetic Response	Fe, Co	Superparamagnetism and magnetic susceptibility	Magnetic Fluid Hyperthermia (MFH), magnetic targeting and MRI enhancement	Cancer therapy, molecular imaging, image-guided interventions
Reactive Oxygen Species (ROS) Generation	Mn, Cu, Cr	Catalytic ROS generation under external stimulation	Photodynamic Therapy (PDT) and oxidative therapies	Cancer treatment, antimicrobial therapy, infection control
Photonic / Luminescent Response	Er, Cr	Luminescence and fluorescence enhancement	Optical probes and photonic biomaterials	Optical imaging, fluorescence-guided surgery, biosensing
Magnetic Resonance Imaging (MRI)	Gd, Fe, Mn	Paramagnetic contrast enhancement	Multimodal imaging platforms	MRI-guided diagnosis, precision medicine, theranostics
Antibacterial Activity	Ag, Cu, Zn	Membrane disruption and bacterial metabolic inhibition	Antimicrobial coatings and bioactive implant surfaces	Implant-associated infection prevention, wound healing
Biosensing	Er, Gd, Sr	Surface charge modulation, fluorescence and electrochemical signal enhancement	Smart biosensors and bioelectronic interfaces	Molecular diagnostics, wearable biosensors, precision medicine

The concept of theranostics has profoundly reshaped the development of multifunctional biomaterials by integrating diagnostic and therapeutic capabilities into single platforms. Instead of employing independent systems for imaging, treatment, and tissue regeneration, current engineering approaches increasingly seek multifunctional materials capable of performing these functions simultaneously.

This convergence has stimulated the integration of magnetic fluid hyperthermia, photothermal therapy, photodynamic therapy, molecular imaging, biosensing, controlled drug delivery, and tissue regeneration into unified biomaterial systems. Such multifunctionality enables image-guided therapies, real-time treatment monitoring, and personalized therapeutic strategies while reducing invasiveness and improving clinical precision.

Beyond material development itself, recent advances indicate a progressive transition toward engineering-oriented design strategies. Artificial intelligence, computational materials science, high-throughput screening, digital manufacturing, additive manufacturing, and multimodal characterization are beginning to transform how multifunctional bioceramics are conceived, optimized, and translated into biomedical devices. Nevertheless, despite these remarkable technological advances, current research remains fragmented across materials science, chemistry, biology, photonics, and biomedical engineering.

The absence of an integrated translational strategy capable of connecting these individual advances into a unified development pipeline represents one of the major challenges currently facing the field. Addressing this gap requires a comprehensive engineering framework capable of guiding the rational design of next-generation theranostic bioceramics from fundamental material development to clinical implementation.

The TEB Framework was also informed by the authors' technology-development experience. Between 2010 and 2018, Innovacura Biomateriais developed advanced biomaterials through a predominantly materials-science team, revealing the need to integrate clinical, regulatory, manufacturing, and business requirements earlier and iteratively. These lessons, together with the literature gaps, informed the TEB Framework, currently being prospectively applied and evaluated within RenovCure. This ongoing implementation does not yet constitute empirical validation.

IV. A TRANSLATIONAL ENGINEERING FRAMEWORK FOR NEXT-GENERATION THERANOSTIC BIOCERAMICS

Based on the scientific and translational gaps identified in the literature, we propose the Translational Engineering of Bioceramics (TEB) Framework as a literature-informed conceptual model for organizing the development and prospective evaluation of multifunctional theranostic bioceramics. Rather than representing a validated translational pathway, the framework defines a sequence of interconnected engineering stages and corresponding evaluation targets that can be tested in future experimental and real-world studies.

The proposed framework comprises eight iterative stages: (1) clinical need identification, (2) rational ion co-doping design, (3) material engineering, (4) multimodal characterization,

TABLE II
CURRENT RESEARCH GAPS AND PROPOSED ENGINEERING DIRECTIONS FOR NEXT-GENERATION THERANOSTIC BIOCERAMICS.

Current Limitation	**Scientific or Technological Consequence**	**Proposed Engineering Direction**
Empirical ion selection	Time-consuming optimization and limited understanding of synergistic effects	Artificial intelligence-assisted rational ion selection and computational materials design
Single-function biomaterials	Limited therapeutic performance and reduced clinical applicability	Development of multifunctional theranostic platforms integrating diagnosis, therapy, and tissue regeneration
Fragmented material characterization	Incomplete understanding of structure–property–function relationships	Multimodal characterization combining structural, magnetic, optical, chemical, and biological analyses
Isolated biological evaluation	Poor correlation between physicochemical properties and biological performance	Integrated in vitro, in vivo, and mechanistic biological validation
Laboratory-scale synthesis	Limited reproducibility and difficulty in industrial scale-up	Standardized, scalable, and reproducible manufacturing protocols
Limited prototype development	Low Technology Readiness Level (TRL) and poor translational potential	Engineering-oriented prototyping and biomedical device development
Lack of regulatory and clinical planning	Delayed clinical translation and commercialization	Early integration of regulatory science, clinical validation, and translational engineering strategies

(5) computational and AI-assisted candidate prioritization, (6) biological validation, (7) prototype development, and (8) translational planning and evaluation. Each stage is associated with prospective evaluation targets intended to determine whether a candidate material should progress, be reformulated, or return to an earlier development stage. Accordingly, progression through the framework should not be interpreted as evidence of increasing technological maturity unless predefined stage-specific criteria are prospectively demonstrated.

Table III summarizes the proposed stages, their engineering objectives, and the corresponding targets for future evaluation. The framework is intended to operate iteratively rather than as a strictly linear pipeline, allowing experimental, biological, computational, manufacturing, or regulatory findings to inform previous stages and guide subsequent design decisions.

Despite advances in multifunctional bioceramics, their development remains fragmented across materials science, biology, clinical sciences, and biomedical engineering. Materials research commonly emphasizes synthesis, crystal chemistry, and physicochemical characterization, whereas biological and clinical studies focus on biocompatibility, therapeutic performance, and safety. Limited integration among these domains may contribute to promising biomaterials remaining at the experimental stage rather than progressing toward biomedical technologies.

Ion co-doping further increases this translational complexity because interactions among dopants may affect crystal chemistry, phase stability, degradation, physicochemical properties, and biological performance in nonlinear and potentially synergistic or antagonistic ways. Since most studies investigate a limited number of compositions, candidate selection still frequently relies on empirical trial-and-error approaches. Beyond material design, reproducibility, scalable manufacturing, long-term biosafety, regulatory requirements, prototype development, and clinical evaluation represent additional translational barriers.

These interconnected challenges support addressing material design, biological validation, manufacturing, and translational requirements iteratively rather than as isolated downstream activities. Within the proposed TEB Framework, progression is therefore conditional on predefined evaluation criteria, allowing evidence generated at each stage to support progression, refinement, or return to earlier design decisions. This stage-gate logic provides a testable structure for prospectively evaluating the framework's practical utility.

A. Computational and AI-Assisted Ion Co-Doping Optimization

Within the TEB Framework, computational and AI methods are conceived as decision-support tools for prioritizing candidate ion combinations and experimental conditions rather than autonomous material-selection mechanisms. The proposed iterative data–model–experiment workflow may integrate experimental, literature-derived, and simulation data using descriptors such as dopant identity and concentration, Ca/P ratio, synthesis conditions, particle size, crystallinity, phase composition, porosity, and surface properties. These inputs may be associated with target outcomes including magnetic, photothermal, optical, antimicrobial, cytotoxic, osteogenic, and angiogenic responses. Regression, classification, and multi-objective approaches may then predict relevant properties and rank candidate formulations against predefined performance and safety criteria.

TABLE III
TRANSLATIONAL ENGINEERING OF BIOCERAMICS (TEB) FRAMEWORK: ENGINEERING STAGES, INPUTS, AND EXPECTED OUTPUTS FOR THE DEVELOPMENT OF NEXT-GENERATION THERANOSTIC BIOCERAMICS.

Framework Stage	**Engineering Objective**	**Prospective Evaluation Targets**
Clinical Need Identification	Define the intended clinical problem, application, and required functions before material design.	Explicit target product/application profile, intended use, clinical requirements, and predefined performance and safety criteria.
Rational Ion Co-Doping Design	Select candidate dopants and concentration ranges based on expected physicochemical and biological mechanisms.	Candidate ion combinations and concentration ranges prioritized for experimental testing against predefined functional and biological criteria.
Material Engineering	Develop and control synthesis, processing, composition, microstructure, and physicochemical properties.	Reproducible candidate formulations meeting predefined compositional, structural, and processing specifications.
Multimodal Characterization	Characterize structural, chemical, surface, optical, magnetic, thermal, and other application-relevant properties.	Experimentally measured property profiles compared with predefined performance criteria and suitable for informing subsequent design decisions.
Computational and AI-Assisted Ion Co-Doping Optimization	Predict relevant properties and prioritize ion combinations and processing conditions for experimental validation.	Ranked candidate formulations with predicted performance and uncertainty, followed by prospective comparison with experimentally measured outcomes.
Biological Validation	Evaluate safety and application-specific biological responses using progressively relevant experimental models.	Evidence of cytocompatibility and predefined biological functionality in appropriate in vitro and, where justified, subsequent preclinical models.
Prototype Development	Integrate selected bioceramics into application-specific biomedical prototypes and assess manufacturability and functional performance.	Prototype feasibility, reproducibility, functional performance, and manufacturing requirements suitable for subsequent TRL assessment.
Translational Planning and Evaluation	Examine regulatory, manufacturing, quality, clinical, and implementation requirements for further development.	Defined regulatory and manufacturing pathway, identified evidence gaps, and criteria for subsequent preclinical, clinical, and technology-maturation studies.

Regression, classification, or multi-objective optimization models may then be used to predict relevant properties and rank candidate compositions according to predefined application-specific requirements. Thus, rather than directly selecting an ion combination, the computational stage would prioritize experimentally testable candidates predicted to provide the most favorable balance among multiple desired functionalities and safety constraints.

Model performance should be evaluated according to the prediction task. Continuous-property predictions may be assessed using mean absolute error (MAE), root mean squared error (RMSE), and coefficient of determination (R^2), whereas classification tasks may use precision, recall, F1-score, and area under the receiver operating characteristic curve (ROC-AUC), when applicable. Cross-validation should be used during model development, while independent or prospectively generated experimental data should be preferred for evaluating generalizability.

Importantly, computational performance alone would not establish the utility of the approach within the TEB Framework. Candidate compositions prioritized by the model should subsequently be synthesized and experimentally characterized, allowing predicted and measured outcomes to be compared and the ranking of candidate formulations to be evaluated.

The experimental results would then be incorporated into subsequent model iterations, creating an iterative learning cycle between computational prediction and laboratory validation. Future prospective studies could further assess practical utility by comparing AI-assisted candidate prioritization with conventional empirical selection in terms of predictive agreement, proportion of successful top-ranked candidates, and the number of experimental iterations required to identify formulations meeting predefined multifunctional performance and safety criteria. This computational component therefore remains a proposed and testable element of the TEB Framework whose added value must be established through prospective experimental validation.

V. LIMITATIONS AND FUTURE PERSPECTIVES

The future development of multifunctional theranostic bioceramics will require greater integration between rational material design, biological validation, prototype development, scalable manufacturing, and regulatory planning. Rather than focusing on isolated material properties, future research should

advance toward multifunctional platforms combining diagnostic, therapeutic, regenerative, and sensing capabilities. This transition will require multidisciplinary collaboration and standardized workflows capable of supporting reproducibility, safety, and subsequent translational evaluation.

Computational materials science, computational chemistry, artificial intelligence, digital twins, and high-throughput experimentation may complement experimental approaches by enabling more systematic exploration of complex compositional and processing spaces. Within the TEB Framework, these tools are intended to support hypothesis generation, candidate prioritization, and experimental design rather than replace experimental validation. Computationally prioritized ion combinations and predicted material properties should therefore be evaluated through synthesis, physicochemical characterization, and biological testing before progression toward prototype development.

The TEB Framework should be interpreted as a literature-informed conceptual and hypothesis-generating framework rather than an experimentally validated translational pathway. It has not yet been prospectively tested in experimental programs, biomedical device development, or real-world clinical settings; therefore, its stages and proposed outputs represent engineering targets rather than demonstrated gains in technological maturity or clinical translation. Future studies should progressively evaluate and refine the framework through experimental case studies, computational–experimental validation, prototype development, and prospective translational applications, using measurable indicators such as predictive agreement, reproducibility, experimental efficiency, prototype performance, and independently assessed progression against relevant TRL criteria.

VI. Conclusions

Multifunctional calcium phosphate bioceramics offer increasing opportunities to integrate diagnostic, therapeutic, regenerative, and sensing functions; however, their progression toward biomedical technologies remains constrained by fragmented development approaches. This work proposed the Translational Engineering of Bioceramics (TEB) Framework as a literature-informed conceptual methodology that organizes clinical needs, rational ion co-doping, material engineering, multimodal characterization, computational and AI-assisted candidate prioritization, biological validation, prototype development, and translational planning within a unified engineering framework.

The main contribution of the TEB Framework is a systems-oriented perspective connecting materials science, biomedical engineering, computational approaches, and translational considerations rather than proposing a new material composition or claiming a validated development pathway. The framework may provide a structured basis for designing and prospectively evaluating multidisciplinary research on theranostic bioceramics and potentially other multifunctional biomaterials. Its practical utility, including whether it can improve experimental efficiency, reproducibility, technological maturation, or progression toward clinical translation, remains to be established through prospective experimental and real-world validation.

Resumo—Os alinhadores ortodônticos transparentes são hoje uma das principais alternativas aos aparelhos convencionais devido à sua estética, conforto e previsibilidade clínica. Entretanto, o desempenho biomecânico desses dispositivos depende diretamente das propriedades físico-químicas e termomecânicas dos polímeros utilizados em sua fabricação. Entre as técnicas de caracterização de materiais poliméricos, a Calorimetria Exploratória Diferencial (Differential Scanning Calorimetry – DSC) destaca-se por possibilitar a determinação de parâmetros fundamentais para compreender a estabilidade termofísica dos alinhadores. O presente artigo teve como objetivo revisar a literatura científica e caracterizar, por DSC, três tipos de polímeros comerciais, utilizados como alinhadores ortodônticos, discutindo a influência da composição dos polímeros sobre suas propriedades e desempenho. Os resultados obtidos mostraram as principais diferenças na caracterização termofísica dos polímeros analisados, mostrando-se uma importante ferramenta para o desenvolvimento de materiais mais estáveis, previsíveis e duráveis, contribuindo para a evolução tecnológica dos alinhadores ortodônticos.

Palavras-chave—Alinhadores ortodônticos; DSC; Biomateriais.

I. INTRODUÇÃO

Os materiais termoplásticos empregados na fabricação de alinhadores ortodônticos devem apresentar elevada transparência óptica, biocompatibilidade, estabilidade dimensional, resistência mecânica e capacidade de manter forças leves e contínuas durante todo o período de utilização clínica [1, 2]. As propriedades desses materiais dependem da estrutura molecular dos polímeros, do grau de cristalinidade, da massa molar e do processamento industrial utilizado na fabricação das placas termoplásticas.

Entre os materiais mais empregados destacam-se o poliuretano termoplástico (TPU), o politereftalato de etileno modificado por glicol (PETG), o polipropileno (PP) e polímeros multicamadas desenvolvidos especificamente para aplicações ortodônticas [2, 3, 4]. O TPU apresenta elevada elasticidade e boa resistência ao desgaste, favorecendo a manutenção das forças ortodônticas durante períodos prolongados. O PETG destaca-se pela excelente transparência, facilidade de conformação e boa estabilidade dimensional, enquanto o polipropileno apresenta menor densidade e maior resistência química, embora seja mais sensível às alterações provocadas pelo processamento térmico [3, 4, 5].

A termoformagem constitui uma das etapas mais importantes da fabricação dos alinhadores. Durante esse processo, placas termoplásticas são aquecidas acima da temperatura de transição vítrea e moldadas sobre modelos tridimensionais da arcada dentária. O aquecimento promove reorganização parcial das cadeias poliméricas, podendo modificar o grau de cristalinidade, a orientação molecular e a distribuição de tensões internas do material [4, 5, 6, 9].

Diversos estudos demonstram que essas modificações estruturais influenciam diretamente as propriedades mecânicas dos alinhadores. Alterações no módulo de elasticidade, na resistência à tração e na recuperação elástica podem reduzir a magnitude das forças aplicadas aos dentes durante o tratamento ortodôntico, afetando a eficiência clínica dos dispositivos [1, 2, 3, 4, 5, 6, 8, 9].

Nesse contexto, a Calorimetria Exploratória Diferencial (Differential Scanning Calorimetry – DSC) tornou-se uma das principais ferramentas para caracterização dos polímeros utilizados na Ortodontia [1, 4, 5, 7]. A técnica baseia-se na medição da diferença de fluxo de calor entre uma amostra e um material de referência durante ciclos controlados de aquecimento e resfriamento [1, 5, 7]. A partir dessas curvas térmicas é possível determinar importantes parâmetros, como temperatura de transição vítrea (Tg), temperatura de cristalização (Tc), temperatura de fusão (Tm), capacidade calorífica e entalpia de fusão, permitindo avaliar a estabilidade térmica e estrutural dos materiais [1, 5, 7, 9].

A temperatura de transição vítrea representa um dos parâmetros mais importantes para materiais poliméricos utilizados em alinhadores [7, 9]. Abaixo da Tg, o polímero apresenta comportamento rígido e vítreo; acima dessa temperatura, ocorre aumento da mobilidade molecular, tornando o material mais flexível. Como a temperatura intraoral situa-se próxima de 37°C, pequenas variações na Tg podem

modificar significativamente o comportamento do alinhador durante sua utilização clínica [5, 7, 9].

Outro parâmetro importante obtido pela DSC é a entalpia de fusão, utilizada para estimar o grau de cristalinidade dos polímeros [1, 5, 7, 9]. Em materiais semicristalinos, maior cristalinidade normalmente está associada ao aumento da rigidez e da resistência mecânica, porém pode reduzir a flexibilidade do material. Dessa forma, o equilíbrio entre regiões amorfas e cristalinas torna-se fundamental para garantir desempenho clínico adequado [6, 8, 10].

Além do processamento térmico, diversos fatores relacionados ao ambiente bucal contribuem para o envelhecimento dos alinhadores [11, 12]. A absorção de água, as oscilações térmicas decorrentes da ingestão de alimentos quentes e frios, as soluções de limpeza e as cargas mastigatórias promovem alterações graduais na estrutura dos polímeros [11]. Esses fenômenos podem resultar em plastificação, relaxação molecular e diminuição das propriedades mecânicas, comprometendo a estabilidade dimensional dos dispositivos [6, 8, 9, 10, 11, 12].

Recentemente, a impressão tridimensional direta de alinhadores ortodônticos surgiu como uma alternativa promissora aos processos convencionais de termoformagem [2, 8, 10]. Essa tecnologia reduz etapas de processamento e pode minimizar alterações estruturais induzidas pelo aquecimento, embora ainda existam limitações relacionadas à estabilidade dos materiais fotopolimerizáveis e à necessidade de validação clínica em longo prazo [2, 10].

Assim, a literatura demonstra que a associação entre técnicas de caracterização térmica, mecânica e microestrutural representa uma importante estratégia para o desenvolvimento de biomateriais ortodônticos mais estáveis e duráveis, possibilitando avanços significativos na previsibilidade dos tratamentos realizados com alinhadores transparentes.

Diante dessa necessidade de investigação, esse trabalho teve como objetivo iniciar as caracterizações de diferentes alinhadores ortodônticos, começando pelos ensaios de Calorimetria Exploratória Diferencial (Differential Scanning Calorimetry – DSC).

II. MATERIAIS E MÉTODOS

A. Aquisição e preparação das amostras

Foram utilizadas placas de polímeros comerciais de três empresas diferentes. A placa da empresa 1 é identificada, na sua etiqueta, como Placa PET-G. A placa da empresa 2 é identificada como Placa de Acetato Flexflow. A placa da empresa 3, como Placa de Copoliéster. Todas as placas possuem diâmetro de 125mm e espessura entre 0,75 e 0,80mm.

Para os ensaios de Calorimetria Exploratória Diferencial (Differential Scanning Calorimetry – DSC), foram cortadas, de cada placa, 03 pequenas amostras circulares com aproximadamente 5mm de diâmetro e massa entre 5 e 10mg.

B. Parâmetros dos ensaios de DSC

As análises foram feitas num equipamento DSC, marca TA Instruments, modelo Discovery DSC25, com temperatura entre -90 e 550°C. A Figura 1 mostra o equipamento.

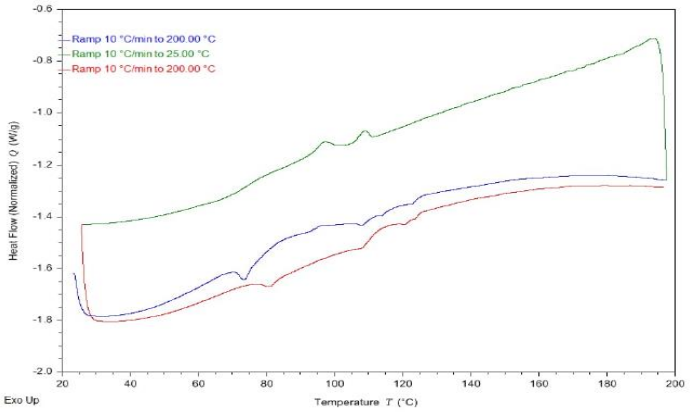
Fig. 1 – Equipamento DSC

As amostras foram colocadas em cadinhos de alumínio hermeticamente fechados. A atmosfera utilizada foi o nitrogênio (N_2) com fluxo de 50 ml/min, para evitar termo-oxidação.

O programa de temperatura foi:

- Rampa de aquecimento de 25°C até 200°C a uma taxa de 20°C/min. (Este primeiro aquecimento apaga a história térmica do material).
- Isoterma de 1 minuto em 200°C.
- Rampa de resfriamento de 200°C a 25°C a uma taxa de 20°C/min.
- Rampa de segundo aquecimento de 25°C a 200°C a uma taxa de 20°C/min.

Os ensaios foram repetidos para as três amostras de cada placa polimérica comercial.



III. RESULTADOS E DISCUSSÕES

Os resultados obtidos das análises de Calorimetria Exploratória Diferencial (DSC), serão apresentados e discutidos a seguir.

A. Amostra de PET-G

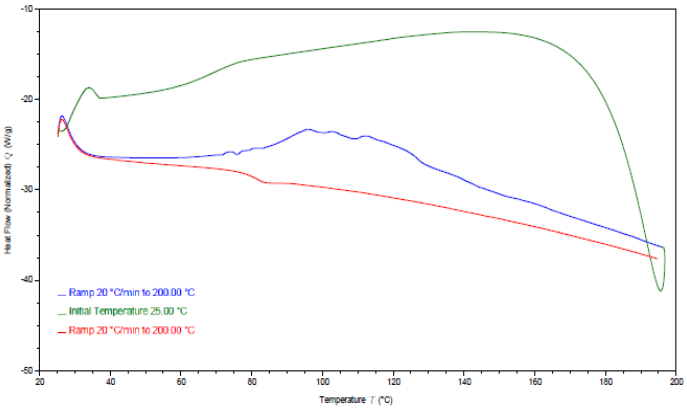
A Figura 2 mostra a curva obtida pelo ensaio de DSC da amostra de PET-G.

Fig. 2 – Curva de DSC do PET-G

A curva do PET-G apresenta comportamento típico de um polímero predominantemente amorfo, caracterizado pela presença de uma transição vítrea relativamente bem definida e ausência de pico pronunciado de fusão. A ausência do pico de fusão se deve ao fato que a curva corresponde a um ensaio

limitado a 200°C e o pico de fusão de materiais baseados em PET-G, normalmente ocorre entre 220 e 250°C, dependendo da formulação.

A curva de DSC evidenciou uma transição vítrea bem definida na faixa de 74 a 78 °C, acompanhada por discreto evento exotérmico entre 95 e 105 °C, associado à cristalização a frio de baixa intensidade. Não foi observado pico de fusão dentro da faixa analisada, o que é compatível com a predominância de fase amorfa e com o limite superior do ensaio.



Esse comportamento é coerente com a estrutura do PET-G, uma vez que a incorporação de glicol à cadeia do PET reduz a capacidade de empacotamento molecular e, consequentemente, a cristalização. Do ponto de vista clínico, tal característica é positiva, pois materiais com maior fração amorfa tendem a apresentar melhor transparência óptica e maior facilidade de conformação durante a termoformagem. Contudo, a presença de cristalização a frio indica que o material ainda possui certa capacidade de reorganização sob aquecimento, o que pode interferir em sua estabilidade ao longo do uso.

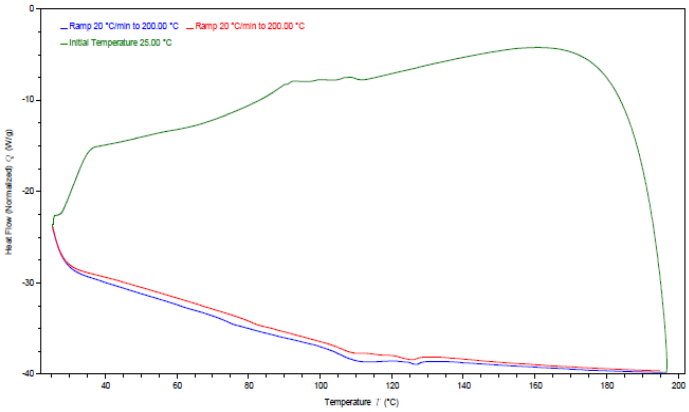
Além disso, a Tg observada encontra-se relativamente próxima à faixa de temperaturas que podem ser alcançadas durante a ingestão de bebidas quentes ou em etapas de processamento térmico. Isso sugere que o PET-G, embora adequado para aplicações ortodônticas, pode sofrer alterações de desempenho se exposto repetidamente a condições térmicas extremas. Estudos com alinhadores termoplásticos têm mostrado que envelhecimento em saliva artificial e ciclos térmicos podem reduzir a rigidez e a estabilidade dimensional, reforçando a importância da seleção criteriosa do material [4, 5, 12]. Esse comportamento é esperado para o PET-G, pois a introdução do glicol na cadeia do PET reduz significativamente sua capacidade de cristalização.

B. Amostra de Acetato

A Figura 3 mostra a curva obtida pelo ensaio de DSC da amostra de Acetato.

Fig. 3 – Curva de DSC do Acetato

A amostra de acetato apresentou perfil térmico distinto do PET-G, com transição vítrea semelhante, entre 72 e 76 °C, porém com evento exotérmico mais largo e mais intenso entre 95 e 110 °C. Esse comportamento sugere maior reorganização molecular durante o aquecimento, refletindo maior mobilidade das cadeias e menor estabilidade térmica em comparação ao PET-G.



Na prática, isso indica que o acetato pode ser mais sensível a variações de temperatura e a processos de relaxamento estrutural. Em materiais usados como alinhadores, maior mobilidade molecular pode ser vantajosa em etapas de conformação inicial, mas representa desvantagem durante o uso, pois pode favorecer perda de forma, redução do armazenamento de tensões elásticas e queda da eficiência de ativação ortodôntica. Em outras palavras, o material pode deformar-se com mais facilidade e recuperar-se com menor previsibilidade.

Outro aspecto relevante é que a maior amplitude do evento térmico sugere heterogeneidade na estrutura interna do polímero, possivelmente associada à formulação comercial, ao processamento industrial ou à presença de aditivos. Em sistemas poliméricos odontológicos, essa heterogeneidade pode comprometer a repetibilidade do desempenho entre lotes e aumentar a variabilidade clínica. Assim, o acetato analisado mostrou-se menos estável do que o PET-G sob as condições do ensaio, o que merece consideração em aplicações de longa duração ou em situações nas quais a manutenção de forças é crítica.

C. Amostra de Copoliéster

A Figura 4 mostra a curva obtida pelo ensaio de DSC da amostra de Copoliéster.

Fig. 4 – Curva de DSC do Copoliéster

Entre os materiais avaliados, o copoliéster exibiu o comportamento termofísico mais estável. A curva apresentou Tg entre 120 e 130 °C e ausência de eventos relevantes de cristalização ou fusão no intervalo estudado. Além disso, observou-se boa sobreposição entre as curvas, sugerindo repetibilidade experimental e estabilidade estrutural durante os ciclos térmicos.

A Tg mais elevada indica que o copoliéster possui maior resistência à mobilidade molecular quando comparado aos outros materiais. Isso é particularmente relevante para alinhadores ortodônticos, pois um polímero com Tg distante da temperatura intraoral tende a manter suas propriedades mecânicas com menor variação durante o uso. Em termos clínicos, isso pode se traduzir em melhor manutenção da força exercida sobre os dentes e menor suscetibilidade à deformação permanente.

A ausência de cristalinidade significativa também é favorável, uma vez que materiais amorfos e termicamente estáveis costumam oferecer boa transparência e previsibilidade dimensional. Em copoliésteres desenvolvidos para uso

odontológico, a formulação visa justamente combinar estabilidade térmica, clareza óptica e resistência ao impacto. Os resultados observados neste estudo são compatíveis com essa finalidade e reforçam o potencial do copoliéster como material promissor para alinhadores de maior desempenho.[9, 12, 13].

D. Implicações clínicas

A comparação entre os três materiais evidencia que, embora todos apresentem caráter predominantemente amorfo, suas respostas térmicas são distintas e refletem diferenças importantes de formulação e comportamento em serviço. O PET-G mostrou equilíbrio entre processabilidade e estabilidade; o acetato demonstrou maior suscetibilidade à reorganização estrutural; e o copoliéster apresentou a maior resistência às variações térmicas.

Essas diferenças têm impacto direto sobre a previsibilidade clínica dos alinhadores. Materiais com Tg mais baixa e maior tendência à reorganização podem perder forças com mais rapidez, exigindo substituição mais frequente ou comprometendo a eficiência da movimentação dentária. Já materiais mais estáveis tendem a conservar melhor sua geometria e suas propriedades mecânicas ao longo do uso, favorecendo resultados mais consistentes.

Outro ponto a considerar é que a resposta térmica do material não deve ser analisada isoladamente. Na prática, fatores como absorção de água, desgaste por escovação, ataques químicos de soluções de limpeza e exposição a ciclos térmicos orais podem atuar de forma sinérgica na degradação do polímero. Portanto, a DSC fornece uma base importante, mas deve ser complementada por análises mecânicas, morfológicas e de envelhecimento acelerado para uma avaliação mais completa do desempenho dos alinhadores [1,4-6,10-13].

IV. CONCLUSÕES

Os resultados obtidos por Calorimetria Exploratória Diferencial (DSC) demonstram que os três materiais analisados apresentam comportamento predominantemente amorfo, característica desejável para polímeros empregados na fabricação de alinhadores ortodônticos, uma vez que essa condição favorece a transparência óptica e a conformabilidade durante o processamento. Entretanto, cada material apresentou respostas térmicas distintas, evidenciando diferenças em sua estrutura molecular e em sua estabilidade frente ao aquecimento.

O PET-G apresentou temperatura de transição vítrea (Tg) entre 74 e 78 °C, acompanhada por um discreto pico de cristalização a frio entre 95 e 105 °C, indicando baixa capacidade de reorganização cristalina. Esse comportamento confirma que a modificação da cadeia polimérica pela incorporação de glicol reduz significativamente a cristalinidade do material, mantendo sua estrutura majoritariamente amorfa.

O acetato exibiu Tg semelhante à do PET-G (72 a 76 °C), porém apresentou um evento exotérmico mais amplo e intenso entre 95 e 110 °C, evidenciando maior reorganização molecular durante o aquecimento. Esse resultado indica maior mobilidade das cadeias poliméricas e menor estabilidade térmica quando comparado ao PET-G, sugerindo que o material é mais suscetível a alterações estruturais em temperaturas elevadas.

Por sua vez, o copoliéster apresentou o comportamento térmico mais estável dentre os materiais avaliados. A elevada temperatura de transição vítrea, situada entre 120 e 130 °C, associada à ausência de eventos de cristalização ou fusão durante o ensaio, demonstra elevada estabilidade térmica e excelente manutenção da estrutura amorfa ao longo do aquecimento. A sobreposição das curvas obtidas também confirma a boa repetibilidade experimental e indica que o material possui elevada homogeneidade e estabilidade química.

De forma comparativa, verifica-se que o copoliéster apresenta a maior resistência às variações térmicas, seguido pelo PET-G, enquanto o acetato demonstrou maior tendência à reorganização estrutural. Esses resultados evidenciam que as diferenças observadas nas curvas de DSC estão diretamente relacionadas à composição química e ao grau de mobilidade molecular de cada polímero. Assim, a análise térmica confirma que o copoliéster apresenta o comportamento mais adequado para aplicações que exigem estabilidade dimensional e térmica, enquanto o PET-G mantém um equilíbrio entre estabilidade e processabilidade. Já o acetato, embora permaneça predominantemente amorfo, mostra maior sensibilidade ao aquecimento, característica que pode influenciar seu desempenho em aplicações sujeitas a variações de temperatura.

De modo geral, os resultados reforçam que a escolha do material para alinhadores ortodônticos deve ir além da transparência e do conforto, incorporando também critérios de estabilidade térmica e resistência à degradação estrutural. A análise por DSC mostrou-se uma ferramenta útil para triagem e comparação de materiais, oferecendo subsídios importantes para o desenvolvimento e a seleção de polímeros mais adequados ao uso clínico.

Como limitação, destaca-se que a presente avaliação considerou apenas o comportamento termofísico inicial dos materiais, sem a integração de ensaios mecânicos, de envelhecimento e de caracterização morfológica. Estudos futuros devem incluir essas abordagens combinadas, além de comparar o desempenho de materiais termoformados e impressos em 3D, de modo a ampliar a compreensão sobre a durabilidade e a efetividade dos alinhadores ortodônticos.

AGRADECIMENTOS

Os autores agradecem à FATEC Ribeirão Preto e a FATEC Sertãozinho, pelo suporte institucional e pela infraestrutura utilizada nas etapas desse estudo.

I. ABSTRACT

Polymer-gel dosimeters enable volumetric recording of absorbed ionizing-radiation dose, but conventional readout relies mainly on magnetic resonance imaging (MRI). This study investigated ultrasound elastography as a complementary approach for three-dimensional dosimetry using formaldehyde-modified MAGIC (MAGIC-f) gel and an optimized formulation with 6 percent gelatin and 2.5 percent agar. Phantoms were irradiated laterally at 20 and 40 Gy. Ultrasound elastography was performed using two shear-wave excitation approaches: acoustic-radiation-force shear-wave elastography (SWE) and mechanical perturbation generated by a shaker coupled to a metallic plate. The resulting shear- wave velocity maps were spatially sampled every 3 mm and reconstructed in 3D. MRI transverse relaxometry was acquired with a 12-echo spin-echo protocol (TE 17–204 ms). In the modified phantom, representative shear-wave velocities increased from approximately 3.0–3.4 m/s in non-irradiated regions to 4.4 m/s at 20 Gy and 4.6 m/s at 40 Gy. In the original formulation, values up to 4.3 and 5.0 m/s were observed at 20 and 40 Gy, respectively."Additionally, a comparison of the maps was performed for 30 Gy and 50 Gy. Mean R2 increased from 8.99±0.15 to 12.09±0.29 and 17.42±0.24 1/s in the original phantom and from 4.79±0.14 to 8.96±0.17 and 11.54±0.31 1/s in the modified phantom for 0, 20, and 40 Gy. These findings demonstrate dose-dependent mechanical and magnetic-relaxation changes and support ultrasound-based volumetric mapping of irradiated MAGIC-f gels.

II. INTRODUCTION

The first studies on dosimetric gels for ionizing radiation date back to the 1950s, when Day and Stein investigated radiation-induced chemical changes in gels [1]. Subsequent polymer-gel formulations improved the ability to record three-dimensional dose distributions, but limitations related to oxygen sensitivity and the toxicity of some monomers restricted their handling and broader application. MAGIC gel (Methacrylic and Ascorbic Acid in Gelatin Initiated by Copper) emerged as an alternative with reduced oxygen sensitivity and toxicity, while formaldehyde-modified MAGIC (MAGIC-f) further increased the gel melting point and sensitivity [2].

MAGIC-f acts as a three-dimensional dosimeter because ionizing radiation induces water radiolysis and generates reactive species that initiate monomer polymerization. The resulting changes in the polymer network modify the physicochemical and mechanical properties of the gel in a dose-dependent manner. MAGIC-f also presents acoustic and mechanical properties compatible with ultrasound- based characterization, supporting its use as a tissue- mimicking dosimetric phantom [3]. Previous ultrasound studies have demonstrated that radiation-induced changes in gel phantoms can be detected acoustically and used to investigate absorbed-dose distributions [4].

These mechanical changes can be interrogated through shear-wave-based methods. Magnetoacoustography (MAG) combines ultrasound with magnetic excitation of embedded magnetic nanoparticles to generate mechanical perturbations,

while acoustic radiation force impulse (ARFI) excitation produces propagating shear waves directly with focused ultrasound. The resulting wave propagation can be used to estimate viscoelastic properties and identify regions with different stiffness. Magnetomotive and transient shear-wave approaches have previously been used to characterize tissue-mimicking phantom viscoelasticity [6], and magnetomotive ultrasound has been implemented using programmable ultrasound research interfaces [7]. Shear-wave elastography is a well-established quantitative approach for mapping mechanical properties from shear-wave propagation [8], [9].

Magnetic resonance imaging (MRI) relaxometry provides a complementary and well-established readout for polymer-gel dosimetry. Transverse relaxation measurements quantify T2, or equivalently R2 = 1/T2, which changes as radiation-induced polymerization modifies spin-spin interactions in the gel [5]. Thus, MRI relaxometry provides an independent quantitative reference for assessing the dose-dependent changes detected by ultrasound.

In this study, an original MAGIC-f formulation and a thermally optimized formulation were investigated using two ultrasound elastography approaches: shear-wave elastography (SWE) based on acoustic-radiation-force excitation and a second approach based on mechanical perturbation generated by a shaker coupled to a metallic plate. Magnetoacoustic measurements and MRI R2 relaxometry were also performed. The objective was to determine whether radiation-induced mechanical changes can be spatially identified and reconstructed in three dimensions and to compare their dose dependence with the MRI relaxometry response.

III. Materials and Methods

A. Phantom preparation and optimization—Original MAGIC-f gel was prepared using bovine gelatin, methacrylic acid, ascorbic acid, copper sulfate, deionized water, glass powder as an acoustic scatterer, and formaldehyde. A magnetic layer containing iron-oxide nanoparticles (30 mg/mL stock; 1.75 mL added to 35 mL of gel) was deposited on the phantom surface for magnetoacoustic experiments. To improve thermal stability and glass-powder dispersion, gelatin/agar concentrations were varied. Mechanical testing with a texture analyzer was performed in triplicate for the tested formulations. The formulation selected for subsequent comparison contained 6 percent gelatin and 2.5 percent agar, whereas the original formulation contained 8.3 percent gelatin and no agar.

B. Irradiation—After at least 24 h of refrigerated stabilization, one original and one optimized phantom were irradiated using an X-ray system at CIDRA, University of São Paulo. Irradiation was delivered laterally from opposite faces to reduce depth-dependent attenuation effects. Adjacent regions received 20 and 40 Gy and other phantom with 30 and 50 Gy; the incident beam diameter was approximately 1 cm.

C. Ultrasound elastography: SWE and mechanical perturbation—Ultrasound acquisitions were performed with a programmable Verasonics platform using experimental protocols developed at GIIMUS. Spatial scanning was performed with a 3-mm step, generating eight two-dimensional displacement and shear-wave- velocity maps per investigated region. RF data were processed by cross-correlation. For the SWE measurements, shear waves were generated by acoustic- radiation-force excitation, and the analysis used a region of interest lateral to the excitation focus to track the first propagating shear-wave front. Displacement maps were filtered in space and time, and local shear-wave velocity was estimated from spatially separated displacement signals. For the mechanical-perturbation measurements, a shaker drove a metallic plate with a surface area larger than the lateral face of the phantom, generating a mechanical excitation consisting of a single 1000-Hz cycle at 15 dB. The resulting shear waves were tracked with the same ultrasound acquisition platform and processed using the same spatial mapping criteria. For both modalities, the two-dimensional velocity matrices were concatenated along the scan direction, exported in NIfTI format, and visualized in 3D Slicer.

D. MRI relaxometry—Transverse relaxometry was acquired with a 12-echo spin-echo protocol, with TE values from 17 to 204 ms in 17-ms increments and 1-mm inter-slice spacing. R2 was estimated from the exponential decay $S=S0\ \exp(-R2\cdot TE)$. Circular regions of interest of approximately 8 mm diameter were defined with MicroDicom. Ten intermediate frames were analyzed for non-irradiated, 20-Gy, and 40-Gy regions in eachphantom, and the resulting R2 values are reported as mean±SD. Signal intensities were sampled from circular ROIs with an average diameter of 8 mm. For each spatial frame, the exponential decay was fitted over the selected echoes, and R2 values were extracted from ten intermediate frames for each region. The analysis compared matched non- irradiated, 20-Gy, and 40-Gy regions within each formulation.

IV. Results

A. Phantom optimization—Among the tested recipes, the formulation containing 6 percent gelatin and 2.5 percent agar showed the smallest temperature-dependent variation in the measured elastic response and improved glass-powder dispersion. This formulation was therefore selected as the optimized MAGIC-f phantom for the ultrasound and MRI comparisons. Comparing Figures 1.a. and 1b, it can be observed that the phantom produced with the new agar/gelatin concentration exhibits a greater stiffness contrast between the irradiated and non-irradiated areas.

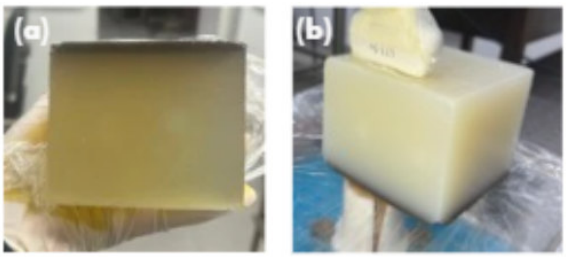

Fig. 1. Original Magic phantom (a) and modified Magic phantom (b) irradiated with 20 Gy and 40 Gy.

B. Shear-wave elastography (SWE)—The 3D reconstruction workflow produced spatially coherent shear-wave velocity maps. In a homogeneous test phantom, the reconstructed mean shear-wave velocity was 5.2±0.5 m/s, supporting the internal consistency of the mapping pipeline. In the optimized MAGIC-f phantom, non-irradiated regions showed velocities of approximately 3.0–3.4 m/s, whereas representative irradiated regions reached approximately 4.4 m/s at 20 Gy and 4.6 m/s at 40 Gy. In the original MAGIC-f phantom, representative values reached approximately 4.3 m/s at 20 Gy and 5.0 m/s at 40 Gy. The irradiated regions could therefore be distinguished from surrounding non-irradiated material by the increase in shear-wave velocity.

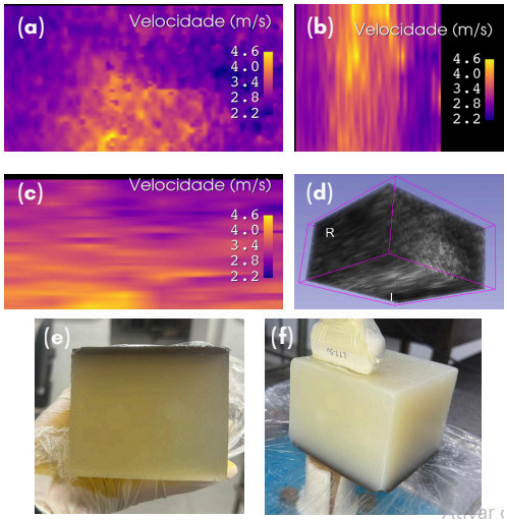

Fig. 2. Shear wave velocity analysis by SWE in **(a)** axial plane image, **(b)** sagittal plane image, **(c)** coronal plane image, and **(d)** 3D image of the irradiated modified Magic phantom with 40 Gy. Original Magic phantom **(e)** and modified Magic phantom **(f)** irradiated with 20 Gy and 40 Gy.

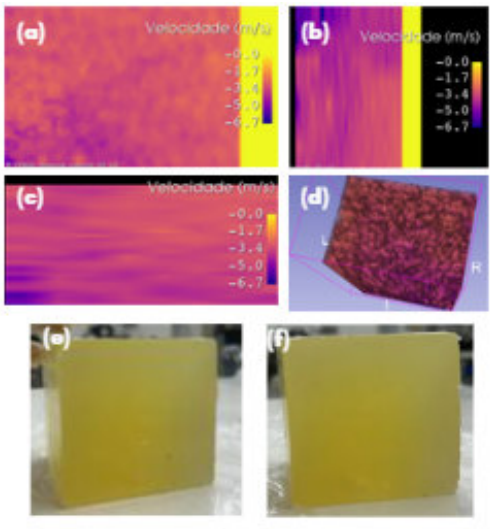

Fig. 3. Shear wave velocity analysis by SWE in **(a)** axial plane image, **(b)** sagittal plane image, **(c)** coronal plane image, and **(d)** 3D image of the irradiated Magic-f phantom with 40 Gy. Original Magic phantom **(e)** and **(f)**.

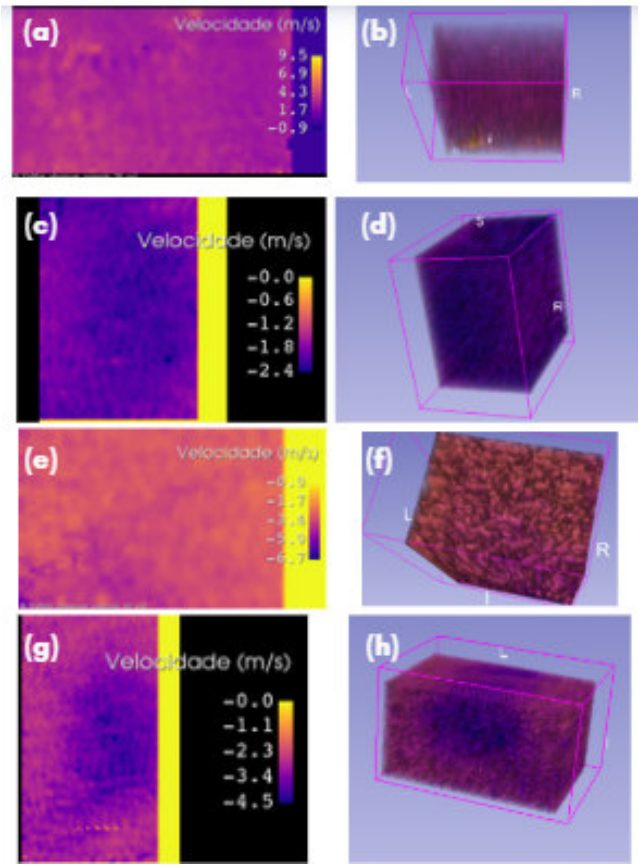

Fig. 4. Shear wave velocity analysis by SWE in axial plane image and 3D image of the irradiated Magic-f phantom with **(a)** **(b)** 20 Gy, **(c)** **(d)** 30 Gy, **(e)** **(f)** 40 Gy and **(g)** **(h)** 50 Gy.

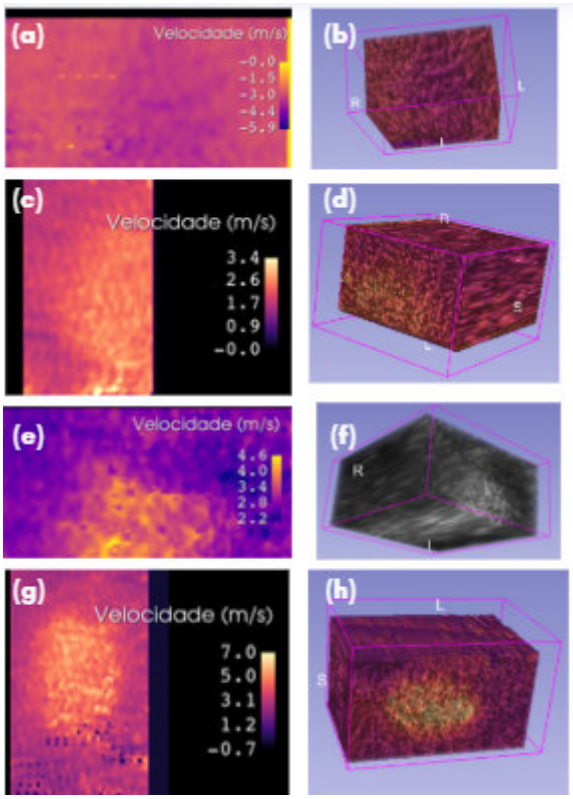

Fig. 5. Shear wave velocity analysis by SWE in axial plane image and 3D image of the irradiated modified Magic phantom with **(a)** **(b)** 20 Gy, **(c)** **(d)** 30 Gy, **(e)** **(f)** 40 Gy and **(g)** **(h)** 50 Gy.

The maps obtained in Figures 4 and 5 also demonstrate that the change in stiffness was more noticeable in the modified phantoms, making them more viable for dosimetric mapping. It can be observed that, in the case irradiated with 50 Gy, the change in shea'r wave velocity from the non-irradiated to the irradiated area is approximately 2.2 m/s for the MAGIC-f phantom and 3.9 m/s for the modified MAGIC-f phantom.

C. Mechanical perturbation with shaker—The shaker- based mechanical perturbation also generated shear waves that enabled spatial differentiation of irradiated and non- irradiated regions. In the optimized MAGIC-f phantom, the 40-Gy region reached approximately 5.4 m/s in the later acquisition, and the velocity difference between the irradiated and non-irradiated regions was approximately 1.4 m/s. The 20-Gy region was less clearly distinguished in this modality. Because the mechanical-perturbation measurements were performed approximately three weeks after the SWE acquisitions, partial phantom dehydration likely affected the absolute shear-wave velocity values. Nevertheless, the irradiated region remained identifiable, supporting mechanical perturbation as a second ultrasound-based elastographic approach for mapping radiation-induced changes.

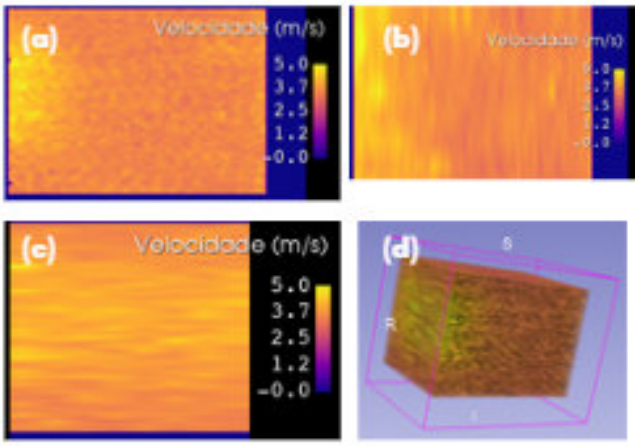

Fig. 7. Shear wave velocity analysis by Mechanical perturbation in **(a)** axial plane image, **(b)** sagittal plane image, **(c)** coronal plane image, and **(d)** 3D image of the irradiated Magic-f phantom with 40 Gy.

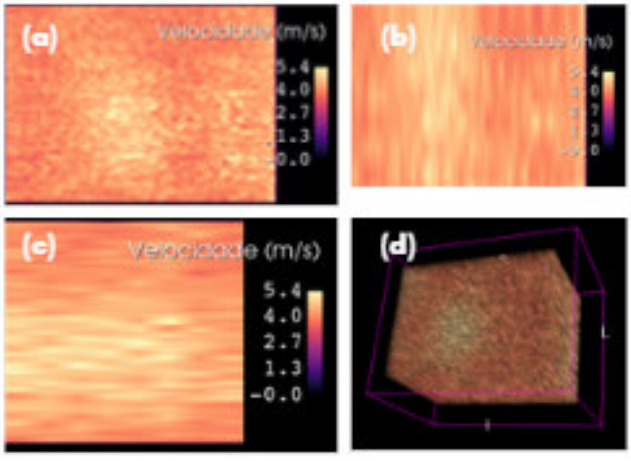

Fig. 6. Shear wave velocity analysis by Mechanical perturbation in **(a)** axial plane image, **(b)** sagittal plane image, **(c)** coronal plane image, and **(d)** 3D image of the irradiated modified Magic phantom with 40 Gy.

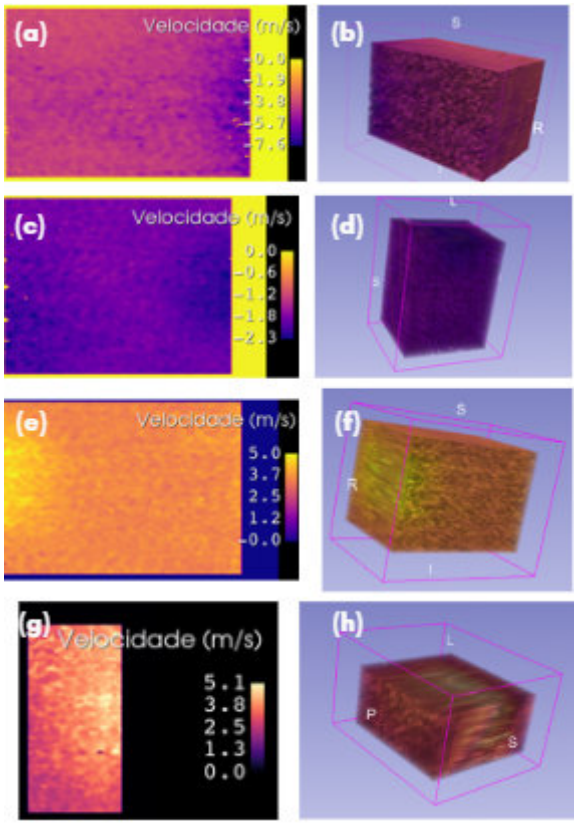

Fig. 8. Shear wave velocity analysis by Mechanical perturbation in axial plane image and 3D image of the irradiated Magic-f phantom with **(a)** **(b)** 20 Gy, **(c)** **(d)** 30 Gy, **(e)** **(f)** 40 Gy and **(g)** **(h)** 50 Gy.

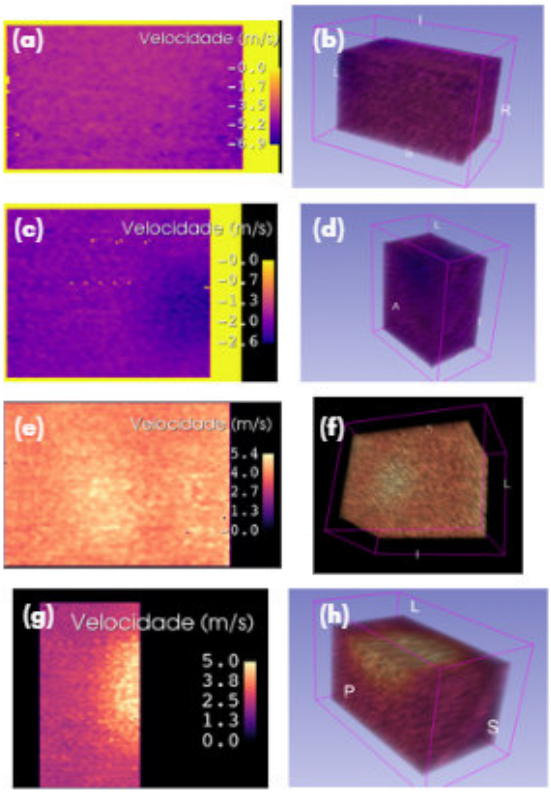

Fig. 9. Shear wave velocity analysis by Mechanical perturbation in axial plane image and 3D image of the irradiated modified Magic phantom with **(a) (b)** 20 Gy, **(c) (d)** 30 Gy, **(e) (f)** 40 Gy and **(g) (h)** 50 Gy.

It was noted that a distinct difference between the irradiated and non-irradiated areas could be seen across all analyzed maps (20, 30, 40, and 50 Gy in the original and modified phantoms).

D. MRI relaxometry—R2 increased with absorbed dose in both formulations (Table I). In the original MAGIC-f phantom, the mean increase was 3.10 1/s from 0 to 20 Gy and 5.33 1/s from 20 to 40 Gy. In the optimized phantom, the corresponding increases were 4.17 and 2.58 1/s. A linear fit to the three mean values yielded R²0.98 for both formulations, indicating a monotonic dose-dependent relaxometric response over the investigated range.

Dose (Gy)	Original	Optimized
0	8.99 ± 0.15	4.79 ± 0.14
20	12.09 ± 0.29	8.96 ± 0.17
40	17.42 ± 0.24	11.54 ± 0.31

Fig. 10. Mean transverse relaxation rate R2 (1/s) from MRI relaxometry (mean±SD).
